Sinusitis can present as an acute or chronic infection, characterized by different but overlapping groups of symptoms. Acute sinusitis is estimated to complicate between 5% and 10% of upper respiratory infections.^{2,13} A child with sinusitis may not present with the typical symptoms seen in an adult (i.e., facial pain, headache, fever).¹⁴ Instead, the parent may describe a persistent cold (more than 10 days) that is more severe than usual, with copious nasal discharge (clear to purulent) and associated cough that is present during the day but may worsen at night. Parents commonly note that their preschool child has fetid breath without evidence of pharyngitis.^{12,14} A less common but severe presentation of acute sinusitis is high fever (greater than 39.0°C), purulent nasal discharge, headache, and, occasionally, periorbital swelling.^{5,12} Subacute or chronic sinusitis (which may be infectious, allergic, or related to chronic nasal ostia obstruction) can present as a persistent cold with prolonged nasal congestion, causing nasal obstruction, cough of more than 30 days without improvement, and sore throat due to mouth breathing. On physical examination, there is mucopurulent discharge in the nose or pharynx, with erythematous nasal mucosa. Usually, there is not impressive cervical adenopathy. In more severe cases, there can be periorbital swelling or facial tenderness.

Major complications of sinusitis include periorbital cellulitis, orbital cellulitis or abscess, meningitis, osteomyelitis, epidural abscess, subdural empyema, cavernous sinus thrombosis, and cerebral abscess.^{1,2,7,12,16}

DIFFERENTIAL DIAGNOSIS

Sinusitis is predominately a clinical diagnosis based on history and clinical examination and, occasionally, on supportive radiographic studies and cultures. Standard radiographic projections of the cranium include an anteroposterior (Caldwell) view for the frontal and ethmoidal sinuses, lateral and submentovertex views for the sphenoid sinus, and occipitomental (Waters) view for the maxillary sinuses. The findings most diagnostic of bacterial sinusitis include air–fluid levels or complete opacification of the sinuses. However, children less than 5 years of age with biopsy-proven sinusitis do not always show air–fluid levels or opacification, and the amount of sinus mucosal thickening that is diagnostic of bacterial sinusitis is not agreed on (most authors suggest that mucosal thickening of greater than 4 mm is diagnostic).^{2,14}

Complete opacification and air–fluid levels of the maxillary sinuses on plain radiography correlates well with computed tomography (CT).⁸ When clinical signs and symptoms suggesting acute sinusitis are accompanied by abnormal maxillary sinus radiographs, bacteria will be present in the sinus aspirate more than 75% of the time.¹⁵ However, a normal radiograph does not rule out bacterial sinusitis.⁶ Radiographic evaluation is recommended only if the child has been seriously ill, has had recurrent episodes, has chronic symptoms, or has a suspected suppurative complication.^{1,13,14,16} When the diagnosis is obvious on clinical grounds, radiologic evaluation may not be necessary.

Transillumination of the sinuses is not reliable, and ultrasound evaluation has not been used enough in children to recommend universally.^{12,13} CT scans may be helpful in evaluating sinus involvement but are reserved for patients with severe disease, or those with orbital involvement usually undergoing CT for other reasons. Although useful in defining the soft-tissue structures surrounding the sinuses, magnetic resonance imaging (MRI) does not image the bone well; hence, MRI is useful in delineating the spread of a nasal tumor, but CT scan remains the modality of choice in evaluating sinus disease.¹¹

The “gold standard” for clinical diagnosis is sinus aspiration or functional endoscopic sinus surgery (biopsy is more sensitive as a research tool).⁵ These techniques are usually reserved for those with severe pain unresponsive to medical therapy, those who are seriously ill, those with immunologic deficiencies, or those presenting with suppurative complications of sinusitis.^{1,10,12,14} In a study of 79 aspirates from 50 children with acute maxillary sinusitis, 28% grew *Streptococcus pneumoniae*, 19% grew *Moraxella catarrhalis*, 19% grew *Haemophilus influenzae*, 7% grew *Streptococcus* spp., *Eikenella corrodens*, *Peptostreptococcus*, and other *Moraxella* spp., and 34% were culture negative.⁵ Surface cultures of the nasopharynx, nose, or throat are not at all predictive of the causative organism.¹⁵ Directed cultures of the middle meatus, however, correlate with chronic maxillary or ethmoid sinusitis organisms.⁹

The complications of sinusitis are secondary to the contiguous spread or hematogenous spread of infection and include periorbital (preseptal) and orbital cellulitis, blindness, meningitis, epidural abscess, subdural empyema, venous sinus thrombosis, cerebral abscess, and cranial osteomyelitis.

EMERGENCY DEPARTMENT EVALUATION

All patients presenting to the emergency department with signs or symptoms of sinusitis require a thorough history and physical examination to rule out serious sequelae. Only those children with severe illness, recurrent symptomatology, or suspected suppurative complication deserve radiographs. Referral to an otorhinolaryngologist for further evaluation and management should be considered in cases of systemic toxicity, severe pain unresponsive to medical outpatient therapy, failure of medical therapy, suppurative complications or immune compromise.^{1,10}

EMERGENCY DEPARTMENT MANAGEMENT

Medical therapy with an antimicrobial agent is recommended in children diagnosed with acute sinusitis. Treatment should be directed toward *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*.³ In areas where the prevalence of beta-lactamase–positive, ampicillin-resistant *H. influenzae* and *M. catarrhalis* is relatively low, amoxicillin is the drug of choice. In areas of prevalent ampicillin resistance or in treatment failures, alternative therapies include amoxicillin–clavulanate or cefaclor.

For patients allergic to penicillin, alternatives include trimethoprim–sulfamethoxazole or the combination of erythromycin–sulfisoxazole. In older children, cefuroxime axetil may be used. The trimethoprim-sulfamethoxazole combination may be ineffective in patients with concomitant group A beta-hemolytic streptococcal infections. Cefixime, which is less active against *S. pneumoniae*, is a less optimal choice.^{2,10,12}

Clinical improvement should be rapid, with resolution of the fever and reduced nasal discharge and cough within 48 to 72 hours. The duration of recommended therapy is 10 to 14 days (after 1 week in an adult study, 20% of sinus aspirate cultures still grew pathogenic bacteria). If the patient is improved but not completely recovered, continuation of antibiotic therapy for another week is recommended.

Chronic infectious sinusitis should be treated with antibiotics. In addition, in children with chronic sinusitis and asthma, in whom underlying allergic rhinitis is suspected, a course of topically applied corticosteroids (beclomethasone or flunisolide) may be useful.¹⁰

DISPOSITION

Emergent consultation with an otorhinolaryngologist, neurologist, or ophthalmologist may be indicated if the sequelae of sinusitis are apparent on presentation. The otorhinolaryngologist may be asked to evaluate and aspirate sinus fluid in patients who are severely ill, are recurrently or persistently infected, are immunocompromised, or have suppurative complications. These patients also warrant admission. All patients should be followed up at the completion of therapy, and those with persistent nasal discharge treated with an additional 7 days of antibiotics. Patients should be advised to return if symptoms of fever, headache, facial swelling or pain, cough, and purulent nasal drainage worsen or do not improve within 72 hours of initiation of therapy.

COMMON PITFALLS

- Because pneumatization of the sinuses is variable in children, radiographs may be misleading.
- Typically, children with sinusitis do *not* exhibit the classic triad of adult symptoms: fever, headache, and facial pain.
- Complete a thorough neurologic examination to reduce the chance of missing associated intracranial or suppurative sequelae.

CHAPTER 293

Submersion Injuries

Madeleine Matar Joseph and Lisa Santer

[Pathophysiology](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Alert Patients with Spontaneous Respirations](#)
[Patients without Spontaneous Respirations](#)
[Prevention](#)
[Common Pitfalls](#)
[Chapter References](#)

Submersion injuries are the result of a person's being submerged in a liquid, with at least a temporary loss of consciousness. Traditionally, they are divided into drownings (fatal submersion injuries) and near-drownings (survival for at least 24 hours after submersion injury). Although the number of deaths due to unintentional drowning had declined from 5,700 in 1986 to 3,959 in 1996, drowning rates have barely declined among children. In fact, the mortality rate has increased among children younger than 1 year.⁸

An even greater number of lives are affected by nonfatal submersion injuries. For every child who drowns, four children are hospitalized for near-drowning. One-third of those who are comatose on admission and survive suffer significant neurologic impairment.² Submersion injuries have a bimodal age distribution, with peaks in toddlers and adolescents.

The availability of bodies of water and the climate, geography, and socioeconomics of a community determine its most likely site of submersion injury. Databases from state surveillance systems have identified for each age category both the location of drowning and the activity performed. Children less than 1 year of age most frequently drown in bathtubs and buckets; children aged from 1 to 4 years most often drown in swimming pools. Children and adolescents aged from 5 to 19 years most frequently drown in lakes, ponds, rivers, and pools.² Lack of adult supervision is a factor in most pediatric submersion injuries.⁹ Alcohol is a factor in many adult and adolescent submersion injuries.^{3,7}

Predisposing conditions of the victim include seizures, alcohol ingestion, and trauma (unintentional and intentional child abuse and homicide). The possibility of child abuse must be considered in home submersion injuries, such as in bathtubs or buckets.⁵ Morbidity and mortality are related more to the promptness and quality of field care than to hospital care.

PATHOPHYSIOLOGY

The injury of submersion is global hypoxia. The events of a submersion injury follow a predictable pattern. Initially, the victim struggles to reach the surface. During this struggle, the victim consciously controls the urge to breathe. Eventually, asphyxia forces the submerged person to inspire. Liquid enters the larynx and causes laryngospasm, which temporarily prevents liquid from entering the lungs. Because the mouth is full of water, the swallowing mechanism tries to clear the oral cavity, and fills the stomach with water. As asphyxia worsens, the laryngospasm relaxes and the diaphragm contracts, pulling water into the lungs in about 85% of cases. This aspiration causes surfactant washout or inactivation (fresh and salt water, respectively), with subsequent atelectasis. Aspiration can also cause transient electrolyte changes, particularly with fresh-water submersion.

The pulmonary response to hypoxia is reflex-mediated pulmonary hypertension with intrapulmonary shunting. Aspiration-induced atelectasis worsens ventilation-perfusion mismatch and produces further hypoxia. Aspiration of pulmonary irritants such as emesis or caustic substances also contributes to pulmonary injury. Myocardial hypoxia results in cardiac arrest within minutes of the submersion. In addition, hypothermia can cause decreased myocardial contractility and dysrhythmias. Prompt, effective resuscitation can minimize these effects.

In the patient who has been severely asphyxiated, the delayed responses of vital end organs to hypoxia and resulting acidosis include acute tubular necrosis and sloughing of bowel mucosa, resulting in profuse, bloody diarrhea. Cerebral edema results from generalized neuronal death and develops within hours (cytotoxic cerebral edema). Cerebral edema leads to increased intracranial pressure, which decreases the cerebral perfusion pressure and cerebral blood flow, causing further ischemic injury. Central nervous system (CNS) injury is the most common cause of death after successful cardiac resuscitation, and the most common cause of permanent sequelae.

Acute respiratory distress syndrome, which also begins within hours of the injury, is present in 5% to 15% of submersion victims ill enough to require intensive care. The delayed immersion syndrome is an uncommon, delayed pulmonary response to hypoxia, occurring up to 24 hours after submersion in victims who initially looked well. Myocardial failure due to hypoxia occurs within hours of submersion. Although uncommon, coagulopathies or renal failure may develop after hypoxia and hypothermia. Myoglobinuria or hemoglobinuria may also precipitate renal failure. Despite transient electrolyte changes due to aspiration and absorption of fresh and salt water, electrolytes are almost always normal by the time the patient arrives in the emergency department. There are, however, reports of a correlation between an elevated initial blood glucose level and poor outcome.^{1,4}

The outcome of submersion victims is generally bimodal: intact survival or death. The duration of submersion and resuscitation are the most common predictors of outcome, but no set of parameters is absolutely predictive for bad outcome in all cases. Criteria predicting death or survival with severe neurologic sequelae are submersion for more than 10 minutes and a resuscitation that lasts more than 25 minutes.⁷ The most reliable predictors for poor outcome (death or survival with severe neurologic sequelae) include cardiac arrest requiring more than 25 minutes of advanced cardiac life support, ongoing cardiopulmonary resuscitation in the emergency department, and a submersion duration of more than 25 minutes.⁹

Criteria predicting good outcome are the presence of sinus rhythm, reactive pupils, and neurologic responsiveness.⁷ Among comatose children, unfavorable outcome (vegetative state and death) was predicted by a combination of absent pupillary light reflex, increased initial blood glucose concentration, and male sex.⁴

EMERGENCY DEPARTMENT EVALUATION

As always, the ABCs are primary: the airway is cleared of vomitus or other foreign material, adequate breathing efforts are ensured, and circulation is assessed by monitoring heart rate, rhythm, pulse pressure, and capillary refill time. The cause of the submersion injury is noted. Initial signs and symptoms usually reflect cardiopulmonary and cerebral hypoxic injury. However, because occult injury to the head, cervical spine, or other areas may be present, the cervical spine must be immobilized if trauma is suspected. Hypothermia may not be recognized unless a rectal temperature is obtained along with other vital signs. The temperature is taken with a thermometer that can register low temperatures.

Altered mental status, if present, is probably due to cerebral hypoxia, but other possibilities, such as drug ingestion, intracranial injury, hypothermia, or a postictal state, should be considered. A blood alcohol and drug screen is recommended on all but the youngest children. A baseline hematocrit level, electrolyte measurements, and a chest x-ray are obtained. A blood gas measurement should be obtained in patients with respiratory or CNS symptoms.

EMERGENCY DEPARTMENT MANAGEMENT

The goal of therapy is to reverse hypoxia. Appropriate, aggressive airway management in the field is essential. Many apneic, unresponsive victims respond to positive-pressure ventilation alone by breathing and waking. Intensive care protocols have failed to improve outcome. The patient in cardiac arrest is resuscitated in the usual manner. If hypothermia (less than 34°C) is present, death should not be pronounced before the asystolic victim is rewarmed.

Arterial oxygen levels are kept at normal levels or above by increasing positive end-expiratory pressure, F_{iO_2} , and other parameters as needed. Borderline oxygenation or ventilation is unacceptable in a brain-injured patient. Positive end-expiratory pressure is helpful when there is evidence of intrapulmonary shunt on the arterial blood gas. Avoid high positive end-expiratory pressure, which can compromise the cardiac output. The patient is hyperventilated ($PaCO_2$ of 25 to 30 mm Hg) to decrease intracranial pressure.

If the patient is in shock and not responding to respiratory therapy, fluid boluses and inotropes can be given. The physician should consider myocardial infarction secondary to asphyxia, even in young children. Unless hypovolemia is present, the rate of intravenous fluids can be restricted to minimize intracranial pressure. Cerebral perfusion pressure should be maximized. Fluid shifts and electrolyte changes are not significant clinical problems for submersion victims. ⁹ Glucose levels are often high in severely asphyxiated patients, so glucose-containing intravenous fluids should be used only if hypoglycemia occurs.

Gastric aspiration is avoided by placing a nasogastric tube, as the stomach is usually full of swallowed liquid.

DISPOSITION

Alert Patients with Spontaneous Respirations

Patients with a history of at least temporary loss of consciousness should be observed for 12 to 24 hours for organ failure, especially of the lungs. The observation should be done in a setting that can recognize deteriorating pulmonary function and provide appropriate intensive care or transport.

If a child has had a momentary period of asphyxia, admission to a local hospital may still be appropriate. If the child was submerged longer than 5 minutes or did not waken at the scene, observation close to a pediatric intensive care unit is suggested.

Patients without Spontaneous Respirations

The decision to transfer a patient who has been treated aggressively in an emergency department but does not have spontaneous respirations is problematic. The patient who has only a return of heartbeat has little, if any, chance of intact survival. The prognosis should be communicated to the family at an appropriate time. Too often, the family feels that if the patient has a heartbeat on arrival at the intensive care unit, his or her condition will markedly improve.

Patients with causes of decreased mental status other than hypoxia and no spontaneous respirations may have a better outcome. They should be admitted to an intensive care unit. Victims who are potential organ donors also merit consideration of intensive care unit admission.

PREVENTION

It is much easier to prevent a submersion injury than to treat one. Emergency physicians can support groups such as the American Red Cross, American Heart Association, and Safe Kids, which educate lay people, legislators, and professionals about water safety.

COMMON PITFALLS

- Failure to place a nasogastric or orogastric tube may result in vomiting and aspiration.
- Inadequate oxygenation may worsen the hypoxic insult that occurred as a result of submersion.
- Inadequate fluid resuscitation and the use of inotropes in a hypovolemic patient can worsen the ischemic insult.
- The asymptomatic patient with a history of significant submersion may be at risk for respiratory deterioration.
- Many bathtub near-drowning victims suffer from abuse or neglect. Therefore, medical evaluation should include social services consultation and a search for other accompanying injuries.

CHAPTER 294

Torticollis

Gregory G. Gaar

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Congenital Torticollis](#)
[Acquired Torticollis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The word *torticollis* is derived from the Latin words *tortus*, meaning “twisted,” and *collum*, meaning “neck.” Medically, *torticollis* is defined as “a contraction, often spasmodic, of the muscles of the neck, chiefly those supplied by the spinal accessory nerve; the head is drawn to one side and usually rotated so that the chin points to the other side.”¹² It is a manifestation of illness, not a disease in itself, which means the etiology and pathophysiology can be very wide-ranging. As many as 80 different etiologies have been documented in the medical literature.¹¹

CLINICAL PRESENTATION

The clinical presentation of torticollis in the newborn is often a firm, nontender, unilateral enlargement in the sternocleidomastoid muscle, which is noticed shortly after birth.⁵ Older children and adults present with the head rotated on the neck, tilted to the affected side, with the chin pointed to the opposite direction.

DIFFERENTIAL DIAGNOSIS

The most commonly accepted categories of torticollis are congenital and acquired, depending on the etiology and time of onset and recognition.

Congenital Torticollis

The congenital causes can be subdivided into those caused by malformations and those caused by deformations. Malformations are due to a defect during morphogenesis, whereas deformations occur secondary to intrauterine postures and crowding.

Malformations can develop in the cervical spine, the cervical musculature, or the central nervous system. Rare cervical spine anomalies cause torticollis: odontoid hypoplasia, cervical spine fusions (Klippel-Feil syndrome), hemivertebrae, spina bifida, or congenital scoliosis.^{1,13} Hypertrophy or absence of the cervical musculature is one etiology.¹³ An arteriovenous fistula at the craniocervical junction has been reported.²

Pseudotumor of infancy and congenital muscular torticollis are reported with an incidence of 0.4% to 1.3%, respectively.⁶ The condition results from a unilateral fibrous contraction of the sternocleidomastoid muscle.^{1,4,6} It usually appears at ages younger than 1 month and resolves by the age of 6 months.⁴ Physical examination often reveals a firm, nontender, immobile mass in the sternocleidomastoid muscle.⁵ The exact etiology is unknown. There is a higher prevalence in breech and difficult deliveries assisted by forceps. Although most cases resolve spontaneously, some 10% to 20% of the cases will develop progressive torticollis.⁴

Congenital ocular disturbances can be a cause of torticollis that presents later in life. In one series, 4% of the total number of children with torticollis had ocular abnormalities. These were usually a fourth nerve palsy with resultant strabismus.¹

Deformations of the spine leading to torticollis can happen in the presence of uterine tumors, oligohydramnios, and multiple fetuses.¹³ These cases of torticollis secondary to intrauterine postures are usually transient and resolve within a few months.

Brachial plexus palsies due to birth trauma can also cause torticollis.¹

Acquired Torticollis

The causes of acquired torticollis are extremely varied. Often, the cause is associated with involvement of the cervical spine. Trauma to the cervical spine, resulting in subluxations or fracture and dislocations, is one cause. This trauma can be relatively minor, such as the hyperflexion or hyperextension of a “whiplash” injury. Onset of symptoms can be delayed by several months.¹³ The most common areas affected are the atlantoaxial area and C-2 on C-3.¹³ Ligamentous laxity in the atlantoaxial region is commonly a cause of subluxation, which can present as torticollis. These cases are often associated with underlying disorders, such as trisomy 21 (Down syndrome), mucopolysaccharidosis, and invasive erosion from surrounding soft-tissue infections.^{1,10} Infections of the cervical spine, such as osteomyelitis and discitis, can present as torticollis,¹³ as can metastatic or primary osteomas.¹⁰

Other causes of torticollis do not involve the cervical spine. Clavicle fractures, with resultant splinting of that area because of pain, has been recognized as a cause.^{1,10} Infections of the surrounding soft tissues, such as nasopharyngeal abscesses, retropharyngeal abscesses, cervical adenitis, tonsillitis, mastoiditis, and sinusitis, have been reported in the literature as etiologic agents.^{1,13} The twisting of the neck found on physical examination in these cases is felt to be due to pain from underlying cervical muscle spasms and not from an underlying spinous abnormality. If the infection is extensive, erosion of paraspinal ligaments has been reported, with subsequent rotatory subluxation in the atlantoaxial region.¹³

Torticollis appearing later in childhood can be due to compensation for underlying strabismus or diplopia.^{1,10}

Paroxysmal torticollis of infancy is due to vestibular dysfunction. It typically presents between the ages of 2 and 8 months.⁸ This episodic torticollis often is associated with vomiting, pallor, ataxia, or irritability.⁹ It is usually a self-limiting disease that resolves by age 2 to 3 years.³

Dystonic reactions to medication can present as torticollis. These are most commonly due to phenothiazine ingestions. Differentiation, in these instances, is usually made by the presence of ocular symptoms suggestive of oculogyric crisis.

The nuchal rigidity of bacterial meningitis can be confused with torticollis in younger patients. The mental status, behavioral, and physiologic changes that accompany meningitis are the key to differentiation.

EMERGENCY DEPARTMENT EVALUATION

Careful historic questioning concerning the location, severity, and onset of pain and abnormal posture of the neck is important. Patients should be asked about radiation of any pain. In classic cases of torticollis, there is unilateral neck pain. The pain may radiate to the ipsilateral shoulder but no further. Historic information about fever and constitutional signs and symptoms is important in determining infectious or inflammatory causes of torticollis. The possibility of phenothiazine exposure should be explored.

In older children and adults, acute torticollis often presents after trauma. Even with seemingly mild trauma, careful evaluation of the cervical spine, including appropriate radiographs, is necessary to rule out cervical spine fractures. In the absence of such fractures, a thorough examination of the head, eyes, ears, nose, and

throat should be performed to search for inflammatory causes. Careful physical examination should distinguish torticollis from the nuchal rigidity of bacterial meningitis. Palpation of the clavicles is necessary to isolate bony pain or crepitus. On neurologic examination, there should be no motor or sensory deficit in congenital muscular torticollis or that due to muscle spasm.

In infants, especially those less than 1 month of age, historic data concerning the birth should be collected. Information concerning birth presentation and the use of forceps may be found only by review of the birth medical records. Careful physical examination in these cases is likely to find the mass in the sternocleidomastoid, which helps to make the diagnosis of pseudotumor of infancy. Signs consistent with brachial plexus palsy are diagnostic of torticollis due to that etiology.

The evaluation of chronic torticollis differs if it is episodic or static in nature. For patients with recurring episodes, the emergency physician should perform a careful history of drug usage and a careful neurologic examination. Torticollis that is constant requires careful ophthalmologic and neurologic examination for strabismus and subtle cerebellar or other neurologic signs, which might be indicative of central nervous system lesions.

EMERGENCY DEPARTMENT MANAGEMENT

Patients who are younger than 1 month and present with a physical examination consistent with pseudotumor of infancy or brachial plexus palsy from a birth injury can be referred to their pediatricians for further workup and follow-up. Similarly, those whose history and examination are consistent with an intrauterine deformity due to multiple births, uterine tumor, or oligohydramnios can be referred for follow-up.

All other patients who present with an acute onset of torticollis that is not chronic and paroxysmal in nature, and those who present to be evaluated for the first time with a history of static torticollis, should have radiographs of their cervical spines after proper immobilization. This is necessary to rule out fracture or subluxation. It must be remembered that ligamentous instability from a congenital cause can often present as the result of a minor injury received several months prior to the emergency department visit.

When no radiographic fracture or subluxation is identified, further history and physical examination will help to uncover the underlying etiology of the torticollis. The management then follows based on the etiology and pathophysiology. If there are any abnormalities on neurologic examination, computerized tomography of the brain or magnetic resonance imaging is indicated. If there are signs and symptoms of an infection or inflammatory process, appropriate diagnostic studies should be obtained prior to institution of antibiotic therapy. If the torticollis is felt to be related to phenothiazine use, diphenhydramine or benztropine in appropriate dosages can be given to counteract the dystonic reaction.

Depending on the etiology, consultation with neurosurgery, neurology, or radiology colleagues should be considered.

DISPOSITION

Neurosurgical consultation and admission should be obtained for all patients with evidence of cervical spine fractures, subluxation, or dislocation. Ambulatory follow-up by the primary care pediatrician is sufficient in those infants with pseudotumor or congenital muscular torticollis. In some cases, conservative therapy in the form of manual stretching is all that is necessary.⁷ Some children eventually require surgical treatment.⁷

Appropriate treatment for the underlying cause of the torticollis is the mainstay of good therapy.

COMMON PITFALLS

- Failure to consider the myriad nonmuscular causes of torticollis
- Failure to immobilize the neck
- Failure to obtain cervical spine films to rule out a fracture or subluxation in the patient with potential traumatic etiology
- Failure to consider phenothiazine side effects, even when used in an appropriate therapeutic dosage

[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Urinary tract infections (UTIs) in children pose particular problems in diagnosis and management. A high index of suspicion is necessary to diagnose UTI in infants because they present with nonspecific symptoms. Diagnosis and management depend on the age and sex of the child. Accurate diagnosis and prompt therapy are important in infants and young children because they are at higher risk for vesicoureteral reflux (VUR) and renal scarring.

The cumulative risk for a primary symptomatic UTI to occur in a child from age 1 to 11 years is 1.1% for a boy and 3% for a girl, with the highest risk occurring during infancy and decreasing with increasing age.¹⁹ Among febrile children 2 months to 2 years of age with no apparent source of fever, the prevalence of UTI is 5%. Girls are at higher risk, with a 2:1 predominance in the first year of life and a 4:1 predominance in the second year of life. In circumcised boys, the prevalence is very low, 0.2% to 0.5%. Recurrence rates are higher in girls, reaching 40%.¹⁹

Evidence suggests that most infections in children under 5 years involve the renal parenchyma.¹⁸ The incidence and severity of VUR are highest among the youngest infants. Delay in treatment and recurrent UTIs increase the risk of renal scarring, emphasizing the importance of early diagnosis and treatment. The long-term consequences of childhood UTIs may include hypertension, impaired renal function, and end-stage renal disease. These adverse effects are more common in children with intrauterine renal damage.⁵

CLINICAL PRESENTATION

The clinical presentation of patients with UTI varies with age. Children younger than age 2 usually present with fever alone or other nonspecific symptoms. Other symptoms include vomiting, diarrhea, failure to thrive, and irritability. A rash or jaundice may be present. In evaluating febrile children, the likelihood that a UTI is the source varies by the presence of associated illnesses as well as the patient's age and sex. Patients with bronchiolitis have been shown to have a relatively decreased risk of UTI.¹³ The presence of otitis media does not affect the risk of UTI.¹⁷

Clinical presentation does not reliably differentiate cystitis from pyelonephritis nor predict those with associated bacteremia. The large majority of young children with UTIs have renal parenchymal involvement seen by technetium 99m dimercaptosuccinic acid (DMSA) renal scan.¹⁹ In this age group, all UTIs should be presumed to be pyelonephritis. The overall risk of bacteremia in children less than 5 years old with UTI is 5%, with the highest prevalence in those less than 6 months of age (8%).² Routine blood cultures are appropriate in those less than 6 months and those who appear toxic.

Preschool children may present with traditional symptoms of suprapubic pain, urgency, dysuria, and frequency. At this age, they still have symptoms not localized to the urinary tract, such as fever, generalized abdominal pain, and diarrhea. Enuresis that has recurred in a previously continent child is also an indicator of possible infection.

In the school-age child with a UTI, symptoms referable to the urinary tract are usually present. Fever is frequently present, and although it suggests upper tract disease, it is seen with cystitis as well. Fever may be absent in a patient with significant renal involvement. In this age group, the overwhelming majority of patients are girls, with a higher risk among white girls.

DIFFERENTIAL DIAGNOSIS

In infants, UTI should be included in the differential diagnoses of fever, irritability, gastroenteritis, failure to thrive, and sepsis. Although the infant will present with nonspecific symptoms, such as those listed previously, careful questioning may uncover additional symptoms that would direct attention to the urinary tract. Signs such as dribbling, poor stream, frequency, and malodorous urine may be present, although not the presenting complaint ([Table 296.1](#)).

ABSOLUTE
All febrile infants younger than 2 months
Temp: 39°C without a source and male younger than 6 months
Temp: 39°C without a source and female younger than 2 years
Enuresis in previously continent child
Symptomatology of urinary tract infection
Failure to thrive
CONSIDER
Child with abdominal pain
Infants with vomiting, diarrhea, poor feeding, and irritability

Table 296.1. Indications for Obtaining Urine Specimens for Analysis and Culture

When the preschool-age and older child present with urgency, dysuria, or frequency, the differential diagnosis for this complex of symptoms should include urethritis, pinworms, vaginitis, and child abuse. Children with constipation are at increased risk of UTIs, and the diagnosis should also be considered in these patients.

EMERGENCY DEPARTMENT EVALUATION

Screening tests for UTIs include the reagent tests nitrite and leukocyte esterase (LE) and microscopy for leukocytes and bacteria. In a recently published practice guideline, the American Academy of Pediatrics reviewed the literature on these tests, and estimated their sensitivities and specificities as seen in [Table 296.2](#).¹

Test	Sensitivity %	Specificity %
LE	67-94 ~83	64-92 ~78
Nitrite	15-82 ~53	90-100 ~98
LE or nitrite	90-100 ~93	58-91 ~72
WBCs (>5)	32-100 ~73	45-98 ~81
Bacteria	16-99 ~81	11-100 ~83
LE, nitrite, or WBCs	99-100 ~99.8	60-92 ~70

Table 296.2. Screening Tests for UTI

Several considerations are important. The large range in specificity and sensitivity for the microscopy tests reflects the inconsistency in technique and quality in various laboratories. The white cell count is an unstandardized test. There is no agreement between studies of what constitutes significant pyuria on spun specimens. Most clinicians consider greater than 5 white blood cells (WBCs) to be significant. An “enhanced urinalysis” has been proposed that consists of an unspun urine sample using a standardized hemocytometer (Neubauer) and a Gram stain using a standardized amount of urine. The enhanced urinalysis (UA) was found to have a sensitivity of 85%, compared with 65% for the standard spun UA and microscopy.⁹ Presence of pyuria is a nonspecific test, because children with other febrile illnesses, dehydration, appendicitis, or inflammatory processes also may have this finding. Spun samples reduce the specificity of microscopy, probably by releasing cellular fragments that appear similar to bacteria.¹⁴ Sensitivity of the reagent tests may be reduced up to 35% by a 3-hour delay in processing.¹² Also note that when urine is collected and promptly analyzed, the combination of LE, nitrite, or bacteria on microscopy is sensitive but not specific. Although samples for these screening tests can be collected by the most convenient means, they do not replace the need for appropriately collected specimens for culture.

Interpretation of culture results depends on the collection technique. In incontinent children, urine for culture should be collected by catheter or bladder tap. Bag samples have no practical value because the contamination rate is so high. In continent children, the clean-catch technique is quite sensitive, but the specificity depends on interpretation of the quantitative results.

Bacteria may be introduced into a specimen when it is obtained with a catheter. With growth of 100,000 colony-forming units (CFU)/mL from such a specimen, there is a 95% likelihood of infection; with 10,000 CFU/mL, there is a 50% likelihood of infection.³ Many authors consider $> 10^4$ CFU/ml of a single organism or a catheterized sample to be diagnostic of UTI.¹⁹ Any bacteria seen on examination per high-power field, or growth on culture from a specimen obtained by suprapubic aspiration, probably represents infection.¹⁶

Various strategies have been proposed for evaluating children with UTIs. Clinical judgment and circumstances will play an important role. Regardless of the particular strategy, remember to always obtain an appropriate sample of urine for culture prior to starting antibiotic therapy. The following approach is recommended. In children less than 2 months of age with fever (greater than 100.4°F), a UA and culture should be obtained routinely as part of the “sepsis workup.” The sample should be collected by bladder catheterization or suprapubic bladder aspiration. UA and culture should also be strongly considered in any child less than 3 years of age with fever without an identified source. In incontinent children, catheterization is recommended, while continent children can provide a sample from a clean-catch, midstream void. A negative UA in circumcised boys older than 1 year may be sufficient to rule out UTI, but a culture should be sent for younger boys, girls, and uncircumcised boys, even when the UA is negative. Additionally, when there are clinical signs and symptoms of UTI in older infants and children, UA and culture should be collected.

Many tests have been proposed to aid in localization of infection within the urinary tract, including urinary lactate dehydrogenase, antibody-coated bacteria, and serum antibodies. Results have been conflicting, and none has been shown to be reliable in children. The presence of WBC casts indicates origin of an inflammatory process in the kidney but does not necessarily indicate infection. Failure to maximally concentrate the urine is an indicator of renal involvement and is usually a transient finding with acute pyelonephritis.¹⁸ Elevated C-reactive protein and erythrocyte sedimentation rate are seen with pyelonephritis, but absence of elevation does not rule out upper tract infection.⁴

Renal cortical scintigraphy (99m DMSA scan) can reliably diagnose pyelonephritis in children,¹⁵ but its role in the acute evaluation of UTI is not well established. In short, localization of UTIs in children is unreliable and generally unnecessary for acute management. UTIs should be considered pyelonephritis until proven otherwise in children under 5 years of age.

EMERGENCY DEPARTMENT MANAGEMENT

Management of patients with suspected UTIs in the emergency department includes making a presumptive diagnosis, appropriate collection of urine samples for culture, and initiation of antibiotic therapy. Collection of blood for complete blood count, blood culture, electrolytes, blood urea nitrogen, and creatinine should be considered in those less than 3 years of age and should be routinely collected in those less than age 6 months. For patients with equivocal clinical and negative laboratory findings, treatment may be postponed until culture results are available.

Treatment is indicated if there is any growth from a specimen obtained by suprapubic aspiration. Growth of more than 150,000 CFU/mL of a single organism from a catheterized specimen or from a voided specimen represents infection and should be treated. For patients who are febrile or otherwise highly symptomatic, treatment before availability of culture results may be indicated. In less symptomatic children, results of the UA and microscopy can be used to determine the likelihood of infection and the need to start treatment empirically. The presence of pyuria, urinary nitrites, or bacteriuria suggests infection, and empiric therapy while awaiting culture results may be appropriate.

Antibiotic coverage depends on the age of the child. For febrile infants younger than 2 months of age, broad-spectrum antibiotic coverage with ampicillin and gentamicin or ampicillin and a third-generation cephalosporin is appropriate until culture results are available.

Treatment options for children greater than 2 months of age depend on the patient's clinical state. All children who appear toxic, are vomiting, and are unlikely to tolerate PO medicines, or those who may be noncompliant, should be admitted for intravenous antibiotics until they are afebrile, culture results are available, and indicated imaging studies are completed. In addition, most clinicians recommend hospitalization and intravenous antibiotic therapy for all children less than 1 year of age. Initial parenteral antibiotic therapy should be with ceftriaxone (75 mg/kg/d divided q24h), cefotaxime (150 mg/kg/d divided q6h), gentamicin (7.5 mg/kg/d divided q8h). One should keep in mind the ototoxicity and nephrotoxicity of aminoglycosides. The change to an appropriate oral drug may be made after clinical response, and is based on culture sensitivity and resistance.

A recent study evaluated outpatient management of children greater than 1 month of age, using oral cefixime (16 mg/kg administered in the emergency department, followed by 8 mg/kg/d for 13 additional days), and found outcomes similar to a 3-day course of intravenous cefotaxime followed by oral cefixime.⁷ While this study suggests an increasing role for outpatient management of pyelonephritis in children, routine application is not appropriate. Only patients who are nontoxic, are tolerating PO administration, and are likely to be compliant can be considered for outpatient management.

Older children with cystitis can be treated as outpatients. Antimicrobials for outpatient treatment include trimethoprim–sulfamethoxazole, amoxicillin–clavulanate, and second- or third-generation cephalosporins. Community resistance patterns of *Escherichia coli* to trimethoprim–sulfamethoxazole are important and may be higher than 15% in some areas.⁸

Recommendations on the duration of therapy vary. Because short-course and single-dose therapies have been successful with women, short-course regimens may be acceptable for uncomplicated cystitis in adolescent girls. Because studies of short-course therapy in children have yielded conflicting results, a 7- to 10-day course of antibiotics is recommended in prepubertal children. In addition, the difficulty with accurately identifying all cases of upper tract disease in children makes

short-course therapy less acceptable in children.

DISPOSITION

Hospital admission is indicated for all infants younger than age 2 months and should be strongly considered in those less than 1 year of age. As noted previously, clinical judgment may be used for those infants who do not appear ill, who are more than 2 months old, and who will comply with oral antibiotics and recommended follow-up in 24 hours. In any patient managed as an outpatient, an initial oral dose of antibiotics or an i.m. or i.v. dose of ceftriaxone should be given in the emergency department. All admitted infants need evaluation by ultrasonography or intravenous pyelography (IVP), for possible obstruction and renal involvement. All children less than 5 years of age with UTI and fever should have a renal ultrasound and voiding cystourethrogram (VCUG) as soon as possible. For those patients who are treated as outpatients, it is essential to establish follow-up for radiographic evaluation of the urinary tract, if indicated, and repeat cultures.

Radiographic assessment of the urinary tract generally includes a renal ultrasound and either a VCUG or radionuclide cystography (RNC). Although these studies are not performed in the emergency department, an understanding of their role in the management of UTIs is important when determining a patient's disposition. The ultrasound evaluates renal and bladder anatomy. It is effective in revealing renal anomalies, hydronephrosis, ureteral dilatation, ureteroceles, calculi, and bladder wall thickening. It does not diagnose VUR and is not sensitive for renal scarring. The VCUG is obtained after the acute inflammation has subsided and details the anatomy of the urethra, bladder, and renal fossa. It demonstrates the presence of reflux and posterior urethral valves quite well. The RNC also demonstrates reflux but does not evaluate the urethra, and is thus unreliable in ruling out posterior urethral valves. Males of any age and girls less than age 5 should have an ultrasound (or IVP) as soon as possible to detect any obstructive process or renal disease. In those with a poor response to antibiotic therapy, the ultrasound should be performed in 48 to 72 hours.¹ A VCUG for evaluation of reflux may be delayed until after the infection has cleared, because infection predisposes to reflux.

In the past, radiographic evaluation of girls older than 1 year of age was reserved for those with pyelonephritis or those with recurrent lower tract infections. As many as 40% of UTIs have been found to be inadvertently diagnosed as respiratory or gastrointestinal infections, making history regarding previous infections unreliable.⁶ Also, because younger children are most likely to have renal injury with UTIs, most experts now recommend radiographic evaluation for all symptomatic children younger than 5 years of age with their first UTI.^{3,6} One study found fever to be indicative of a treatable urologic problem in 42% of girls younger than 5 years of age with UTIs.¹¹

COMMON PITFALLS

- Failure to consider UTI as a source of fever in otherwise asymptomatic children leads to missed or incorrect diagnoses.
- Failure to obtain appropriate specimens before administering antibiotics in the septic infant may lead to delay in diagnosis of obstructive lesions of the urinary tract.
- Mild respiratory and gastrointestinal symptoms do not preclude UTI as the source of fever in the young child.
- Failure to arrange adequate follow-up for radiographic studies and repeat cultures may result in failure to find treatable causes of renal disease.

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of Linda Settle, who wrote the previous version of this chapter.

There is an increasing population of children with ventricular shunts placed for obstructive hydrocephalus. Emergency physicians must familiarize themselves with the different types of cerebrospinal fluid (CSF) shunts that are commonly used in their area of practice and be able to evaluate shunt function, dysfunction, and infection.¹¹ Early diagnosis and management of ventricular shunt problems are important to prevent the sequelae of increased intracranial pressure (ICP) (e.g., death, blindness, and cerebral white matter destruction).

Children are shunted for a variety of congenital and acquired conditions. These include congenital aqueductal stenosis, myelomeningocele and Arnold-Chiari malformation, Dandy-Walker cyst, brain tumor, postinfectious or posttraumatic scarring, and growths related to tuberous sclerosis or neurofibromatosis. There is an increasing number of children born prematurely who were shunted after intraventricular hemorrhage.

Ventricular shunts are one-way calibrated systems made of silicone rubber, a material biologically well tolerated by the body. They consist of a ventricular catheter, a reservoir, and a distal catheter. The ventricular catheter allows CSF drainage through perforations along its length. Valve mechanisms in the tubing allow only unidirectional flow of CSF away from the ventricles; they are calibrated to open when a certain pressure differential is reached.⁶ A pumping chamber enables easy assessment of shunt function. When compressed, CSF should empty distally without resistance; when released, CSF should refill the chamber without delay. Distal tubing consists of silicone rubber. Most shunts end in the peritoneal cavity. Another site of CSF drainage is the atrium, and, rarely, the pleura, gallbladder, or urethra may be the distal site of drainage. A reservoir is placed proximal to the valve apparatus. CSF can be removed for sampling, or antibiotics and dyes can be instilled after manually occluding the system downstream from the reservoir.

An antisiphon device may be added to the shunt system to alleviate symptoms associated with excessive CSF runoff related to the creation of a negative intraventricular pressure on standing or with respirations. This device runs a serious risk of CSF underdrainage, leading to increased ICP. On-off devices are added distal to the valve mechanism to shut off the shunt so that alternative means of fluid drainage can be tested and the patient can gradually be weaned off the shunt. These devices drain automatically under high pressure, in case they are turned off for long periods of time.

Shunt problems include infection, mechanical dysfunction, and miscellaneous complications, depending on the terminal site of the shunt.^{3,12}

Infection is the main complication in shunted patients, but a majority of shunt revisions occur for malfunction rather than infection of the shunt.¹² Some important risk factors for infection are age younger than 6 months, duration of surgery, reinsertion after previous infection, and postsurgery wound infection. Five percent to 15% of ventricular shunts become infected, 70% within the first month of surgery and 90% within 6 months of surgery.⁴ A single preoperative dose of ceftriaxone may be a safe and effective way of preventing shunt infections.¹

Common mechanical problems of ventricular shunts include proximal obstruction, distal obstruction, and "slit ventricle syndrome." Miscellaneous, less common complications are related to the site of distal tubing insertion. In the peritoneum, migration of the tubing out of the peritoneal cavity into a hollow or solid organ, kinking or plugging of the distal end, volvulus, intestinal obstruction, and pseudocyst formation may occur. In the atrium, complications include endocarditis leading to shunt nephritis, pulmonary embolism, cardiac tamponade, and pulmonary hypertension. Gallbladder complications include atony, cholecystitis, obstructive jaundice, and fistula formation. Hydrothorax, pneumocranium, and pneumothorax occur in the pleura.

CLINICAL PRESENTATION

Shunted children may present with problems ranging from fever or headache to impending herniation related to ICP.

In most cases, the symptoms of shunt dysfunction are nonspecific but suggestive of increased ICP. These include fussiness, irritability, poor feeding, poor suck, altered sleep pattern, paradoxical crying, mental status changes, bulging fontanelle, seizures, apnea, bradycardia, and vomiting. Seizures occurring in children with therapeutic anticonvulsant levels should be suspected to be secondary to shunt malfunction. In a child old enough to talk, the most common presenting symptom associated with a shunt malfunction is headache. The problem with this complaint is that most individuals with shunts have headaches regularly. Headaches that are associated with shunt malfunction, however, are relentlessly progressive and are not ameliorated by lying down. Irritability and lethargy follow, as do personality change, lack of interest, and poor school performance.¹⁴ Other presenting symptoms include blurred vision, neck pain, back pain, puffiness around the eyes, gait disturbances, urinary incontinence, and subtle behavior change.^{9,13} When a patient is shunt dependent, the time between the onset of shunt obstruction and coma may be only a few hours.¹⁴

Children with ventriculitis may present with an insidious onset of symptoms of increased ICP, meningismus, abdominal pain (with ventriculoperitoneal shunts), and fever. Infection with *Staphylococcus epidermidis* accounts for more than 50% of shunt infections and usually presents with low-grade fever and an illness of insidious onset. *Staphylococcus aureus* and gram-negative infections may present as fulminating, life-threatening situations.

Patients with slit ventricle syndrome present with signs and symptoms of increased ICP, but a computed tomography (CT) scan shows either normal or slitlike collapsed ventricles and may sometimes show calvarial thickening and premature synostosis.² Some of the factors contributing to slit ventricle syndrome include low pressure from overdrainage of CSF; normal pressure and shunt function, but development of secondary high pressure waves from sudden vasodilation; periods of high pressure from intermittent proximal catheter obstruction; and intermittent high pressure despite normal catheter function.

DIFFERENTIAL DIAGNOSIS

The symptoms and signs of ventricular shunt problems are nonspecific. As such, they may mimic myriad common pediatric emergencies, ranging from viral infections, ear infections, and gastroenteritis to sepsis and shock. The prompt diagnosis and treatment of shunt malfunction and its discrimination from routine childhood illnesses such as gastroenteritis are critical to the well-being of the child.¹⁴ It is important to avoid treating all the presenting complaints as shunt related, thereby failing to investigate all other diagnostic possibilities. As with nonshunted children, other causes of fever and increased ICP must be included in the differential diagnosis.

Migraine headaches are a difficult diagnostic dilemma. Children with migraine headaches may present with headache, vomiting, and altered sensorium. If the ventricles are small on CT scan, adequate shunt function can be documented by physical examination and shunt series; if family history is positive, the diagnosis of migraines can be entertained and unnecessary surgery avoided.⁷

EMERGENCY DEPARTMENT EVALUATION

A detailed history should document the number of shunts in place, underlying cause for placement, time of initial placement, number of revisions, types of infections, and other complications.

The site and type of shunt, number of craniotomy scars, and skull defects should be evaluated. Signs of increased ICP include a bulging fontanelle, bulging craniotomy site, distended scalp veins, widely split sutures, and sun-setting eyes. Older children present with headaches, vomiting, and photophobia. Cushing's triad is a late finding of impending herniation. If the fontanelle or craniotomy site is sunken, overdrainage of CSF and decreased ICP should be suspected. A mobile reservoir or fluid-filled swelling over the shunt site suggests a disconnection or perforation. The presence of cellulitis, frank pus, or skin breakdown is associated with a high incidence of ventriculitis and shunt malfunction. The tubing should be palpated all the way down to the abdomen. Swelling, kinking, or disruption of continuity should be sought. Shunt breakages tend to occur most commonly 2 to 4 cm above the neck incision in ventriculoatrial shunts and just cephalad to the clavicle in ventriculoperitoneal shunts.⁸

Manual Testing

Once the pumping chamber is identified, the system can be tested by compressing the pump. Effortless emptying on compression suggests distal patency of the tubing, whereas difficulty on compression suggests distal obstruction rather than loculated CSF. If there is immediate refill on release of the pumping chamber, the tubing is probably patent proximally. If there is delayed refill or no refill, partial or complete proximal obstruction should be suspected. A click on compression may be felt with a malfunctioning valve. The sensitivity of the shunt pumping test is only 18% to 20%, and the predictive value of a negative pumping test, indicating shunt patency, is only 65% to 81%.¹³

A patient who is unstable at presentation, with or without signs of increased ICP, should be monitored with telemetry as well as a pulse oximeter and should never be transported for further radiologic evaluation without establishing a stable airway, undertaking measures to control ICP, and obtaining vascular access.

Radiologic Testing

A shunt series and neuroimaging⁵ are essential for further evaluation. Shunt series include anteroposterior and lateral skull and neck films, anteroposterior chest film, and right and left decubitus films of the abdomen. The latter are obtained to note the change in position of the abdominal end of the shunt tubing to determine whether the tip is free-floating. Tube migration, a fixed or stuck distal catheter, and curling within the abdominal wall or in pseudocysts can all be shown on plain film. Fusiform swelling of the distal end of the catheter suggests distal end obstruction. Abdominal ultrasound is a useful adjunct to plain films in detection of abdominal complications.

Initial evaluation requires head CT without contrast. The most important point in evaluating cranial CT scans is to have the last CT scan available for comparison of ventricular size. Normal or minimally enlarged ventricles may be related to increased ICP if the previous film showed small ventricles. The CT scan may also be helpful in delineating proximal shunt migration outside the ventricles. The most common malfunction is that of occlusion of the ventricular catheter by choroid plexus or glial tissue that has grown into the lumen of the catheter. Diagnosis can only be inferred from static imaging studies and plain x-rays that show enlarged lateral ventricles despite a well-placed ventriculostomy tube and intact connections of the shunt system.²

Pressure measurements, CSF assay, and radionuclide clearance are studies used to assess shunt function and infection. Using sterile technique, the clinician accesses the reservoir or pumping chamber with a 23-gauge butterfly needle, and the opening pressure, drip interval, and closing pressure are measured.¹⁵ Fluid is obtained for analysis and, if indicated, for decompression of the ventricles. A "shuntogram" may be obtained by injecting technetium Tc 99m (to check for patency and clearance of CSF) through the system when the symptoms are vague and clinical testing and CT scan are equivocal. Fifty percent of radionuclide activity should clear in 5 minutes, and scout films at 15, 30, and 45 minutes should show steady clearance of dye into the abdominal cavity. Flow studies (using Tc 99m) may be falsely normal in one-third of cases with shunt disconnection, because the dye may be transported in a fibrous band of tissue surrounding the disconnected shunt tubing, even when there is increased ICP secondary to shunt malfunction.

A pressure of more than 15 cm H₂O or reflux of dye into ventricles without spontaneous clearance suggests distal obstruction, whereas difficulty in obtaining CSF suggests proximal obstruction. Extravasation of dye into the surrounding soft tissue occurs with disruption of tubing continuity. An abnormal cell count, culture, or Gram stain suggests ventriculitis. Normal function is determined if ICP is less than 20 cm H₂O, 50% of technetium is cleared in 5 minutes, there is good dissemination in the abdominal cavity, and fluid is easily obtained for laboratory analysis.

EMERGENCY DEPARTMENT MANAGEMENT

History, physical examination, and laboratory and radiologic evaluation enable the emergency physician to determine whether the patient's presenting complaint is related to a shunt problem and whether the cause is mechanical dysfunction or infection, or both. In either case, in the presence of increased ICP, the initial emergency department management is the same.

Mildly elevated ICP may be managed with osmotic agents or diuretic agents alone, whereas extremely elevated pressures would require rapid-sequence intubation, hyperventilation, osmotic diuretics, and, sometimes, manual decompression of the ventricles through a butterfly needle.

Emergency department management of ventriculitis consists of obtaining the appropriate laboratory data and early institution of broad-spectrum intravenous antibiotics. Blood cultures are rarely positive unless the shunt terminates in the circulation (e.g., ventriculoatrial shunts), so CSF cultures must be obtained before starting antibiotics. If CSF cannot be obtained from the shunt, a lumbar puncture should be considered after ruling out increased ICP. Initial therapy consists of antibiotic coverage for gram-positive and gram-negative organisms. Vancomycin 10 mg/kg and ceftazidime 50 mg/kg offer optimal initial antibiotic coverage. Oral rifampin 10 mg/kg may be added for synergy. Operative and antibiotic management of ventriculitis is controversial, especially regarding intraventricular antibiotic therapy. A high degree of success has been documented with intravenous antibiotic therapy, externalization of the distal catheter, and subsequent revision of the shunt, once the infection is under control.¹⁰

Slit ventricle syndrome is managed surgically by placement of an antisiphon device.

DISPOSITION

Role of the Consultant

Neurosurgical consultation is necessary for all patients diagnosed with shunt malfunction, ventriculitis, or any other shunt-related problems. Most neurosurgeons prefer to tap the shunt themselves; therefore, the ED physician should consult the neurosurgeon before attempting to tap a ventricular shunt. Most shunt malfunctions and some shunt infections require shunt revision or externalization.

Indications for Admission

If there are any signs of increased ICP, the patient should be admitted to the intensive care unit for close monitoring with telemetry and pulse oximetry. All patients with shunt-related infections should be admitted for antibiotic therapy.

Transfer Considerations

For patients with shunt-related problems who are being transferred to a tertiary care center, ensure an adequate airway, adequate control of ICP, and intravenous access. The patient's status and the transferring physician's concerns should be discussed in depth with the accepting agency's physician. Only Advance Cardiac

Life-Support units should be used, and, in the case of an unstable patient, air transport should be used.

COMMON PITFALLS

- The most common pitfalls in assessing children with shunts are the tendency to attribute all presenting complaints to shunt-related problems and failure to pursue other possible diagnoses. On the other hand, failing to assess for shunt-related problems, even when the child presents with an upper respiratory infection, can be potentially fatal.
- All patients with ventricular shunts do not necessarily require a shunt series and a CT scan at every emergency department presentation, but they do require clear documentation of an infectious focus, if they present with fever, and a thorough assessment of the central nervous system and shunt and tubing sites. If there is any doubt that the symptomatology is related to shunt malfunction, a neurosurgical consultation and isotope clearance studies are necessary.
- Lack of availability of comparison films can pose a problem. If the CT scan shows no signs of hydrocephalus, then there is no issue. However, in the face of dilated ventricles, one is left with the dilemma of determining the clinical significance when comparison views are not available. In most cases, the neurosurgeon will opt to observe the patient if symptoms suggestive of increased ICP present.

Nearly 22 million children are injured each year in the United States—almost one out of every three children.³ Trauma is the leading cause of death in children aged 1 to 15 years and is responsible for over one-third of all deaths in children younger than 1 year of age. More than 20,000 children (birth to 19 years) die of injuries from trauma each year.²³

Although injuries from trauma are a common cause of death and disability in children, these injuries are spread over such a wide geographic area that it is uncommon for any single emergency department or emergency physician to have extensive experience in the care of pediatric trauma victims. One reason for this is that the majority of ill and injured children are initially taken care of in the community emergency department setting.

It is extremely important to recognize that any well-trained emergency physician should have the diagnostic and therapeutic skills required to care for the pediatric multiple trauma victim. The numerous significant differences between adult and pediatric trauma victims preclude a totally unified approach to all multiple trauma patients. A protocol-oriented approach to the care of pediatric victims with multiple trauma, accentuating differences between adults and children, is presented in this chapter.

Most important to the care of the pediatric multiple trauma victim is *preparation* of the entire emergency department and surgical backup teams to care for pediatric patients with acute injuries. There is a thin margin for error in caring for severely injured children: The physician and nurse must be familiar with the appropriate elements of evaluation and resuscitation, including normal baseline parameters in children. Although caring for seriously injured children can be among the most demanding of emotional and psychological experiences, the appropriate preparations can result in a well-organized resuscitation with excellent outcomes. A general emergency department seeing 20,000 undifferentiated patients per year may see only four or five seriously injured children per year, but the time and effort necessary to prepare for such events are well worthwhile. In this respect, pediatric multiple trauma is a low-frequency but extremely high-yield event.

The major causes of pediatric trauma include motor vehicle accidents, automobile–pedestrian collisions, burns and smoke inhalation, falls, poisonings, and child abuse. Data from the National Pediatric Trauma Registry indicate that about 90% of childhood injuries are due to blunt trauma.²⁰ The remaining 10% of injuries are penetrating and tend to occur in urban settings or are due to farm-related accidents or hunting injuries. Mechanisms of injury vary considerably by age. Most infants or toddlers suffer trauma as a result of falls, vehicular accidents as a passenger, or child abuse.¹³ As the child approaches the preschool and grade-school age group, automobile–pedestrian accidents become increasingly common as a source of injury for the child. However, passengers in motor vehicles also account for a large percentage of injuries in this age group. In the adolescent years, motor vehicle accidents (with or without the influence of drugs and alcohol) become the most common cause of pediatric trauma.

ANATOMIC AND PHYSIOLOGIC DIFFERENCES

One of the most common statements in pediatric training programs is, “Children are not simply small adults.” This is true, and it is important to review the differences between adults and children that result in differences in therapy and evaluation.

Because children are smaller, the amount of medication or fluids given to injured children varies according to a child's lean body mass. The most accurate way of calculating fluid or medication dosages is by using lean body mass calculations, but, in the emergency department setting, this is impractical at best and futile at worst.¹² Instead, fluid and medication dosages can be calculated on the basis of the child's overall weight. At the time of evaluation, the child's weight is not often known; more important, when a child is severely injured and requires resuscitative efforts, there is no time to weigh the child or check with the parents regarding the last known weight. Because of this, it is important to establish general guidelines for predicting the child's weight by age or length.

First, many pediatric critical care centers publish charts and tables that can be placed on the wall of the resuscitation area. These include weight as related to age and indicate the appropriate-sized tubes and drug calculations for resuscitation. Second, Luten and Broselow have developed a resuscitation tape that can be used to measure the child's length; from this measurement, the child is placed in a color zone that lists specific fluid and drug dosages, as well as resuscitative equipment.¹² Third, the child's weight can generally be predicted, with a fair degree of accuracy, based on age. The Broselow Resuscitation Tape or some other length-based system is the method of choice in estimating the child's weight.

There are important anatomic differences between adults and children. The child's head occupies a larger total body surface area and weight than in the adult. Head injuries occur in approximately 75% of all seriously injured pediatric patients but in only about 50% of adult patients.¹³ Because the head is the major organ for heat loss, a greater percentage of loss, and therefore temperature instability, may occur in children. The occiput is more prominent in children, which affects airway positioning. The child's cranial sutures are open at birth and gradually fuse by the age of 12 to 18 months. Because of this, palpating the anterior and posterior fontanelles can be an important source of information in children with increased intracranial pressure. The child's brain also has a higher percentage of white matter versus gray matter, resulting in a greater overall “plasticity” and the ability to withstand deceleration injuries.

The child's neck is considerably shorter and has more subcutaneous tissue than in an adult. In addition, the cervical spine is more cartilaginous and is far less commonly fractured than an adult's. Nonetheless, cervical cord injuries are not uncommon in children, although fully two-thirds of such injuries result in spinal cord injuries without radiographic abnormalities (SCIWORA) present to the cervical spine (see [Chapter 300](#)). Because the young child has a shorter neck, with more subcutaneous tissue, evaluating the midline position of the trachea and neck veins can be considerably more difficult.

The larynx is located in a more cephalad and anterior position in children, which makes intubation considerably more difficult. The epiglottis sits at nearly a 45-degree angle and is far more cartilaginous in children. The narrowest portion of the pediatric airway is not at the glottis, as in the adult; rather, the level of the cricoid cartilage is the narrowest portion until about age 10.¹³ In addition, the cricoid cartilage is also the site of very loose, abundant areolar columnar epithelium, which reacts easily

to either infectious processes or pressure necrosis.

The chest in children is more compliant, less bony, and more cartilaginous than in an adult. There is far less overlying muscle and fat in the child, so that forces applied to the chest can easily be transmitted to underlying tissues. The mediastinum is not well fixed in children, so pneumothorax easily progresses to tension pneumothorax in children. Children's diaphragms are much more distensible than adults', and they insert at a more horizontal angle. As a result, gastric distention may easily cause pulmonary compromise by pushing the diaphragm superiorly.

As with the chest, the child's abdomen is less protected by overlying muscle and fat, so that mild forces applied to the abdominal wall can injure the abdominal structures. Children are diaphragmatic, or "belly," breathers, which means they require full diaphragmatic excursion to produce normal respirations. They are far less able to recruit the intercostal muscles to assist in respiration than are adults. For this reason, the restriction of movement of the diaphragm from irritation secondary to blood may cause respiratory compromise. The bladder is well protected by the overlying pubic bone in adults, whereas this organ is an intraperitoneal structure in young children and is far more prone to injury from blunt trauma.¹¹

The long bones of children accommodate growth through the epiphyses or growth plates. The epiphyseal–metaphyseal junction is the weakest portion of the child's joint, so that ligamentous structures are actually stronger than the growth plate junction. For this reason, epiphyseal fractures are common in children.

THE PRIMARY AND SECONDARY SURVEYS

Because of the numerous differences between adults and children, the emergency physician must clearly understand a protocol approach to evaluating such patients in a rapid but thorough fashion. By far, the easiest way of attaining this is to integrate the child's care with the adult's to whatever extent possible. The simplest way of doing this is to use the primary survey–secondary survey format initially described by the American College of Surgeons Committee on Trauma in the *Advanced Trauma Life Support (ATLS)* course.³ The primary survey is an initial assessment of the patient's airway, oxygenation, ventilation, circulation, perfusion, and overall level of consciousness. It is a physiologic survey that assesses the overall compromise to the patient's vital systems.

Differences between adults and children require modification of the primary survey ([Table 297.1](#)). This modification simply recognizes the important differences in the diagnosis and treatment of shock in children, as well as the importance of maintaining a normal homeostatic thermoregulatory environment for infants and young children. The essential tenets of the primary survey are similar, however.

TABLE 297.1. Primary Survey Approach to the Pediatric Trauma Patient

Because it is common to encounter serious physiologic derangements in children, it may be necessary to interrupt the primary survey to provide life-saving resuscitative measures. Using such a protocol approach allows the emergency physician to give this care and then to return immediately to a structured evaluation.

The primary survey resuscitative phase should take only a few minutes to perform, but it gives the emergency physician an accurate baseline assessment of the child's overall physiologic status. By using a protocol approach to the patient, the emergency physician can be assured that potential threats to life and limb are identified in sequential yet complete fashion. One must remember the important differences between adults and children in provision of an airway; maintenance of cervical spine immobilization; use of appropriate ventilation; recognition of circulatory stability and shock; provision of vascular access; role of oxygenation, ventilation, and perfusion in pediatric head injury; and maintenance of a normal homeostatic regulatory environment.

During the primary survey, the patient is fully undressed for a detailed secondary survey, which is a timely, directed evaluation of each body area, usually performed in head-to-toe fashion. The secondary survey assesses the type and severity of injury, as well as the body system's potential contribution to physiologic instability. The examination should not delay evaluation or treatment of life-threatening injuries. In addition to identifying specific injuries in each body region and their overall severity, it is also important to begin to assess the appropriate definitive care for the injury, as well as the priority of therapy as compared with others identified in the secondary survey.

AIRWAY

The highest priority in caring for either adult or pediatric patients with multiple trauma is providing a patent airway with adequate ventilation and oxygenation. However, significant differences in the pediatric airway require an approach different from that for an adult.

Although cervical spine injuries are less common in children than in adults, it is extremely important to protect the cervical spine throughout all airway manipulations in injured children. As mentioned, fully two-thirds of all children with spinal cord injuries have no radiographic abnormalities apparent on initial or follow-up radiographs. Most of these children have symptoms of transient paresthesias or numbness that occur at the time of the impact injury.¹³ In particular, extreme caution must be used in caring for children who are at extremely high risk for the development of cervical spine injuries (e.g., unrestrained infants in motor vehicle deceleration injuries, children struck by automobiles, or any patient who has fallen from a height greater than 10 ft). In these children, even if the initial lateral cervical spine radiograph is normal, cervical spine integrity must be protected.

By far, the most underrated mechanism of protecting the cervical spine in children is in-line cervical immobilization. Because of the child's smaller size, providing such immobilization is more often effective in children than in adults, although it often requires a two-rescuer approach in the struggling child. One rescuer holds the cervical position while maintaining the airway, while the other ensures that the distal portions of the body are also immobilized until more permanent means can be obtained. All emergency medical services providers should have rigid pediatric cervical spine collars available for field use. Children injured in infant seats should usually be left in the infant seat and transported after appropriate padding has been placed to prevent movement during transport.

If the patient's cervical spine has not been immobilized in the field, the emergency physician should immediately provide in-line cervical immobilization while a rigid cervical collar, sandbags, and tape are applied. It is often possible to use both a rigid cervical collar and sandbags with tape to immobilize a child's cervical spine without compromising the airway. The anterior portion of the rigid collar can be removed once sandbags and tapes are present, so that the airway can be evaluated.

Concurrently with stabilizing the cervical spine, the airway should be evaluated and positioned. Although many common errors are made in the evaluation and maintenance of the pediatric airway, by far the most frequent and obvious is failure to position the airway properly. Because the larynx is both more anterior and more cephalad in a child, positioning the airway similar to the adult trauma patient will not result in effective airway positioning. In addition, in severely injured children, the tongue and other muscular tissue attached to the mandible often fall posteriorly. This "mandibular block" of tissue can cause significant respiratory compromise. [Figure 297.1](#) summarizes the significant differences in the child's airway.

Figure 297.1. (A) Airway at high risk for occlusion. Flexion of the neck on the thorax is caused by a prominent occiput. (B) Sniffing position, which gives maximum possibility for a patent airway. Note the mild extension of the head. Flexion is now corrected by elevation of the head (I) and/or posterior neck support (II).

To ensure that the airway is patent in a child, the child is placed in the “sniffing position” (with the neck slightly flexed on the spinal axis and the head slightly extended on the neck). It is called the sniffing position because it approximates the position a child’s airway would be in if he or she were sniffing a flower. In practical terms, this position can be obtained by placing either the rescuer’s hand or a small towel under the occiput of the head. Because the occiput is more prominent, only slight elevation is usually required. In addition, a jaw thrust or chin lift maneuver should be provided to ensure that the mandibular block of tissue does not fall posteriorly and obstruct the airway, and also to provide appropriate extension of the head on the neck. The jaw thrust maneuver is far more practical in the child and is also easily obtainable because of the child’s smaller size.

Unless the airway is appropriately positioned as described here, it is often difficult to provide appropriate oxygenation or ventilation, even in the presence of otherwise acceptable bag-valve-mask ventilation or endotracheal (ET) intubation. Proper airway positioning in the child must be practiced in advance, both on mannequins during appropriate training and also in evaluating non-critically ill children in the emergency department. *It is the emergency physician’s responsibility to ensure that prehospital care providers and emergency department staff are fully aware of these factors and can provide appropriate airway positioning in the child.*

Once the airway has been appropriately positioned, a rapid assessment should be made for airway patency and adequacy of ventilation. If airway obstruction exists, manual clearing or suction with a rigid tonsillar suction should be provided, after which the airway should be repositioned. In addition, the respiratory effort should be at the appropriate rate and should provide adequate bilateral chest wall rise. The presence or absence of cyanosis should also be noted. Supplemental oxygen should be provided to all pediatric multiple trauma victims until the airway can be completely evaluated. Up to about age 4 to 6 months, children are obligate nasal breathers, so nasal obstruction must be quickly and effectively relieved to allow spontaneous ventilation.

A second common error in the evaluation of the pediatric patient is failure to recognize the presence or absence of adequate ventilation. Because children have small tidal volumes, the chest wall rise that is usually present may be subtle. For this reason, it is important to observe normal ventilation in children who present to the emergency department who are *not* in respiratory distress. Both the rate and depth of ventilation should be assessed rapidly but effectively. [Table 297.2](#) indicates the appropriate ventilation ranges for children by age. To assess the adequacy of air movement, it is often helpful for the examiner to moisten his or her cheek and place it close to the child’s nose and mouth to feel whether air is being exchanged. Placement of the cheek close to the child’s mouth also allows simultaneous assessment of rise of the chest wall.

Age	Pulse/min		Respiratory Rate/min		Systolic Blood Pressure (mm Hg)	
	Min	Max	Min	Max	Min	Max
6-1 mo	100	160	30	60	60 (term)	80
1 mo-1 yr	100	160	20	40	70	100
1-2 yr	90	130	20	30	70+2×age (yr)	105
2-4 yr	75	120	20	30	70+2×age (yr)	105-110
6-14 yr	60	110	15	25	70+2×age (yr)	115-130

Min, 2nd percentile, minimal acceptable value (adult, sleeping); Max, 95th percentile, maximal acceptable value (agitated, crying).
*Vital signs must be correlated with clinical picture.

TABLE 297.2. Ranges for Pediatric Vital Signs^a

Although this assessment may seem relatively simple, it is often neglected by even the best emergency physicians and trauma surgeons in the early care of the pediatric multiple trauma patient. It cannot be overstated that *the positioning and initial assessment of the child’s airway are critical to appropriate care.*

Oral and Nasal Airways

In unconscious adult trauma patients, oral or nasal airways are often used to assist in ensuring airway patency. However, such airways are less commonly useful in children for several reasons. First, in the conscious child, oral or nasal airways can produce significant vomiting or laryngospasm. For that reason, their use should be strictly limited to unconscious patients. Second, the posterior pharynx of a child is the site of highly vascular adenoidal tissue, which is almost always traumatized by the insertion of a nasal tube. The significant amount of bleeding that can be produced from such tubes may interfere with further efforts to secure the airway. Third, and most important, there is a tendency to assume that the placement of an oral or nasal airway helps ensure that the child’s airway is in a proper position. This is certainly not the case in children, as the mandibular block of tissue can easily obstruct the portion of the airway just above the glottis, even in the presence of either a nasal or oral airway. For all of these reasons, airways have a much more limited role in pediatric patients. ¹³

Bag-and-Mask Ventilation

In pediatric multiple trauma patients with a compromised airway, there is a natural tendency to rush toward ET intubation. This is an extremely common but potentially fatal mistake. Most children can be initially ventilated in an adequate fashion by bag-and-mask ventilation, assuming the physician remembers several factors.

First, giving bag-and-mask ventilation to children is much easier than in adults because of the child’s smaller size: It is much easier to generate appropriate tidal volumes and airway pressures in children than in adults.

Second, providing an adequate seal by face mask is usually much easier in children than in adults. In the adult, there are often significant air leaks around the mask, but in a child it is usually easy to provide an adequate seal between the face and the mask (assuming that the appropriate size is used) by pressing firmly with one hand on the mask and with the other either under the child’s head or neck. In small children or infants, the thumb can be placed on the mask and the fingers underneath the head. The appropriate-sized mask can be selected by choosing one that easily fits from the bridge of the nose to the bony portion of the symphysis of the mandible. A full range of sizes of pediatric ventilation masks should be available in all emergency departments, as well as to all prehospital care providers. The bag-and-mask technique should be taught to all emergency services personnel in both the prehospital and in-hospital settings.

One of the most frequent criticisms of bag-and-mask ventilation versus ET intubation is protection of the airway from aspiration. However, the judicious use of Sellick’s maneuver precludes the possibility of aspiration if applied appropriately. This maneuver consists of placing pressure on the cricoid cartilage posteriorly, which occludes the esophagus against the spinal column, thereby preventing regurgitation. Although care should be taken not to occlude the carotid arteries, this maneuver

can be performed easily and ensures that vomiting and subsequent aspiration will not occur.

The adequacy of assisted ventilation should be assessed by ensuring that there is equal bilateral chest wall rise at appropriate rates. Listening to the child's chest with a stethoscope may be of some benefit, but it is important to recognize that children's chests transmit sound easily. This results in inaccurate estimations of presence or absence of pneumothoraces, right main stem bronchus intubation, and so forth. By far, the best single guide to adequacy of ventilation is the presence of bilateral chest wall rise.

Nasogastric Tube Placement

Whenever assisted ventilation is provided to the pediatric multiple trauma victim, a nasogastric tube should be placed. Aerophagia and gastric distention are common in the pediatric multiple trauma victim and may result in distention of the left hemidiaphragm, compromising ventilation. Placement of an appropriate nasogastric tube should empty both air and some particulate matter from the patient's stomach.

Assessment of appropriate nasogastric tube position should not be done by injecting air into the stomach. In addition to further filling and distending the stomach, the pediatric patient's gastroesophageal junction is far less patent than in the adult. It is common to hear air bubbling over the stomach, even when the nasogastric tube is in the esophagus. More importantly, the purpose of the nasogastric tube is to empty the stomach. It is possible that the tube may be in the stomach but positioned anteriorly, and therefore not emptying the stomach. Therefore, the best means to assess appropriate positioning of the nasogastric tube is to place 15 mL of normal saline through the tube and ensure that a like quantity can be aspirated easily.

Endotracheal Intubation

As indicated previously, most children can be adequately ventilated initially by bag-and-mask ventilation, but there are three general indications for ET intubation in the pediatric multiple trauma patient¹⁸:

1. Inability to adequately ventilate the child by bag-and-mask methods
2. The need for prolonged control of the airway, including prevention of aspiration
3. The need for controlled hyperventilation in patients with serious head injury

When any of these indications are present, adequate bag-and-mask ventilation with 100% oxygen is continued until appropriate preparations can be made for ET intubation. A length-based system can be used to select the appropriate-sized ET tube and intubation equipment.¹²

Other preparations necessary before ET intubation include adequate preoxygenation of the patient by bag-and-mask ventilation with 100% oxygen. In most cases, a stylet should be placed in the ET tube to prevent deflection of the tube away from the vocal cords. However, it is important to ensure that the stylet does not advance past the level of the ET tube, because tracheal perforation has been reported in such instances. The child should be suctioned adequately to allow optimal visualization of the cords.

In general, a straight laryngoscope blade is more helpful in children. A curved blade that is adequately lodged in the vallecula may not allow adequate visualization of the vocal cords, because the larynx is both more anterior, more cephalad, and obscured by the floppy epiglottis that sits at a nearly 45-degree angle. For this reason, a straight laryngoscope blade is usually better able to allow visualization of the cords in the child. In any cases in which there is a chance of cervical spine injury, in-line cervical immobilization during ET intubation should be maintained.

Airway positioning is critical during ET intubation. The child is placed in the sniffing position, and a Sellick maneuver is used to prevent vomiting and aspiration. Pulse oximetry readings should be monitored to assess oxygenation. If oxygen saturation drops, the intubation attempt should be stopped and 100% oxygen should be administered prior to further attempts.

Once the tube has been placed within the trachea, the best way to ensure proper position is to watch for bilateral, symmetric chest wall rise commensurate with the rescuer's efforts of using bag ventilation on the child. Listening to the chest in the child is much less helpful than in the adult, because the chest transmits sound very easily in children. It is not uncommon for the rescuer to hear relatively clear breath sounds on both sides in the child, even though the tube is either in the esophagus or in the right main stem bronchus. The presence of bilateral, symmetric chest wall rise and improvement in the child's overall color and condition should confirm placement of the tube. Colorimetric or quantitative end-tidal CO₂ detectors are also recommended for confirmation. If there is any question, one can try to revisualize that the tube is between the vocal cords. A chest radiograph can be obtained to ensure that the tube is in the proper position in the trachea.

The tube is secured to the upper lip with benzoin and taped to ensure that it is not dislodged during further resuscitative efforts.

Oral Versus Nasotracheal Intubation

In adult trauma patients in whom ET intubation is required and in whom the cervical spine has not been adequately cleared, blind nasotracheal (NT) intubation is sometimes utilized, assuming that in-line cervical immobilization is carefully maintained. Should blind or visualized NT intubation be used in the pediatric patient? Several facts argue against the *routine* use of this procedure in children.

First, as indicated previously, although cervical spine injuries are less common in children than in adults, they still occur with sufficient frequency to require careful maintenance of cervical spine protection in children at risk for injury.

Second, numerous anatomic differences between the adult and the child make it much more difficult to perform either blind or visualized NT intubation in the child. First among these differences is the fact that the larynx sits farther forward and more cephalad and is protected by the nearly 45-degree angle of the epiglottis. For this reason, blind NT intubation in a child requires the tube to take a sharp anterior angle after clearing the level of the nasopharynx. This can sometimes be obviated by firm rearward cricoid pressure (Sellick maneuver), but this does not always produce sufficient posterior displacement.

In addition, the child's nasopharynx is the site of highly vascular adenoidal tissue, which is often traumatized by the passage of the NT tube. Once such bleeding is present, it is extremely difficult to stop and may complicate efforts at oral intubation.

The rapid sequence induction (RSI) technique for emergency intubation has gradually become the standard for intubating most critically injured trauma patients. This technique is described in detail in [Chapter 235](#). Most patients will have a suspected cervical spine injury or will require intubation before adequate radiographs and definitive examination. Appropriate measures must be taken to stabilize the cervical spine, and a neurologic examination must be done before RSI. The RSI technique in a trauma patient requires one person to stabilize the cervical spine, one to hold cricoid pressure, and a third to intubate and supervise the airway. In those exceedingly rare cases in which direct laryngeal injury is present and precludes ET intubation, needle cricothyroidotomy should be performed.

Needle cricothyroidotomy should be used only in rare circumstances in children.^{13,18} It is largely a means to avoid surgical cricothyroidotomy, which is difficult in the child. Because the child can almost always be ventilated by bag-and-mask techniques, even with severe laryngeal injury, needle cricothyroidotomy and surgical cricothyroidotomy are rare in children. Although surgical cricothyroidotomy has been performed successfully in numerous adult series of patients, the cricoid is the narrowest portion of the pediatric airway, and significant bleeding often occurs during this technique. Several series in pediatric trauma patients have indicated that this technique should not be used in children, except in the extremely experienced hands of pediatric surgeons or pediatric otolaryngologists.^{9,13,18}

In those rare circumstances in which an airway is needed immediately because of massive facial or laryngeal trauma in the child, needle cricothyroidotomy is an alternate technique. In this technique, a 14- to 16-gauge catheter is placed in the midline through the cricoid cartilage and is advanced distally ([Fig. 297.2](#)).

Figure 297.2. Needle cricothyroidotomy. **(A)** The cricothyroid cartilage is palpated in the midline, between the thyroid and cricoid cartilage, and is punctured at a 45-degree angle with a 5- or 10-mL syringe attached to a 14-gauge catheter. **(B)** As the catheter is advanced, the syringe should be aspirated, with free and rapid entry of air into the syringe indicating position in the trachea. **(C)** After initial entry into the trachea, the catheter is carefully advanced distally. **(D)** After the catheter is advanced, tracheal position should be carefully rechecked by again aspirating the syringe. **(E)** Ventilation is provided either by bag and mask (as shown) or by jet ventilation. **(F)** A 3.5-mm pediatric endotracheal tube adapter fits easily into the hub of the catheter, allowing ventilation. (From Mayer T, ed. *Emergency management of pediatric trauma*. Philadelphia: WB Saunders, 1985.)

Summary: Airway

Evaluating and managing the pediatric airway is the most critical aspect of the care of the pediatric trauma victim. In most cases, bag-and-mask ventilation can be used to maintain adequate oxygenation and ventilation during the initial evaluation. When the airway must be secured on a more definitive basis, the emergency physician should be skilled at performing RSI. Cervical spine immobilization should be maintained during all types of airway manipulations.

CIRCULATION

Once the airway has been secured and adequate ventilation and oxygenation are provided, attention is turned to the patient's circulation. The major goals are to assess overall circulatory status, including pulse and perfusion, while obtaining reliable venous access with the fewest possible complications and controlling any internal or external hemorrhage. Assessing and treating the circulatory system correspond closely to an accurate assessment of the presence and degree of shock in the pediatric patient.

The initial assessment of the overall circulatory status of pediatric multiple trauma patients involves determining the patient's *pulse* and *perfusion*. Palpating the carotid, femoral, brachial, or radial pulse may be done during proper airway positioning. The initial circulatory assessment should include palpating the pulse for quality (strong, normal, thready), rate, and regularity.

Although tachycardia is a normal response to hypovolemia in both adult and pediatric patients, the tachycardic response to blood loss is much more profound in children than in adults. Therefore, the earliest sign of altered circulation in impending shock in children is tachycardia. In general, any child with tachycardia (as defined by rates exceeding those in [Table 297.2](#)) should have a venous access line in place and appropriate fluid bolus.

Assessing the patient's overall tissue perfusion lies at the heart of the early diagnosis and recognition of shock and is discussed more fully in [Chapter 236](#). Basic measures of peripheral perfusion include assessment of capillary refill and pallor of the mucous membranes. However, children's total peripheral resistance rises rapidly in response to initial blood loss, so they tend to "clamp down" in their peripheral circulation rapidly. For this reason, capillary refill is an early sign of shock. Pallor of the mucous membranes usually takes somewhat longer to occur but should be assessed.

Indicators of central perfusion include more sensitive measures of total peripheral resistance (diastolic blood pressure or pulse pressure), maintenance of central nervous system perfusion, and decreases in renal blood flow (decreased urine output). Because head injury occurs in up to 80% of patients with serious multiple trauma, following the status of the central nervous system may be difficult as a measure of central perfusion. Measuring urine output, essential in the care of the shock patient, requires at least 30 minutes to 1 hour to ensure accuracy, because it is a dynamic rather than a static measurement. For this reason, the emergency physician must be able to follow the pulse rate, pulse pressure, and diastolic blood pressure as indirect measurements of the central perfusion of the child in shock.

Venous Access

Rapid, efficient venous access is one of the most challenging problems facing the emergency physician responsible for caring for pediatric multiple trauma victims. The alternatives include percutaneous peripheral venous cannulation, intraosseous infusion, peripheral venous cutdown, and percutaneous central venous access. One should select the route that is the most rapid and yet involves the fewest possible complications for the child. In addition, the vascular access site and technique should allow for the most rapid means of replenishing vascular volume.

In most cases, the pediatric patient will be well served by initial placement of a percutaneous peripheral venous catheter whenever possible. When this fails in a child younger than age 6, intraosseous infusion should be used immediately. Following this, or in cases in which an intraosseous line cannot be placed, one must decide whether to pursue central venous cannulation or peripheral venous cutdown. Whichever technique is used, the emergency team should have prepared in advance for such eventualities and should plan carefully which vascular access technique is to be used. Appropriate equipment for either procedure should be available in most emergency departments.

See [Chapter 237](#) for a detailed review of vascular access techniques.

HEAD INJURY

Because the primary survey is a resuscitative survey of the critically injured patient, the assessment of the level of head injury is an important yet secondary one in the pediatric multiple trauma patient. As mentioned previously, head injuries are present in nearly 80% of all severely injured multiple trauma patients. However, maintaining a patent airway with adequate ventilation and ensuring adequate central and peripheral perfusion are extremely important in treating the head-injured child. Providing the "ABCs" is critical to the survival of head-injured children.

During the primary survey, the goal is simply to assess the general level of injury, and the best way to assess the overall central nervous system injury is the patient's level of consciousness. The Glasgow Coma Scale (GCS) is the best way to assess level of consciousness in a definitive fashion, but during the primary survey, it is only important to get a general assessment of the patient's overall level of consciousness. For this reason, the ATLS course recommends the AVPU mnemonic ³:

A: Alert
 V: Responsive to verbal stimuli
 P: Responsive to painful stimuli
 U: Unresponsive

By using this brief, simple assessment, the emergency physician can gain a sense of whether any neurologic injury is present. In general, a patient who responds only to painful stimuli or does not respond at all should be assumed to have a major head injury until a GCS score can be assessed. Although children with severe head injuries (GCS less than 8) were often hyperventilated (pCO₂ 28 to 32) in the past, more recent studies clearly indicate that children should receive only minimal hyperventilation (pCO₂ 35 to 40) unless intracranial pressure cannot be controlled by other means. ¹

In addition to assessing the overall level of consciousness, the examiner should quickly check for the size and reactivity of the pupils and the presence of any

posturing or lateralizing findings. A more detailed neurologic examination can be done in the secondary survey.

SHOCK

To recognize the early stages of hypovolemic shock in children, the emergency physician must have an astute eye and a clear understanding of the differences between adults and children. *The earliest finding in pediatric patients in shock is tachycardia.*^{9,14,18} [Table 297.2](#) lists pulse values by age. Any child who has undergone major trauma and has a pulse rate above these values should be assumed to be in shock until proven otherwise, particularly if other findings of shock are present. A vascular access line is established rapidly, and at least 20 mL/kg of a crystalloid solution (usually lactated Ringer's) is given. Strict attention is paid to preinfusion and postinfusion parameters to assess the patient's response to fluid therapy. See [Chapter 236](#) for more details on shock.

SECONDARY SURVEY

After an overall survey of the patient's cardiorespiratory, neurologic, and shock status, the patient is undressed fully for an adequate secondary survey. Although it is important to ensure the child is undressed rapidly and appropriately, infants and small children, up until the age of about 2 years, may require warming lights or blankets to maintain their temperature at a normal level. Even in older children, particularly in the development of hypovolemic shock, the child should be covered when the secondary survey is not being performed. Children's homeostatic thermoregulatory responses are not nearly as well developed as those of adults. Undressing a small child in an air-conditioned emergency department, infusing relatively cold intravenous fluids, and placing alcohol or povidone-iodine solutions on the skin all serve to make the child hypothermic.

Two additional points are important before proceeding to the secondary survey. First, because the condition of pediatric patients may deteriorate rapidly and because these patients often present with subtle signs and symptoms, the elements of the primary survey must continually be reassessed over the course of the patient's initial emergency department resuscitation. The examiner must keep updated on the status of the airway, breathing, circulation, response to shock therapy, neurologic disability, and core body temperature. If there are signs of sudden deterioration, one can quickly run through a mental checklist of possible causes of deterioration ([Table 297.3](#)).

AIRWAY
Adequate airway position?
Adequate tidal volume?
Adequate rate?
Pneumothorax?
Tension pneumothorax?
ENDOTRACHEAL TUBE
Dislodged?
Plugged?
Right main stem bronchus?
INTRAVENOUS ACCESS
Functional?
Adequate size?
Medications infusing?
UNRECOGNIZED BLEEDING
Pelvis
Chest
Abdomen
Thighs
Extremities
UNRECOGNIZED INJURIES

TABLE 297.3. Checklist for Sudden Deterioration

Second, if a nasogastric tube and indwelling bladder catheter have not been placed, the examiner should assess whether they are necessary. A nasogastric tube should be placed in any child receiving assisted ventilation, even bag-and-mask ventilation, and in patients in which there is suspicion of intraabdominal trauma or when aerophagia or crying is causing appreciable abdominal distention. An indwelling bladder catheter is placed in all patients who have signs or symptoms of shock or who may develop shock. The amount of fluid in the bladder at the time of catheterization is noted and saved in a separate container. One must not routinely place a bladder catheter in extremely young children or in those with evidence of urethral injury.

The secondary survey is usually performed in a head-to-toe fashion, which allows for an easily followed protocol approach. One must not neglect the cardiorespiratory system during the head-to-toe evaluation: The major threats to life in the *early* evaluation of the pediatric multiple trauma patient come from the cardiorespiratory system.⁹ Although head injury is the most common cause of death in pediatric multiple trauma victims, providing oxygenation and ventilation, as well as central perfusion, addresses the earliest threats to life.

Finding one severe injury during the evaluation should not cause the physician to cease evaluation, except to treat life-threatening injuries. Multiple systems injuries are common in pediatric patients, and a detailed evaluation of each body system is necessary.

Early in the secondary survey, an appropriate history is taken from the patient, the family, or the paramedics who brought the patient to the emergency department. The history should include all events leading up to the accident, the mechanism of injury, the biomechanics of injury, time of injury, initial status at the scene of injury, and clinical course during transportation. Additional details on chronic illnesses or injuries, allergies, medications, and the time of the last meal should be taken. The ATLS course of the American College of Surgeons Committee on Trauma uses the AMPLE mnemonic:

- A: Allergies
- M: Medications
- P: Past illnesses or injuries
- L: Last meal eaten before injury
- E: Events preceding the injury

Physical Examination

Head

The secondary survey should begin with an in-depth evaluation of the child's head and neck, including the soft tissues, bones, ears, eyes, and neck. Any signs of obvious trauma are noted. Bleeding is stopped with pressure dressings. Mucous membranes are examined for paleness and overall hydrational status. The eyes are examined for random eye motions, pupil size and reactivity, and foreign bodies. A funduscopic examination should be performed. When direct ocular trauma is suspected, the presence or absence of hyphema must be documented. The bones and soft tissues of the midface are examined for evidence of instability or direct trauma. "Raccoon eyes" or the Battle sign may indicate anterior or posterior basal or skull fractures, respectively. The patient's upper airway, including the nasopharynx and oropharynx, is reexamined. If blood or clear fluid is present in the nares, it should be tested for cerebrospinal fluid rhinorrhea. The ears, including the tympanic membranes, should be examined for perforation, infection, or hemotympanum. In children younger than age 2, one should carefully examine the fontanelles, because they may reveal important information regarding intracranial pressure.

A detailed neurologic examination is performed during the secondary survey but is usually delayed until after the rest of the survey, unless the patient has a rapidly declining level of consciousness.

Neck

Children have shorter, more cartilaginous necks with a great deal of subcutaneous tissue, making this area more difficult to evaluate. Any evidence of cervical spine injury should be noted, including detailed information regarding the mechanism of injury and history of the accident. Pediatric patients in motor vehicle accidents occurring at over 45 mi/h, in motor vehicle accidents in which the occupant is unrestrained, in automobile-pedestrian collisions, in falls from greater than 10 ft, and with direct trauma to the posterior neck are all at higher risk for cervical spine injury. Muscular spasm is much less common in young children than it is in adults and older children, and, until proven otherwise, one should assume that a cervical spine injury is present whenever muscular splinting does occur. Because up to

two-thirds of children with spinal cord injuries have no radiographic abnormality, whenever either focal muscular splinting or neurologic findings are present or if the history strongly suggests a cervical spine injury, the neck should remain immobilized, even if the cross-table lateral cervical spine film is normal.

Tracheal deviation and shifting of the midline position of the trachea are more difficult to determine in children because of their inherent anatomic differences, but both should be carefully assessed. Distended neck veins may be a sign of tension pneumothorax or cardiac tamponade, and tracheal deviation is often seen in cases of tension pneumothorax.

Chest

Examination of both the chest and the abdomen should follow the “look, listen, and feel” rule. One of the most neglected aspects of the chest examination in children is looking at the patient’s spontaneous respirations and chest wall movements. Emergency physicians should be adept at noticing the normal pattern of respiration in children and how it differs from that of adults. Bilateral, symmetric chest wall rise should be present unless there is some element of chest injury. Decreased chest wall rise may be due to chest wall contusion, splinting, pneumothorax, hemothorax, or inadvertent ET intubation of the right main stem bronchus. When splinting is present, that side of the hemithorax is evaluated for any additional signs of trauma. Any signs of abrasions, lacerations, contusions, or ecchymosis may be associated with underlying pulmonary or cardiac injury.

Because the chest wall in children has less muscle and fat, it is not uncommon for forces applied to the external thorax to be transmitted to the underlying pulmonary parenchyma. The presence of retractions is a significant finding and indicates significant respiratory difficulty. Whenever such external signs of trauma are seen, a chest film is obtained to ensure that there is no underlying pulmonary contusion or hemopneumothorax.

After one looks carefully at the chest, then both sides of the thorax should be listened to in all lung fields, including both anteriorly and posteriorly. As mentioned previously, breath sounds are easily transmitted across the child’s small, resilient thorax, so the value of the presence or absence of lung sounds is less important in children than in adults. Nonetheless, the chest should still be carefully auscultated, because the soft crackling sounds of subcutaneous emphysema may occasionally be heard in patients with pneumothorax or penetrating chest injury.

Finally, all aspects of the thorax should be carefully felt for tenderness or other signs of injury. Conscious patients should be asked where they hurt, and palpation should be begun away from that site.

Abdomen

Examining the abdomen of the pediatric trauma patient can yield a great deal of information regarding the presence or absence of abdominal injury. The abdominal examination requires extensive expertise in evaluation of children, but this does not necessarily mean that only the surgeon or pediatric surgeon has the skills to do it. Indeed, most emergency physicians should have a wealth of experience in examining the normal pediatric abdomen, because up to 25% of all patients presenting to the emergency department are children. Only by doing a careful, detailed examination on each pediatric patient presenting to the emergency department can this expertise be gained.

The examination is begun by carefully looking at the child’s abdomen for evidence of splinting, contusions, abrasions, ecchymosis, or distention. Both the front and back of the abdomen are examined for these signs of trauma. Listening to the abdomen for bowel sounds is probably the least helpful of the aspects of the physical examination, because the presence or absence of bowel sounds neither indicates nor precludes the presence of abdominal injury in children.

The most helpful aspect of the pediatric abdominal examination is palpation. Conscious patients should be asked where they hurt, and the examination is then begun as far away from that site as possible. The patient needs to be reassured as much as possible, and the examination should be done gently. It may help to have the patient place a hand on top of the examiner’s hand to reassure the patient that no undue pain or pressure will be exerted. Rebound tenderness should always be evaluated last, because it is difficult to obtain information from palpation after this potentially painful procedure. Attention must be paid to examining the suprapubic area, because the bladder is an intraperitoneal organ in the child.

Repeat examinations of the abdomen are necessary in the child. The child will initially be frightened and will cry during the examination, which may make abdominal examination difficult. Repeated examinations commonly reveal significant findings that would have been missed with a single examination. In cases in which potential abdominal injury is present, a soft nasogastric tube is placed to prevent abdominal distention and to empty the stomach to whatever degree possible. The abdominal girth is measured and marked on the child’s skin with a pen so that any difference may be noted on reexamination. In children, abdominal distention may be an early finding of abdominal injury.

A rectal examination must be performed on all children, gently and with a well-lubricated, gloved finger. Most children can be talked through this examination quite easily, and the entire pelvic rim can be palpated for signs of injury.

Pelvis

After the abdomen is examined, the bony pelvis and the perineum are inspected. The entire bony pelvis is palpated for instability or tenderness. The patient is asked to gently flex and abduct the hip, because this may detect subtle pelvic fractures. Assessment is done for urethral meatal blood and evidence of scrotal hematoma or swelling.

Musculoskeletal Evaluation

The examiner should palpate carefully over the entire bony skeleton for tenderness or swelling. All bony areas are examined visually for deformity, abrasion, contusion, or hematoma. An obvious deformity is splinted and compared with the opposite side; appropriate radiographs should be taken. In particular, any asymmetric motions of the extremities should be noted, because this may be an early sign of a fracture. In general, one should assume a fracture exists, until proven otherwise, in any extremity that the child is not moving normally. The examiner should evaluate and document the pulse and neurologic status of the extremities.

Neurologic Examination

In completing the secondary survey, a neurologic examination is done. Correlation of the history is critical in determining whether a neurologic injury is present, as well as the extent of the injury. The mechanism of injury and any potential injury transfer are carefully assessed, as well as the progression of neurologic findings since the time of injury. The paramedics are critical in obtaining this information and should be spoken to directly when they present to the emergency department with a pediatric multiple trauma patient.

By far, the most critical aspect in evaluating the potentially head-injured patient is the overall level of consciousness. The best way to accomplish this is with the GCS.^{5,15} The GCS assesses patients with regard to eye opening, verbal stimuli, and motor responses. This scale has been tested on thousands of adult and pediatric patients and has been found to correlate extremely well with outcome. In children in the preverbal age group (younger than 2 to 3 years old), the score is modified by giving any child who cries a full verbal score; this reflects the fact that comatose children do not cry.¹⁵ In testing motor response, the response is recorded on both the right and left sides, although the best response is considered the GCS score. A pediatric GCS has been proposed but is not widely used ([Table 297.4](#)).

Glasgow Coma Score	Pediatric Modification
No opening	No opening
4 Eyes closed	4-7 year
3 Eyes partially open	Spontaneously
2 Eyes open	To sound
1 No response	To pain
No verbal response	No response
5 Oriented	Best verbal response
4 Oriented	4-7 year
3 Oriented	Normal spontaneous movements
2 Oriented	Withdraws to touch
1 No response	Spontaneous vocalization
No verbal response	Best verbal response
5 Oriented and converses	2-3 year
4 Disoriented and converses	Appropriate words and phrases
3 Inappropriate words	Inappropriate words
2 Incomprehensible words	Comes out
1 No response	No response

TABLE 297.4. Pediatric Glasgow Coma Score

Patients with a GCS score of 10 or less are considered to have a potentially serious head injury, and neurosurgical consultation is obtained after ensuring ventilation, oxygenation, and perfusion. The GCS is also extremely accurate in evaluating changes in the level of consciousness. A loss of two points in the score indicates severe neurologic deterioration, while a three-point decline usually is an indication for immediate neurosurgical intervention. The overall level of consciousness, and thus the GCS score, can be affected by hypoxia, hypotension, the presence of intoxicants, or a postictal state, but one must assume that the patient has a head injury until proven otherwise. See [Chapter 299](#) for a detailed discussion of pediatric head trauma.

After the level of consciousness is assessed, the patient's vital signs are reassessed to ensure adequate oxygenation, ventilation, and perfusion. The pupils are examined for size and reactivity, as well as the presence of random eye movements. Movement of the extremities, including lateralizing findings, are evaluated. The plantar responses, deep tendon reflexes, and presence of oculovestibular reflexes are tested. Oculocephalic reflexes ("doll's eyes" reflexes) should not be assessed until it is absolutely certain that the cervical spine is uninjured.

Laboratory Studies and Radiologic Evaluation

In any patient in which the primary and secondary surveys have identified possible or documented evidence of shock, altered level of consciousness, or evidence of either single- or multisystem injury, a complete set of trauma laboratory studies should be ordered. This should consist of the following: blood cell count; determination of electrolyte, glucose, blood urea nitrogen, and amylase levels; urinalysis; type and screen or cross-match for one-half to one-fourth the total blood volume; prothrombin time; partial thromboplastin time; and platelet count. In patients with respiratory compromise or on whom artificial ventilation is being performed, an arterial blood gas analysis is obtained. The nasogastric and rectal contents for occult blood are examined. In older children, alcohol or other intoxicants may contribute to the patient's response to injury, so appropriate toxicologic studies are ordered. The need for additional laboratory studies should be guided by the patient's physical findings and clinical course.

Radiography has a limited role in the initial management of the pediatric trauma victim. Certainly, the cervical spine may need radiographic evaluation, although its limitations have been pointed out earlier. The physical examination is the clinician's first resource in caring for all injured pediatric patients; radiographic studies should simply confirm or verify suspicions. In evaluating the pediatric multiple trauma victim, chest and cervical spine radiographs have the highest priority, while abdominal, pelvis, and extremity films are less urgently needed. Additional radiographic studies, such as computed tomography of the head, chest, and abdomen; ultrasonography; and contrast studies, should be guided by the patient's physical findings, the clinical course, and the availability of such resources. [6,8,10,11](#) The emergency physician, trauma surgeon, and radiology department should agree in advance on the appropriate protocols for pediatric multiple trauma victims. Controversies regarding radiologic studies should be settled in advance whenever possible.

DEFINITIVE CARE

Consultation

Whether the pediatric multiple trauma victim is resuscitated in a general hospital emergency department or a pediatric trauma center, the best available resources for the child's care should be implemented at the earliest possible time. *Immediate surgical consultation is required for any pediatric multiple trauma victim with either single-system or multisystem injury or in whom there has been an altered level of consciousness or documented shock.* Although an increasing number of pediatric multiple trauma victims can be managed without surgery, this in no way implies that the evaluation and care of such patients can be handled by nonsurgeons. Indeed, the decision whether to operate requires considerable surgical expertise. [4](#)

Because 80% of children have head injuries in association with multiple trauma, appropriate neurosurgical consultants should be readily available. One must use caution in assuming that children have isolated head injuries: Although up to 50% of patients with severe head trauma have relatively minor additional injuries, each child requires a detailed evaluation to ensure that no occult injuries are present. In such cases, consultation with both the neurosurgeon and the appropriate pediatric or trauma surgeon should be obtained.

Indications for Transfer

The decision to transfer a pediatric multiple trauma patient to a definitive care facility depends largely on the patient's stability and on the availability of resources of a nearby pediatric trauma center. In some cases, severe intraabdominal bleeding may require immediate operative intervention to obtain appropriate hemostasis. However, these cases represent a small minority of pediatric trauma cases. For that reason, it is important to consult in advance with the appropriate pediatric trauma centers within each emergency department's geographic area to ensure that the initial resuscitation reflects the standards of the nearby center. Whenever possible, the initial resuscitative and management approach in the emergency department should reflect standards similar to those of the tertiary pediatric critical care center to which the patient may be transferred. Most centers are extremely active in outreach education and appreciate the opportunity to work with outlying hospital emergency departments in continuing medical education and quality assurance programs. *The overall outcome of the pediatric patient depends less on how long it takes the child to reach the pediatric critical care center than it does on ensuring that the regional center's expertise is applied as early as possible in the referring hospital.*[4](#)

Indications for Admission

Obviously, a child with a GCS score of 8 and major cardiovascular instability needs to be admitted to the intensive care unit, but determining the criteria for admission for the "gray area" patients is much more difficult. In general, any pediatric patient who has lost consciousness (however briefly) or in whom single-system or multisystem injury has required the placement of an intravenous line should be observed in the hospital for at least 24 hours. This is to ensure that continued and complete observation of the patient results in a clear delineation of the extent and severity of injuries. Furthermore, the numerous differences between adults and children require a careful approach to children's injuries and a complete evaluation.

OUTCOME FROM PEDIATRIC MULTIPLE TRAUMA

The single most important determinant of outcome in pediatric multiple trauma patients is the presence or absence of severe head injury. [5,7,8,15,16,21](#) Numerous outcome studies have documented that patients with severe head injuries have a poorer outcome than those without such injuries. However, the outcome from head injury in pediatric patients is much better than in adults. [5](#) Even in patients with GCS scores of 3 or 4, a good recovery can be expected in fully 30%. For that reason, virtually all pediatric multiple trauma patients should be resuscitated aggressively. In general, the overall mortality from severe pediatric trauma (in which two or more body systems are injured to a severe degree) is still only 10% to 15%. Recent data from numerous pediatric trauma centers indicate that these mortality figures may be decreasing with the advent of a systems management approach to such patients.

Pediatric Trauma Scoring

As with any medical or surgical disease, the only way to appropriately study a subject is to be able to quantify it. Because detailed studies on pediatric trauma have been relatively recent, specific efforts to quantify pediatric trauma have also been limited to several recent studies. Mayer and colleagues developed the Modified Injury Severity Scale (MISS) score to reflect differences in pediatric versus adult trauma victims.^{15,16} This scale focused on neurologic injuries and used elements of the GCS score to quantify the nature of head injury in pediatric patients. This score was later modified to include the presence or absence of a mass lesion, as well as other details on the severity of initial impact, to allow for more accurate scoring of pediatric trauma victims. This scale was used in retrospective studies primarily, and it was well recognized that a prehospital score was needed to help classify injury severity in pediatric patients.

Accordingly, Tepas and Ramenofsky developed the Pediatric Trauma Score (PTS) in an attempt to further recognize the importance of the unique needs of the pediatric trauma with regard to prehospital and emergency department classification.^{17,18,20} This score (Fig. 297.3) allows easy classification of the pediatric trauma victim in either the prehospital or emergency department setting. Studies on over 6,000 pediatric patients indicate that the PTS has a high validity as a predictor of injury severity in both settings.

Component	+2	+1	-1
Size	>20 kg	10-20 kg	<10 kg
Airway	Normal	Maintainable	Unmaintainable
CNS	Awake	Obtunded	Coma
Systolic BP	>90 mm Hg	90-50 mm Hg	<50 mm Hg
Open Wound	None	Minor	Major
Skeletal	None	Closed Fx	Open/Mult Fx's
TOTAL (PTS) _____			

Figure 297.3. Pediatric trauma score.

Nonetheless, some studies indicate that comparison of adults and children in utilizing the Trauma Score (TS) and Revised Trauma Score (RTS) shows fewer differences between adults and children than have been predicted in the past.^{7,8} Most pediatric surgeons and pediatric emergency physicians use the PTS to calculate injury severity in the prehospital setting.

COMMON PITFALLS

- Failure to complete the primary survey before starting the secondary assessment may lead to missed opportunities to provide treatment of life-threatening injuries.
- Lack of advance preparation and organization of equipment, medications, resources, and personnel will result in a disorganized resuscitation phase with the potential for poor outcomes.

% Blood Loss	Clinical Signs
≤15	Slightly increased heart rate Local swelling, bleeding
15-25	Increased heart rate Increased diastolic blood pressure Prolonged capillary refill
25-50	Above findings plus: Hypotension Confusion Acidosis Decreased urine output
>50	Refractory hypotension Refractory acidosis

TABLE 298.1. Clinical Signs of Acute Hemorrhagic Shock

Physicians too often assume that tachycardia is due to either anxiety, fright, pain, or reaction to parental stimulation. This is a dangerous precedent: Many such children are in the earliest stages of shock and require immediate fluid resuscitation. The patient's vital signs should always be noted carefully, paying particular attention to the pulse rate. During the initial evaluation, the pulse rate should be retaken, because the patient's initial anxiety and pain should have abated somewhat. If tachycardia persists, one should assume that the patient is in shock and administer appropriate treatment.

In addition to changes in the normal pulse rate, children also have a different normal circulating blood volume and blood pressure than do adults. ^{9,11} Children have larger total blood volumes, about 8.5% of body weight; the average blood volume of a man is about 7% of body weight, and it is about 7.5% in women. The best general estimate for general circulating blood volume in children is 85 mL/kg.

Children's blood pressure also varies according to age. Again, tables and charts are available to indicate a child's appropriate blood pressure, but the following simple formula gives a *minimal* systolic blood pressure:

Newborn: 60 mm Hg
 Infant: 70 mm Hg
 Child: 70 + (2 × age in years)

The diastolic blood pressure in a child should be about two-thirds of the systolic blood pressure. ¹ Both the systolic and diastolic blood pressures should be assessed in every pediatric patient. Because an increase in the total peripheral resistance causes an early rise in the diastolic pressure (and therefore a fall in the pulse pressure), diastolic blood pressure should be assessed routinely in all children. All emergency departments should have a wide range of pediatric blood pressure cuffs. A correctly sized cuff should cover two-thirds of the distance between the point of the child's shoulder and the olecranon process.

When the child has lost about 15% of total blood volume, the sole sign of shock may be a slight increase in pulse rate. When 15% to 25% of blood volume has been lost, additional factors come into play. Adrenergic stimulation is maximal, venous beds are fully contracted, and peripheral resistance is elevated, resulting in increased diastolic blood pressure (or decreased pulse pressure). In addition, prolonged capillary refill time and further increases in heart rate may be seen. Although increased respiratory rate, anxiety, and thirst are often present in adults with shock at this level, these criteria are more difficult to evaluate in the child.

Although up to 25% of the child's total blood volume may have been lost, shock can be detected only by looking carefully at the heart rate, the diastolic blood pressure, and the capillary refill time. *Not until blood loss reaches 25% to 30% of total blood volume are hypotension, confusion, decreased urine output, and acidosis evident.*

The accentuated response to adrenergic stimulation is the primary reason that hypotension develops so late in the child with hemorrhagic shock. ^{6,7,11} Waiting for hypotension to develop before recognizing shock threatens the child's life. A complete set of vital signs should be obtained, including an accurate pulse rate and systolic and diastolic blood pressures, on each patient who presents with even minor trauma. Paying careful attention to such details in all pediatric patients helps the clinician develop the clinical judgment necessary to recognize pediatric patients in early stages of shock.

If blood loss continues or progresses, decreased urine output, altered mental status, and the development of systemic acidosis occur. However, using any of these factors to recognize shock has severe limitations. Up to 80% of all pediatric multiple trauma victims have some element of head injury, making it difficult to follow mental status as a primary indicator of central perfusion. In addition, it can be difficult to assess mental status in young children.

Urine output is an excellent indicator of overall central perfusion in the ongoing management of the pediatric and adult shock victim, because it accurately reflects renal blood flow (in the absence of postrenal obstruction). One of the body's earliest responses to hypovolemia is to decrease blood flow to the renal bed, which, under normal conditions, receives 20% of the cardiac output. However, although urine output is an excellent ongoing measure of central perfusion, it is difficult to assess within the first 15 to 30 minutes of trauma resuscitation, because it is a dynamic rather than a static value. If children are delayed in the emergency department for an hour or more, the normal urine output in a child is at least 1 mL/kg/h. In any patient with signs or symptoms of shock, a catheter should be placed and the amount of urine present in the bladder at the time of trauma should be noted. This urine should be placed in a separate container, because it does not reflect ongoing urine output after the development of shock.

EMERGENCY DEPARTMENT MANAGEMENT

There are three primary goals of shock therapy: (1) to restore effective circulatory volume, (2) to maximize oxygen delivery, and (3) to decrease ongoing blood loss.

Restoring Effective Circulatory Volume

Any increase in blood flow will result in an increase in overall cardiac output and tissue perfusion. The central tenet in shock therapy in pediatric patients is to immediately restore the effective circulatory volume. Any child with any signs of shock, including persistent tachycardia, should receive an intravenous line and an appropriate fluid bolus.

All emergency physicians should be skilled in placing percutaneous peripheral intravenous lines in children, as well as alternative means of obtaining vascular access in children (percutaneous central venous cannulation, intraosseous infusion, or, rarely, peripheral venous cutdown). ^{3,10} Although peripheral venous cutdown and percutaneous central venous cannulation require a moderate level of skill, placement of a needle into bone marrow can be mastered with minimal training. ⁸

Regardless of the site of infusion, children require an immediate and appropriate fluid bolus of 20 mL/kg. The bolus is given as quickly as possible, over no more than 5 to 10 minutes. In many cases, this initial fluid bolus therapy occurs over 20 to 30 minutes, during which time the child continues to bleed internally.

The prevailing wisdom in both adult and pediatric trauma patients is that the initial fluid infusion should be a crystalloid solution, even though some pediatric authorities claim that colloids are better in the resuscitation of the pediatric patient. Colloids play virtually no role in the emergency department, and crystalloids should be used in the initial treatment of the pediatric patient presenting in shock. ^{2,4,6,7} The initial fluid bolus therapy is usually lactated Ringer's solution. Normal saline can also be used, but large fluid infusions with 0.9% sodium chloride can result in hyperchloremic acidosis.

Children who present with hypotension in addition to tachycardia and a decreased pulse pressure have lost at least 25% to 30% of their total circulating blood volume and are in extreme danger of rapid decompensation. Under such circumstances, immediate infusion of an initial fluid bolus of 40 mL/kg is done. Weight can be estimated by a length-based system such as the Broselow Resuscitation Tape. ⁵

One of the most common problems in pediatric trauma resuscitation is the physician's reluctance to infuse the appropriate fluid volume to a child with signs and symptoms of shock. For example, if a 4-year-old boy presents after a motor vehicle accident, with a pulse rate of 130 beats per minute and a blood pressure of 90/75 mm Hg, some clinicians may not recognize the presence of shock. This preschooler's heart rate is above 120 beats per minute, while the systolic blood pressure is adequate and the diastolic blood pressure is elevated. This child has therefore lost at least 15% to 25% of his total blood volume and requires immediate infusion of 20 mL/kg for effective therapy. If this child's weight is an estimated 20 kg, he should immediately receive about 400 mL of lactated Ringer's solution.

The single most important determinant of the adequacy of ongoing fluid resuscitation is the child's response to the fluid infusion. For this reason, one must make a mental note of the initial pulse, respirations, blood pressure, and diastolic blood pressure at the time the initial fluid infusion is begun. Furthermore, the nurse responsible for charting should also note carefully the time that the infusion is begun. After infusion of the appropriate fluid bolus, the shock parameters are reassessed to determine whether the patient's condition is improving, staying the same, or deteriorating.

The second aspect of restoring effective circulatory volume is transfusion. In the pediatric patient, packed red blood cells are infused if the patient fails to respond to a total of 40 to 60 mL/kg of crystalloid infusion. Based on the extent of physical findings, rapid infusion of 5 to 10 mL/kg of packed red blood cells is warranted, through a blood warmer if possible. Rapidly infusing cold blood into a child can cause major problems with hypothermia, which may make the child resistant to the usual resuscitative measures.

If the child's cardiovascular parameters respond to the initial fluid bolus of 20 mL/kg, one should monitor the child closely. If the cardiovascular parameters remain stable, the total fluid infusion should be according to the principles in [Table 298.2](#). If the child has lost less than 25% of total blood volume, the total amount of blood lost should be replaced with 3 mL of lactated Ringer's solution for each estimated milliliter of blood lost. (This formula accounts for the phenomenon of transcapillary refill, in which interstitial fluid is mobilized into the vascular space by the body's normal physiologic response.) If the patient has lost more than 25% of total blood volume, half of the loss is corrected with lactated Ringer's solution on the basis of 3 mL of lactated Ringer's solution per milliliter of blood loss. The rest of the child's lost blood volume is corrected on a milliliter-per-milliliter basis with packed red blood cells. All patients who require transfusion to maintain their cardiovascular parameters should be observed closely, because major hemorrhage has occurred.

% Blood Loss	Replacement
<25	3 mL LR per mL blood loss
25-50	1/2 volume = 3 mL LR per mL blood loss 1/2 volume = 1 mL PRBC per mL blood loss
>50	Type specific or O negative or O positive Amount: titrated to ongoing urine output

LR, lactated Ringer's solution; PRBC, packed red blood cells.

TABLE 298.2. Total Fluid Infusion in Pediatric Hemorrhagic Shock

One additional means of potentially restoring effective circulatory volume is by using pneumatic antishock garments, also known as military antishock trousers (MAST). It was initially thought that antishock trousers could result in large "autotransfusions" of blood to the body, but studies in adults indicated this was not so. MAST have not been effective in the treatment of hemorrhagic shock in major pediatric trauma, with the occasional exception of pelvic fractures, and may cause complications such as compartment syndrome and ischemia. Because of the child's dramatic increase in vasomotor tone to adrenergic output, it is highly unlikely that antishock trousers result in any significant autotransfusion in the child. ¹

Maximizing Oxygen Delivery

The second goal of shock therapy is to maximize oxygen delivery. By far, the most important aspect in doing so is to ensure an adequate airway. A stable airway is critical in the pediatric multiple trauma victim, particularly one in hemorrhagic shock. In addition, adequate oxygen should be supplied. Virtually all multiple trauma patients should receive 100% humidified and warmed oxygen in both the prehospital and emergency department phases of care.

Other potential means of maximizing oxygen delivery is by transfusing packed red blood cells to increase oxygen-carrying capacity and by improving myocardial contractility in patients in whom this factor is depressed. Decreasing oxygen demand is also of potential benefit but is usually more pertinent to the intensive care unit phase of care.

Decreasing Blood Loss

The time-honored principles of decreasing blood loss in the shock victim have remained largely unchanged. Pressure is placed on any external bleeding points, which are then elevated. The head of pediatric trauma patients with external hemorrhage should be elevated, but pressure dressings must always be put on the head before elevating it; in the event of a dural sinus tear, an air embolism could be produced by elevating the head without an appropriate dressing. In general, the only bleeding sites that should be controlled with hemostats are ones that are extremely superficial and those on the head. On the extremities, the vascular and neurologic bundles travel in close proximity, and nerves may be inadvertently clamped unless extreme caution is used. Patients who continue to hemorrhage, either externally or internally, may need surgery. Finally, transfusion with either platelets, fresh-frozen plasma, or cryoprecipitate may be necessary in selected patients with specific bleeding disorders. Such transfusions are limited only to patients with documented bleeding abnormalities.

DISPOSITION

Role of the Consultant

The immediate resuscitation of the pediatric trauma victim with hemorrhagic shock is the emergency physician's responsibility. Emergency physicians should be trained in evaluating and resuscitating pediatric trauma victims, including those with hemorrhagic shock. They should be capable of recognizing the manifestations of shock, placing an appropriate intravascular line, and beginning initial fluid resuscitation. However, in virtually all patients who require intravenous fluid therapy, either a pediatric surgeon or a general surgeon skilled in the care of the pediatric trauma patient should be consulted for final disposition. Patients who receive intravenous lines and fluid bolus therapy and those whose shock parameters do not immediately return to normal should be observed for at least 24 hours to rule out unrecognized ongoing bleeding.

In most cases in which ongoing fluid therapy is required, the skills of a radiologic imaging specialist should be obtained to determine which studies will be required. Additional expertise in the field of pediatric neurosurgery, pediatric intensive care, and other surgical subspecialties may be necessary, depending on the type and extent of the patient's injuries.

As with any emergency, the patient is best served by a prospective approach. Emergency departments can provide better care for injured children by discussing in advance the appropriate treatment and diagnostic therapy protocols. Emergency physicians should consult with trauma surgeons, pediatric surgeons, and radiologists to develop a consensus approach to all phases of pediatric trauma care.

Indications for Admission

Any patient who manifests any signs or symptoms of hemorrhagic shock should be admitted for observation. Exceptions are patients who present with relatively minor

trauma and signs of tachycardia who respond immediately to initial fluid bolus therapy and are not found to have any significant injuries, but even these patients need to be observed in the emergency department for several hours before discharge.

Transfer Considerations

Each emergency department caring for pediatric patients should have appropriate transfer arrangements with a pediatric critical care center or pediatric trauma center in the area. Although 75% to 85% of all pediatric trauma victims can be cared for locally, the remainder who require the resources of a regional pediatric trauma center must be transferred rapidly, so that the center's resources can be used as early as possible. Consultation with the center is done ahead of time, so that the protocols for patient care can be used at the referring hospital as well.

For children with hemorrhagic shock who are transferred to a regional pediatric trauma center, one must ensure there is a functioning intravenous line before the transfer. It is better to take the extra time to ensure a functioning line than to risk having no intravenous access during the transfer. Providing an adequate airway with appropriate oxygenation and ventilation, in most cases, will require placing an endotracheal tube in patients with serious illnesses or injuries. Patients in mild phases of hemorrhagic shock may not require endotracheal intubation.

In most cases, an indwelling bladder catheter will be required to allow ongoing monitoring of urine output during the transfer. Because 80% of pediatric trauma victims have head injuries, appropriate care should be given to management of head injury during the transfer.

COMMON PITFALLS

- Lack of attention to detail while evaluating the patient. The only way to recognize the sometimes subtle signs and symptoms that present in early pediatric hemorrhagic shock is to become familiar with normal physical findings and their variance in the wealth of pediatric patients seen in the emergency department.
- Failure to recognize that tachycardia is the earliest and most consistent sign of shock in the pediatric patient
- The tendency to attribute tachycardia to factors such as anxiety or pain rather than to shock. Because tachycardia's role in the early development of shock often goes unrecognized, many physicians fail to place an intravenous line in such patients and give an appropriate fluid bolus.
- The tendency to underinfuse with an appropriate intravenous fluid. Some physicians fail to give at least 20 mL/kg. Some patients still are given nonisotonic crystalloid solutions.
- Failure to follow the ongoing shock parameters in the pediatric multiple trauma victim, even after appropriate fluid bolus therapy

Trauma is the leading cause of death in children older than 1 year in the United States; 75% or more of these deaths are associated with significant central nervous system (CNS) injury.¹⁷ Approximately 150,000 to 300,000 children are hospitalized each year as a result of head injury.^{2,10} Falls are the leading cause of head injuries in children, especially in those younger than 5 years of age.

Motor vehicle collisions with bicyclists and pedestrians become more significant in school-age children, while motor vehicle occupant injuries, assaults, and sports injuries are more common in the adolescent age group. Motor vehicle collisions are the leading cause of severe and fatal head injuries for all pediatric age groups, except for infants, for whom nonaccidental trauma is the most common cause of serious injury.^{1,22}

ORGAN SYSTEMS

Anatomy

[Figure 299.1](#) shows the cross-sectional anatomy of the head and associated CNS injuries.¹⁸ The types of injury can be grouped by location.

Figure 299.1. Cross-sectional anatomy of the head and associated central nervous system injuries. 1, Subgaleal hematoma; 2, cephalohematoma; 3, porencephalic cyst; 4, epidural hematoma; 5, subdural hematoma; 6, cerebral contusion; 7, cerebral laceration. (Modified from Rosman NP, Oppenheimer EY, O'Conner JF. Emergency management of pediatric head injuries. *Emerg Med Clin North Am* 1983;1:141.)

Injuries to the scalp are the most common complication of head injury. These injuries include swelling, contusions, and lacerations. Causes of swelling of the scalp must be differentiated. Subgaleal hematomas are common in children. In neonates, subgaleal hematomas present with diffuse swelling that does not transilluminate. This presentation differs from that of the cephalohematoma, which is focal swelling. Porencephalic or leptomeningeal cysts also present as focal swelling, but these have increased transillumination.

The presence of skull fractures means that significant force has been applied to the cranium, but the presence of fractures does not guarantee intracranial hemorrhage. Likewise, intracranial hemorrhage is seen in the absence of skull fracture. Seventy-five percent of skull fractures are linear fractures. Basilar skull fractures involve the frontal, ethmoid, sphenoid, temporal, and occipital bones. Signs of basilar skull fracture include “raccoon eyes,” the Battle sign, cerebrospinal fluid (CSF) otorrhea or rhinorrhea, and hematotympanum. Compound fractures, those with laceration of the scalp, carry a risk of complicating infection of the CNS.

Depressed skull fractures are seen when force is applied over a small surface area. A depressed fracture greater than a few millimeters needs surgical elevation. Diastatic fractures are unique to children and are seen in the first 4 years of life. These fractures represent separation of the sutures. “Growing” fractures are caused by the formation of porencephalic or leptomeningeal cysts in the site of linear or diastatic fractures. These cysts occur during the first 6 months after injury and are most often seen in children younger than 3 years of age.

Traumatic intracranial hemorrhage includes subdural, epidural, and subarachnoid hemorrhages. Subdural hemorrhages occur five to ten times as often as epidural hemorrhages. There is a relatively slow onset of symptoms because these are usually venous in origin. Signs and symptoms of the hemorrhage are secondary to increased intracranial pressure. In infants, these hemorrhages may present with seizures. Although rare in children, the mortality rate of 10% to 20% associated with epidural hematomas makes their early recognition essential. The usual presentation is one of rapid and focal neurologic deterioration. The classic triad is of concussion with an intervening lucid phase, followed by deterioration. These hemorrhages usually represent a tear in the middle meningeal artery. In the child, hemorrhages from the meningeal and diploic veins are also seen. Although these hemorrhages are always associated with fractures in adults, this association is observed in only 50% of the pediatric patients. Subarachnoid hemorrhages are a common computed tomographic (CT) finding in severe pediatric head trauma.

Penetrating head injuries are less common in children. Puncture wounds are seen with lawn darts, other missile-type projectiles, and dog-bite wounds in young children. These injuries are often associated with lacerations of the brain.

Contusions and lacerations of the cerebral cortex are often adjacent to sites of significant focal impact or at locations that predispose the brain to accelerative forces. Coup injuries represent contusions directly beneath the site of impact, while contrecoup injury occurs against the skull surface opposite the site of impact. The signs are often focal and are associated with local swelling on a CT scan. These injuries are not necessarily the cause of unconsciousness.

Concussions are a functional injury. Mild concussions are associated with brief impairment of consciousness. Associated symptoms include anorexia, vomiting, pallor, or abnormal behavior lasting up to several hours. Severe concussions may present with signs ranging from lethargy to coma. All grades have an associated amnesia either retrograde, permanent retrograde, or temporary posttraumatic antegrade. Alternative presentations in infants and younger children include lethargy, irritability, and vomiting not associated with loss of consciousness. These symptoms usually subside within 48 hours.

Pathophysiology

The types of injuries can also be classified as primary and secondary. Primary injuries occur at the time of impact and cannot be prevented. These include fractures, contusions, lacerations, and neuronal or vascular injury on impact. Secondary injuries occur after the initial impact and include cerebral hyperemia, vascular autoregulatory dysfunction, cerebral edema, hemorrhagic lesions, and seizures. These CNS reactive lesions are either preventable or may be minimized by

good medical management. If untreated, these lesions lead to mechanical distortion, ischemia, and hypoxic injury.

Cerebral edema and increased intracranial pressure account for a large degree of the morbidity in the pediatric head trauma patient. Injury occurs because the volume of the cranium is fixed. The relationship is expressed by the following formula:

$$\text{Volume CSF} + \text{volume blood} + \text{volume brain} + \text{volume other} = \text{constant}$$

An increase in the volume of one means a reduction in the size of the others. A buffering capacity is important in the early stages of increasing pressure. With an increase in brain volume or a mass lesion, CSF is displaced, followed by a decrease in blood flow. Once the intracranial volume increases beyond the buffering capacity, the intracranial pressure increases and the brain subsequently herniates. ⁷

Differences in the growth and maturation of head structures account for the different injuries seen in children and adults. The prevalence of head trauma in children is partly because the young child's proportionally larger head size and weight give a higher center of gravity. The cranial vault is more pliable and less dense in young infants. The open fontanelle and sutures in the younger child, along with the larger subarachnoid space and cisterns, offer a greater extracellular space. This allows better tolerance of expanding mass lesions, up to a point. The dura mater's tight adherence to the skull accounts for the lower incidence of mass hemorrhages in children (less than 30%, compared with 40% to 50% in adults) and the variable and occasional subacute presentation of epidural hemorrhage. Because myelination continues for the first 6 months of life, subcortical white matter tears are often present in this age group, as opposed to the contusions and hemorrhages seen in toddlers. Finally, cerebral edema and increased intracranial pressure as a result of severe head injury occur in 80% of pediatric cases, as opposed to 40% to 50% of the cases in adults. ^{1,11,16}

EMERGENCY DEPARTMENT EVALUATION

As with most emergencies, evaluation, assessment, and management is a multifaceted, ongoing process until the patient is stabilized and appropriate disposition is made. Although the classic systematic approach of history, physical examination, radiographic evaluation, and management are presented here, these often occur simultaneously.

The history is often obtained from an adult caretaker who may or may not have been present at the time of injury. One must elicit and document details of the accident, including the height of any falls and the type of surface struck, and include a history of loss of consciousness, memory loss, disorientation, and visual disturbance. A brief seizure at the time of impact may be part of the history but may have no diagnostic or prognostic significance, in contrast to seizures that occur after injury. Vomiting is another useful symptom, especially when it is protracted or occurs more than 6 hours after injury.

The physical examination should not be limited to the head; significant physical findings may be found elsewhere. The initial respiratory rate and pattern are noted, and pulse and blood pressure are measured. The examiner should quickly evaluate the level of consciousness using the mnemonic AVPU (alert, responds to voice, responds to painful stimuli, unconscious). The Glasgow Coma Scale, a fast, objective, and reproducible scoring system, evaluates the best eye opening, verbal, and motor response of the patient (Table 299.1) and has been modified for the preverbal child (Table 299.2).¹³ Ocular signs, including pupil size and response and extraocular movement, should be checked, and an early fundoscopic examination, looking for retinal hemorrhages and papilledema, should be done. The head is examined for signs of trauma, including scalp lacerations and abrasions, hematomas, hematotympanum, the Battle sign, raccoon eyes, and CSF leaks from the ears or nose. A complete neurologic examination should be part of the secondary survey. This should also include a search for signs of injury at other sites. ¹⁶

TABLE 299.2. Glasgow Coma Scale Modified for the Preverbal Child

Recommendations for imaging remain somewhat controversial; however, most experts do not advocate routine skull radiographs in the evaluation of head-injured children. Although the risk for intracranial injury is increased with the presence of a skull fracture, as many as 50% of intracranial injuries occur without skull fractures.^{4,9,12,15} Head CT has become the imaging modality of choice for the evaluation of possible intracranial injury, including epidural and subdural hematomas, and parenchymal contusions and edema. The head CT can also delineate facial, orbital, and sinus injuries, as well as linear and depressed skull fractures.

Clinical features, such as depressed level of consciousness, focal neurologic deficits, palpable skull depressions, seizures, and signs of a basilar skull fracture, indicate children at higher risk for intracranial injuries. ^{4,13,15} These children should undergo head CT imaging. However intracranial injury also occurs in the absence of these findings in 3% to 7% of symptomatic children who appear neurologically normal. ^{4,9,15,19} Head CT imaging should be considered in symptomatic children who are neurologically normal; however, careful observation by a reliable caretaker may be another option.

The presentation of intracranial injury in infants may be very subtle, often occurring without symptoms. ^{6,8,15} Unlike older children, the great majority of intracranial injuries in infants occur in association with a skull fracture. Moreover, most skull fractures in infants are associated with scalp hematomas or contusions. ^{5,20} In asymptomatic infants with scalp hematomas, skull radiographs may serve as a screen for serious head injury. If a skull fracture is present, these infants should undergo head CT imaging. Any symptomatic infant should also undergo head CT imaging.

EMERGENCY DEPARTMENT MANAGEMENT

Major Head Trauma

Patients with major head trauma are at the highest risk for intracranial injury. They may have findings of depressed level of consciousness, focal neurologic signs, decreasing level of consciousness, penetrating injury or palpable depressed skull fracture, or a combination of these problems.

Airway and cervical spine control are critical in these patients. Airway patency is assessed and any obstructions are removed. Once the airway has been opened, ventilatory effort is assessed and assisted with bag-valve-mask ventilation in an attempt to keep the PaO₂ above 100 mm Hg. Good cerebral oxygenation is necessary for the prevention of secondary injury. Cricoid pressure is useful to avoid regurgitation and aspiration. A secure airway must be maintained. Endotracheal intubation should be considered in children with a Glasgow Coma Scale score less than 8; rapid-sequence intubation is the method of choice in this situation. With an assistant providing cricoid pressure and oxygenation, atropine sulfate 0.02 mg/kg is given intravenously to reduce secretions and for vagolytic effect; then a sedative and amnestic agent (diazepam, midazolam, thiopental, or etomidate) should be administered. Etomidate is preferred in the hypotensive patient. Confirmation that the patient can be ventilated manually is followed by the administration of succinylcholine, rocuronium, vecuronium, or pancuronium, for muscle relaxation (see [Chapter 235](#), "Rapid Sequence Induction and Emergency Airway Management").

Circulation is maintained within normal physiologic limits. Shock may be explained by large scalp lacerations in older children or epidural hemorrhage in infants, but, more commonly, the source of blood loss is elsewhere. Shock is treated with crystalloid boluses. Once normal blood pressure is established, fluids are given at one-half to two-thirds of the maintenance rates.

The goal of treatment of increased intracranial pressure is to prevent displacement (herniation) of the brain. Elevating the patient's head to 30 degrees promotes venous drainage. Controlled hyperventilation reduces cerebral blood flow by reducing arteriolar diameter. Some studies have promoted the use of moderate hyperventilation. PaCO₂ is maintained in the 30 mm Hg range.^{14,21} Diuretic therapy is used in an attempt to shift water from the brain into the vascular compartment, but these agents should be used with caution in the hypovolemic patient. Intravenous mannitol at 0.25 g/kg is generally recommended. Intracranial pressure increases initially after mannitol administration as a result of an increase in cerebral blood flow secondary to expansion of the vascular volume and increased cardiac output. Intravenous furosemide (Lasix) 0.5 to 1.0 mg/kg is useful in cases of diffuse cerebral edema.

Patients with major head trauma require emergency CT scanning as soon as they are stable enough to tolerate the procedure. Neurosurgical consultation is obtained as soon as possible.⁷

Minor Head Trauma

Children with altered mental status, focal neurologic deficit, signs of a basilar skull fracture, palpable skull depression, or seizure should undergo head CT imaging. Head CT imaging should be considered for neurologically normal children who are symptomatic with a history of vomiting, headache, amnesia, loss of consciousness, drowsiness, or irritability. Careful observation of these children at home by a reliable caretaker may be an alternative strategy. Children with progressive or persistent symptoms should return for reevaluation and head CT imaging. Children who have a normal head CT scan after minor head injury will very rarely develop delayed intracranial sequelae.³ They can be safely discharged home for further observation. Neurologically normal children without symptoms may also be discharged home without imaging studies.

Skull radiographs are recommended only for evaluation of nonaccidental trauma and for asymptomatic infants with scalp hematomas or contusions. Infants with skull fractures should have head CT imaging to exclude intracranial injury. Infants younger than 12 months who develop symptoms following head trauma should also undergo head CT imaging.

DISPOSITION

Neurosurgical consultation should be sought for patients with major head trauma, including those with abnormal head CT scans, altered mental status, focal neurologic deficit, penetrating injury, or depressed skull fracture. A patient with major head trauma should be stabilized and transported to a facility with a pediatric intensive care unit. The patient should be transported by personnel experienced in caring for critically ill and injured children. Vital signs and neurologic status must be followed closely. The patient's head should be elevated at 30 degrees, and adequate ventilation should be maintained in intubated patients. An intravenous infusion of dextrose 5% in an isotonic solution should be given at one-half to two-thirds of maintenance rates.

Children with minor head trauma should be hospitalized for intracranial injuries identified on the head CT and for persistent neurologic abnormality despite a normal head CT. Children with suspected child abuse and children without a reliable caretaker should also be admitted for observation. Discharge instructions for home observation following head trauma should include indications to return for persistent vomiting, weakness, worsening headache, pupillary asymmetry, lethargy, or difficulty with gait or balance. Symptomatic children and children with isolated skull fractures should be seen by their physician 24 hours after discharge from the emergency department.

COMMON PITFALLS

- Failure to recognize the protean manifestations of head injury in children. Because the open fontanelle and sutures in the younger child, along with the larger subarachnoid space and cisterns, offer a greater extracellular space, a better tolerance of expanding mass lesions is allowed, up to a point.
- Failure to take an adequate history, perform a complete examination, and recognize signs of retinal hemorrhage and increased intracranial pressure. This can lead to a delay in diagnosis and treatment.
- Failure to suspect child abuse, especially shaken-baby syndrome
- Failure to consider other causes of altered mental status, such as CNS infections, metabolic disorders such as hypoglycemia, and toxins, when there are no obvious signs of trauma.

CHAPTER 300

Evaluation of the Cervical Spine

David M. Cosentino and Francis M. Fesmire

[Developmental Anatomy](#)
[Normal Variants and Congenital Anomalies](#)
[Clinical Aspects](#)
[Emergency Department Management](#)
[Common Pitfalls](#)
[Chapter References](#)

Unlike the adult cervical spine, the developing pediatric cervical spine has unfused synchondroses, incomplete ossification centers, and epiphyseal growth plates. To understand the nuances of radiographic interpretation, the emergency physician must have an understanding of developmental anatomy. Because of the dynamic changes that occur with bone and ligament development in the pediatric cervical spine, distribution patterns of fractures and dislocations within the cervical spine itself differ from the distribution of injuries in the adult spine. Furthermore, a significant percentage of pediatric spinal cord injuries occur in the absence of radiographically identifiable fractures and dislocations.

DEVELOPMENTAL ANATOMY

The first cervical vertebra (atlas) develops from three primary ossification centers: the body and two neural arches ([Fig. 300.1](#)). The neural arches ossify *in utero* and fuse posteriorly at approximately the third year of life. The body of C1 is not ossified at birth and does not become visible until approximately 1 year of age. The synchondroses between the body and neural arches (neurocentral synchondroses) fuse at approximately the seventh year of life. ^{3,8,22}

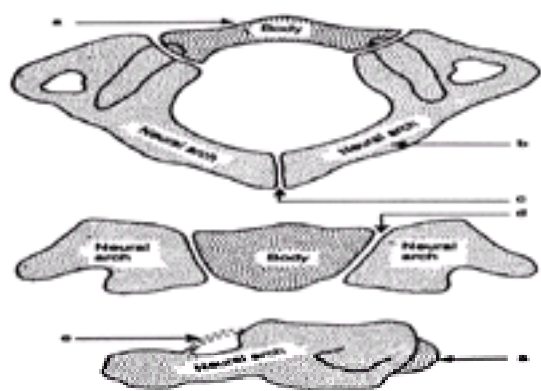

Figure 300.1. The first cervical vertebra (atlas). (a) Body: ossification center becomes visible during first year of life. (b) Neural arches: ossification center appears *in utero* at approximately the seventh fetal week. (c) Synchondrosis of spinal process: fuses at approximately the third year of life. (d) Synchondrosis about the body (neurocentral synchondrosis: fuses at approximately the seventh year of life. (e) Ligament surrounding the superior vertebral notch: may ossify later in life. (From Fielding JW. Cervical spine injuries in children. In: The Cervical Spine Research Society, eds. *The cervical spine*. Philadelphia: JB Lippincott Co, 1983:268–281, with permission.)

The second cervical vertebra (axis) is the most difficult to interpret radiographically because of its four primary ossification centers: the odontoid, body, and two neural arches ([Fig. 300.2](#)). All four ossification centers are visible at birth. A secondary ossification center appears at the apex of the odontoid (summit ossification center) at approximately 3 to 6 years and fuses with the odontoid by the twelfth year of life. The synchondroses of the posterior neural arches fuse at approximately the third year. The synchondrosis between the odontoid–body of C2 and the neural arches fuses at approximately the third to sixth year. Before fusion, these synchondroses may be confused with fracture lines. The fusion line of the synchondrosis between the odontoid and the body of C2 commonly remains visible until age 11, and one-third of individuals have a visible fusion line throughout life.

Figure 300.2. The second cervical vertebra (axis). (a) Body: ossification center appears by the fifth fetal month. (b) Neural arches: appear by the seventh fetal month. (c) Synchondrosis of spinous process: fuses by the third to sixth year of life. (d, e) Neurocentral synchondrosis: fuses by the third to sixth year. (f, G) Inferior epiphyseal ring: appears at puberty and fuses to body at approximately 25 years of life. (g) Summit ossification center for odontoid: appears at approximately the third to the sixth year and fuses with the odontoid by the twelfth year of life. (h) Odontoid: develops from two ossification centers that fuse by the seventh fetal month. (j) Synchondrosis between the odontoid and body: fuses at approximately the third to sixth year of life. (From Fielding JW. Cervical spine injuries in children. In: The Cervical Spine Research Society, eds. *The cervical spine*. Philadelphia: JB Lippincott Co, 1983:268–281, with permission.)

In the remaining C3 to C7 cervical vertebrae, there are three major ossification centers—the body and two neural arches—all of which are visible at birth ([Fig. 300.3](#)). The posterior synchondroses of the neural arches fuse at approximately the third year of life. The neurocentral synchondroses fuse at approximately the third to sixth year of life. Secondary ossification centers appear at puberty along the superior and inferior aspects of the cervical bodies (superior and inferior epiphyseal rings) and at the tips of the spinous processes. Before fusion, these ossification centers may be mistaken for chip fractures of the cervical bodies and clay shoveler's fractures of the spinous processes, respectively. These secondary ossification centers fuse with the main body by age 25 years. [Table 300.1](#) summarizes the major radiographic changes seen in the development of the pediatric cervical spine.

Figure 300.3. Typical cervical vertebrae (C3-C7). (a) Anterior portion of transverse process: may develop from a separate ossification center that fuses by the sixth year. (b) Synchondrosis between the spinous processes: fuse by third year. (c) Secondary centers for bifid spinous processes: appear at puberty and fuse by 25 years of life. (d) Neurocentral synchondrosis: fuses at approximately third to sixth year of life. (e) Superior and inferior epiphyseal rings: appear at puberty and fuse with body by 25 years of life. (From Fielding JW. Cervical spine injuries in children. In: The Cervical Spine Research Society, eds. *The cervical spine*. Philadelphia: JB Lippincott Co, 1983:268–281, with permission.)

Age	Developmental Change
6 mo	Body of C1 not visible; all synchondroses open
1 yr	Body of C1 visible
3 yr	Synchondroses of posteriorly located spinous processes fuse
3-4 yr	Neurocentral synchondroses fuse; synchondrosis between odontoid and body of C2 fuses; summit ossification center appears at superior aspect of odontoid; anterior wedging of vertebral bodies resolves
8 yr	Pseudosubluxation and widening of predental space resolve; spine assumes a more lordotic appearance
Puberty	Secondary ossification centers appear at the tips of the spinous processes; superior and inferior epiphyseal rings appear; summit ossification center of odontoid fuses
25 yr	Secondary ossification centers at tips of spinous processes fuse; superior and inferior epiphyseal rings fuse to the main body

TABLE 300.1. Radiographic Development of the Pediatric Cervical Spine

NORMAL VARIANTS AND CONGENITAL ANOMALIES

Because of the laxity of the ligaments in the pediatric cervical spine, absent lordosis is a frequent finding on the lateral radiograph. In adults, this finding may signify ligamentous injury. In one study, lordosis was absent in 14% of 160 healthy children aged 16 years and younger.⁶

During the ossification process of the immature cervical bodies, an appearance of anterior wedging is produced. The finding of anterior wedging in several adjacent vertebrae suggests that it is a developmental finding and not a compression fracture ([Fig. 300.4](#)).

Figure 300.4. Three-year-old with a 4-mm anterior pseudosubluxation of C2 on C3 and a nonpathologic, widened predental space of 4 mm. Note that the anterior aspect of the spinous processes of C1 through C3 lies on a straight line. This line would be broken in a true subluxation. The synchondrosis between the dens and body of C2 is unfused. Also note the normal anterior wedging of the vertebral bodies, as well as the increased soft-tissue space anterior to the cervical spine. (From Fesmire FM, Luten RC. The pediatric cervical spine: developmental anatomy and clinical aspects. *J Emerg Med* 1989;7:133–142, with permission.)

The extreme laxity of ligaments creates a pseudosubluxation of adjacent vertebrae in 46% of children younger than 8 years old.⁶ This finding is most pronounced at the level of C2 to C3 (see [Fig. 300.4](#)). To distinguish pseudosubluxation from true subluxation, Swischuk^{21,22} has developed the concept of the posterior cervical line ([Fig. 300.5](#)). This line is drawn by connecting the anterior aspects of the spinous processes of C1 and C3. If the anterior aspect of the spinous process of C2 misses this line by 2 mm or more (1.5 mm is borderline), this finding is suggestive of a true subluxation or a hangman's fracture of the neural arches of C2. This posterior cervical line can be applied only in children demonstrating subluxation or pseudosubluxation of C2 on C3. If no subluxation or pseudosubluxation exists, the anterior aspect of the spinous process of C2 commonly misses the posterior cervical line by more than 2 mm.

Figure 300.5. The posterior cervical line (PCL) is drawn by connecting the anterior aspect of the spinous processes of C1 and C3. The concept of the PCL can be applied only if subluxation or pseudosubluxation is present. (A) Pseudosubluxation is absent: The anterior aspect of the spinous process of C2 will commonly miss the PCL by 2 mm—*Normal or Abnormal* (PCL cannot be applied). (B) Pseudosubluxation is present: The anterior aspect of the spinous process of C2 lies on the PCL—*Normal*. (C) Subluxation is present: The anterior aspect of the spinous process of C2 misses the PCL by 2 mm. This finding is suggestive of a hangman's fracture of the neural arches of C2—*Abnormal*. (From Fesmire FM, Luten RC. The pediatric cervical spine: developmental anatomy and clinical aspects. *J Emerg Med* 1989;7:133–142, with permission.)

In adults, widening of the predental space frequently signifies a rupture of the transverse ligament or subluxation of C1 on C2. Twenty percent of children younger than 8 years old demonstrate a predental space of 3 mm or more, and distances up to 5 mm may be seen in nonpathologic instances (see [Fig. 300.4](#)).^{6,10} Distances greater than 3.5 mm should be considered abnormal, however, until proven otherwise.

Widening of the prevertebral soft tissue due to hemorrhage and edema is an important adult radiographic finding. In children, suggested norms have included soft-tissue space less than 7 mm anterior to C2 or less than three-fourths of the adjacent vertebral body's width.² The younger the child, however, the more unreliable these norms, because dramatic increases in soft-tissue density occur during expiration or when the neck is held in mild flexion (see [Fig. 300.4](#)).

Excluding major congenital malformations, os odontoideum and ossiculum terminale are two congenital malformations that occasionally occur.^{9,25} Os odontoideum is a failure of the odontoid to fuse with the body of C2. The odontoid is separated from the body of C2 by a thin layer of hyaline cartilage, and fairly insignificant trauma can result in odontoid subluxation, resulting in death or quadriplegia. Os odontoideum can also occur secondarily from the failure of an odontoid fracture to heal. Ossiculum terminale is a failure of the apical segment of the odontoid (summit ossification center) to fuse with the main body of the odontoid. This is generally a benign condition, but one case of this anomaly has led to progressive atlantoaxial dislocation, resulting in quadriplegia and death.²⁰

CLINICAL ASPECTS

Radiographically apparent cervical spine injury is rare in the pediatric age group. Approximately 2% of all cervical spine fractures and dislocations occur in children younger than 16 years old, and only approximately 1.2% of all pediatric cervical spine radiographs reveal an abnormality.^{11,19}

The incidence of cervical spine fractures and dislocations increases with age. Radiographically apparent cervical spine injury, excluding birth trauma, is virtually nonexistent in children younger than 16 months of age.^{2,7,11,13,19} The cause of cervical spine fractures and dislocations is broad, but motor vehicle accidents account for approximately 35% to 50%; diving injuries and falls, approximately 30% to 35%; and sports injuries, approximately 20% to 25%.^{2,7,11,13,19}

Types of pediatric cervical spine injuries can be divided into those of the upper cervical spine (C1 to C2) and those of the lower cervical spine (C3 to C7). Injuries most commonly seen in the upper cervical spine are fracture or synchondral separation of the odontoid, with atlantoaxial dislocation and hangman's fracture of the neural arches of C2. Abnormalities most frequently encountered in the lower cervical spine are anterior subluxation or dislocation, compression fractures, teardrop fractures, and spinous process fractures.

Children younger than 8 years old have a high preponderance of upper cervical spine fractures and dislocations, whereas children older than 12 years have a distribution of injuries resembling that of adults, with a preponderance of low cervical lesions ([Table 300.2](#)).^{2,7,11,13} Children aged 8 to 12 years are in a transition state between the two. The preponderance of high cervical injuries in children younger than 8 years of age relates to the relatively heavy head of the child, coupled with the laxity of ligaments and nearly horizontal facet joints. This combination results in high torques and shear forces being applied to the C1 to C2 regions.

Level of Fracture	Age	Henry ⁸	Hill ¹¹	Apple ²	Detrick ⁷	Total	C1-C2 (%)
C1-C2	<8yr	7	6	4	11	28	
C3-C7	<8yr	1	0	0	6	7	80
C1-C2	8-12yr	4	6	5	6	21	
C3-C7	8-12yr	0	6	2	4	12	64
C1-C2	>12yr	2	13	4	7	26	
C3-C7	>12yr	2	41	13	18	74	26

⁸Excluding birth trauma.

TABLE 300.2. Correlation of Level of Cervical Fractures/Dislocations with Age ^a

The incidence of pediatric spinal cord injuries ranges from less than 1% to 9.4% of all spinal cord injuries.^{5,16} The incidence of spinal cord deficits resulting from cervical spine fractures and dislocations is approximately 30%.^{2,11,13} Of those children with a spinal deficit, approximately 12% are rendered quadriplegic. The incidence of neurologic deficit with cervical spine fractures and dislocations increases with age, with neurologic deficit occurring in 20% of children younger than 8 years of age and in approximately 40% of children aged 8 to 16 years.^{2,11,13}

Pediatric cervical injuries related to the use of front-passenger airbags have been increasingly described in the literature. Airbag deployment has produced a pattern of cervical injuries in older children traveling in front seats and crush injury to the skull of infants in rear-facing safety seats.¹⁷ Currently, the National Highway Traffic Safety Administration recommends placing infants in rear-facing child safety seats in the back seat and that children under 12 should ride seat-belted in a rear seat at all times.

The reported incidence of spinal cord injury without radiographic abnormality (SCIWORA) ranges from 4% to 67% of all pediatric spinal injuries.^{1,16,18} An extensive epidemiologic analysis of 16 California counties found an incidence of 20% of all pediatric spinal injuries that probably most accurately reflects true incidence of this syndrome.¹⁶

The pathophysiology of SCIWORA is thought to result from a combination of a diverse multitude of mechanisms, all resulting in a disruption of microvascular blood supply. Mechanisms proposed include hyperextension with inward bulging of the interlaminar ligaments, reversible disc prolapse, flexion compression of the cord, longitudinal distraction of the cord, and vertebral artery spasm.

A detailed study of SCIWORA in 24 children revealed that 83% of these lesions involved the cervical spinal cord.¹⁷ There were seven cases of complete cord transection, all of which occurred in patients younger than 8 years old. In this study, 54% of the children had a delayed onset of neurologic deficit (range, 30 minutes to 4 days; mean, 1.2 days). More than half of the children in the delayed-onset group later recalled transient paresthesias at the time of the injury.

EMERGENCY DEPARTMENT MANAGEMENT

All children with potential cervical spine injury should have their necks immobilized. Prehospital cervical spine immobilization is best accomplished using a rigid plastic cervical collar and a backboard, combined with tape, sandbags, or a commercially available head-immobilization device.¹⁴ The disproportionate head size of young children causes cervical flexion to occur in children younger than 7 years old when they are immobilized on a standard flat backboard.¹² This flexion can be prevented either by placing padding underneath the back to raise the level of the thoracic spine or by using a spinal backboard with a recess for the occiput. The cervical spine is properly positioned when a line drawn through the external auditory meatus and the anterior aspect of the shoulder is parallel to the backboard. When an alert child vigorously resists attempts at immobilization, however, these attempts could potentially worsen an injury. As a general rule, children rarely ingest central nervous system depressants such as ethanol and, if alert, will not move a significantly injured portion of the body. Thus, it is acceptable to not immobilize the cervical spine of a young alert child with no obvious injuries who is vigorously resisting all attempts.

All children who arrive at the emergency department with a new neurologic deficit consistent with a spinal cord injury and a history of trauma or suspected trauma should undergo treatment with high-dose methylprednisolone as soon as possible.⁴ Recommended dosing consists of a loading dose of 30 mg/kg over 15 minutes, followed by a maintenance infusion of 5.4 mg/kg/h for 23 hours. Due to the existence of SCIWORA, workup should not delay the initiation of high-dose

methylprednisolone in patients with spinal cord injury.

The management of the threatened airway in a child can be an urgent dilemma.²⁴ Ventilation can frequently be accomplished with a chin lift alone (which elevates the tongue off the hypopharynx) or in combination with bag-valve-mask ventilation. Oral intubation, which is preferred in younger children, is best performed using manual in-line traction to maintain cervical immobilization. Young children require little, if any, extension to visualize the glottis. Nasotracheal intubation should be attempted only in older children with spontaneous respirations.

Jaffe and coworkers¹⁵ retrospectively analyzed 206 children with suspected cervical spine injury and developed a clinical algorithm for identifying patients at high risk for cervical spine injury. They found that the clinical criteria of any one of the following—history of direct neck trauma; neck pain; neck tenderness; limitation of mobility; abnormality in flexion, strength, or sensation; or decreased mental status—had a sensitivity of 98% and a specificity of 54% for detecting cervical spine injuries. They also found that the standard lateral roentgenogram detected 95% of the injuries, and 100% of the injuries when combined with the anteroposterior view. Until further studies are performed, however, attempts should still be made to also obtain an open-mouth odontoid view, although, in our experience, this radiograph is frequently impossible to obtain in young children. [Figure 300.6](#) demonstrates an approach to children with no history of direct neck trauma who arrive at the emergency department with the cervical spine immobilized by rescue personnel.

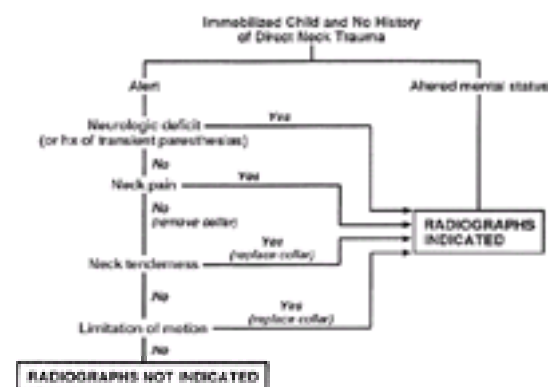

Figure 300.6. Protocol for deciding which pediatric patients arriving immobilized in the emergency department need radiographs. (Modified from Wales LR, Knopp RK, Morishima MS. Recommendations for evaluation of the acutely injured cervical spine: a clinical radiologic algorithm. *Ann Emerg Med* 1980;9:422, with permission.)

Due to the potential of SCIWORAs developing despite normal radiographs, all children with potential spinal injury should be questioned specifically concerning transient paresthesias at the time of the injury. Such children should be assumed to have a spinal injury until a neurosurgical consultation establishes otherwise. The diagnosis of SCIWORA should be a diagnosis of exclusion and should not be made until occult bony, ligamentous, or disc injuries are ruled out by fluoroscopically guided flexion and extension radiographs, computed tomography scanning, magnetic resonance imaging, or myelography.

Pending further studies concerning the nature of cervical spine fractures and dislocations, as well as the nature of SCIWORA, it seems prudent to conservatively admit to the hospital all children with suspected cervical spine injury.

COMMON PITFALLS

- Physicians may confuse open synchondrosis and secondary ossification centers with fractures.
- Physicians may not realize that absent lordosis, anterior wedging of cervical bodies, pseudosubluxation of C2 on C3, increased prevertebral soft-tissue density, and widening of the predental space can be normal.
- A normal radiograph does not rule out cervical spinal cord injury in the pediatric age group, because spinal cord injuries frequently occur in the absence of radiographically detectable injuries. All children with suspected neck injury should be questioned specifically for transient paresthesias at the time of the injury, because approximately one-half of all patients with delayed onset of SCIWORA have this finding.

EPIDEMIOLOGY

Data from the National Pediatric Trauma Registry (NPTTR) indicate that the incidence of abdominal injuries in children is 8%. Multiple injuries are twice as common as isolated abdominal injuries and twice as lethal. Abdominal injuries are present in up to 30% of children admitted to the hospital because of trauma, and 2% of all trauma-related deaths are secondary to abdominal organ injury. The mortality of serious abdominal organ injury is 15%.^{6,7}

Over 85% of abdominal injuries in children are due to blunt trauma.⁷ Motor vehicle-related accidents (passenger, pedestrian, motorcycle, bicycle, and other motor vehicles) are, by far, the most frequent mechanism of injury in children, followed by falls, sport-related injuries, and assault.^{6,7} Penetrating abdominal injuries in children are uncommon; however, with the increase in urban violence in recent years, the number of children with gunshot or stab wounds to the abdomen is increasing.^{12,16}

Abdominal trauma from child abuse is uncommon,^{10,16} but it should be suspected if any of the following apply: history of accidents, vague or unclear accident history, history of injury incompatible with the child's developmental stage or the type of trauma, admission by the child that he or she has been abused, delay in seeking medical attention, unstable family situation, or unusually withdrawn or compliant behavior on the part of the child.

CLINICAL PRESENTATION

Children with abdominal trauma can present with a variety of complaints, from the rare child who is completely asymptomatic to the patient *in extremis*. Most children with abdominal injury complain of abdominal pain, nausea, or vomiting. From a management perspective, children with abdominal trauma can present in one of two ways.

The first and most common presentation is that of a hemodynamically stable patient transported to the emergency department (ED) minutes to hours after the injury. Prehospital personnel have usually instituted initial resuscitative measures, such as administration of supplemental oxygen and intravenous fluids and application of a cervical immobilization collar. The evaluation of a hemodynamically stable patient in the ED can then proceed in a calm and unhurried fashion. The second type of presentation is that of a hemodynamically unstable child, usually transported from the scene, where the immediate diagnostic and therapeutic maneuvers of trauma physicians are necessary for the patient's survival.

EMERGENCY DEPARTMENT EVALUATION

Children with abdominal trauma, either blunt or penetrating, can have one or more organs injured. The management of these injuries can vary from bed rest and observation (e.g., a splenic laceration) to abdominal exploration (e.g., a small-bowel perforation).⁶ Although clinical assessment is very helpful in reaching the correct diagnosis, a diagnostic test, usually radiologic, is essential in many patients to identify the specific injury.^{2,4,5,11,14} The primary focus of the evaluation performed in the ED is to determine the organ injured and the severity of the injury, in order to initiate appropriate management.

Advanced Trauma Life Support (ATLS) guidelines must be followed in the evaluation of all trauma patients.² First, the primary survey is performed to identify and treat any life-threatening injury. This is followed by the secondary survey, in which a head-to-toe examination of the patient is completed. The abdomen is evaluated during the secondary survey.^{2,10}

Because the ED evaluation and management differ according to the hemodynamic status of the patient, they are discussed separately.

The Hemodynamically Unstable Patient

After thoracic and central nervous system (CNS) causes of hemodynamic instability are excluded, the evaluation of a hemodynamically unstable child is directed toward the immediate identification of the source of bleeding. Although a small amount of pericardial blood can cause hypotension (ascertained by pericardiocentesis or echocardiography), there are only a few areas of the body in which exsanguinating hemorrhage can accumulate: the pleural space (quickly identified by clinical assessment, a chest radiograph, or placement of chest tubes), the thigh (diagnosed clinically), the pelvis or retroperitoneum (determined with ultrasound or computed tomography [CT]), and, most commonly, the peritoneal cavity.² Diagnostic peritoneal lavage (DPL) or ultrasound, especially focused abdominal sonography for trauma (FAST), are the two best modalities to quickly and reliably diagnose exsanguinating intraperitoneal hemorrhage.¹⁴ Differentiation between intraperitoneal hemorrhage and other sources of bleeding is important, because bleeding from a pelvic fracture is managed optimally by pelvic stabilization and angiographic control rather than by laparotomy.

The hemoglobin, hematocrit, and blood type and crossmatch are the most important laboratory values in hemodynamically unstable patients. Chest and pelvis radiographs can provide very helpful information. In cases in which immediate surgical intervention to control bleeding is indicated, x-rays should not be obtained if to do so would cause any delay in exploration.

The Hemodynamically Stable Patient

In the hemodynamically stable child, a thorough clinical assessment can provide very useful information and help guide further diagnostic tests. The likelihood of preexisting medical conditions in children is low, but pertinent information regarding the patient's medical history should be obtained in addition to the information related to the accident. Abdominal examination focuses on the presence of any sign of significant injury, including abdominal distension, rigidity, tenderness,

especially diffuse abdominal tenderness, abrasions, ecchymoses, and the “seat belt” sign. ¹⁷ Abdominal examination includes inspection and palpation of both flanks, the back, genitalia, perineum, and a rectal digital examination. ^{5,10}

Laboratory values useful for decision making or therapeutic intervention in blunt abdominal trauma include hemoglobin and hematocrit to assess bleeding, serum transaminase (AST and ALT) levels (60% of patients with levels over 100 to 200 IU have identifiable hepatic injuries), amylase (for suspected pancreatic injuries), and urinalysis. ^{1,11} A blood type and screen should be obtained if it is anticipated that blood products will be used later in the hospital course.

Plain x-rays are of little help in most cases of blunt trauma to the abdomen. The vast majority of abdominal films only show nonspecific findings that do not add information helpful to management decisions. One exception is in children with intestinal perforation, in which the demonstration of free intraperitoneal air on a plain film necessitates proceeding to the operating room for laparotomy.

Plain films will show bony abnormalities and should be performed in cases of suspected spine or pelvic fractures. Plain x-rays of the abdomen and chest should be obtained in patients with penetrating injuries. Two views, with entrance and exit skin markers at the site of the projectile, can yield very helpful information on the type of projectile, trajectory, fragmentation, and location of fragments.

Chest radiographs can provide useful information in patients with an abdominal injury. They may show lower-rib fractures (ribs 6 to 12), hemothoraces, or abnormal diaphragmatic contour, all of which may be associated with an abdominal organ injury or a diaphragmatic tear. Also, trauma patients often have injuries to more than one anatomic area, especially in motor vehicle accidents (MVAs). These radiographs may demonstrate thoracic injuries that are not suspected from clinical assessment.

Currently, CT is the preferred radiologic test for the evaluation of children with suspected intraabdominal injuries who are hemodynamically stable. ^{4,11,14} Helical or spiral CTs, with intravenous contrast, can be performed rapidly (in minutes), with a sensitivity and specificity greater than 90%. CT is noninvasive; can evaluate intraabdominal, retroperitoneal, and lower thoracic structures; is not operator dependent; and is widely available. Some of the drawbacks of CT include expense, having to transport the patient to the scanner's location, radiation exposure, and the possibility of a side effect from intravenous contrast. Although its sensitivity in identifying intestinal perforations is only about 50%, it still is the most sensitive radiologic test for these injuries. ¹⁴

Ultrasonography, both the complete abdominal sonographic examination and FAST, are emerging as useful radiologic tests in the evaluation of children with suspected abdominal injuries. Ultrasound is noninvasive and portable, requires no intravenous contrast, and poses no radiation risks. In addition, FAST can be performed in minutes by members of the trauma team during the resuscitation phase. A complete abdominal ultrasonogram is more time consuming and is similar to CT in cost. Both tests, however, are operator-dependent and less sensitive than CT. FAST is used primarily as a screening test, while complete abdominal ultrasound examinations are performed instead of CT in a few trauma centers. ¹⁴

DPL is a quick, inexpensive, and extremely sensitive test for the presence of free intraperitoneal blood (98%); however, it is also nonspecific and invasive, it does not evaluate the retroperitoneum, and it is associated with a 1% to 2% risk of intestinal or vascular injuries. ^{2,5} Because the vast majority of children with abdominal trauma have blunt injuries, are hemodynamically stable, and are now managed nonoperatively, the mere presence of blood in the peritoneal cavity (detected by DPL) does not provide information useful in the management plan. ^{9,16} The more sensitive and specific CT has now replaced DPL as the preferred test for the evaluation of blunt abdominal trauma in children. DPL is used mainly to determine the need for immediate laparotomy in the hemodynamically unstable child who suffered blunt injury. ^{5,10,16}

Penetrating Injuries

In children (as in adult trauma patients) with penetrating injuries, the velocity and trajectory of the projectile, in addition to clinical findings, determines the necessary diagnostic tests and the need for laparotomy. Most (greater than 85%) high-velocity penetrating injuries that violate the peritoneum cause enough organ damage that surgical repair is necessary. ⁸ A smaller percentage of low-velocity injuries cause significant organ damage, but surgical intervention depends on the projectile trajectory, clinical findings, and results of laboratory tests and x-rays. ^{8,12} Patients with stab wounds require surgical repair in only one-third of cases and can therefore be managed selectively with exploration reserved for patients with worsening clinical findings. ⁸

EMERGENCY DEPARTMENT MANAGEMENT

The Hemodynamically Unstable Patient

All hemodynamically unstable patients should undergo resuscitation concurrent with the primary and secondary survey, as per ATLS protocols. Ringer's lactate (preferably) or normal saline should be administered via intravenous or intraosseous access, with at least one site above the diaphragm. ^{2,10,16} Resuscitative fluids must be infused as rapidly as needed to maintain vital organ perfusion. Many children with abdominal injuries have an associated head injury. In these patients, avoiding hypotension and maintaining adequate cerebral perfusion are important to minimize any secondary brain injury.

Nasogastric tubes (NGTs) should be inserted unless a contraindication is identified. Contraindications include visible blood or cerebrospinal fluid in the nose, significant facial injury, or a basilar skull fracture. Urinary drainage catheters should also be placed, unless a contraindication is found. These include blood at the urethral meatus, a perineal or scrotal hematoma, or a high-riding prostate.

After excluding an intrathoracic or CNS cause for the hemodynamic instability, abdominal sources of bleeding are then sought in an orderly fashion. DPL or FAST is performed to determine the presence of intraperitoneal blood, which would justify immediate laparotomy. Blood samples are obtained for type and crossmatch and hemoglobin and hematocrit measurement, and intravenous antibiotics are administered. Analgesics and tetanus prophylaxis are administered, as indicated.

The Hemodynamically Stable Patient

For the hemodynamically stable patient, management depends on the injuries identified and investigations planned. Laboratory values and radiographic studies are performed with specific indications. In most pediatric cases, a hemoglobin and hematocrit, AST/ALT, urinalysis, and a blood type and crossmatch are done. NGTs and Foley catheters should be placed for specific indications, not routinely. NGTs are indicated for nausea, vomiting, or suspected gastric distension, and Foley catheters are placed to decompress the bladder or if urine output measurement is important. As mentioned, Foley catheters should not be placed routinely in children. In addition to the psychological trauma of their placement, they can cause significant urethral injury in boys, especially if they are younger than 5 years of age.

Most blunt solid-organ (liver, spleen, kidney, and pancreas) injury in children can be successfully managed nonoperatively. Surgical intervention is needed for intestinal perforations, intraperitoneal bladder rupture, and most high-velocity penetrating traumas. A selective approach can be safely followed in children with abdominal stab wounds. Therefore, once the patient's workup is completed, he or she is promptly admitted to the surgical service.

SPECIFIC INJURIES

Spleen and Liver

The spleen and liver are the most commonly injured abdominal organs in children. Splenic injury should be suspected in children with a history of left-sided trauma, complaints of left upper quadrant or left shoulder pain, and anemia. Hepatic injuries are associated with a higher morbidity and mortality. Stable children with hepatic injury usually complain of right upper quadrant pain and have an elevation in hepatic enzymes.

The majority of hepatic and splenic injuries can be successfully managed nonoperatively. Nonoperative management consists of strict bed rest for 5 to 7 days, followed by a gradual return to full activities. Monitoring of hemodynamic parameters and measurement of serial hemoglobin and hematocrit values are required for the first few days after injury. Requirements for nonoperative therapy include hemodynamic stability, operating capabilities on a 24-hour basis, and blood transfusion

requirements less than 40 cc/kg (one-half blood volume).⁴

Intestinal Perforation

Intestinal perforations are unusual in children and often have a nonspecific presentation. Intestinal injuries are usually diagnosed on clinical grounds within the first 24 hours after injury, occasionally with radiologic investigations. Surgical intervention is always required.⁹

Kidney, Bladder, and Urethra

Minor trauma can unmask asymptomatic renal anomalies. Between 5% and 10% of children with congenital anomalies of the genitourinary (GU) system are first diagnosed because of renal trauma.¹ Similar to splenic and hepatic injuries, renal trauma is usually due to a blunt mechanism and can be managed nonoperatively in over 90% of patients, even with urinary extravasation. Usually, a CT scan is performed to evaluate microscopic hematuria, regardless of the hemodynamic status of the patient. Bladder perforation can be diagnosed with cystography or CT scan and usually requires surgical repair.

Urethral injury in girls is rare; however, in boys, it should be suspected in those with a pelvic fracture, blood at the meatus, scrotal hematoma, a high-riding prostate, and inability to void or pass a Foley catheter. A retrograde urethrogram must be performed in these patients to evaluate the urethra and guide surgical repair.¹³

Pancreas

Because of the location of the pancreas in the retroperitoneum, pancreatic injuries are uncommon. The identification of injuries to this organ, however, remains difficult, and delays in diagnosis are common. Serum amylase level, lipase level, and abdominal CT are the most useful tests, but they still have a low sensitivity when performed during the initial evaluation. Most types of pancreatic injuries can be managed successfully nonoperatively, although this subject remains controversial.¹¹

Diaphragm

Diaphragmatic injuries are rare in children and are usually due to penetrating trauma.⁷ Irregular contour of the hemidiaphragm on radiologic examinations can suggest the diagnosis, although this finding is present in less than 50% of patients. Laparoscopy and DPL have been suggested as diagnostic tools, and surgical repair remains the standard of care for these injuries.⁵

Musculoskeletal

Pelvic fractures are uncommon in children, occurring in only 2% to 3% of all trauma admissions. Pedestrian injury poses the biggest risk. A pelvic x-ray quickly establishes the diagnosis and guides management. Pubic rami fractures are the most common, followed by those of the ilium or pelvic rim and, finally, the sacrum.³ DPL can be performed in children with pelvic fractures, with specific modifications in the technique and a recognized higher false-positive rate. Open supraumbilical placement is recommended.

Angiographic intervention, for diagnosis and treatment, should be considered in hemodynamically unstable children without other sources of bleeding. The presence of multiple fractures of the pelvic rim is a predictor of associated abdominal or GU injury.³ Lumbosacral spine fractures are unusual but should be suspected in patients with the “seat belt” sign or tenderness on palpation. A Chance fracture consists of a transverse lumbar fracture due to hyperflexion over the fulcrum of the seat belt.

“Seat Belt Syndrome”

Seat belt use has been clearly shown to decrease MVA-related deaths.¹⁵ It is associated, however, with a specific pattern of injuries to the small intestine and lumbar spine from compression, burst, or shearing. A seat belt sign across the lower abdomen should be investigated, preferably, with a CT scan, and the patient should be admitted for observation because of the increased risk of small-bowel perforation.¹⁷

DISPOSITION

Role of the Consultant

All children suspected of having intraabdominal organ injury must be evaluated by a surgeon familiar with pediatric trauma. Clinical assessment, including history of significant injury, radiologic findings, and laboratory results, should be considered when deciding on the need for surgical consultation. Surgical consultation is especially indicated in any one of the following conditions:

Hemodynamic instability
Seat belt sign
Penetrating trauma
Abdominal tenderness (localized or diffuse)
Elevated AST/ALT, decreased hemoglobin and hematocrit, or hematuria
Pelvic fracture

Indications for Admission

All children with abdominal tenderness on clinical evaluation, laboratory abnormalities, or radiologic evidence of an intraabdominal organ injury must be admitted for monitoring. Children who appear well but are unable to tolerate liquids should also be admitted. The determination of which hospital unit is most appropriate for the care of these children depends on the severity of the injury and the type of monitoring provided in each unit. Patients with a major solid-organ injury (e.g., grade IV splenic laceration) should be admitted to the intensive care unit and monitored closely. Children with suspected pancreatic or renal injury based on elevated amylase or hematuria, but without radiologic abnormalities, may be admitted to the general ward. A small group of children who appear well, have minimal abdominal discomfort, or near-normal workup can even be observed in the ED for a few hours, reexamined, and then discharged home from the ED if their symptoms resolve.

Transfer Considerations

The reasons for transferring a patient to a higher-level trauma unit depend on the patient's clinical status and the medical facilities and expertise available. Transfer indications related specifically to abdominal injury include blunt abdominal trauma, with either hemodynamic instability or signs of intestinal perforation, or penetrating abdominal injury. These represent the patients with the highest possibility for requiring surgical intervention.

COMMON PITFALLS

- Inability to promptly recognize hemodynamic instability in children
- Failure to quickly identify patients with exsanguinating intraabdominal or retroperitoneal bleeding
- Inadequate volume resuscitation (crystalloid and blood products) in patients with significant bleeding
- Failure to recognize clues of child abuse

Annually, burns result in 10,000 severe disabilities and in 2,000 deaths among children, a significant cause of morbidity and mortality. Burns represent the third leading cause of traumatic death in children, surpassed only by motor vehicle collisions and drownings. Most children with minor burns are treated at home without the aid of a physician, while the majority of patients treated in the emergency department are managed on an outpatient basis. Thus, it is important that emergency department physicians are skilled in the up-to-date care of acute and complicated pediatric burn injury.

The majority of children admitted to the hospital have total body surface area (TBSA) burns of less than 20%. The most common burn injury in children is a scald before age 4, typically involving the head, chest, and arms. Seventy percent of pediatric burns are scalds from hot liquids associated with cooking or bathing, and nearly 20% of these involve abuse, particularly tap water immersion. The remaining 30% are the result of flame, contact burns, chemical injury, high-voltage electrical burns, or tar injuries.⁹

CLINICAL PRESENTATION

The severity of thermal trauma is most closely related to the depth and extent of injury, but may also be related to inhalation injury or specific locations of the burn injury, such as joints, face, or genitalia. Other factors that contribute to the severity of the injury include the causative factors, age of the patient, toxic exposures, and concomitant traumatic injuries. The depth of injury depends on the source type, the source temperature, and the length of exposure. A scald injury usually results in partial-thickness burns, while a flame injury typically results in full-thickness burns. Infants and young children have a much thinner dermal layer of skin (compared with adults), which has a greater propensity for deep burns. Certain causative agents, such as grease, chemicals, and electricity, have the potential to cause a deeper, more severe injury because of their higher temperature, greater heat-transferring ability, sustained effect, and internal effect.

Depth of burn trauma refers to the level of destruction of the epidermis, a thin layer of epithelial cells, and the dermis, which is composed of fibrous connective tissue, blood vessels, nerves, hair follicles, and sebaceous and sweat glands ([Fig. 302.1](#)). A *first-degree* burn involves only the epidermis and presents as intact erythematous skin; this type of burn is not included in calculations of TBSA. A *second-degree* burn involves the dermis and is characterized by blistering and pain. *Third-degree* burns destroy the epidermis and dermis down to the subcutaneous fat, and if the subcutaneous fat is completely involved, the burn injury can be described as *fourth degree* ([Fig. 302.1](#)).

Figure 302.1. Cross-section of skin demonstrates various depths of burn

Another nomenclature describes burns as *superficial partial-thickness* burns that extend into the upper dermis and present with erythema, tenderness, and blistering. The pain associated with these injuries reflects the intact nerve endings in the dermis. These burns heal completely within 21 days without scarring because of epidermal cell migration from appendages remaining in the dermis. *Deep partial-thickness* burns involve more of the dermis, with fewer remaining epidermal appendages. These deeper burns can heal without grafting over prolonged periods of time, but the functional result is often improved with grafting. Superficial partial-thickness burns tend to have more exudative moisture and be hypersensitive compared with deep partial-thickness injuries, which are pale and sensitive only to deep pressure. Pain is related to the depth of injury but is not reliable for determining the depth of injured dermis, because receptors may not function in the acute phase of injury.

Full-thickness burns destroy the entire epidermis and dermis. As a result, these wounds are insensate and generally appear dry and leathery, with a pale-to-brown color. These injuries will not heal spontaneously unless the injury is very small (2 to 3 cm), because repair results from epithelial cell migration from the wound edges. Differentiating between deep partial-thickness and full-thickness burns in infants and children may be difficult or impossible in the emergency department because of the relative thinness of children's skin and overlapping clinical presentations.

The extent of burn injury can be mathematically described in terms of TBSA involvement. An accurate assessment is essential for calculating fluid requirements and determining the severity of injury. Children have relatively larger heads and smaller lower extremities than do adults, making the "rule of nines" inaccurate for patients younger than 10 years of age. By the pediatric rule of nines, the head is calculated as 18% of the TBSA and the legs as 14% each of the TBSA. A modification of the Lund and Browder chart considers these unique anatomic factors in children ([Fig. 302.2](#)). Another useful method for smaller burns is estimating the area of the burn using the patient's hand. The palm of the hand is approximately equal to 0.5% of the TBSA, and the entire palmar surface is 1% of the TBSA. Calculating the extent of the injury requires complete examination of the undressed patient and should be performed only after initial stabilization.

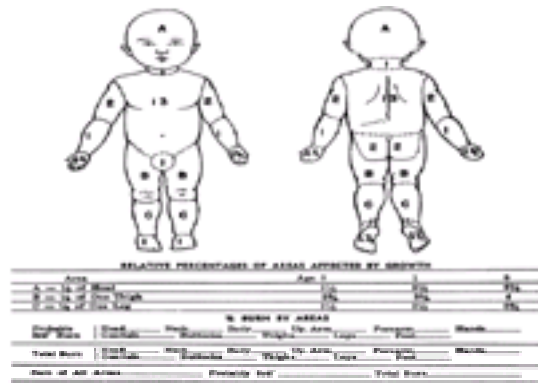

Figure 302.2. Modified Lund and Browder chart for estimation of body surface area burn involvement in infants and children.

Electrical Burns

Electrical burns may present with small, unimpressive external wounds that obscure extensive deep-tissue destruction. The electrical current passes along neurovascular bundles, causing thrombosis of blood vessels and damage to adjacent muscle and bone. Patients with extensive muscle damage may develop myoglobinuria and may require intravenous fluids to prevent acute renal failure.

Myocardial injury from the electrical current can result in infarction and arrhythmias. An electrocardiogram should be obtained along with determination of cardiac isoenzyme values and continuous cardiac monitoring. An injury peculiar to children is the burn to the lip and commissure of the mouth caused by chewing an electrical cord. These patients should be admitted and observed for delayed hemorrhage of the labial artery and oral splinting.

Chemical Burns

Household cleaners often cause chemical burns in children. Ingestion should be suspected in any young child with a chemical burn. The burn should be copiously irrigated with warm water or normal saline for 20 minutes after removal of the child's clothing. Then the extent and depth of the burn can be assessed and treated with appropriate topical agents.

DIFFERENTIAL DIAGNOSIS

Children sometimes present to the emergency department with apparent burn injuries but no witnessed burn event. Although such a presentation is often the result of a self-inflicted injury denied by the child or can be indicative of a nonaccidental injury, other medical conditions should be considered before a burn wound is conclusively diagnosed. *Toxic epidermal necrosis* produces diffuse epidermal sloughing related to drug usage. Severe presentations involving the mucosa and conjunctiva are known as *Stevens-Johnson syndrome*, and oropharyngeal involvement may require intubation. Clinically, it is difficult to distinguish from staphylococcal scalded skin syndrome, and a biopsy is necessary for final confirmation. Topical antibiotics are used to prevent superinfection and desiccation, and grafting may be necessary in large affected areas.

Purpura fulminans can present with extensive blistering of the skin as a complication of meningococcal sepsis. Treatment is initially directed toward resolution of the septicemia but may include excision and grafting of wounds. *Scalded skin syndrome* is associated with staphylococcal exotoxin that causes separation of the epidermal granular layer. Mucosal surfaces and conjunctiva are never involved, and the wounds heal spontaneously, provided infection and desiccation are avoided.

EMERGENCY DEPARTMENT EVALUATION

Airway

Inhalation injuries are relatively uncommon, with only 15% of admitted patients having such complications, but the high correlation with mortality emphasizes the need for careful initial evaluation of the patency and adequacy of the airway of any child with a burn injury. Airway injuries result from mucosal exposure to heat or toxins, and cause edema to the epithelial lining of the larynx, trachea, and bronchus. Clinical or historic evidence of inhalation injury demands prophylactic intubation in children, because the smaller overall size of the airway creates more flow resistance with even minimal edema, as well as the inherent difficulties associated with pediatric intubation.⁴

Physical findings consistent with inhalation injury include tachypnea, stridor, wheezing, cough, hoarseness, dysphonia, head and neck burns, oronasopharyngeal soot, swallowing difficulties, loss of consciousness, or altered mental status. Historic information that suggests the need for intubation includes a fire in a closed space and exposure to superheated gas vapor. Carbon monoxide and oxygen levels, as well as pulmonary function tests, are not helpful in determining the need for intubation. Chest radiographs and bronchoscopy are likewise not useful, and lateral cervical radiographs are not sensitive for identifying airway edema.⁸

Breathing

All burn patients should be treated with 100% oxygen during the initial evaluation period. Absolute indications for endotracheal intubation of the burned infant or child include upper airway obstruction, confirmed inhalation injury, respiratory depression, nasolabial full-thickness burns, and circumferential neck burns. Circumferential burns of the chest or abdomen may also lead to respiratory compromise that requires intubation. The choice of nasotracheal or orotracheal intubation depends on the patient's clinical condition and physician's technical skill. Of paramount importance is careful stabilization of the endotracheal tube with adhesive tape, if possible, or by other means if the face is burned, because reintubation of a patient with edema of the neck or posterior pharynx may be difficult or impossible.

Circulation

Circulation can be initially evaluated by the presence of peripheral pulses, and the character of the pulse is a clue to the overall volume status. If pulses cannot be evaluated because of overlying burns or poor overall perfusion, capillary refill can provide evidence of adequate circulation. Circulation distal to circumferential burns should be evaluated frequently to identify compromised distal perfusion. The absence of circulation should first be addressed with adequate fluid resuscitation, followed by emergent escharotomy if circulation remains poor after adequate volume resuscitation.

Secondary Survey

Although the tendency is strong to focus on the obvious burn injury, a disciplined, systematic approach to the patient is critical, particularly if other mechanisms of potential injury are reported, such as an explosion, vehicle collision, or abuse. With these mechanisms, altered mental status may reflect a head injury rather than the effects of narcotics or respiratory insufficiency, and a computed tomography (CT) scan of the head must be considered. The potential of a head injury necessitates evaluation of the cervical spine with a lateral radiograph and a cervical collar until assessment is complete.

A chest radiograph should be performed as part of the initial evaluation for any significant burn injury, and attention should also be directed toward traumatic injuries such as pneumothorax, skeletal fractures, and mediastinal injuries. Suspicion of abdominal injury should prompt careful observation, laboratory evaluation of hepatocellular enzymes and amylase, and possibly a CT of the abdomen. The remainder of the examination should evaluate the extremities and back for skeletal and soft-tissue injuries distinct from the burn injuries. A baseline neurologic examination will provide important information for future comparison, because the initial examination will be least complicated by the sequelae of the burn injury.

Abuse

As many as 20% of all hospitalized burn patients incur their injuries as a result of child abuse⁷; thus, the physician must consider the possibility that each pediatric burn injury represents a nonaccidental injury. Circumstances suggestive of intentional burn injury include a history of “accidents,” a history inconsistent with the injuries, conflicting stories from the caregivers and child, or a history incompatible with the child’s developmental stage. Over one-half of children with intentional burn injuries have previous injuries or abuse, and almost the same percentage have delays in their presentation.⁷

Findings consistent with abuse include a contact burn with a recognizable or symmetric pattern, coexistent musculoskeletal or soft-tissue trauma, and well-demarcated, bilateral, or circumferential burns of buttocks, perineum, or extremities. Scald burns represent the majority of intentional burns and commonly result from immersion into hot water. Typically, these injuries have an absence of splash marks and a sparing of flexion creases. Victims of abuse are more likely to have an unstable family situation, a single-parent home, and lower socioeconomic status.

EMERGENCY DEPARTMENT MANAGEMENT

Fluid Resuscitation

Once the depth and extent of the burn injury are determined, the injury can be categorized according to the system in [Table 302.1](#). Children with burns of greater than 20% TBSA require intravenous fluid resuscitation due to the systemic impact of burns of this extent. Patients with lesser burns who have suspected inhalation injury should be treated cautiously with intravenous fluids in order to minimize contributions to airway edema. Two intravenous catheters of the largest possible size in an unburned area are preferable.

Minor burn injury	<15% TBSA burn <10% TBSA burn in children <10 yr old <2% TBSA full-thickness burn
Moderate burn injury	15%–25% TBSA burn 10%–20% TBSA burn in children <10 yr old <10% TBSA full-thickness burn involving the face, eye, ear, hand, foot, or perineum
Major burn injury	>25% TBSA burn >20% TBSA burn in children <10 yr old >10% TBSA full-thickness burn Injury involving the face, eye, ear, hand, foot, or perineum, with likely functional and/or cosmetic disability High-voltage electrical burn injury All burn injuries with concomitant inhalation injury or major trauma

TABLE 302.1. Burn Classification

If peripheral intravenous access cannot be established, intraosseous access can be established at the tibia, femur, or sternum, especially in children less than 6 years of age. Other intravenous options include a saphenous vein cutdown at the medial ankle and central venous access via the jugular, subclavian, or femoral routes. Due to the higher BSA-to-weight ratio in children, fluid losses are increased relative to body weight. As a result, the classic burn resuscitation formula has been modified for children.

The modified Parkland formula administers lactated Ringer’s solution over the first 24 hours from the time of injury, using the following calculation: 4 mL/kg/%TBSA plus maintenance volume. One-half of the burn resuscitation fluid is given over the first 8 hours, and the remainder over the subsequent 16 hours. For example, a child weighing 20 kg with a 40% burn should receive 3,200 mL of resuscitation fluid in the first 24 hours plus 60 mL of maintenance fluid hourly. If the child arrives 1 hour after the injury with an intravenous line at 100 mL/h, the new rate would be 283 mL/h $((1,600 - 40)/7 = 223 + 60 = 283)$ for the next 7 hours and 160 mL/h $(1,600/16 + 60)$ for the subsequent 16 hours. This formula provides only a guideline and should be adjusted according to urine output, which should be greater than 1 mL/kg/h for children less than 14 years of age, and greater than 2 mL/kg/h for those less than 3 years of age.

The insertion of a Foley catheter is essential for following the adequacy of the resuscitation. Additional parameters that are useful for assessing response to intravenous fluids are pulse quality, heart rate, and peripheral perfusion.

Initial laboratory tests should include a complete blood cell count, electrolytes, type and screen, urinalysis, and arterial blood gas analysis. A carboxyhemoglobin level should be obtained, and a cyanide level considered, on patients with suspected inhalation injury or a history of fire in a closed space. The urine should be screened for free hemoglobin or myoglobin in significant burns. A nasogastric tube is necessary in all patients with burns greater than 20% TBSA, due to anticipated intestinal ileus.

Escharotomy

Full-thickness burns create a leathery coagulum of necrotic tissues known as the eschar. If the full-thickness burn is circumferential in an extremity, the inflexible eschar and progressive edema beneath the eschar can lead to increased compartment pressures that impede venous return initially and arterial inflow ultimately. If this circumferential burn involves the chest and upper abdomen, the restriction of chest expansion and diaphragm excursion can result in respiratory embarrassment. Either of these circumstances may warrant an escharotomy. If a surgeon is not available or is delayed, emergent escharotomy may be necessary to preserve a limb or a life in the case of thoracic circumferential burns. Skeletal trauma and electrical burns may necessitate a fasciotomy, which should be accomplished in the operating room.

An incision through the burn eschar to the underlying subcutaneous fat can be accomplished by using a scalpel or electrocautery. Because the eschar and underlying tissue are insensate, analgesia is not required, but sedation should be considered. Bleeding should be minimal and can be treated effectively with gentle pressure. Release of the eschar is accomplished with medial and lateral incisions of the arms and legs, including involved joints, with care to avoid superficial blood vessels and nerves.

Escharotomy is indicated in limbs with distal cyanosis, decreased capillary refill, decreased pulses, or progressive neurologic change. Serial Doppler flow measurements of vessels distal to the burn are useful in deciding whether an escharotomy is adequate. Impending respiratory failure should prompt intubation and bilateral escharotomy of the chest along the anterior axillary line. If ventilation remains impaired, the chest escharotomy can be extended with one or two horizontal incisions connecting the lateral escharotomies at their superior or inferior extents.

Hands and fingers with circumferential burns are important areas to assess because of the potential disability that can result from delay in diagnosis of ischemia or from injury related to attempted escharotomy. Doppler signals of the radial and ulnar arteries do not adequately predict hand perfusion; thus, flow in the superficial palmar or digital arteries must be confirmed to ensure adequate hand circulation.

Other clinical indications for escharotomy in the hand or fingers include pain, inability to passively straighten the fingers, loss of nailbed capillary refill, and tenseness of the tissue on palpation. Escharotomy of the fingers requires only one incision axially on the ulnar surface between the neurovascular bundle and the extensor apparatus. The thumb can be approached similarly, with an incision along the radial aspect. The dorsum of the hand can be released with one or more incisions between the metacarpals. The wrist can be released medially and laterally, avoiding the superficial radial and ulnar nerves.

Outpatient Care of the Burn Wound

The care of burn wounds in the emergency department can be complicated and time consuming. Keys to success include adequate pain relief and thorough cleansing of the burn wound. Analgesia in the form of narcotics and sedation in the form of benzodiazepines should be used liberally for the initial phase. Moist saline dressings provide some pain relief and may limit the ultimate depth of burn injury, but they should be employed only with small wounds, due to the risk of hypothermia. Thirty

minutes after the administration of narcotics and cool towels, the wound should be cleansed thoroughly, using mild antiseptic soap, and loose tissue should be debrided. Intact blisters that are not over mobile areas can be left intact, although large blisters should be unroofed.

Following cleansing and debridement, burns can be covered with a 3- to 5-mm layer of silver sulfadiazine (Silvadene 1%), which provides broad-spectrum bacterial coverage. The topical agent can then be covered with a nonstick, porous gauze and wrapped in a bulky occlusive dressing. For wounds that require further debridement, the nonstick gauze can be omitted; thus, the dressing removes loose tissue when it is taken off. This dressing will need to be changed twice daily, with all topical agents completely removed. Caregivers should be informed that the yellow color in the dressing is not indicative of infection.

Mafenide (Sulfamylon 8.5%) has properties similar to those of silver sulfadiazine but has little role in the outpatient care of burns because of the pain experienced with application. Povidone-iodine 1% ointment can be used in areas prone to maceration, because this ointment has a drying effect. For children with sulfa allergies or burns of the ears, gentamicin cream can be applied twice daily. This agent should not be considered a first-line agent, because it does not cover gram-positive organisms, and it should not be used on large burns because of the risk of ototoxicity and nephrotoxicity. Bacitracin ointment can be applied four times daily for minor neck and facial burns, because silver sulfadiazine is irritating to the eyes.

Tetanus toxoid (0.5 mL intramuscularly) should be given to any child who has not had a booster within 5 years or whose last immunization date is unknown. If the child has had no immunizations, 250 U of intramuscular tetanus human immune globulin should be given, along with the first of a series of active immunizations with tetanus toxoid.

The goals of outpatient care are to prevent infection and maintain mobility of involved joints. Education of the caregiver becomes the most critical aspect of the patient's care. Oral pain relief in the form of codeine (often with acetaminophen) is essential. The patient should also be given a prescription for diphenhydramine for pruritus. The child's caretaker needs to be carefully instructed in dressing care and given prescriptions for necessary supplies and topical medications. Caregivers should be instructed to immediately initiate mobilization at least five times daily, with gentle stretching, to prevent loss of function. All patients should be reevaluated in 24 to 48 hours in the emergency department or with a primary physician.

Hospitalization for Burn Wound Care

Once the decision to admit a patient with burns has been made ([Table 302.2](#)) and the patient is physiologically stable, transport should be expedited so that debridement and dressings can be initiated. No topical treatments should be applied prior to transfer, as they will interfere with initial inspection of the wound and may preclude the use of some types of burn wound coverings.

Greater than 10% second-degree burns	Other major medical problems
Greater than 2% third-degree burns	Oral pain management insufficient
Burn of hand, foot, face, perineum, or genitalia	Family cannot perform dressing changes
Inhalation injury	Inadequate social support
Significant electrical or chemical burn	Suspicion of child abuse or neglect
	Follow-up compliance dubious

TABLE 302.2. Admission Criteria

Transfer to Burn Care Centers

Patients with major burns should be transferred to burn centers, where an integrated team approach can decrease mortality by 30% and morbidity by 40%.² Because sepsis resulting from burn wound infections is the major source of mortality in extensive burns (greater than 15%), some consideration should be given to prevention of burn wound contamination during the initial evaluation. Dry and clean dressings allow adequate dissipation of wound heat without contributing to hypothermia and protect the wound from further contamination. A "sterile" approach to the burn patient is both unrealistic and unnecessary; at the same time, gloves and masks should be worn by health care providers, and sterile sheets should cover the patient.

Meticulous attention must be paid to stabilizing the patient before transport, including two peripheral intravenous lines, a nasogastric tube, and Foley catheter. The patient's airway must be secured; if there is any question about a child's respiratory status, intubation should be performed before transport. Appropriate intravenous fluid resuscitation should be initiated, and monitoring should be employed throughout transport. Analgesics should not be administered intramuscularly in major burns, because absorption may be unpredictable.

COMMON PITFALLS

- Intubation is often delayed because inhalation injury is unrecognized or unappreciated.
- Inappropriate discharge can result from underestimation of the depth and extent of the burn.
- The severity of electrical injury is easily underestimated, resulting in delayed transfer to a burn center.
- Child abuse cannot be recognized if it is not suspected.
- Too narrow an approach to the patient can result in failure to identify associated injuries.
- At discharge, do not forget to explain dressing care to caretakers, to provide adequate pain control, to arrange appropriate follow-up, and to provide or give a prescription for necessary wound-care supplies.

Fractures account for up to 10% to 15% of emergency department (ED) visits of children, owing to their high activity level, youthful fearlessness, poor judgment, and underdeveloped motor coordination. High-energy trauma has become more significant, although the incidence may decrease with stricter car seat and seat belt laws and enforcement. Also, over the past decade, as participation in organized youth sports programs has increased, so has the spectrum of injuries sustained by children.

Children's fractures are not smaller versions of adult fractures. Because children's bones are actively growing, children have a distinct bony architecture different from that of adults, and active growth may make different growth areas more susceptible at different stages. Actively growing bones are described by three areas: the epiphysis, metaphysis, and diaphysis.

Generally, children's bones are more porous, more pliable, and overall have less strength than those of adults. Likewise, because ligamentous attachments are stronger than their bony attachments, fractures (e.g., avulsions) are more common than sprains, strains, or dislocations. Children's fractures have a high rate of healing and potential for deformity correction through remodeling. Pediatric fracture healing is complicated by problems such as plastic deformation, growth arrest, and progressive angulation.

A thorough examination is necessary, not only of the fracture site, but also to rule out any associated or occult injury. This can be challenging with a frightened, uncooperative patient who is in pain, and with concerned parents hovering nearby. After taking a history and performing a searching physical examination, further diagnostic studies, usually plain radiographs, are obtained. Laboratory evaluation has minimal utility in most fracture decision making. If an isolated extremity injury is the presumptive diagnosis, adequate pain control should be strongly considered and may be started before plain films are performed. Occasionally, pelvic fractures and multiple long-bone fractures may cause enough blood loss to result in hemodynamic compromise. Barring suspicion of these injuries, hemodynamic instability merits a careful examination to seek other sources of blood loss.

Treatment is based on the complete diagnosis and should include pain control. Options include definitive treatment by the emergency physician, splinting and referral, or immediate consultation with orthopedic or other specialists.

EMERGENCY DEPARTMENT EVALUATION

Accurate, complete diagnosis is of paramount importance. Common fracture patterns and associations are easily recognized if the treating physician is familiar with them. Management, based on some knowledge of the natural history, is usually straightforward if the diagnosis is correct and complete. An incorrect or delayed diagnosis can result in complications. Although the rapid healing of children's fractures is generally beneficial, it can decrease the time frame in which interventions are possible, usually to about a week or so.

History

It is tempting to take a quick history, believing that the x-rays will show everything, but it is important to establish the circumstances and mechanism of injury. The time spent obtaining the history also allows the physician time to establish rapport with the parent and to calm and gain the trust of the child.

When the nature of the injury seems implausible, child abuse must be considered. If high-energy trauma was involved, occult intraabdominal or intracranial injury must be sought. If the cause of the fracture is a mystery to the child, the physician must consider the possibility of seizures, leading to a fall.

The mechanism of injury provides clues as well. The common fall on an outstretched arm can produce wrist, forearm, or elbow fractures, or a combination of these. Falls from a height may result in calcaneus fractures associated with lumbar spine fractures. A dashboard injury can fracture the patella and can cause a hip fracture or dislocation.

Physical Examination

It is difficult to overemphasize the importance of the physical examination. The uninjured extremities and the spine are examined first; the physician should reassure the child that he or she will not cause pain unexpectedly. This may reveal occult injuries while the child is most cooperative and least upset.

When examining the injured extremity, the examiner should start at the end farthest from the painful area. Careful, thorough palpation of the entire limb is important. Any significantly tender areas should be x-rayed.

When possible, joints should be taken through a range of motion to assess for possible dislocation, particularly in the older child. This is most important for the shoulder, elbow (including pronation and supination), and hip. The joints should be palpated as well; radial head and proximal fibula fractures are frequently missed.

The skin should be thoroughly assessed, including the part hidden by splints applied as first aid. A laceration over a joint requires exploration to rule out an arthrotomy, a condition requiring urgent management. A break in the skin associated with a fracture is usually an open fracture, particularly if it has a continuous, slow oozing of dark blood, characteristically associated with fat droplets. This requires emergent intervention as well.

Neurologic and vascular examinations must not be omitted. Frequently, the child will cooperate with at least a sensory examination for light touch. More encouragement may be rewarded with a limited motor examination. A wiggle is better than nothing.

Compartment syndrome must not be overlooked. It is most common in the forearm and lower leg as a result of either fracture or crushing injuries, leading to bleeding and swelling within inelastic fascial compartments. Elevated pressures lead to ischemia at the capillary level and, untreated, can threaten the entire limb from muscle and nerve necrosis. The hallmarks are pain out of proportion to the degree of injury, and extreme pain with passive range of motion of the fingers or toes. Paresthesias, pulselessness, and pallor are all late manifestations. A compartment syndrome is a true orthopedic emergency, and early consultation with an orthopedist is warranted. Definitive diagnosis should be in concert with an orthopedist to measure compartment pressure. Emergent fasciotomy is required to preserve limb function.

Unfortunately, a fracture during childhood may be a manifestation of child abuse in up to 5% to 18% of cases. Suspicion for child abuse should be high when an infant (less than 1 year old) has a fracture, there are inconsistencies between the history and the fracture type or developmental abilities of the child, there are multiple fractures in different stages of healing, or there are multiple complex or depressed fractures. Certain fracture types are associated with child abuse. Especially noteworthy would be a spiral fracture of the femur or tibia in a nonambulating child, spiral fracture of the humerus, an avulsion of the clavicle or acromion process, or a metaphyseal chip fracture. Any suspicious finding constitutes grounds for reporting to local social service officials and consultation with the nearest center providing comprehensive care for the abused child.

Radiographic Evaluation

Obtaining high-quality radiographs is nearly as important as the physical examination. Performing an inadequate examination and accepting poor radiographs can mean missing a fracture. Long bone fractures should be splinted, preferably with plaster, before taking x-rays. Unstable joint injuries also may be splinted, although this sometimes obscures crucial detail.

X-rays should be made at 90 degrees (orthogonal) to each other. With diaphyseal fractures, radiographs should be taken of the joint above and below, particularly if there is any tenderness or if the physical examination is limited. The wrist and elbow cannot be adequately evaluated with regular forearm films. Foregoing additional radiographs and missing an associated fracture is, obviously, a false economy.

Comparison views can be helpful. An anteroposterior view of the pelvis, with a lateral view of the affected hip, should be routinely ordered, rather than an anteroposterior and lateral view of the hip. Elbows can be difficult to evaluate without a contralateral control, even for the subspecialist. Comparison views are also frequently indicated for ankle fractures or shoulder injuries. Oblique x-rays can aid in diagnosis as well, particularly in the knee, ankle, and elbow.

Some injuries have a high rate of missed associated fractures. Cervical spine and pelvic radiographs should be part of the protocol for high-energy trauma. Chest x-rays should be evaluated for bony injuries. A calcaneus fracture due to a fall should prompt lumbar spine films. Suspected child abuse should be routinely pursued with a skeletal survey.

Poor-quality films must not be accepted. The child may be uncomfortable and the radiologic technician may shy away from getting good films, but the duty of diagnosis ultimately rests with the physician, who should insist on films with good anteroposterior views and truly lateral laterals. Excessive obliquity easily obscures subtle fractures. After the failure to perform an adequate physical examination, the most common cause of overlooked injuries is probably poor-quality films.

Additional imaging techniques are sometimes helpful. Stress views are commonly used to evaluate acromioclavicular joint injuries and occult knee-joint growth plate or ligament injuries. Computed tomography (CT) scanning is frequently used for spine injuries and has replaced tomography in most areas. More intensive techniques, such as arthrography, arteriography, bone scanning, and magnetic resonance imaging are of great benefit when indicated, but are typically considered to be the domain of the consultant.

DESCRIPTION OF FRACTURES

Proper use of fracture nomenclature can do much to elevate the status of the emergency physician in the eyes of the consultant. Simplicity is the key, avoiding unfamiliar eponyms and references to bony landmarks.

The description should begin by naming the injured bone. In the hand, use of the terms *thumb*, *index finger*, *long finger*, *ring finger*, and *small finger* is preferable to numeric description, due to confusion as to whether the thumb is counted or if the count starts medially or laterally.

Fractures are classified by where they are on the bone. Shaft fractures are diaphyseal. The flare is the metaphysis. The radiolucent growth plate is the physis, and the epiphysis is the secondary ossification center. "Proximal" or "distal" is the best way to distinguish one end of the bone from the other.

Displacement is relative to the width of the shaft. Nondisplaced fractures show only a hairline fracture. Displacement of only 5% to 10% of the shaft width is termed *minimally displaced*. Further displacement is described by percentage.

Angulation is described separately from displacement, by both degrees of angulation and direction, with the apex as the reference direction. For example, the common Colles' fracture is volar angulation, even though the hand is deformed in a dorsal direction.

Various fracture configurations are described below ([Fig. 303.1](#)).

Figure 303.1. Descriptive terminology for pediatric fractures.

Growth plate injuries are classified by the Salter-Harris scheme ([Fig. 303.2](#)), with the risk of growth problems increasing with grade. Salter III and IV are further complicated by the potential for intraarticular displacement. Salter V fractures are often diagnosed only in retrospect.

Figure 303.2. Salter-Harris nomenclature of representative fractures involving the growth plate in children.

It is important to describe any associated injuries, particularly the nature of the injury (i.e., open or closed) and the child's neurovascular status, as these can alter crucial treatment decisions.

EMERGENCY DEPARTMENT MANAGEMENT

The treatment options are to treat the fracture definitively in the ED, to splint and provide temporary treatment with later referral to a specialist, or to seek immediate consultation.

Some simple fractures with low risk of problems and uniformly good outcomes may be cared for completely in the ED. Factors in this decision include the physician's degree of confidence in fracture management, ease of providing follow-up care, and acceptance by the parents of the treatment plan.

Temporary splinting with later referral is more common. Common indications are nondisplaced or minimally displaced fractures and fractures with a low risk of short-term complications such as neurovascular compromise or compartment syndrome.

Immediate consultation should be sought for all open fractures, arthrotomies, and unreduced dislocations. Open fractures should be regarded as orthopedic emergencies. They should be treated with prophylactic intravenous antibiotics (e.g., broad-spectrum cephalosporins), tetanus prophylaxis, and orthopedic consultation. Neurovascular injury and compartment syndrome require emergent surgical intervention. Consultation is also indicated when there is a high index of suspicion but adequate evaluation has failed to establish a diagnosis. Triage of displaced fractures that require reduction depends on the relationship between the emergency physician and the orthopedist. Many orthopedists prefer to see the child initially and perform the reduction in the ED, where there is appropriate equipment and support personnel.

Immobilization

Immobilization decreases the discomfort in the injured limb. It also can maintain the fracture in a reduced position and prevent further injury by jagged fracture fragments.

Choices for immobilization are varied. Splints are the most popular, and plaster of Paris is best, owing to its ease of molding, although prepadded, fiberglass splint material is being used in many areas. A good plaster splint requires adequate padding, with particular attention to bony prominences. The splint should hold the joint above and below the fracture. Too long is better than too short. Fifteen layers of plaster is the standard. It should be applied and overwrapped while wet for a good mold. Movement while hardening greatly weakens the splint. Commercial splints are much less desirable due to the difficulty of proper fitting and the resulting poor immobilization. Inflatable splints may exert external pressure on already traumatized tissue.

Casts are less commonly used by emergency physicians due to problems associated with swelling inside a rigid cast. This difficulty may be alleviated to some degree by splitting the cast. Ice and elevation are critically important in managing swelling in all fractures. Proper cast application requires skill and practice to achieve the proper balance between being tight enough to maintain the immobilization and loose enough to avoid problems with swelling. Overall, a splint is more easily applied and is superior to a poorly fitting cast. Neurovascular status distal to the affected limb should be evaluated and documented both before and after splinting.

If the child is being transferred or referred for later treatment, the fracture fragments must not be left in a position that tents the skin. Skin necrosis can result in conversion to an open fracture in only a few hours.

Operative Treatment

Detailed discussion is beyond the scope of this chapter. Operative intervention is usually indicated for fractures with a high degree of instability, such as supracondylar humerus fractures; a high risk of problems from displacement, such as intraarticular fractures or severe growth plate injuries; and open fractures, to remove contaminated, necrotic tissue and to reduce the risk of infection. Internal fixation is also used to make overall management easier in head-injured and multiply injured children.

Complications

Neurovascular injury and compartment syndrome, discussed previously, may result in loss of function or even loss of the limb. Angular deformity is common, but many deformities remodel if sufficient growth remains and the deformity is in the plane of joint motion. A general rule is that remodeling will be adequate if the child's deformed bone fits within the outline of the adult bone. No remodeling is to be expected in rotational deformity, nor in displaced Salter III and IV fractures.

The child's growth potential can lead to problems with physeal fractures. Partial or complete growth arrest leads to progressive angular malalignment or limb-length discrepancy, respectively, and requires surgery for correction, often with compromised results.

Discharge Instructions

The parents should be taught routine care of the cast or splint, the importance of frequent neurovascular checks, and that adequate pain medication should be provided, and the importance of ice and elevation must be stressed. The parents must understand the need for follow-up care and the risk of complications if this is neglected.

Treatment of Specific Fractures

Shoulder

The clavicle is the most commonly fractured bone in childhood. Usually resulting from a fall in children less than 10 years old, the majority can be managed without orthopedic referral. Clavicular fractures in children less than 2 years of age should raise concern for intentional injury. Fractures of the clavicle can usually be treated with a figure-of-eight strap or a sling for comfort. Minimally displaced proximal or diaphyseal humerus fractures can be splinted. A shoulder injury requires either an axillary or a good "Y" scapular lateral view to rule out dislocation. The hallmark of posterior dislocation is loss of external rotation.

Elbow

Pediatric elbow fractures have high rates of complications, even in the hands of experts. In order to confirm the diagnosis, a true lateral film of the elbow is required. Radiographic evidence of a torus fracture may be subtle, and a nondisplaced fracture may be difficult to diagnose. Radiographs must be carefully inspected for the presence of abnormal fat pads, especially the presence of a posterior fat pad. Also important is the alignment of the radial head with the capitellum. To evaluate this alignment, a line drawn through the central axis of the radius should pass through the center of the capitellum. Comparison views of the unaffected extremity may prove helpful if the diagnosis is not clear. Isolated abnormalities in the fat pads should be considered signs of occult fracture; immobilization and prompt follow-up should be arranged in consultation with an orthopedist. In general, any displaced distal humerus fracture requires pinning. Supracondylar fractures have a high incidence of neurovascular injury and compartment syndrome. Late deformity results from less-than-anatomic reduction. Medial epicondyle fractures in younger children have a high association with elbow dislocation. Minimally displaced radial head fractures are usually treated with early motion.

Forearm

Forearm fractures are common fractures of childhood. Good results are the norm, even with growth plate injury. Isolated distal ulna torus fractures usually have an associated distal radius physeal fracture. True buckle fractures require only 3 to 4 weeks of immobilization.

Hand

Children's hand fractures, unless the injury is severe, are generally free of the stiffness problems that plague adults. Phalangeal fractures involving the growth plate or through the joint should be followed up by an orthopedist, but can be splinted in the ED. Before splinting, each phalangeal injury should be examined for the presence of rotational or malrotation deformity, which may be missed if the digit is examined only in extension. To examine for rotational deformity, the fingers should be flexed to make sure all fingers point in the same direction. Overlapping of the digits occurs if rotational deformity is present and reduction is needed. A nailbed injury with the nail pulled out proximally and overlying the eponychial fold is generally associated with a Salter fracture of the distal phalanx. This is an easily overlooked open fracture. Nailbed injuries require precise repair.

Hip

A slipped capital femoral epiphysis is easily missed. The child usually presents with no or minimal trauma, groin aching, or simply medial thigh and knee pain. Hallmarks on physical examination are mandatory abduction and external rotation when the hip is brought into flexion. Delay in diagnosis is associated with progressive slipping. Radiographic findings can be subtle, especially in early cases; therefore, good lateral radiographs are required.

Knee

Knee pain can be referred from the hip. Strong consideration should be given to the routine use of anteroposterior pelvic and lateral hip x-rays when evaluating knee pain. Ligament injuries are less common in children's knees than are occult growth plate injuries. Stress views can establish the diagnosis only if the child is relaxed and cooperative. A dislocated patella may be reduced simply by bringing the knee into extension. Tibia fractures may be a common cause of compartment syndrome.

Leg

The term *toddler fracture* refers to an oblique nondisplaced fracture of the distal tibia, usually occurring in children under 4 years of age. These children may present to the ED with complaints of a limp and a history of a minor accident, and physical findings may be subtle. Pain with gentle twisting of the leg may be the only localizing physical finding. Because they may poorly localize, complete radiographs of both lower extremities are needed. Immobilization usually provides relief of symptoms, and at least telephone consultation with a pediatric orthopedist is advisable.

Ankle

The fracture pattern varies with age. An example of this age variation is the distal tibia fracture called a "Tillaux fracture," which is unique to adolescents. As skeletal maturity is achieved and growth plates are beginning to close, the medial distal tibial epiphysis closes prior to the lateral. This creates a fulcrum through which a Salter-Harris III fracture may occur, just lateral to the point of fusion. Due to growth plate involvement and a potential need for open fixation, a prompt orthopedic consultation is indicated. Intraarticular injury is common. Widening of the mortise may require surgery. CT scans are useful in evaluating complex fracture patterns. Comparison views may help in difficult cases.

Foot

Lawn mower injuries are a common cause of open fractures. Severe contamination and degree of injury may require operative debridement. Athletes are subject to metatarsal stress fractures, particularly in adolescence. Fractures at the very base of the fifth metatarsal require only minimal treatment, but proximal metaphyseal fractures outside the articular area (Jones fractures) need cast immobilization and a period of non-weightbearing. Malalignment at the base of the metatarsals, particularly the second, suggests a Lisfranc dislocation, which has a high risk of associated complications.

Sports Injuries

Over the past decade, larger numbers of children began to participate in organized youth sports programs. This has led to an increase in sports-related injuries. Common among these injuries, other than various acute fractures, are overuse injuries, avulsion fractures, stress fractures, and ligamentous injuries. The following are specific examples.

Peripheral Nerve Injuries: The Stinger

A "stinger" is a peripheral nerve injury that involves an upper limb unilaterally. This nerve injury is most commonly caused by a compressive overload of the head and neck, such as caused by tackling in football. The athlete experiences a burning pain in the affected limb, which may last from seconds to hours, and there may be associated weakness. More than single-limb involvement should raise concern for possible cervical spine injury. The athlete should be immobilized on the field and transported to the ED. Most athletes transported to the ED with cervical immobilization for a tackling injury require cervical spine radiographs before removing the cervical collar. Cervical spine fracture is a rare diagnosis. Most patients should be advised in the ED to discontinue play until cleared by a follow-up visit with their primary care, sports medicine, or orthopedic specialist, and some will require aggressive physical therapy.

Overuse Injuries

Stress Fractures. Stress fractures are becoming more common in children. Risk factors include a high-"volume" or repetitive activity and improper training or overtraining. The most common sites of injury in children are the tibia, fibula, and the pars interarticularis segment of the vertebra (i.e., spondylolysis). Each of these stress fractures may cause localized tenderness; most require more than plain films, and so are not usually diagnosed in the ED. One exception may be spondylolysis, the most common cause of back pain in a child to yield an anatomic diagnosis. The thin segment of bone between facet joints is subject to high forces, especially with marked lordosis, or heavy lifting. Most commonly seen in the early teen years, the frequency may reach 20% of those athletes competing in wrestling, gymnastics, or weight lifting. While pain will be exacerbated by straight leg raising, radiation of pain into the legs is rare. Plain film radiography may reveal the diagnosis and is best visualized on oblique views. The most frequent location is at L5, followed by L4. Management is conservative, and the athlete should be discouraged from sports participation if activity is painful. Outpatient follow-up with a bone scan may be needed.

Little League Elbow. Little League elbow is an overuse injury seen in young pitchers. The usual presentation is elbow pain and a subtle flexion contracture, most commonly caused by valgus strain during the acceleration phase of throwing. Plain films of the elbow are normal. Treatment should include rest from play until the child is cleared by a qualified physician. No immobilization is needed.

Iliac Crest Apophysitis. Iliac crest apophysitis is an overuse injury commonly seen in runners and hockey, soccer, or football players. The main symptom is pain over the affected iliac crest that is worsened with running. Plain radiographs are normal. Treatment is conservative.

Patellofemoral Stress Syndrome. Patellofemoral stress syndrome is the most common complaint in young female athletes. The common presentation is of aching knees, with pain increased by jumping or climbing. Physical findings usually include pain on compression of the patellar region; joint effusion and swelling are rare. Plain films are normal. Treatment includes relative rest and physical therapy.

Sever Disease. Sever disease, or calcaneal apophysitis, is a common complaint of adolescent boys. The chief complaint is pain in the heel that is worsened by running. No swelling or deformity is noted on physical examination; only tenderness is noted with lateral and medial compression of the calcaneus. Radiographs are not helpful. Treatment includes plantar flexibility exercises. The disease is usually self-limited.

Avulsion Fractures

Avulsion fractures may occur at virtually any muscular insertion point. Two noteworthy examples in children include avulsions about the pelvis and avulsions about the tibial spine or intercondylar eminence. Avulsion fractures of the hip may occur at a muscular attachment typically pulled off during strong, active resistance. Pain is localized but may be significant with weight bearing. Often, the diagnosis can be made by plain film radiographs. Treatment is conservative, with partial or no weight

bearing for 4 to 6 weeks.

Intercondylar eminence or tibial spine fracture occurs from anterior cruciate ligament injury resulting from either noncontact or collision trauma. Typically, this happens with abrupt decelerating or direction changes, with or without an audible “pop.” Gross swelling about the knee joint is a prominent physical finding, as is intense pain. Plain film radiographs may reveal the fragment as nondisplaced (type I), minimally displaced (type II), or with rotation or significant displacement (type III). This injury should prompt consultation with an orthopedist, and treatment may include drainage of the associated effusion or open reduction and pinning.

COMMON PITFALLS

- Most pediatric fractures heal very well, but proper treatment is essential.
- Misdiagnosis is avoided by taking a history, performing a searching and thorough physical examination, and obtaining acceptable radiographs. Based on the diagnosis, proper treatment can be initiated and appropriate referral or consultation made.
- Complications are minimized by early recognition and, while uncommon, have significant long-term consequences.
- Child abuse should be considered when there are inconsistencies between the history of injury, developmental stage, and the fracture type.
- Children with fractures need adequate outpatient pain control.

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of John Churchill, who wrote the previous version of this chapter.

Pediatric facial trauma is a relatively common occurrence. Fractures of facial bones in children under the age of 12, however, constitute less than 5% of all maxillofacial skeletal injuries.⁷ Under age 5 years, this percentage falls to 1% or less. The low incidence of facial fractures in young children is due to significant plasticity of the facial bones and the prominence of the calvarium. Essentially, the forehead and cranium “protect” the upper midface from impact injury.

Additionally, the fact that the sinuses are poorly pneumatized in the young child further decreases the likelihood of upper facial fractures. Maxillofacial injuries can be caused by a variety of mechanisms. Posnick et al.⁸ reported that 50% of pediatric facial fractures were caused by motor vehicle accidents and 25% by falls, and 15% were sports-related.

The mandible is the site of 75% to 90% of all pediatric facial fractures.^{4,5,10} Fractures of the mandible in the young child, however, are a relatively rare phenomenon because of the resiliency and small size of the lower jaw.⁶ The nasal bones also account for a significant portion of skeletal–facial injuries in the pediatric population, and injuries to them may be the most difficult to diagnose. Other associated injuries are common and of greatest significance to the emergency physician. Gussack et al.³ found that other systemic injuries are associated with pediatric facial trauma in 73% of presentations.

The care of a child with maxillofacial injuries is not unlike that of the adult. There are, however, some special considerations when caring for the child. For example, blood loss from facial injuries is rarely life-threatening in the adult but can be a concern in the younger child. As in the adult patient, reconstruction and achievement of a good esthetic repair are important. The effects of trauma on future facial growth and development, however, are a concern unique to the pediatric population. Discussions with the child’s family about these issues are probably best managed by the surgeon, who will be primarily responsible for definitive care.

CLINICAL PRESENTATION

Obtaining a complete history of the traumatic event and clinical evaluation can be quite difficult in the pediatric patient. For example, examination of extraocular muscles to determine the extent of orbital injuries requires that the child be able to follow commands. Dentoalveolar, mandibular, and lower maxillary fractures may alter the dental occlusion. Changes may be so slight that only the patient can feel the mild change in the way the teeth come together. Getting the child to relay this information following a traumatic incident is often impossible.

The child with the isolated dental injury usually presents in a stable condition. There may be some mild bleeding from the gingiva and pain. If a tooth has been completely avulsed, there can be bleeding from the socket and possibly associated lacerations. As the severity of the maxillofacial injuries increases, so does the risk to hemodynamic stability. For example, a simple scalp laceration with blood losses of 200 cc that does not cause blood pressure instability in the adult may account for a significant loss of blood volume in the small child. There also may be significant loss of blood from skeletal fractures posterior to the oropharynx that go unnoticed.

Airway compromise is always a potential issue in oral and maxillofacial injuries. The lost single tooth can be aspirated and should be accounted for. Bleeding, swelling, and displaced fractures can contribute to the loss of an airway.

DIFFERENTIAL DIAGNOSIS

The diagnosis of simple dental and dentoalveolar injury is easily made. Injury will be missed only if associated with more significant facial or systemic injuries. Tumors and infections can cause oral and facial swelling. Usually, the general appearance and a brief history will lead to the appropriate differential diagnosis of traumatic facial injury in the child.

EMERGENCY DEPARTMENT MANAGEMENT

The initial assessment of the pediatric patient with facial trauma is the same as that for the adult. The risk of airway compromise is clear. Loose tissues, malpositioned facial bones, dental segments, edema, and foreign debris can easily occlude the airway and should be dealt with early in the emergency department (ED) presentation. Blood in the airway should be suctioned, and loose debris, bone fragments, and avulsed teeth, loose teeth, or dental prosthesis (from orthodontic treatment) are to be removed. The specialist who will definitively treat the child can address replacement.

Certain types of fractures (i.e., bilateral subcondylar fracture of the mandible and retrodisplaced maxillary fractures) can compromise the airway; temporary reduction (traction) may restore adequate breathing. Interestingly, Siegel et al.⁹ found the association between mandibular fractures and airway compromise to be very low. The airway can often be protected by intubation, although nasal intubation should be avoided when there are injuries to the nasoethmoidal region.

Obtaining a surgical airway in the emergency setting is rarely indicated and is reserved for massive midface and mandibular fractures. A formal tracheotomy, if required, can be done under more controlled circumstances when the patient is brought to the operating room for definitive management of the injuries.

Blood loss from maxillofacial injuries can cause hypovolemic shock in children. Control, using direct pressure, is the first line of therapy and may include packing of the lacerations or the placement of intranasal packs to control bleeding from nasal and maxillary fractures. On rare occasions, repositioning of displaced fractures will control the bleeding; this is most likely to be effective with maxillary fractures but is generally ineffective with mandibular and dentoalveolar injuries.

Initial evaluation of the alert child with maxillofacial injury requires patience and compassion. Often, the patient and family’s apprehension may exceed that normally associated with similar adult injuries. This apprehension and the effects of the injuries themselves can increase the difficulty or make impossible a complete clinical examination. Sedation, in those cases in which neurologic injuries are not suspected, may help in examination and treatment of the injured child.

After the ABCs, the clinical examination proceeds in an orderly manner. The general appearance of the head and face is reviewed for obvious deformity.

Facial Soft-Tissue Injuries

It is important to consider that lacerations can cause injury to the facial nerve. When possible, function of the nerve should be tested. In children who will follow instructions, facial nerve function can be grossly evaluated by having the child purse the lips as if he or she is going to whistle, raise the eyebrows, and wrinkle the nose. The examiner may help the process by demonstrating these movements to the child. Of note, edema from the injury may temporarily decrease facial nerve

function, even with intact nerve fibers. Lacerations can also transect the parotid duct. If transection is suspected, the duct may cannulated intraorally and the wound checked for duct integrity.

Management

Soft-tissue injuries to the face should be vigorously irrigated and debris removed. Simple wounds can be closed in the ED; sedation may be necessary. Ketamine has been found useful, particularly in the younger population. Shallow, simple wounds can be closed with tissue glue.

The long-term outcome of facial laceration repair is highly dependent on the techniques used in closure. Wide scars are due to lack of or inadequate approximation of deep tissues. Depressed scars result from improper repair of underlying muscles or extensive loss of subcutaneous tissue. Therefore, after local anesthesia has been obtained, more complex wounds are closed in layers, using 5.0 Vicryl deep sutures.

The skin may be closed with a 6.0 nonresorbable suture. In young children, in whom removal may be difficult, fast-absorbing gut suture can be used. Minimal tissue should be removed initially, although very ragged edges and devitalized tissue can be trimmed to enhance the esthetic outcome.

Take great care when attempting to close lacerations that cross over the vermilion border of the lip and those involving the eyebrows. The first skin suture should precisely line up the borders, because any discrepancy leads to a visually obvious deformity. Do not shave the eyebrow prior to closure, as this structure aids in wound-edge alignment. Lacerations to the eyelids and to structures with underlying cartilage (nose and ear) require special care and should be referred to a specialist in otolaryngology, plastic surgery, or maxillofacial surgery. All skin closures should be well everted to diminish scar width. Eversion may be accomplished with the aid of mattress suturing techniques.

Annually, there are over 1 million dog bites; 70% of those in the pediatric population occur in the face and neck.² Treatment includes tetanus prophylaxis and, possibly, management for potential rabies. Antibiotics should be given and, particularly in the case of dog bites, cover *Pasteurella multocida*. Augmentin is often prescribed in these cases, although penicillin can cover most of the potential organisms transferred with the bite. Copious irrigation is very important prior to closure.

Intraoral Soft-Tissue Injuries

Intraoral examination is the next stage of the evaluation. Any remaining debris or loose fragments are dealt with at this time. As with lacerations of the scalp and face, all of these must be examined for underlying skeletal injury. Mucosal ecchymosis often represents loss of underlying periosteal integrity, indicating potential associated skeletal injury.

Management

Treat lacerations of the oral mucosa by closing them with a resorbable suture such as Vicryl or chromic gut (3.0 to 4.0). Scarring is not a major concern. Tongue lacerations may not always need closure. If they are not very deep and there is little or no bleeding, they can be left untreated. Severe, uncontrollable bleeding from the tongue may be managed by passing a large suture through the midline from dorsal to ventral surface (near the base of the tongue) and tying it laterally on the side that is bleeding. This "tourniquet" suture is left in place until the source of the bleeding is found and definitely controlled.

Skeletal Injuries: Skull and Upper Face

Use palpation and gentle manipulation to search for skeletal injury. Examine the scalp for depressions or "rough" edges that would indicate underlying skull fractures. Palpate the forehead for depression, crepitus, and tenderness, which might indicate fractures of frontal bone or the frontal sinus. Examine the orbital rims for step-off or depressions, which might indicate orbital fractures.

Adjunctive examination would include visual acuity and extraocular muscle function. For example, limitation of upward gaze and binocular diplopia is suggestive of orbital floor fracture with entrapment, which limits the eye movement in the upward direction. A decrease in the sensation of the infraorbital nerve (checked grossly by brushing the skin from just beneath the orbit to the top of the upper lip) is suggestive of an orbital or zygomaticomaxillary complex fracture. The presence of the latter fracture would be supported by depression of the malar eminence (a flattening of the cheeks).

Standing behind the seated, partially reclined patient (bird's-eye view) might help in observing the depressed and rotated zygomaticomaxillary segment. However, these changes may not be readily obvious when swelling is significant.

Placing the thumb and forefinger on the bridge of the nose and gently moving from side to side and up and down will help test for upper maxillary fractures (LeFort II and III) and nasoethmoidal injuries. Widening of the space between the medial canthi (telecanthus) suggests nasoethmoidal fractures with disruption of the canthal attachments.

The "bowstring" test would support the presence of such an injury. This test is accomplished by placing a finger beneath the medial attachment and pulling laterally on the lower eyelid. A rounding out of the medial corner of the eye indicates loss of canthal attachment. If the corner of the eye remains sharp, there probably is no disruption of the medial canthal ligaments.

Determination of isolated nasal injuries is more difficult; diagnosis may require knowledge of the traumatic event as well as what the nose looked like before the event. Generally, there is pain on palpation, and there may be deviation of the tip of the nose. A depression of the nasal dorsum or of the lateral nasal bones indicates the presence of treatable fractures.

Computed tomography (CT) scans are the standard for suspected fractures in this region. On occasion, a thin-section coronal CT series is useful for evaluation of orbital floor injuries.

Management

Only significant depression of the skull fractures may require treatment. Basilar skull fractures may cause otorrhea or rhinorrhea, which may need to be addressed. Often, only conservative follow-up is needed, and antibiotic coverage is controversial. Neurosurgical intervention may be needed in cases that do not resolve spontaneously, or with reduction of associated fractures.

Fractures of the frontal sinus may need to be treated. Generally, if the depression of the outer table is equal to the thickness of the bone of the outer table, open reduction is required to prevent deformity. Additionally, the sinus lining should be removed and the sinus obliterated with bone, fat, or fascia to prevent remucosalization and the potential for mucopyocele formation. Fractures involving the posterior wall of the frontal sinus may require removal of the posterior wall (cranialization) of the sinus. Fractures in this region in the very young child are rare, because the sinus may not be fully formed.

Initial ED management of potential orbital injury centers on ruling out direct injury to the globe and retrobulbar hematoma. Both of these injuries require emergent care. Ophthalmologic consultation is required for globe injury, and lateral canthotomy is the choice of emergent care for retrobulbar hematoma. A sharp scissors is placed in the corner of the eye between the lateral attachments of the upper and lower lids. A full-thickness cut is made, ensuring that the lateral canthal attachments (particularly the inferior limb) are fully transected and released from the bone. This incision should allow decompression of the hematoma and prevent further injury to the eye. Treatment of orbital floor fractures follows when the patient is stable.

Persistent diplopia and entrapment lasting for more than 1 to 2 weeks are indications for exploration. Other indications include CT evidence of a large orbital defect, early enophthalmos, or associated fractures of the rim.⁶ Unfortunately, diplopia in younger children (0 to 9 years of age) has been found to take much longer to resolve (10 to 18 months) than diplopia in an older population.¹

No management in the ED is necessary for zygomaticomaxillary complex fractures. Reduction during definitive therapy usually results in an acceptable aesthetic

outcome.

If nasal injury is suspected, careful examination of the internal nose, to rule out the presence of septal hematoma, is of primary importance. The presence of such an injury requires early drainage and nasal packing to prevent the loss of septal cartilage.

Midface Fractures (LeFort I)

Asking the patient whether the occlusion feels like it did before the injury is the first step in the examination for maxillary and mandibular fractures. If the patient feels that the bite is "off," the suspicion for fracture increases. The presence of an anterior open bite that was not present before the traumatic event also is suggestive of skeletal injury. The examiner should place the forefinger on the inner surface and the thumb on outer surface of the upper teeth (if still present) or alveolar ridge and test for mobility. Placing the thumb and forefinger of the other hand on the nasal bridge may help in the detection of movement, which is indicative of maxillary injury. There can be confusion with an alveolar fracture, which can also show mobility in this area. Crepitus is suggestive of violation of the maxillary sinus, which occurs in LeFort fractures as well as in isolated anterior wall fractures of the maxilla. A CT scan helps to determine the extent of the injuries.

Management

The severely impacted, retrodisplaced maxillary fracture can impinge on the airway. Therefore, the initial care provided in the ED should be to ensure patency of the airway. If there is evidence of airway compromise secondary to the maxillary injury, then grasping the anterior maxilla and pulling down and forward may alleviate the problem.

On occasion, this maneuver requires the use of special disimpaction forceps, which is best accomplished in the operating room and with an established airway (intubation or tracheostomy). There also can be bleeding from maxillary fractures, which is stopped by reduction of the segments. There remains some controversy as to the effects on growth due to maxillary injuries. Some authors suggest that these injuries, particularly those associated with the nasomaxillary complex, can interfere with normal facial development.⁶

Mandibular Fractures

Checking for changes in occlusion (using wear facets and patient feedback) helps in the determination of mandibular fractures. There may be deviation on opening in the presence of condyle injury. The lower jaw will shift to the contralateral side if the condyle is dislocated anterior to the fossa; a unilateral condylar fracture causes deviation to the ipsilateral side on opening. A patient with bilateral condylar injuries may present with an anterior open bite that was not obvious prior to the trauma. The examiner should be aware that the presence of a fracture in the anterior mandible (parasymphysis) could be associated with a contralateral subcondylar injury (contrecoup).

Evaluation of the mandible includes bimanual palpation both intra- and extraorally to look for mobile, fractured segments. As mentioned previously, the presence of lacerations or ecchymosis can be suggestive of an underlying fracture. CT studies of the mandible should be ordered for the severely traumatized patient who cannot have plain studies performed. When possible, a panoramic film of the mandible, a Towne's view for the condyles, and lateral oblique mandibular films should be obtained. Careful review of these studies is important, because nondisplaced fractures of the mandible in young children can be difficult to see on radiographs due to the presence of numerous tooth buds.

Management

Severely displaced mandible fractures can cause airway compromise that must be addressed early in the ED management. In grossly mobile segments, a 23- or 24-gauge stainless steel wire can be wrapped around the teeth on either side of the fracture to gain temporary stabilization and make the patient more comfortable. On occasion, the specialist may not come to the ED, but will ask that the stable child with an isolated mandibular injury be discharged for follow-up and treatment. Pain medication should be prescribed, as well as antibiotics (penicillin or clindamycin) for open fractures. Of note, all fractures that pass through segments of the mandible containing teeth are considered open, whether or not there is an obvious laceration. Closed fractures of the condyle and ramus do not require antibiotic therapy. The lack of erupted teeth, the presence of primary teeth only, and underlying tooth buds make the definitive care of mandibular fractures in children more of a challenge when compared with that of the adult. The use of splints and resorbable bone plates to treat fractures is more commonplace in the pediatric population.

Dentoalveolar Injuries

Evaluation

The intraoral examination, in addition to checking for fractures, should look for injury to teeth and supporting alveolar bone. The empty tooth socket with associated bleeding is suggestive of an avulsed tooth. It is important to ascertain that the tooth was lost during the traumatic incident rather than as part of normal development. If the tooth cannot be accounted for, a chest film to rule out aspiration might be indicated. Loose teeth, particularly permanent teeth, and loose alveolar segments are managed by the specialist.

Management

Primary teeth are not to be reimplanted. Permanent teeth that have been completely avulsed need to be handled with care. The best technique is to replace the tooth into the socket after minimal manipulation. If replacement is not feasible, then the tooth should be placed in saliva, balanced salt solution, or milk. A dental specialist should be immediately notified, because the chance of successful reimplantation of the tooth is critically dependent on timing of treatment. The greatest success rate occurs if reimplantation takes place within 30 minutes. The dental specialist, generally with splinting of various methods, manages loose teeth and alveolar fractures.

DISPOSITION

The type of institution and the level of trauma care it can provide determine the timing and the role of the maxillofacial specialist. In level-one trauma centers, the physicians in the ED or the trauma surgeons initially manage the patient. They will establish the airway as needed. Hemorrhage may be controlled by the primary service; however, on occasion, the maxillofacial specialist may be required to obtain hemostasis because of their specialized skills. Early consultation with the specialist is recommended regardless of the level of trauma care provided by the institution.

Indications for Admission

Clearly, the young patient with multiple system injuries should be admitted. Admission is indicated for a potential closed head injury associated with facial injuries. Patients with isolated maxillofacial injuries require admission if these injuries involve possible airway compromise or uncontrollable bleeding. Severely mobile fractures are uncomfortable and are treated quickly; therefore, patients with these injuries are admitted. The threshold for admission of children with facial injuries is much lower than that of the adult. Transfer to another facility is essentially dependent on whether a maxillofacial specialist is on staff. Many smaller hospitals do not have such expertise; therefore, transfer is recommended.

COMMON PITFALLS

- Do not forget to account for all missing teeth, to ensure that a tooth is not aspirated.
- Do a complete assessment, because facial injuries are often associated with other systemic trauma.
- Do not forget that intracranial injuries are more common in pediatric maxillofacial trauma than they are in that of adults.
- Mandibular fractures in the pediatric population can be associated with child abuse.

[Sedative Analgesics](#)
[Reversal Agents](#)
[Nonpharmacologic Therapy](#)
[Common Pitfalls](#)
[Chapter References](#)

Appropriate relief of pain and anxiety should always be a priority in the overall management of the acutely sick or injured child. Historically, the medical profession has done a poor job of alleviating such symptoms, preferring to focus on the diagnostic evaluation.¹⁶ This attitude has been especially prevalent in the care of children.¹⁵

Dramatic advances in procedural sedation techniques, along with a greater understanding of the pharmacodynamics of available sedatives and analgesics, have led to safer, more effective sedation and analgesia in children. The Agency for Health Care Policy and Research, noting the widespread inadequacy of pain management, has stated in its guidelines that it is the physician's "ethical obligation to manage pain and relieve the patient's suffering" and that such pain management should be at the core of every health-care professional's commitment.¹

GUIDELINES FOR PEDIATRIC SEDATION AND ANALGESIA

The first attempts at developing uniform guidelines for children requiring sedation or analgesia for diagnostic or therapeutic procedures occurred in 1985, when the National Institutes of Health (NIH) and the American Academy of Pediatrics (AAP) published consensus documents on procedural sedation.³ Subsequent revisions have attempted to accurately define the various states of sedation encountered in the management of these patients. In 1996, the American Society of Anesthesiologists (ASA) Task Force on Sedation and Analgesia by Non-Anesthesiologists published their own guidelines, which were, in essence, a compromise of those proposed by the various subspecialty societies.⁴ The ASA rejected the term *conscious sedation* and offered the following definitions, stressing that these states represent different points on a continuum and that movement along this continuum can occur in any direction at any time:

Analgesia: Relief of perception of pain without intentional production of a sedated state.

Sedation–analgesia: Medically induced state of depressed consciousness, during which there is a margin of safety wide enough to have a reasonable expectation that the patient

- will be easily aroused
- will maintain intact protective reflexes
- will maintain patent airway independently
- will have appropriate responses to stimulation, commands

Deep sedation: Medically induced state of depressed consciousness, during which it is reasonable to expect that the patient

- may not be easily aroused
- may developed partial or complete loss of protective reflexes
- may lose ability to maintain independent airway
- may be unable to respond appropriately to physical stimulation or verbal commands

General anesthesia: Medically induced state of unconsciousness, during which the patient has

- complete loss of protective reflexes
- inability to maintain independent airway
- inability to respond to any stimulation or command

The nature of procedures performed in the emergency room often necessitates deep sedation to ensure an appropriate level of analgesia and cooperation. Besides attempting to define the various states of sedation, these guidelines also discuss the preparation that should be undertaken prior to the start of a procedure. It is important to note that these are not absolute rules but rather recommendations that may be adopted, modified, exceeded, or rejected according to clinical needs and constraints.⁷ The Joint Commission on Accreditation of Hospital Organizations (JCAHO) does not recommend a specific set of guidelines, but mandates that hospitals develop institution-specific policies and procedures regarding procedural sedation that ensure all patients receive "one standard of care," regardless of what area of the hospital it occurs in.⁷ This mandate should not be misinterpreted as requiring *identica* care in all areas of the hospital.

PATIENT SELECTION AND MONITORING

Administration of sedatives–analgesics should occur in a facility suitable for appropriate evaluation and monitoring of the patient and for the performance of emergency resuscitative measures if needed. Monitoring and emergency equipment suitable for children of all ages and sizes must be available ([Table 305.1](#)). It should include a positive-pressure oxygen delivery system, suction apparatus, blood pressure and CR monitor, pulse oximeter, and an emergency crash cart. Reversal agents should be readily available. The practitioner responsible for administering the sedative and monitoring the patient must be someone other than the one performing the diagnostic or therapeutic procedure, and should be appropriately trained and certified.

Positive-pressure oxygen delivery system
Suction apparatus
Blood pressure and CR monitor
Pulse oximeter
Emergency crash cart

TABLE 305.1. Equipment

A full evaluation of the patient's health and medical history should be performed, with consideration given to the physiologic reserve of the patient's major organ systems, as defined by the ASA physical status classification ([Table 305.2](#)). Patients who are ASA class I or II are usually considered appropriate candidates for sedation–analgesia or deep sedation. Patients in ASA class III or IV present special problems that require additional and individual considerations. ⁴

TABLE 305.2. American Society of Anesthesiologists Physical Status Classification

Class I	A healthy patient
Class II	A patient with mild systemic disease
Class III	A patient with severe systemic disease
Class IV	A patient with severe systemic disease that is a constant threat to life
Class V	An ill patient not expected to survive without an operation

TABLE 305.2. American Society of Anesthesiologists Physical Status Classification

Evaluation of the patient's recent food and fluid intake must also occur. Standard NPO guidelines are as follows:

1. Infants less than 6 months: no milk or solids for 4 hours prior to procedure
2. Infants greater than 6 months: no milk or solids for 6 hours prior to procedure

All patients, regardless of age, are allowed to ingest clear liquids until 2 hours prior to the procedure. In emergent circumstances, in which NPO guidelines cannot be followed, sound clinical judgment should be exercised and the risks of aspiration versus the benefits of the procedure should be weighed very carefully.

Most guidelines dictate that the following parameters be monitored carefully: oxygenation, ventilation, airway, and level of consciousness. Proper documentation calls for the person who administers sedation to obtain appropriate informed consent from the parents and to record the patient's vital signs, oxygen saturation, medications given, and any remarkable or unexpected events ([Table 305.3](#)). The frequency of documentation varies with the level of sedation. It is recommended that the heart rate, respiratory rate, blood pressure, and oxygen saturation be recorded prior to the sedation, every 15 minutes during sedation–analgesia, every 5 minutes for deep sedation, and once again prior to discharge. After the procedure is terminated and sedation is no longer desired, monitoring and recording should be continued until the patient has recovered sufficiently to meet the following discharge criteria:

Monitor	Document
Oxygenation	Consent
Ventilation	Vital signs
Airway	Oxygen saturation
Level of consciousness	Medications
	Untoward events
	Recovery

TABLE 305.3. Documentation

1. Cardiovascular function and airway patency are satisfactory and stable.
2. The patient can be easily aroused, and protective reflexes are intact.
3. The patient can talk and sit up (age-appropriate).
4. Hydration is adequate.

For the very young or special-needs child who is incapable of the usual expected responses, the pre-sedation level of responsiveness or a level as close as possible to the child's baseline should be achieved. Appropriate discharge instructions include anticipatory guidance regarding sleep, diet, and activity, as well as specific instructions on how to access care in the event of untoward effects or unexpected complications.

PHARMACOLOGIC THERAPY

The ideal drug for sedation or pain control would be painless to administer and easily titratable by virtue of its fast and predictable rate of absorption, onset, and duration of action. It would also be reversible and inexpensive and would have no side effects or contraindications. Unfortunately, such a drug does not exist.

There are, however, many drugs available that, when used alone or in combination for the right indications, are very effective and relatively safe ([Table 305.4](#)). In selecting an agent, the physician must consider the effects desired, the risks and benefits, and the logistics of administration for each situation ([Table 305.5](#)). When pure sedation is the desired end point, agents such as benzodiazepines and barbiturates are excellent choices. These agents, however, do not inhibit perceptions of pain and should never be used as the sole agent for pain management.

TABLE 305.4. Pharmacologic Therapy

Class	Drug	Indication	Contraindication	Precaution
Benzodiazepines	Midazolam	Sedation, amnesia, anxiolysis	Respiratory depression, hypotension	Respiratory depression, hypotension
	Alprazolam	Sedation, anxiolysis	Respiratory depression, hypotension	Respiratory depression, hypotension
	Clonazepam	Sedation, anxiolysis	Respiratory depression, hypotension	Respiratory depression, hypotension
	Lorazepam	Sedation, anxiolysis	Respiratory depression, hypotension	Respiratory depression, hypotension
Barbiturates	Thiopental	Sedation, amnesia, anxiolysis	Respiratory depression, hypotension	Respiratory depression, hypotension
	Propofol	Sedation, amnesia, anxiolysis	Respiratory depression, hypotension	Respiratory depression, hypotension
	Etomidate	Sedation, amnesia, anxiolysis	Respiratory depression, hypotension	Respiratory depression, hypotension
	Barbiturates	Sedation, amnesia, anxiolysis	Respiratory depression, hypotension	Respiratory depression, hypotension

TABLE 305.4. Pharmacologic Therapy

Desired Effect	Age	Options
Moderate-to-severe painful condition	Infant, child, and adolescent	Morphine 0.1-0.2 mg/kg i.v.
Painless diagnostic study	Infant, Child and adolescent	Pentobarbital 2-6 mg/kg i.v., Midazolam 0.1 mg/kg i.v. or 0.5 mg-0.7 mg/kg PO
Sedation-Analgesia	Infant and child, Child and adolescent	Ketamine 3-5 mg/kg i.m. or 1-2 mg/kg i.v., Fentanyl 1-2 µg/kg and midazolam 0.1 mg/kg i.v. (titrate to effect), or Nitrous oxide inhalation

TABLE 305.5. Clinical Applications

Purely sedative agents can be used for painful procedures in conjunction with other agents to provide sedation as an adjunct to analgesia. Sedative analgesics such as narcotics, on the other hand, are excellent choices for painful procedures. Although they have varying degrees of sedation, they should rarely be used as a single agent for providing control for a painless diagnostic study. Combining different classes of agents is a way to produce an effect not present in either agent alone. Such combinations must be used with caution, because they enhance not only desired responses, but also adverse effects.

Pure Analgesics (Nonnarcotics)

Indications: Relief of mild-to-moderate pain

Complications: Gastritis, peptic ulcer disease

Specific Agents

Acetaminophen: Pure analgesic agent with antipyretic properties. Standard dose is 15 mg/kg every 4 hours, can be given orally or rectally, and can be combined with narcotics such as oxycodone and hydrocodone.

Ibuprofen: Nonsteroidal antiinflammatory agent with analgesic and antipyretic properties. Standard dose is 10 mg/kg by mouth every 6 hours.

Ketorolac: Nonsteroidal antiinflammatory agent best suited for relief of biliary and renal colic. Standard dose is 0.4 to 1.0 mg/kg intravenously (i.v.) or intramuscularly (i.m.).

Pure Sedative

Indications: Sedation for nonpainful diagnostic or therapeutic procedures

Complications: Dose-dependent respiratory depression, hypotension, "paradoxical" (disinhibitory) effects

Specific Agents

Benzodiazepines

Midazolam: Potent sedative with amnesic and anxiolytic properties, a rapid onset, and short duration of action. Standard dose is 0.02 to 0.1 mg/kg i.v., 0.5 to 0.7 mg/kg orally, and 0.3 mg/kg intranasally. When titrating intravenously, remember that onset of sedation may take 2 to 5 minutes. Children younger than 5 years of age often will become excited and agitated when given midazolam.¹⁸ Whether this represents a paradoxical or disinhibitory effect and whether higher doses would eliminate the effect are not known. For this reason, the use of midazolam as a single agent for sedation in this age group should be reconsidered.

Barbiturates

Pentobarbital: Sedative agent best used intravenously for nonpainful diagnostic studies. Onset of action is within 1 to 2 minutes, with duration of 30 to 60 minutes. Standard dose is 2 to 6 mg/kg i.v. It is recommended to start with an initial dose of 2 mg/kg and titrate to effect with subsequent doses of 1 to 2 mg/kg every 30 seconds as needed.

Thiopental: Ultrashort-acting agent that can cause profound respiratory depression and hypotension. Standard dose is 3 to 5 mg/kg i.v. or 25 mg/kg rectally.

Methohexital: Ultrashort-acting agent with dose-dependent respiratory depression and apnea but minimal associated cardiovascular side effects. Standard dose is 1 mg/kg i.v.

Others

Etomidate: Ultrashort-acting sedative hypnotic with onset of action less than 1 minute and duration of 3 to 5 minutes; it has minimal cardiorespiratory effects. Standard dose is 0.1 to 0.3 mg/kg i.v. There is minimal experience with this drug for pediatric sedation.

Propofol: Ultrashort-acting sedative hypnotic with onset of action within one circulation time following i.v. administration. Patients are usually awake within 5 to 10 minutes of infusion termination. It has potent, dose-dependent respiratory depressant effects and can produce significant hypotension with rapid bolus injection. Standard initial dose is 1 to 3 mg/kg, followed by either repeated boluses or a constant infusion at 25 to 130 µg/kg/min.

Choral Hydrate: Sedative hypnotic with a long history of safety in pediatrics. Onset of sedation is unpredictable and can be as long as 40 to 60 minutes. Recovery time is also prolonged and highly variable, limiting its use in the emergency setting. Standard dose is 25 to 100 mg/kg orally or rectally.

Sedative Analgesics

Indications: Moderate-to-severe pain management, painful procedures

Complications: Respiratory depression, nausea, vomiting

Specific agents

Narcotics

Morphine: The "gold standard" against which all other narcotics are compared. Standard dose is 0.1 to 0.2 mg/kg i.v.

Fentanyl: The most potent of the commonly used narcotics, it has a rapid onset of action (1 to 10 minutes) and a relatively brief duration of 30 to 60 minutes. It has fewer respiratory and cardiovascular depressive effects than other narcotics but can cause severe respiratory depression and apnea when combined with

benzodiazepines. Standard dose is 1 to 2 µg/kg i.v. administered slowly. Rapid boluses have been associated with chest wall rigidity and should be avoided.¹⁴ Although available in transmucosal form as a lollipop, the high incidence of nausea and vomiting has limited its acceptability.⁶

DPT cocktail: The most widely used “cocktail” for sedation in the pediatric patient has been the combination of Demerol, Phenergan, and Thorazine. Its popularity stems from extensive past experience, reliability, and ease of administration by a single intramuscular injection. Reports questioning the safety of such combinations, along with their unpredictable onset and significantly prolonged duration of action, make them poor choices for procedural sedation in the emergency setting.³

Nonnarcotics

Ketamine: Ketamine is unique among the sedative analgesics in that it produces a dissociative state between the thalamus and limbic systems, which is characterized by four features: sedation, analgesia, amnesia, and catalepsy. It possesses positive inotropic and bronchodilatory effects, with preservation of spontaneous respirations and protective airway reflexes. These qualities make it an ideal choice for outpatient procedures, with an excellent safety and efficacy record documented in over 11,000 children.⁹ Standard dosages are 1 to 2 mg/kg i.v., 3 to 5 mg/kg i.m., and 10 mg/kg PO. The clinical state produced by ketamine differs from that of other sedatives in that the patient’s eyes often remain open but with a disconnected stare and marked nystagmus. This “lights on, nobody home” look can be disconcerting to parents, and they should be forewarned prior to administration of the drug. Potential side effects of ketamine include increased salivary and tracheobronchial secretions and emergence reactions.⁹ Secretions can be ameliorated by adding atropine (0.01 mg/kg) or glycopyrrolate (0.005 mg/kg; max, 0.25 mg). Emergence reactions are uncommon in children under 8 years of age and can be reduced by premedication with a benzodiazepine (midazolam 0.05 mg/kg mixed in with the ketamine and antisialagogue of choice). Laryngospasm following administration of ketamine has been documented in small infants (less than 3 months) with respiratory tract infections, and use of ketamine is therefore contraindicated in this patient population.

Inhalation Agents

Nitrous Oxide. This is the only inhalation agent in common use, usually in concentrations of 30% to 70% N₂O. It is a safe, effective sedative–analgesic with a rapid onset and short duration of action upon withdrawal. Nitrous oxide is inexpensive and easy to administer by experienced hands. It is very operator-dependent, with a substantial learning curve. As with hypnosis, suggestion is very important, and the patient must be well prepared in regard to expectations. This method of sedation is best used in older children and adolescents who are more likely to cooperate.

Reversal Agents

These are available for narcotics and benzodiazepines:

Naloxone (Narcan): Narcotic antagonist; dose: 0.01 mg/kg to 0.1 mg/kg i.v. or i.m.

Flumazenil (Mazicon): Benzodiazepine antagonist; dose: 0.3 mg i.v., repeat q1min to maximum of 3 mg.

NONPHARMACOLOGIC THERAPY

The involvement of child life specialists in the management of pain and anxiety in the pediatric patient can be invaluable. By providing the patient with age-appropriate information regarding the procedures to be undertaken and teaching appropriate coping strategies, these specialists often succeed in lessening the child’s fear and anxiety, thereby reducing and occasionally eliminating the need for pharmacologic intervention. Distraction techniques such as listening to music with headsets, singing, or imagery can also be powerful coping strategies. Finally, parental support at the bedside can play a significant role in reducing the child’s distress.²

COMMON PITFALLS

- Inappropriate monitoring during and after a painful procedure
- Selecting a sedative agent without analgesia for a painful procedure
- Not giving enough medication because of time factors or fears about side effects, especially respiratory depression
- Selecting an agent that titrates too slowly and fails to produce the desired state
- Not having reversal agents readily available
- Not anticipating disinhibitory effects with the use of benzodiazepines in small children
- Not preparing the parents for the nystagmus and catalepsy seen with ketamine

The term *emergency medical services for children* (EMSC) originated in the 1980s, when landmark legislation provided for a federal EMSC grant program based in the Maternal and Child Health Bureau (MCHB) of the U.S. Department of Health and Human Services. The name has come to encompass a wide spectrum of efforts underway to ensure that all children in the United States have access to the same quality of emergency care as adults. Although the term *emergency medical services* (EMS) is generally used to mean prehospital care, the scope of EMS has expanded to include public education, injury prevention, access to public emergency services, emergency department care, inpatient and critical care services, and rehabilitation of the acutely ill and injured patient. The goal of EMSC is not to create a segregated EMS system for children, but to integrate comprehensive pediatric emergency care into existing systems and services and to increase awareness of pediatric issues in all aspects of EMS. The federal EMSC program has provided individual state grants to address all of the issues special to children who experience an emergency illness or trauma.

Despite significant progress, a 1993 study by the National Academy of Science's Institute of Medicine (IOM) documented many remaining gaps and deficiencies in pediatric EMS. In 1995, a panel of expert advisers joined MCHB and the National Highway Traffic Safety Administration (NHTSA) staff to convert the IOM's recommendations into a 5-year plan for EMSC. The achievement of proposed activities led to a data base from which to revise the objectives and restate them in a way that is measurable. As stated in the introduction to the plan, it can be fully implemented only with the assistance and involvement of a variety of groups and organizations, each addressing the aspect of EMSC relevant to its particular area of expertise and work. In addition, the plan's objectives can be met only if there is communication and collaboration among these organizations.

Thus, an interorganizational consortium is needed to further the goals for the program by addressing specific objectives of the plan and by ensuring ongoing communication and collaboration. Contracts were developed with 14 professional associations, with each contract including activities, related tasks, and objectives in the 5-year plan. A new document, *EMSC 5 Year Plan: Midcourse Review 1995–2000*, provides the nation with an updated overview of the plan. As of 1998, EMSC grants had helped all 50 states, the District of Columbia, Puerto Rico, and three territories to make significant progress toward optimum emergency care for all children.

This chapter focuses on prehospital EMSC issues. Emergency department–based caregivers will find that they face many of these issues; in fact, emergency department practitioners have much in common with their partners in the field.

EPIDEMIOLOGY

Children from the newborn to those 12 years of age make up only 3% to 7% of all EMS calls in the United States. This figure increases to 10% when 13- to 18-year-olds are included. About half of all pediatric calls are for trauma; vehicular trauma and falls are the most common mechanisms of injury. Respiratory difficulty, seizures, ingestions, near-drowning, and altered mental status are among the most common medical complaints. Medical complaints predominate in children under age 3 and increase again among adolescents. Traumatic complaints occur at all ages but are more prevalent in school-aged children and adolescents.

The National EMSC Data Analysis Resource Center (NEDARC) provides technical support to the EMSC community in linking various data sets to improve understanding about the unique needs of children and awareness of areas requiring additional system development. Epidemiologic studies suggest that prehospital services are simultaneously over- and underused by children. Only one out of every three to five children transported by EMS has a serious or critical illness or injury. However, this does not mean that all pediatric EMS patients are not sick: Children arriving at an emergency department via EMS are five to eight times more likely to be admitted than those arriving by nonmedical transport. Studies also show that most seriously ill children arrive at the emergency department by private transport. The most important factor in this perceived underuse of EMS may be the relative ease with which a sick small child can be carried from place to place.

In summary, paramedics and emergency medical technicians (EMTs) encounter children on only 3% to 10% of their calls. About half of those children are trauma victims. About a third of pediatric EMS patients require simple or complex advanced life-support (ALS) procedures by field personnel. Private vehicle or other public transport takes many children who might benefit from advanced prehospital care directly to the emergency department.

EMS PREPAREDNESS FOR PEDIATRIC PATIENTS

While the majority of trained prehospital EMS personnel are volunteers, they cover only 20% of the population. Until recently, personal experience has been the primary instructor for EMTs and paramedics. But considering that only three to ten out of every 100 calls involve children, and that only one to three of those patients are significantly ill, personal experience can not adequately suffice. Standard curricula for basic training in the recent past required that EMTs receive only 2 hours of neonatal and pediatric training out of a 100- to 200-hour course. Paramedics were required to cover an additional 6 to 12 hours of pediatrics in a 450- to 1,100-hour course. Curricula have included basic skills such as airway management and assessment of pediatric vital signs, but they have also focused on diagnoses such as meningitis, epiglottitis, and Reye syndrome rather than the assessment of general patient status and common clinical syndromes. Although pediatric clinical experiences are available with varying frequency throughout the country, many training programs have not required their inclusion in basic curricula.

The EMSC movement has helped to produce a positive change in basic and continuing pediatric EMS education. A cornerstone of this movement lies in the training provided to EMTs, who deliver the bulk of the prehospital emergency care in the United States. The new EMT-Basic curriculum is assessment-based, has an expanded pediatric section, and integrates pediatrics through the entire course. EMSC advocates are campaigning for similar changes in the paramedic curriculum. Teaching hospitals and EMS training programs are offering courses in pediatric emergency care, such as the Pediatric Advanced Life Support (PALS) course or Pediatric Education for Prehospital Providers (PEPP). Some of these courses have been modified to suit the special needs of prehospital care providers. Instructor resource manuals and provider assessment-based courses have been developed to help bridge the knowledge gap that still exists in the specialized field of prehospital pediatric care. Pediatric workshops and lectures are increasingly available at regional and national EMS meetings, and several texts and videotapes are available for reference. Many of the available educational programs are products of the federal EMSC grant program.

Recognizing that their basic training and experience may not be enough, many EMTs and paramedics are taking advantage of the new accessibility of pediatric education. As a result, they are gaining not only skills and knowledge, but confidence as well.

EMS systems must also prepare for pediatric patients. Another product of the EMSC movement is the increased participation of pediatricians and other physician advocates in medical control issues. Pediatric ALS and basic life-support (BLS) protocols and procedures for EMS are now widely available. Several consensus documents have been published that provide guidelines for minimum EMS pediatric and neonatal equipment, procedures, and assessment-based protocols. Pediatricians have become more active in local, state, and national EMS advisory and oversight organizations. EMSC issues are now addressed in most EMS texts.

Base-station physicians, nurses, and other direct medical control personnel are also being encouraged to keep pace with their prehospital colleagues' advancing pediatric capabilities and knowledge.

SPECIAL CHALLENGES

Differing Anatomy and Physiology

EMS providers practice in a system that traditionally emphasizes their role in the recognition and treatment of cardiovascular insufficiency, the leading killer of adults. The pediatric patient demands a different focus. Problems with airway and breathing are the most common causes of acute deterioration in children; cardiovascular compromise usually occurs secondary to hypoxia or trauma. For this reason, the basic ABC approach is even more important for children than for adults. The ability to recognize, categorize, and anticipate respiratory dysfunction is key in pediatric management. These assessment skills are best learned and reinforced through guided patient contact and immediate feedback from receiving hospital personnel. Unfortunately, few prehospital providers have access to such pediatric educational experiences.

Treatment priorities must change to conform to assessment priorities. When faced with a very sick child, the reflex of many emergency care providers is to rush to start an intravenous line, but, in reality, few field intravenous lines are truly "lifelines" for children. The real lifelines for the pediatric patient are an intact airway and adequate oxygenation and ventilation. Routine attempts to insert intravenous lines in children may even be counterproductive, as they can increase the patient's oxygen demands (because of pain and anxiety), delay transport to definitive care, and distract the medic from more important tasks, such as monitoring the ventilatory status.

Pediatric anatomy influences both injury patterns and emergency intervention. When assessing both the scene and the patient, the EMT must remember that the child's large head, increased body surface area, relatively poorly protected abdominal cavity, and general soft-tissue and bony elasticity may contribute to or protect against various injuries. Spinal immobilization procedures must be modified to compensate for the large head and narrow body. Airway maneuvers are slightly different because of the large tongue and tonsils, as well as the position and conformation of the larynx. Gastric decompression becomes more important because of the predominance of diaphragmatic breathing. Temperature regulation is a priority because of the increased risk of hypothermia in children. All of these factors must be rapidly assessed and integrated into the EMT's plan of action.

Probably the most important difference between adult and pediatric field management is the emphasis on BLS skills. About two-thirds of all pediatric EMS patients can be managed effectively with only BLS interventions. Even patients for whom endotracheal intubation is the optimal airway can often be treated adequately with a scrupulous bag-valve-mask technique if necessary. Children respond well to simple interventions. Invasive procedures should be performed only if the benefits clearly outweigh the risks; if they are needed, invasive procedures can and should be performed by properly trained paramedics. A good pediatric paramedic needs confidence, strong assessment and BLS skills, patience, and a high degree of comfort with a "low-tech, high-touch" approach.

All of these anatomic and physiologic principles influence practice by both prehospital and emergency department personnel. They present a special challenge, however, to the field provider. Emergency department personnel have the luxury of resources such as advanced diagnostic equipment, reference materials, consultants, and time. EMTs have less experience and training, far fewer specialized resources, and much less time in which to integrate these principles into a focused patient assessment and treatment plan that will form the foundation of the care that will be delivered in the emergency department.

Skills Performance and Maintenance

Table 306.1 lists pediatric ALS skills and procedures performed by paramedics in the United States. Several of the skills in general use for adults may be restricted by local medical directors for use in children. Rectal and aerosolized drug administration and intraosseous line placement are relatively new to the prehospital setting. They are not yet universally performed but are quickly gaining acceptance. Some jurisdictions have been slow to allow their medics to intubate children; this attitude is also changing. Other procedures may be limited because of equipment expense or relative risk. The third column of the table lists procedures used in adults but considered of limited utility for children due to safety considerations or lack of proven efficacy.

General Practice	Subject to Local Variation	Limited Use in Pediatrics
Bag-valve-mask ventilation	Detached intubation	Nasotracheal intubation
Prophylactic versus active	Rectal drug administration	Needle cricothyrotomy
Subcutaneous drug administration	Needle thoracostomy	Surgical cricothyrotomy
Intravenous administration of resuscitation and	Rectal drug administration	Transcutaneous pacing
anticonvulsant drug	Aerosolized drug administration	Automatic external defibrillation
Intravenous catheterization	Non- or single-lumen intubation	Prehospital airway adjunct
Defibrillation	Intraosseous line placement	
	Central line placement	
	Chemical restraint	
	Pulse oximetry	
	End-tidal CO ₂ monitoring*	

*Used mostly for unresuscitated cardiac arrest patients.

TABLE 306.1. Pediatric ALS Procedures Performed by Paramedics

Because of the infrequent need for pediatric ALS interventions in the field, and because of their relative lack of basic pediatric clinical training, paramedics often feel uncomfortable performing such procedures on children. Fortunately, the actual procedural steps vary little from those needed for adults. Continuing education through agency in-service programs or formal courses can help medics gain confidence in their abilities to give the same level of care to children as they give to adults. Hands-on practice with real children in a supervised setting is difficult to arrange, but many pediatric emergency departments welcome paramedics as observers. Even this kind of patient contact can be a valuable educational opportunity.

Triage and Transport Decisions

EMS providers face an additional challenge when formulating a care plan for a child in the field. Not all emergency departments can provide the full spectrum of acute pediatric care, especially trauma, critical care, and subspecialty services. Transport destinations for children are more limited than for adults. EMS personnel must be familiar with the pediatric care capabilities of facilities in their area, and must sometimes be prepared to bypass the closest facility in favor of one better qualified to care for their patient. Formal EMS triage and transport guidelines for children should be established for every service area.

EMTs must also factor resource management and social and medicolegal issues into their triage and transport decisions. Could EMS services to an area be compromised if a unit transports a patient out of its territory to the closest pediatric facility? Should the patient be taken instead to a closer, but less capable, facility? Should an EMS unit transport a child and family members to an emergency department just because the parents are too shaken to drive or have no transportation? Should injured adult and child family members be taken to the same facility, even though the quality of care might be affected? How does the system handle unaccompanied minors with nonemergent complaints or parental service refusals when the child obviously is at increased risk for significant morbidity or mortality? These decisions must all be supported by standing policies that address these pediatric-specific issues, or by knowledgeable on-line medical control assistance. Medics must also be allowed the freedom to use their own judgment to adapt triage and transport guidelines to the case at hand.

Emotional Aspects

An axiom among pediatricians is that the hardest part of pediatrics is not the patients, it is the parents. The medical team works best when family members and other caregivers assist in a child's care. Parents and caretakers must fulfill two important roles during an actual emergency. First and foremost, adults must know how to access and activate their local EMS network. In most communities, that means dialing 911. In a poisoning emergency, however, this may mean calling the nearest poison center. Adults should provide needed first aid to the injured child. This can range from covering the child with a blanket to providing lifesaving procedures such as cardiopulmonary resuscitation. The emotional stress surrounding an ill or injured child sometimes impairs the caregivers' ability to function as a part of the team.

Young children take their cues primarily from the adult caregivers they know best. Parents may feel guilt, fear, or helplessness in aiding their child. Depending on the developmental stage, a child's response and understanding of the situation at hand may be affected by curiosity, need for autonomy, desires for modesty and privacy, fears of death or mutilation, guilt, or misinterpretation of overheard discussions. EMS providers must be sensitive to these reactions and prepared to support the caregivers through applied psychology and good communication skills, while simultaneously providing medical care to the patient. In essence, the family members may become patients as well, requiring supportive therapy to restore their normal psychological and emotional function. This must always be a second priority, after medical support of the child, but it is an important aspect of pediatric emergency care. Such sensitivity improves the perception of EMS care by the family and helps to prepare the caregivers to take an active role in the child's treatment and recovery.

Emergency care providers also have strong emotional reactions to ill and injured children. Many have children of their own and cannot help seeing their child in place of the patient. EMTs are almost universally protective of children and may have significant feelings of anger when faced with a child injured in a preventable accident or one who has been abused or neglected. Likewise, they may suffer from feelings of guilt and self-doubt when a child has a poor outcome. Pediatric calls are common triggers for formal critical incident stress debriefing. Because their emotional instincts and reactions are so similar when it comes to children, it may be helpful to bring together the entire emergency health-care team (prehospital and emergency department staff) for such debriefings.

EMS PROVIDERS AS AN EXTENSION OF THE EMERGENCY DEPARTMENT TEAM

Prehospital care providers are essential members of the emergency care team. They extend the services of the emergency department into the homes and streets of the community. They act as the eyes, ears, and hands that gather necessary information and initiate patient and family care. This information-gathering function is more important for many children than it is for adults. EMTs observe and elicit scene details that help clarify mechanisms of injury, thereby adjusting the index of suspicion for occult injuries through an analysis of the forces applied to children of varying body sizes and maturity. They may also report environmental signs of neglect, or detect incongruities between the scene and the alleged mechanism of injury. EMTs may notice environmental hazards such as chemicals or pill bottles that might explain a puzzling patient presentation. Prehospital providers are often the only medical team members with direct knowledge and access to questions and answers about the scene.

EMTs can, and should, share a voice with their emergency department counterparts. Emergency care providers have long led efforts toward public education and illness and injury prevention. EMTs have the advantages of public trust and respect and the ability to take information to the people who need it most. Every EMS agency should participate in public education programs as a routine part of their mission in the community.

ROLE OF EMERGENCY PHYSICIANS IN EMSC

Encouragement

The pediatric aspects of EMS and the impact of children on EMS providers have long been downplayed or ignored. As a result, the patients may suffer from suboptimal care, and the providers may suffer from a lack of self-confidence and fulfillment. EMTs must be encouraged to develop greater self-assurance and a more positive attitude toward their pediatric patients. Emergency department staff members can assist by reinforcing such attitudes, providing positive feedback to EMTs for tasks well done and constructive input for those that might have been done better. Patient follow-ups provide EMS crews with not only an educational opportunity, but also gratification and emotional closure. Whenever possible, EMTs should be encouraged to spend time with children in the emergency department setting; likewise, emergency department staff will benefit from spending time with EMS crews in the field.

Education

Education begins with each EMS response. Every pediatric EMS patient is a teaching opportunity. Emergency physicians should make an effort to try to answer questions the EMS crew might have about their pediatric patient. They should point out the objective findings that support their immediate clinical impression of "sick" or "not sick." The crew should be encouraged to observe therapeutic or diagnostic procedures and alerted to other interesting cases in the department. EMS crews do not always have time to stay and watch or ask questions, but they truly appreciate the opportunity when they can take advantage of it.

Emergency physicians should alert EMS agencies to formal pediatric education programs sponsored by their facilities. Perhaps the administration could open grand rounds, trauma conferences, and so forth, to EMS personnel. The PALS course, the Neonatal Resuscitation Program, and other standardized pediatric courses should be available to local paramedics. Emergency department staff members with pediatric experience and expertise should be encouraged to share their knowledge with local EMS providers. EMS-oriented pediatric emergency care lectures or skill labs could be assigned as projects for residents and fellows.

Advocacy and Involvement

The EMSC movement needs the support of all emergency care providers. Emergency physicians provide a significant amount of both acute and primary pediatric care as a part of their duties every day. In doing so, they must recognize the importance of providing every child with access to the same quality of care given to adults. Advocacy for EMSC projects and legislation means advocacy for an integrated, comprehensive system of pediatric and family care that spans the continuum from public education to prehospital care to the emergency department and beyond.

Emergency physicians can become personally involved in EMSC projects by participating in formal EMSC grant-supported programs, or through local pediatric and EMS programs and organizations. Pediatric courses need instructors; EMS agencies need guidance in preparing and supervising pediatric protocols, quality improvement, and educational programs. Emergency physicians also can help educate primary care practitioners about the EMS system, helping them better understand its functions as well as teach their patients and families how to use the system properly.

CONCLUSION

Because EMS providers encounter so few children during their everyday interventions, they have fewer opportunities to develop and practice their skills in pediatric care. Until recently, a correspondingly small percentage of time, money, and effort was allocated toward optimizing pediatric care in a primarily adult-oriented system. The EMSC movement works to integrate a comprehensive pediatric care plan into the EMS systems that already exist. EMSC programs affect all emergency care providers and strive to strengthen the EMS team.

This chapter discussed just a few of the EMSC issues challenging prehospital and hospital-based emergency care providers. The EMSC program has undertaken initiatives over the last few years in addition to the ones described in this chapter. Examples include the national EMSC Resource Alliance, national consensus documents developed on pediatric equipment for transport vehicles and on pediatric equipment for hospital emergency departments; children and disasters; children with special health-care needs; cultural competence; injury prevention; family-centered care in emergencies; and data collection and analysis. For more information on EMSC principles and projects, the reader may contact any of the resources listed in [Table 306.2](#) or consult the references in the Bibliography.

CHAPTER 307

Dealing with Death or Catastrophic Illness

Phyllis Hendry Stenklyft

[Epidemiology of Infant and Pediatric Death](#)
[Grief Reactions](#)
[Support and Counseling](#)
[Sibling and Childhood Bereavement](#)
[Autopsy](#)
[Emergency Department Staff Concerns](#)
[Common Pitfalls](#)
[Chapter References](#)

Emergency physicians and prehospital care providers often face the task of telling a family that their child has died or has a catastrophic illness. Dealing with death in the emergency department is difficult for many reasons. The hectic surroundings and the lack of acquaintance with the family or patient make a difficult situation even worse. Deaths in infants or children differ from those in adults in etiology and in the emotions they create in family and staff members.

EPIDEMIOLOGY OF INFANT AND PEDIATRIC DEATH

The common causes of death in infants (less than 1 year of age) are congenital anomalies, sudden infant death syndrome (SIDS), disorders related to prematurity, and respiratory distress syndrome (Fig. 307.1). Infant mortality in the United States has declined by 40% since 1980. Many infant deaths occur in the neonatal period, often before the infant goes home from the hospital. Birth weight is one of the most important predictors of infant mortality.⁸

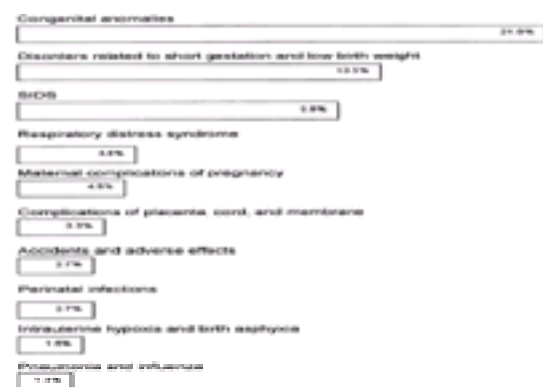

Figure 307.1. Top ten causes of infant mortality in the United States. (Adapted from Guyer B, MacDorman MF, Martin JA, et al. Annual summary of vital statistics—1997. *Pediatrics* 1998;102:1333.)

Death due to suspected SIDS is commonly encountered by the emergency physician. SIDS deaths are particularly tragic: A family puts a happy, well baby down for a nap and faces unanticipated death hours later. The emergency physician should be knowledgeable about the epidemiology and differential diagnosis of SIDS. Many states have death review teams for unexplained infant deaths. Deaths due to carbon monoxide poisoning, asphyxia in mechanically unsafe sleeping environments, and overlying (smothering) are often initially labeled as possible SIDS. Fortunately, after slow declines during the 1980s, SIDS rates have fallen by 42% since 1992, when the American Academy of Pediatrics issued a recommendation to reduce the risk of SIDS by placing infants on their backs or sides to sleep.^{2,3,5,11}

The physical examination of infants who present with sudden, unexplained death or arrest should include a search for signs of abuse, metabolic disorders, and congenital syndromes. Child abuse can be a great imitator of medical and traumatic disease. About 2000 children die each year of abuse or neglect; 50% of these victims are less than 1 year old.^{5,11}

After the infant year, the death rate of children decreases. Injury (usually from motor vehicle accidents) is the most common cause of death in children older than 1 year. Pedestrian accidents, falls, bicycle injuries, and house fires are other common causes of lethal injury. In adolescents, an adult pattern is seen, with death caused by motor vehicle accidents, firearm injuries, and suicide. In some western and southern states, drowning is the leading cause of death in children over age 1 year.^{8,9}

Most pediatric deaths are sudden and unexpected. Malignancy, asthma, congenital heart disease, acquired immunodeficiency syndrome, and seizures are the more common preexisting disorders seen in pediatric sudden deaths. In 1997, mortality due to human immunodeficiency virus infection declined by 47%.⁸

GRIEF REACTIONS

In general, society reacts to pediatric death or terminal illness with disbelief, helplessness, and, often, anger. Children are expected to remain healthy and reach adulthood. The high infant mortality rates of past decades are no longer accepted. Parents and family members will usually express guilt feelings, especially when the death was a result of accidental injury. If the death was associated with inadequate parental supervision, family members may blame one another. Hostility among family members may be increased in cases of divorced or separated parents.⁴

Infants and children have often had a recent primary care visit before a sudden death occurs, and parents commonly express anger at the last physician who treated the child. An example is a SIDS death in an infant who recently received immunization shots. Parents may ask the emergency physician why their regular physician failed to see that something was wrong with the child.

SUPPORT AND COUNSELING

Interventions for helping survivors cope with grief are reviewed in [Chapter 409](#). Parental guilt must be addressed soon after the news of death or illness is given to the family. Assure parents that guilt feelings are an expected reaction, and praise them for the positive things they did for their child. Avoid statements such as, "At least you have other children," after a pediatric or neonatal death or a miscarriage. When SIDS is suspected, inform the family that SIDS is a diagnosis of exclusion and that other investigation is required.

Emergency departments should have a plan addressing notification of family, burial arrangements, organ donation, autopsy requests, and family support. The support team may include physicians, nursing staff, social workers, chaplains, the primary care physician, and other local support groups. An example of an emergency department death protocol is shown in [Fig. 307.2](#).^{1,4,6,10} Encourage, but do not force, family members to view the body or spend time saying goodbye to the child. This experience can be enhanced by providing a quiet room, privacy, blankets, or a rocking chair. Many emergency departments provide foot- or handprints, a lock of hair, or photographs. This is especially applicable in neonatal or infant deaths, when no pictures of the child have been taken before death.

Figure 307.2. Example of emergency department death protocol.

A follow-up support plan should be in place when the parents leave the emergency department. Often, support services will not be accepted for days or weeks after the death. National support organizations are listed in [Table 307.1](#).

SIBLING AND CHILDHOOD BEREAVEMENT

The emergency physician should also be knowledgeable about the grieving process in surviving children. The American Academy of Pediatrics recommends addressing the following questions:

1. What is death?
2. What made the person die?
3. Where is the person?
4. Can it happen to me?
5. Who will take care of me?

[Table 307.2](#) lists manifestations of grief in children by age and developmental level. The child's pediatrician or primary care physician should be involved in monitoring the grief process.¹

Young Children (3 yr of age)	Preschool Children	School-age Children	Adolescents
Regression	Increased activity	Deterioration of school performance	Depression
Bedwetting	Conduct disorder	Withdrawal from social activities	Somatic complaints
Aggression	Discipline	Distorted sense of reality	Delinquent behavior
Failure to thrive	Anger and temper tantrums	Failure to complete assignments	Proximal
Sleep disturbance	"Out-of-control" behavior	and/or dropping in class	Suicide attempts
Social withdrawal	Regression	Resistance to attending school	Dropping out of school
Developmental delay	Crying spells	Coping skills	
Anxiety		Long	
Increased crying		Worrying	
Loss of speech		Nervousness	
		Obsessive-compulsive	
		Headaches	
		Distress	
		Fatigue	

Adapted from American Academy of Pediatrics. The pediatrician and childhood bereavement: Committee on Professional Speech of Child and Family Health Advisory 1982:15.

TABLE 307.2. Manifestations of Grief in Children

AUTOPSY

The emergency department staff should be aware of state and local requirements for reporting deaths and for organ donation. Postmortem examinations by state medical examiners are often required in all sudden deaths of patients in apparently good health. The jurisdiction of medical examiners varies among states but usually includes death as a result of accident, homicide, suicide, or suspected SIDS. Autopsies in infant deaths are strongly encouraged, to find evidence of familial genetic disease, infection, public health threats, or child abuse and neglect.

This subject is difficult to approach. Advise parents that an autopsy allows them and their physician to understand why the child died and how other or future children might be affected. Autopsy results should be made available to the parents in lay terms.

Pediatric autopsies require expertise in pediatrics, pathology, child abuse, and forensic pathology. The fact that many jurisdictions do not have such experts may lead to underreporting, misclassification, and mismanagement of pediatric deaths.

EMERGENCY DEPARTMENT STAFF CONCERNS

A review by Schmidt and Tolle¹³ found that emergency physicians responded to a mean of 17 patient deaths per year and were exposed to a much higher death rate than were other specialties. Pediatric deaths usually make up a very low proportion of these deaths, but the exposure to death varies, depending on the patient population, the number of shifts worked, and other factors. Most emergency physicians feel uncomfortable dealing with death and giving bad news to families, and they receive little training in this area.

Pediatric deaths are particularly stressful for staff members; staff should be observed for signs of depression, hostility, burnout, or substance abuse. A crisis intervention team should be considered if an unusual number of pediatric deaths occur or if a mass-casualty incident exposes the staff to many deaths at one time.

Death policies and crisis counseling skills should be part of the orientation program for new emergency department staff members. [12,13](#) and [14,16](#)

COMMON PITFALLS

- Do not assume that unexplained infant deaths are due to SIDS without looking for signs of abuse, congenital disorders, or sepsis.
- Do not handle deaths on a haphazard, day-to-day basis; have an organized plan or protocol.
- Do not ignore the grieving of the emergency department staff.
- Do not ignore grief reactions in siblings.
- Remember to contact the primary care physician

CHAPTER 308

Optimal Pediatric Care in a Non-pediatric Emergency Department

John P. Santamaria

[Options: Separate Versus Integrated Facilities](#)
[Emergency Department Design](#)
[Staffing](#)
[Equipment](#)
[Quality Improvement](#)
[Summary](#)
[Bibliography](#)

More than 31 million children receive emergency department care in the United States each year, accounting for approximately one-third of the 91 million emergency department visits. The annual rate for visits to the emergency department by people under 21 years of age is 41.2 per 100 persons, compared with 36.1 for the general population. A child or adolescent comes to the emergency department on the average of once every second. Thirty percent of all pediatric visits are for children under 3 years of age, and 50% of pediatric resuscitations occur in infants. Most children are seen in emergency departments of general hospitals, not children's hospitals. Children have special needs in these settings, and general hospital emergency departments should be capable of accommodating the pediatric patient.

The care of children in the emergency department of the general hospital can be separated or integrated, depending on the situation and the pediatric volume. Resources can be shared among different subsections of the emergency department. This chapter discusses emergency department design, staffing, and personnel use, as well as equipment and resources. The differences and complexities of each emergency department necessitate unique solutions, and, if optimally planned, no two emergency departments should be exactly the same.

The realistic pediatric emergency department is a balance of institutional resources and patient care needs. The concept of providing for the needs of a specific patient group is not unique to pediatrics. Women with pelvic disease require specialized beds for their examinations; ear, nose, and throat patients often require a specialized chair. The special needs of children are more diverse than these simplistic adult analogies, but the concept is the same.

OPTIONS: SEPARATE VERSUS INTEGRATED FACILITIES

1. *Separate facility.* An annual volume of at least 15,000 pediatric visits is usually required to justify a separate pediatric emergency department with separate staff. A separate emergency facility for the care of children in a general hospital may have drawbacks. In a separate facility, the staffing patterns, equipment, and support services are less efficient and more expensive than when they are integrated into a general emergency department. Some emergency departments open and staff a separate pediatric facility only during peak hours.
2. *Dedicated space and staff.* Fiscal responsibility usually dictates that pediatric emergency services share facilities with the rest of the emergency department. Needs and resources must be carefully examined so that the proper balance of resource sharing and services is achieved. Such a balance allows the greatest degree of flexibility while allowing hospitals to provide excellent pediatric care.
3. *Complete integration.* Complete integration of pediatric patients into the general emergency department maximizes use of space and staff but has a negative impact on the "pediatric experience." This option should not be seriously considered, because it precludes the delivery of optimal pediatric care.

EMERGENCY DEPARTMENT DESIGN

Emergency department configuration is dictated by financial and structural limitations. A newly designed facility is preferable to a renovated structure. The entrance to the pediatric emergency department should be easily identified at all levels. Curbside assistance and convenient short-term parking should be available. Parents may feel uncomfortable if they cannot accompany their children into the hospital as care is initiated.

Optimally, entry into the emergency department is by a path completely separate from the regular entrance, to minimize the exposure of the child to frightening sights and sounds. It is preferable that ambulatory and ambulance patients enter by different paths. A warm, welcoming environment in the receiving area allays some of the anxiety patients feel upon entering the emergency department. Friendly, courteous staff contribute to a patient's positive first impression. It is important that the patient and family perceive from the outset that the department is oriented to the child and family unit.

Play areas, telephones, and access to food and educational materials ease the stress of the waiting period. Optimal facility planning allows family participation in the child's care when possible. Traffic through the emergency department is minimized by use of alternate hallways that circumvent patient care areas.

Bedside registration, although more staff-intensive, allows the parent to be with the child at all times. Although not always possible, bedside registration should be available if the patient's condition makes central registration impractical. Initial care of the acutely ill patient should not be delayed for the sake of collecting demographic information.

A centrally located nursing station provides optimal patient observation. An effective emergency department design centralizes staff services, minimizes circulation distances, and reduces staffing requirements. If design constraints preclude creation of a centralized station, satellite nursing stations provide a similar reasonable observation point.

The function of each patient care area should be carefully evaluated. Safety issues should be considered, including child access to choking hazards (small parts), electrical outlets, and needle containers. Provision should be made for the isolation of infectious patients. Visual and acoustic isolation is also an important consideration.

A designated pediatric procedure room gives the older patient a sense of security, because painful procedures such as phlebotomy and intravenous line placement only occur in a designated space. If space is limited, an acute care room, which may otherwise be underused, fulfills this purpose and allows centralized stocking of equipment. Allowing children to master their anxiety about procedures by "playing out the event" with an appropriately trained staff member helps reduce anxiety and addresses emotional and developmental needs.

A dedicated resuscitation room is optimal for management of critically ill children. Visual and acoustic isolation helps reduce the anxiety of other patients and families. It is particularly important that equipment in this area be well organized so that it is easily accessible for use during a true emergency.

STAFFING

Medical care is ideally rendered by staff with specific interest, training, and experience in pediatric emergency medicine. Patient volume may not support full-time, dedicated pediatric coverage; a review of patient flow studies may determine appropriate times for such coverage.

Nurses with specific experience in emergency medicine and pediatrics are important resources for the orientation and continuing education of other staff. Cross-training in adult and pediatric emergency medicine maximizes efficiency. Nurse extenders and emergency department technicians allow nurses to function at the highest level possible, minimizing nonnursing functions and clerical duties. All personnel should have a pediatric orientation. Staff should be encouraged to take courses in pediatric advanced life support.

The collection of blood from infants and small children can be emotionally taxing and technically difficult. Unless staffing allows for blood collection by nurses or physicians, it is imperative that phlebotomists be experienced in pediatrics. Phlebotomy is often the most memorable event of the emergency department visit and a frequent focus of patient complaints; it must be performed with compassion and technical competence.

Airway management is crucial to optimal pediatric emergency care. If respiratory therapists are not dedicated to pediatrics, then specific pediatric training and experience should be a minimum requirement.

Radiology technicians with pediatric experience can best cone down views to the smallest appropriate field, are familiar with appropriate restraining and sedation techniques, and can judge exposure requirements in a wide range of patient sizes.

Medical and psychiatric social workers, as well as child life specialists, can be of great help to the patient and family in the emergency setting.

EQUIPMENT

A dedicated pediatric resuscitation cart should be well organized and contain equipment appropriate for the smallest neonate and the largest adolescent. In an emergency setting, the child's weight is often unknown. A Broselow Resuscitation Tape is recommended for determining equipment sizes and medication dosages on a length-based system. Equipment must be restocked after each use. A low-dose defibrillator is an integral part of the resuscitation equipment. Monitoring capability must be consistent with the level of care provided.

Appropriate sizes of all equipment, such as intravenous catheters, endotracheal tubes, orthopedic supplies, and blood sample containers, should be stocked in the pediatric area. The Committee on Pediatric Equipment and Supplies for Emergency Departments, National Emergency Medical Services for Children Resource Alliance, has published a list of recommended pediatric equipment for emergency departments ([Table 308.1](#)).

TABLE 308.1. Guidelines for Minimum Equipment and Supplies for Care of Pediatric Patients in Emergency Departments

QUALITY IMPROVEMENT

Quality improvement is the responsibility of all who serve the emergency department. Even in the busiest emergency department, the presentation of a critically ill or injured child may not be a daily event. It is imperative that the pediatric team be constantly challenged. Coordination of personnel is the key; mock scenarios help clarify team members' roles.

In addition to its role in patient care, the pediatric emergency staff should be involved in continuing education of prehospital and other hospital personnel. National courses, such as Pediatric Advanced Life Support and Advanced Pediatric Life Support, are generally well received and can be included in the education program. It is also beneficial to offer pediatric classes to the general public and first responders. They can be taught that a critically ill child is often more appropriately transported to the emergency department by trained prehospital care providers than by well-intentioned family members or friends. In addition to enhancing prehospital pediatric care, such training courses raise public awareness of the emergency department's pediatric preparedness.

SUMMARY

Emergency department design, staffing, equipment, and quality improvement greatly affect the quality of pediatric care delivered in the emergency department setting. A less tangible factor is the overall pediatric "orientation" of the department. This child-friendly atmosphere is best witnessed by the way staff approaches and interacts with patients and families. The optimal approach to the ill or injured child is greatly dependent on the severity of illness and on the patient's age and developmental stage. Attention to parental concerns enhances the parent–physician relationship, thereby enhancing the overall satisfaction of all involved.

In preparing an emergency department to care for sick children, limitations should also be recognized. In many instances, institutional limitations and the availability of other excellent pediatric emergency care minimize the need for elaborate pediatric resources in all emergency departments. In such cases, coordination of care within a region and cooperative referral patterns best serve the needs of children.

CHAPTER 309

Approach to the Poisoned Patient

William A. Watson and Christopher H. Linden

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Decontamination](#)
[Supportive Care](#)
[Antidotal Therapy](#)
[Enhancement of Elimination](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The principal objectives in the evaluation and treatment of the poisoned or potentially poisoned patient are listed in [Table 309.1](#). Appropriate treatment is determined by both existing and predicted toxicity. The former is relatively easy to assess by the physical examination and routine ancillary studies. The latter requires information that may not always be available: an accurate history and knowledge of the mechanism of action, biologic disposition (pharmacokinetics), and effects of a given dose of a drug or chemical (pharmacodynamics) and of potential interactions between them.

Evaluation	Management
Recognition of poisoning	Provision of supportive care
Identification of the poison	Prevention of poison absorption
Prediction of toxicity	Administration of antidotes
Assessment of severity	Enhancement of poison elimination
	Prevention of reexposure

TABLE 309.1. Goals of Patient Evaluation and Management in Poisoning

The mechanism of action (intrinsic toxicity) of a substance determines the location and nature of toxicity. Effects limited to the site of exposure are usually due to nonspecific chemical reactions such as desiccation, oxidation, protein denaturation, and solvent activity. In contrast, systemic effects usually result from selective interactions between a substance (or its metabolite) and specific target sites (e.g., membrane receptors or enzymes of a particular tissue or organ).

Pharmacokinetic parameters include absorption, protein binding, distribution, and elimination (i.e., metabolism, excretion, or secretion). Pharmacodynamic equations define dose–response and concentration–response relations. A general understanding of these variables as they relate to overdoses is essential for predicting the course of a potential poisoning.

Absorption and distribution and, in some cases, biotransformation are required before systemic toxicity is seen. Pulmonary and intravenous administration produces the most rapid absorption. With toxic doses, the rate of oral absorption is often erratic. More rapid absorption may occur with substances in solution, because most drugs have first-order absorption (i.e., the rate is proportional to the concentration). Solid dosage forms require disintegration and dissolution before absorption can occur. The ingestion of toxic doses can result in slower absorption when these processes are impaired or when the solubility of the compound in gastrointestinal (GI) fluids is exceeded.¹⁸ With toxic doses, the rate of tissue distribution, also a first-order process, usually remains unchanged, but the extent may be increased. This may be due to the presence of more free drug (i.e., the binding capacity of plasma proteins is exceeded) or changes in pH that increase the amount of un-ionized drug available to diffuse across cell membranes.

The severity of systemic effects is determined by the target tissue concentration of a substance: The larger the dose, the greater the tissue concentration, and hence the effect. However, blood concentrations accurately correlate with those in tissue only if distribution (or redistribution) occurs faster than absorption (or elimination). Because these conditions are not always met, blood levels may be higher than tissue levels during absorption and distribution and lower than tissue levels during elimination and redistribution. Hence, the phase of disposition should always be considered when interpreting blood levels.

Elimination is usually accomplished by metabolic (mainly hepatic) inactivation and renal excretion. The rate and route vary from chemical to chemical. Regardless of whether elimination is constant (zero-order), concentration-dependent (first-order), or saturable (Michaelis-Menten equation), it takes longer to reach nontoxic concentrations as the dose increases. Hence, the duration of effects also depends on the dose. When the rate of elimination is constant or becomes constant (i.e., saturable), increasing the dose results in a proportionately greater (i.e., nonlinear) increase in blood levels, time for elimination, and duration of effects.

The response to a substance depends on biologic variables (e.g., the structure, activity, and integrity of external and internal membrane barriers to chemical translocation; body water, fat, and muscle content, which depend on age, sex, and habitus; serum protein levels and organ function, which reflect the current state of health; genetic influences; and prior chemical exposures) and the physical characteristics (e.g., molecular size and charge, and lipid and water solubility) and dose of the substance. Hence, pharmacokinetic and pharmacodynamic relations are distributed within the population according to a normal (gaussian) curve, and the disposition of a substance or the response to a given dose in a particular person cannot be precisely predicted from mean values (those reported in the literature).

CLINICAL PRESENTATION

Poisoning is most frequently reported and encountered by physicians after ingestion, but other routes of exposure include dermal, inhalational, ophthalmic, envenomation (bites and stings), and parenteral injection. Rare exposures may occur by rectal, vaginal, urethral, or other routes. Acute exposures (those that occur over a short period of time) are more common than chronic ones (those that occur repeatedly or over a prolonged period).

Unintentional poisoning may result from misidentification of a substance (the label may be misread or not read at all, or the label is absent), its misuse or abuse, therapeutic misadventures, or true accidents, such as unforeseen exposures in adults or children. Misuse can apply to either accidental exposure (due to carelessness or ignorance) or intentional exposure (excessive self-dosing to achieve a greater or faster response). Abuse is the intentional use of a substance for its psychotropic effects. Therapeutic misadventures may result from dosing errors or may simply be an adverse reaction to an appropriate dose. Intentional poisoning usually implies attempted (or successful) suicide with a chemical agent. It may also refer to the use of substances to harm another person (e.g., attempted murder, child abuse, chemical warfare).

The agents most frequently involved in reported exposures are pharmaceuticals (particularly analgesics and cough or cold preparations), cleaning products, cosmetics, plants, and hydrocarbons. Ingestion of substances available in the home by children under age 6 is, by far, the most common scenario. Serious or fatal poisoning usually occurs in suicidal adults but is increasingly reported in teenagers and the elderly. Agents commonly implicated in poisoning fatalities include carbon monoxide, antidepressants, cardiovascular drugs, sedative–hypnotics, inorganic chemicals, alcohols, glycols, and iron.

Poisoned patients may present with a wide variety of signs and symptoms. Subjective complaints may occur without objective findings. The severity of poisoning may

range from minor to life-threatening. Manifestations may be local (confined to the surface of exposure), systemic, or both.

Chemicals that cause local effects may be classified as weak irritants, strong irritants, or corrosives, depending on whether exposure results, respectively, in mucosal irritation only, mucosal and skin irritation, or severe burns, potentially resulting in permanent tissue damage or death. Systemic effects may be behavioral, biochemical, cognitive, or physiologic. Substances that produce systemic effects may be categorized as extremely toxic, highly toxic, moderately toxic, slightly toxic, practically nontoxic, or relatively harmless, based on a corresponding oral LD₅₀ (median lethal dose) of less than 1 mg/kg, 1 to 50 mg/kg, 50 to 500 mg/kg, 0.5 to 5.0 g/kg, 5 to 15 g/kg, or more than 15 g/kg. Products with the three most potent toxicity ratings may be labeled with the words "Danger," "Warning," or "Caution," respectively.

Patients who eventually become severely poisoned may be relatively asymptomatic on presentation. Substances with toxicity, which is characteristically delayed, include acetaminophen, antitumor agents, antimetabolites, carbon tetrachloride, colchicine, digoxin, ethylene glycol, heavy metals, methanol, mushrooms, opioids (especially diphenoxylate), salicylates, and slow- or sustained-release medications (e.g., carbamazepine, enteric-coated tablets, lithium, phenytoin, theophylline).

A history of exposure may be absent when the victim is confused, comatose, unaware of an exposure or its relation to harmful effects (e.g., victims of animosity, chronic or insidious exposures, and therapeutic misadventures), or unable or unwilling to admit to an exposure (e.g., infants and toddlers, victims of attempted abortion or suicide, drug addicts, these attempting to conceal or smuggle illicit drugs in body cavities, recreational users of illicit drugs, and patients with Munchausen syndrome). Because the signs and symptoms of poisoning are usually nonspecific, the diagnosis may be missed unless it is included in virtually every differential diagnosis.

Poisoning should always be suspected in patients with a sudden or unexplained illness or injury; those with a history of psychiatric problems or a recent change in behavior, health, economic status, or social relations; those who use chemicals at work or for hobbies; and those who become ill soon after arriving from a foreign country or being arrested or incarcerated for criminal activity (suspect illicit drugs concealed in a body cavity), or after ingesting food, drink (especially ethanol), or medications.

DIFFERENTIAL DIAGNOSIS

The vital signs and mental status are the most useful physical findings for determining the cause of poisoning by an unknown substance.¹⁵ The overall clinical picture usually suggests either generalized physiologic stimulation or generalized physiologic depression. Increased blood pressure, pulse and respiratory rates, and temperature and central nervous system (CNS) excitation indicate the former; decreased vital signs and CNS activity are manifestations of the latter.

Physiologic stimulation (Table 309.2) is usually caused by one of four mechanisms of action: sympathetic nervous system stimulation, cholinergic inhibition, central hallucinogenic activity, or drug withdrawal (i.e., sympathetic hypersensitivity). Similarly, physiologic depression (Table 309.3) usually results from one of four mechanisms: sympathetic inhibition, cholinergic stimulation, opioid receptor stimulation, or sedative-hypnotic activity. Agents that commonly cause physiologic stimulation or depression are listed according to mechanism of action in Table 309.4.

Severity	Signs and Symptoms
Grade 1	Diaphoresis, hyperreflexia, irritability, mydriasis, tremors
Grade 2	Confusion, fever, hyperactivity, hypertension, tachycardia, tachypnea
Grade 3	Delirium, mania, hyperpyrexia, tachyarrhythmias
Grade 4	Coma, convulsions, cardiovascular collapse

Adapted from Espelin DE, Dore AK. Amphetamine poisoning: effectiveness of chlorpromazine. *N Engl J Med* 1968;278:1361.

TABLE 309.2. Manifestations of Stimulant Poisoning

Severity	Signs and Symptoms
Grade 1	Lethargic; able to answer questions and follow commands
Grade 2	Comatose; responsive to pain; brainstem and deep tendon reflexes intact
Grade 3	Comatose; unresponsive to pain; most reflexes absent; respiratory depression
Grade 4	Comatose; unresponsive to pain; all reflexes absent; cardiovascular and respiratory depression

Adapted from Reed CE, Driggs MF, Foote CC. Acute barbiturate poisoning: a study of 300 cases based on a physiological system of classification of the severity of intoxication. *Ann Intern Med* 1952;37:290.

TABLE 309.3. Manifestations of Depressant Poisoning

Stimulant Poisoning	Depressant Poisoning	Other Poisoning Effects	Other Poisoning Effects
<ul style="list-style-type: none"> Diaphoresis Hyperreflexia Irritability Mydriasis Tremors 	<ul style="list-style-type: none"> Lethargy Coma Respiratory depression Cardiovascular depression 	<ul style="list-style-type: none"> Seizures Tachyarrhythmias Hyperpyrexia Delirium Mania 	<ul style="list-style-type: none"> Seizures Tachyarrhythmias Hyperpyrexia Delirium Mania

TABLE 309.4. Differential Diagnosis of Poisoning Based on Vital Signs and Mental Status

Less commonly, discordance among or between vital signs and CNS activity may be seen. This usually results from metabolic and membrane effects, multiple mechanisms of action, or selective action leading to compensatory or opposing autonomic responses (refer to Table 309.4). In addition, extreme (preterminal) physiologic stimulation may result in coma and cardiovascular collapse as a consequence of anaerobic metabolism or depletion of neurotransmitters. Analogously, severe poisoning by physiologic depressants (except for sedatives) may result in seizures and tachyarrhythmias as a consequence of shock, hypoxia, stimulation of specific (e.g., opioid) receptors, or membrane destabilization. In most of these cases, however, the overall physiologic picture usually suggests a predominance of either stimulation or depression.

And finally, the vital signs and mental status may be normal. In this situation, care must be taken to exclude exposure to “toxic time bombs” (agents with delayed onset of action; see [Table 309.4](#)) before diagnosing a nontoxic ingestion or psychogenic illness. After the physiologic status has been characterized, an attempt should be made to narrow the diagnosis to a specific syndrome, corresponding to one of the mechanisms of action previously noted, or to a particular causative agent.

Eye, skin, and neuromuscular findings can be helpful in the differential diagnosis. Although mydriasis may be caused by any physiologic stimulant, and miosis by any depressant, markedly dilated pupils that are minimally responsive to light and accommodation are typical of anticholinergic poisoning. Pinpoint pupils suggest opioid poisoning. The alpha-adrenergic blocking effects of phenothiazines may also cause pronounced miosis. Similarly, horizontal nystagmus and disconjugate gaze may be due to any sedative–hypnotic agent, but vertical or rotatory nystagmus suggests lithium or phencyclidine poisoning.

Hot, dry, flushed skin is characteristic of anticholinergic poisoning. Flushing may also be due to boric acid, monosodium glutamate, rifampin, or scombroid poisoning or to a disulfiram–ethanol or niacin reaction. Diaphoresis and pallor suggest either sympathetic stimulation (sympathomimetic, hallucinogenic, or hypoglycemic agent poisoning, or drug withdrawal) or cholinergic hyperactivity. Brown, gray, or purple cyanosis that is unresponsive to oxygen suggests methemoglobinemia. Amiodarone may cause a blue discoloration of the skin that can be mistaken for cyanosis. External contamination of the skin or nails with blue dye may also be confused with cyanosis; wiping the affected area with acetone or isopropyl alcohol will reveal the true cause. Hair loss, nail growth abnormalities, and mucosal pigmentation suggest chronic heavy-metal poisoning.

Tremors may result from poisoning by lithium or physiologic stimulants. Fasciculations are typically seen with cholinergic insecticide poisoning, but they may also be a manifestation of sympathetic hyperactivity. Muscle rigidity may be due to severe sympathomimetic poisoning, the neuroleptic malignant syndrome, or the serotonin syndrome. Dystonic posturing suggests a neuroleptic reaction or strychnine poisoning. Myoclonus and choreoathetoid movements are usually manifestations of excessive anticholinergic activity. Weakness and muscle wasting suggest chronic alcohol, heavy-metal, or solvent poisoning.

Seizures may be caused by physiologic stimulants, cholinergic agents, some opioids (e.g., propoxyphene), membrane-active physiologic depressants (e.g., antiarrhythmics, antimalarials, beta blockers, cyclic antidepressants), and agents with metabolic or mixed effects. Except for theophylline and hypoglycemic agents, seizures caused by poisoning are almost always generalized. Hence, the presence of focal neurologic findings should suggest these agents or another cause (e.g., a structural CNS lesion).

Routine laboratory findings may also suggest the cause of poisoning by an unknown agent. The anion gap, acid–base status, and osmolal gap can be useful, because abnormalities suggest poisoning by agents that require early, specific therapy to prevent progressive toxicity and irreversible tissue damage ([Fig. 309.1](#)).¹ The anion gap—the difference between the serum sodium concentration and the sum of the chloride and bicarbonate concentrations (sodium – [chloride + bicarbonate])—is normally 13 (±4) mEq/L, and the osmolal gap—the difference between the serum osmolality measured by freezing point depression (but not the vapor pressure or head space method) and that calculated from the serum sodium, glucose, and blood urea nitrogen (BUN) ($[2 \times \text{sodium}] + [\text{glucose}/18] + [\text{BUN}/3]$)—is normally 5 (±7).

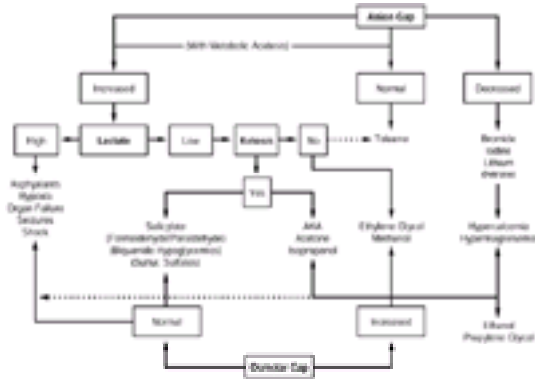

Figure 309.1. Use of routine laboratory findings and calculated gaps in the differential diagnosis of poisoning.

An increased anion gap metabolic acidosis due to lactic acid may occur in any poisoning accompanied by hypoxemia, cellular hypoxia, hypotension, or seizures. In the absence of these complications (and diabetic ketoacidosis or uremia), methanol, ethylene glycol, and salicylate poisoning and alcoholic ketoacidosis are the leading suspects. Concomitant visual symptoms point to methanol; back pain suggests ethylene glycol; tinnitus or hearing loss implicates salicylate. Similarly, the presence of crystalluria and hypocalcemia suggests ethylene glycol, and a mixed acid–base disorder suggests salicylate. Ketosis may be seen in salicylate as well as ethanol poisoning. An increased osmolal gap with an increased anion gap acidosis supports a diagnosis of either methanol or ethylene glycol poisoning. However, the absence of either or both does not necessarily rule out their presence, because the sensitivity of these findings is low.

The osmolal gap may also be increased by other low-molecular-weight substances, including “unmeasured” sugars or electrolytes, and the magnitude of this gap can be used to estimate the amount ([Table 309.5](#)). The presence of an oxygen saturation gap (the difference between the oxygen saturation calculated from the P_{O_2} and that measured directly by co-oximetry) indicates the presence of an abnormal hemoglobin, such as carboxyhemoglobin or methemoglobin.

Solute	Serum Concentration (mg/dL)*
Alcohols, glycols, and ketones	
Acetone	5.8
Ethanol	4.6
Ethylene glycol	5.2
Isopropanol	6.8
Methanol	2.6
Propylene glycol	7.6
Electrolytes	
Calcium	4
Magnesium	2.4
Sugars	
Mannitol	18
Sorbitol	18

*Equivalent to 2 mmol/L of electrolyte and 1 mmol/L of other solutes.

TABLE 309.5. Amount of Solute That Increases Serum Osmolality by 1 mOsmol/kg

Hypokalemia may be due to beta-adrenergic stimulation (e.g., acute poisoning by beta agonists, caffeine, or theophylline), acute barium poisoning, chronic diuretic or laxative use, or toluene abuse. Hyperkalemia may result from alpha-adrenergic stimulation (e.g., by sympathomimetics), beta-adrenergic blockade, and digitalis, fluoride, or lithium poisoning. Hypoglycemia may be a manifestation of poisoning with alcohol, a beta-adrenergic blocker, a hypoglycemic agent, quinine, or salicylate; hyperglycemia may be seen with acetone, beta agonist, calcium channel blocker, iron, or theophylline intoxication.

An elevated serum creatinine with a normal BUN suggests acetone or isopropyl alcohol poisoning, because acetone, a metabolite, or isopropyl alcohol interferes with the colorimetric assay for creatinine. Crystalluria may be seen with primidone as well as ethylene glycol poisoning. Heme (orthotoluidine)-positive urine in the absence of red cells on microscopic examination suggests hemoglobinuria or myoglobinuria due to hemolysis or rhabdomyolysis, respectively. Clear serum with a decreased hematocrit, increased unconjugated bilirubin level, and abnormal red cell morphology is seen in the former; pink serum with increased creatine kinase, aldolase, and lactate dehydrogenase levels is present in the latter.

Agents that cause hemolysis include arsine gas, antibiotics (in patients with glucose-6-phosphate dehydrogenase deficiency), and oxidizing compounds (which also

cause methemoglobinemia). Rhabdomyolysis may result from grade 3 or 4 and occasionally grade 2 physiologic stimulation or depression (see [Table 309.2](#) and [Table 309.3](#)) of any cause. Acute renal failure may result from dehydration, shock, or nephrotoxins such as acetaminophen, cancer chemotherapeutics, carbon tetrachloride, ethylene glycol, heavy metals, immunosuppressants, and nonsteroidal antiinflammatory agents. In most cases, however, the BUN and creatinine levels and the urinalysis are normal at presentation.

The electrocardiogram (ECG) may also provide clues to the diagnosis. Sinus tachycardia or bradycardia with a concomitant increase or decrease in blood pressure may be caused by any physiologic stimulant or depressant, respectively. Tachycardia may also be a reflex response to hypovolemia or vasodilatation. In such cases, the blood pressure is usually low, but it may be normal or even increased. The combination of tachycardia and hypotension may be seen in poisoning by agents such as beta agonists, caffeine, theophylline, carbon monoxide, cyanide, and various antihypertensive drugs (e.g., alpha-adrenergic blockers, nitrates, direct-acting vasodilators). Similarly, bradycardia may be a homeostatic response to hypertension. This combination usually results from alpha-adrenergic stimulation caused by agents such as phenylpropanolamine or imidazoline (e.g., clonidine, guanabenz, and tetrahydrozoline) poisoning.

Ventricular tachyarrhythmias may be due to anticholinergics, chloral hydrate, digitalis, solvents (particularly chlorinated hydrocarbons), sympathomimetics, and agents that cause QRS and Q-T interval prolongation as a result of depressant effects on cardiac membrane activity. Membrane-active agents include amantadine, cardiac drugs (e.g., antiarrhythmics, beta blockers), fluoride (due to its ability to cause hypocalcemia), heavy metals (e.g., arsenic, thallium), magnesium, potassium, organophosphate insecticides, quinine, and psychotherapeutic agents (e.g., antipsychotics, cyclic antidepressants, lithium). Torsades de pointes (polymorphous ventricular tachycardia) suggests a prolonged Q-T interval as the underlying cause.

Atrioventricular block and bradyarrhythmias may be caused by potent alpha agonists (most notably phenylpropanolamine), antiarrhythmics, beta blockers, calcium channel blockers, digitalis, cholinergic agents, and psychotherapeutic medications. In patients with any type of rhythm disturbance, hypoxia, hypoglycemia, hypothermia, hyperthermia, hypovolemia, and acid-base and electrolyte (including calcium and magnesium) abnormalities should be considered as causative or contributing factors.

Radiographs are occasionally useful in the differential diagnosis. An abdominal film that reveals radiopaque densities in the GI tract suggests the presence of calcium salts, chloral hydrate, chlorinated hydrocarbons, enteric-coated tablets, heavy metals, magnesium, phenothiazines, or salicylate. A "double bubble," representing an air-fluid or fluid-fluid interface, may be seen with hydrocarbon ingestion, because this fluid is less dense than water and thus layers on top of the gastric contents. Ingested drug packages may be visible all along the GI tract as uniform oval or round, marble-sized densities.

A chest film that reveals pulmonary edema without cardiomegaly (acute respiratory distress syndrome) may be seen in patients with carbon monoxide, cyanide, opioid, paraquat, sedative-hypnotic, or salicylate poisoning. This picture may also be noted in patients with irritant gas inhalation (e.g., acid fumes, chlorine, mercury vapor, metal or polymer fumes, or nitrogen dioxide) and hydrocarbon aspiration. Pulmonary edema and aspiration pneumonitis are common but nonspecific findings in patients with coma, seizures, or prolonged shock of any cause.

EMERGENCY DEPARTMENT EVALUATION

The history in patients with a known exposure should include the time, route, dose, location (e.g., home or work), surrounding circumstances, and intent. The specific name and amount (weight, volume, concentration, or duration of contact) of all substances involved should be determined. The time of onset, nature, and severity of symptoms; the type of first aid undertaken; and the victim's medical and psychiatric history should also be noted.

If the history is vague or of questionable reliability, an attempt should be made to obtain or verify as much information as possible from paramedics, police, family, and friends. Communicating with the patient's employer, pharmacist, or physician may also be valuable. A search of the patient's clothes, home, or place of discovery may reveal a suicide note, pill bottle, or chemical container. All available chemicals or other evidence of exposure or intent should be brought to the hospital for identification.

If the exposure involves a chemical or product whose ingredients are unknown, consultation with a regional poison control center, reference text, or poison information system may provide the desired data. Drugs can be identified by the pill or tablet imprint code (now required by law) or by their street slang names. The composition of a brand-name product may also be determined from reference sources or by calling the manufacturer. The odor or use of an unknown chemical may also suggest its identity. Local nurseries, horticultural and mycologic societies, botany departments of academic institutions, and field guides may help to identify an unknown plant. Similarly, pet stores, zoos, veterinarians, entomologists, herpetologists, and zoologists may help to identify unknown insects, reptiles, snakes, and other potentially poisonous animals.

A complete physical examination is necessary in all patients. It should begin with vital signs and initially be directed toward assessment of cardiovascular stability, respiratory function, and neurologic status. The accurate measurement of all vital signs, including the respiratory rate (measured over a full minute) and core (rectal) temperature, is essential to detect subtle abnormalities. The neurologic examination should include evaluation of the mental status.

Evidence of underlying illness and coexisting trauma, especially head injury, also should be sought. When the history suggests the possibility of illicit drug concealment, all orifices and body cavities should be visually or digitally examined for the presence of drug packages. The odor of the breath and any vomitus, the urine color, eye findings (e.g., nystagmus, papilledema, pupil size and reactivity), bowel and bladder activity (e.g., bowel sounds, distention, incontinence), and the condition of the skin and mucosa (e.g., color, warmth, moisture, burns, bullae, pressure sores, puncture marks) should be noted.

The vital signs and physical examination must be repeated frequently. Poisoned patients can suddenly and precipitously deteriorate with little or no warning signs.

The need for routine ancillary studies is primarily determined by the clinical presentation. Laboratory studies in symptomatic patients, particularly those with unreliable histories, should include a complete blood count, determination of electrolyte, BUN, creatinine, and glucose levels, and a urinalysis. In asymptomatic patients, blood and urine samples should be obtained on presentation and saved for later (baseline) analysis in the event of subsequent deterioration.

Depending on the history and physical examination, measurement of serum osmolality and ketone levels and arterial blood gas analysis may also be helpful. Patients with respiratory complaints or grade 2 or greater physiologic dysfunction should have a chest radiograph as well as arterial blood gas analysis. The methemoglobin level should be measured in patients with cyanosis despite a normal P_{O_2} . The evaluation of patients with grade 3 or 4 stimulation or depression should include measurement of serum amylase, calcium, magnesium, and creatine phosphokinase levels and liver function tests. Anion, osmolal, and oxygen saturation gaps should be calculated whenever their determinants are available.

Unless the exposure is clearly trivial, evaluation of the cardiac rhythm by continuous monitoring is prudent. Symptomatic patients, those exposed to agents with cardiovascular toxicity, and those with an abnormal rhythm strip should have a 12-lead ECG.

Toxicology screening—the qualitative analysis of urine, blood, and, sometimes, gastric contents, or a sample of the chemical itself—may confirm or rule out a suspected diagnosis.^{9,13} Comprehensive screening is expensive and generally requires 2 to 6 hours to perform. It is of greatest value in patients with severe and unexplained findings, such as acid-base disturbances, cardiovascular instability, coma, multiple-organ dysfunction, nonsinus cardiac rhythms, respiratory depression, and seizures. In these patients, the results may prompt a significant change in treatment but usually not in disposition. Depending on the clinical findings, selective ordering of a stimulant, hallucinogen, depressant (coma), or drugs of abuse screen may increase the speed and utility of qualitative testing. In contrast, routine screening is neither clinically useful nor cost effective in patients who are asymptomatic or have clinical findings consistent with the reported history. Despite increased diagnostic certainty and specificity, only rarely do the results lead to a change in treatment or disposition, particularly in mildly poisoned patients. Because of their ready availability, delayed onset of toxicity, and need for specific therapy, acetaminophen and salicylate are exceptions, and levels of these drugs should generally be measured in all patients with intentional overdose.

Optimal use of the toxicology laboratory requires knowledge of which tests (e.g., thin-layer, gas-liquid, high-performance liquid chromatography; colorimetric, fluorometric, and enzyme-multiplied assays and radioimmunoassays; gas chromatography; mass spectrometry) are used for screening and subsequent confirmation of any chemicals that are detected, and the sensitivity (i.e., limit of detection) and specificity of each test. Personal communication with laboratory personnel is recommended in all cases; it is essential when laboratory results do not agree with clinical findings.

A negative screen should never be interpreted as excluding a diagnosis of poisoning: It may indicate only that the suspected agent cannot be detected by the test used, that a chemical is present but cannot be positively identified, or that its concentration is too low for detection in the specimen submitted.

In many cases, it is more appropriate to obtain a quantitative serum level of a specific chemical than a toxicology screen. The results of quantitative analyses are often available within 1 hour. Acetaminophen, acetone, alcohols (ethylene glycol as well as ethanol, isopropanol, and methanol), antiarrhythmics, antiepileptics, barbiturates, carbon monoxide, digoxin, electrolytes, heavy metals, lithium, salicylate, and theophylline are agents whose quantitative measurement is necessary for optimal patient management.

Antidotes may be used for diagnostic purposes. Prompt resolution of mental status and vital sign abnormalities after the intravenous administration of dextrose, naloxone, or flumazenil is virtually diagnostic of hypoglycemia, opioid poisoning, or benzodiazepine intoxication, respectively. Rapid reversal of an acute dystonic (extrapyramidal) reaction after the intravenous administration of diphenhydramine (or another anticholinergic) indicates a drug etiology. A change in urine color after deferoxamine can be used to confirm but not exclude iron poisoning. A therapeutic response to physostigmine is suggestive but not diagnostic of anticholinergic poisoning, because this agent can cause nonspecific arousal in patients with CNS depression of any cause. Details of antidotal therapy are described in chapters that pertain to the corresponding poison.

EMERGENCY DEPARTMENT MANAGEMENT

The management of the poisoned or potentially poisoned patient depends on the actual or predicted toxicity and the time of presentation relative to the time of exposure.^{12,18} The time of presentation is important, because it reflects the phase of chemical disposition and allows a more refined prediction of toxicity based on knowledge of kinetic data.

During the *preclinical phase*—the time between exposure and the onset of clinical or laboratory evidence of poisoning—management is based solely on the history (the details of exposure). Because histories may be unreliable, the greatest possible exposure should be assumed. The assumption also should be made that all missing pills or contents of commercial products have been ingested by the child who is found with an open container. Every ingestion in suicidal adults and those with unclear histories is potentially serious. When a history is available and reliable, the maximum possible severity should be estimated from either previously reported exposures or predicted blood levels. Unless toxicity is expected to be negligible or the predicted time of peak effects has passed without incident ([Table 309.6](#)), all patients should be decontaminated and undergo a period of observation.

-
1. Time of ingestion and the amount and identity of each and every substance ingested is known with reasonable certainty.
 2. Amount ingested relative to patient weight is less than the smallest dose known or predicted to cause toxicity.
 3. Time elapsed since ingestion is greater than the longest known or predicted interval between ingestion and peak toxicity.
 4. Detailed history and physical examination reveal that the patient is without symptoms and signs of toxicity.
-

TABLE 309.6. Criteria for Nontoxic Ingestion

Early and effective decontamination (discussion follows) may prevent absorption and subsequent toxicity, or at least reduce its severity and duration. Regardless of the method used, the sooner decontamination is performed, the more effective it is. Hence, the history and physical examination should initially be brief or done concurrently with decontamination. Because the onset of toxicity may be precipitous, it is also advisable to establish intravenous access and initiate cardiac monitoring in all patients with potentially toxic exposures.

During the *toxic phase*—from the time clinical or laboratory evidence of poisoning begins until the peak—management is based on the findings of the physical examination; the history and laboratory evaluation are of secondary importance. Resuscitation and stabilization of vital signs are the priorities. If vital signs are abnormal, the history and physical examination should initially be brief, concurrent, or even deferred. Unless toxicity is minimal and expected to remain so, all symptomatic patients should have an intravenous line, cardiac monitoring, supplemental oxygen, continuous observation, and baseline laboratory, ECG, and radiographic evaluation. Those with altered mental status, particularly coma or seizures, should be given an intravenous bolus of glucose and naloxone. Although it will not produce immediate effects, thiamine should be given whenever glucose is given. The empiric use of other antidotes may also be indicated. Unless it is predicted that complete absorption has already occurred, efforts should subsequently be directed toward decontamination and enhancement of poison elimination.

During the *resolution phase*—from the time of peak toxicity to the time of full recovery—management is based primarily on the patient's clinical status. Supportive care should continue until the patient is awake and alert and laboratory and ECG abnormalities have resolved. Clinical relapse may also develop when previously depressed GI function returns and poison still present in the gut is absorbed. A prolonged or cyclic clinical course may indicate a gastric bezoar or drug concretion, necessitating further decontamination. As in the preclinical phase, patients who become asymptomatic may require continued therapy because of a potentially toxic dose or blood level of a chemical, the metabolite of which is more harmful than the parent compound.

Decontamination

Topical Exposures

Immediate flushing with water, saline solution, or any other readily available, clear, drinkable liquid is the initial treatment for topical exposures, particularly those that involve local irritants and corrosives. If possible, particulate material should be manually removed before irrigation. A hand-held vacuum is useful for removing dry or powdered chemicals from the skin. Caregivers should use gloves to avoid contamination. A triple wash (flushing, followed by a soap scrub, and repeat flushing) is suggested for dermal decontamination.

Saline solution is the preferred fluid for eye irrigation. Buffered solutions are better tolerated than unbuffered ones. One or 2 L is usually sufficient. If ophthalmic exposure involves an acidic or alkaline chemical, the tear pH should be determined, although searching for pH paper should never delay treatment. The goal of treatment is a neutral pH (7.0). Tears, not the irrigation fluid, must be tested; the pH of unbuffered normal saline solution averages 5.5.

Patients with inhalational exposures should be rapidly removed from the exposure scene and treated with fresh air or supplemental oxygen. A rescuer should never enter a hazardous gas, vapor, fume, or dust environment without adequate eye, skin, and respiratory protection. Liquid chemicals can be removed from body cavities (e.g., vagina or rectum) by irrigation. Accessible solids (e.g., drug packets and pills) should be removed manually under visual guidance.

Ingestions

The goal of GI decontamination is to prevent the absorption of ingested poisons.¹² Decontamination is accomplished by inducing the evacuation of GI contents either orally or rectally. Syrup of ipecac (SOI), gastric lavage (GL), and activated charcoal (AC), singly or in combination, are the methods most commonly used. Charcoal, in repetitive doses, is also used to enhance the elimination of absorbed poisons. Whole-bowel irrigation (WBI) and endoscopic or surgical removal of the ingested poison are reserved for special situations. Cathartics and dilution are used in conjunction with other modalities but are not, by themselves, effective methods of GI decontamination.

Experimentally, ipecac, lavage, and charcoal are all effective in decreasing poison absorption if used within an hour of the ingestion. The greater the delay between poison intake and initiation of decontamination, the less effective treatment becomes. Unfortunately, the mean time from ingestion of an overdose to presentation to the emergency department is 1 to 2 hours for children and 3 to 4 hours for adults. Not surprisingly, the benefit of performing GI decontamination in most overdose patients has not been clearly established.^{2,3,4,5,6 and 7} Although it is often argued that recovery of pills or pill fragments after ipecac or lavage equates with efficacy of treatment, estimation of drug removal by visual inspection of lavage effluent has not been found to correlate with the measured amount of drug removed. The explanation for this apparent discrepancy is that most pills consist mainly of insoluble excipients. Except for sustained-release formulations, pills are designed so that the drug fraction dissolves and is absorbed rapidly.

Despite these limitations, most overdose histories are uncertain, and it is often difficult to predict which patients will benefit from GI decontamination. Hence, such treatment is recommended for many overdose patients unless the ingestion is clearly nontoxic (see [Table 309.6](#)). Because absorption may be delayed or prolonged after an overdose, it is reasonable to perform decontamination unless more than 2 to 4 hours have elapsed since the time of ingestion. Decontamination may be effective at later times in patients with coma and in those who have ingested agents that have slow dissolution and absorption characteristics (e.g., carbamazepine, enteric-coated tablets, lithium, phenytoin, salicylates, sustained-release preparations, large amounts of solids), form bezoars or concretions (e.g., barbiturates, enteric-coated tablets, glutethimide, iron and other heavy metals, meprobamate, salicylates), or slow gastric emptying and intestinal motility (e.g., anticholinergics, narcotics, sedative-hypnotic agents, salicylates).

The need for decontamination in a particular patient also depends on the predicted severity of poisoning. The method selected should be based on the relative efficacy and contraindications of the different choices or procedures and the nature, severity, and risk of treatment complications as they relate to the substance(s) ingested and clinical toxicity. There is no role for decontamination as an aversive, preventive, or punitive measure in patients who have attempted suicide.

As a guideline, because AC has comparable or greater experimental efficacy and fewer complications and contraindications than ipecac or lavage, it is the preferred method of decontamination for most patients. Awake patients who are easily arousable, coherent, and verbally responsive and who can sit up and drink without assistance can be given charcoal by mouth. The gag reflex alone is not a reliable indicator of the ability to protect the airway. In patients who are uncooperative, awake but confused, or unresponsive, charcoal can be given by a standard-sized nasogastric tube with a negligible risk of complications. In unresponsive patients, an initial dose of charcoal can be given while evaluation, monitoring, and supportive measures are being performed.

Alternative methods of decontamination may be necessary when charcoal is unavailable or the ingested agent is not well absorbed by AC. The safety of ipecac for the home management of asymptomatic patients with accidental ingestions, reliable histories, and mild predicted toxicity is well established. However, there should be compelling reasons (e.g., witnessed ingestion of a potentially severe or lethal overdose) to justify the use of a large-bore lavage tube in a patient with minimal or no symptoms. Much too often, a serious iatrogenic complication (e.g., esophageal perforation) results from the forcible insertion of a large-bore orogastric tube in an uncooperative patient with a trivial ingestion.

Syrup of Ipecac. SOI contains the alkaloids cephaeline and emetine, which produce emesis by irritating gastric mucosa and by stimulating the chemoreceptor trigger zone in the medulla. Emesis can remove ingested material from the stomach and proximal small intestine.³

SOI causes emesis in more than 90% of overdose patients, including those who have ingested antiemetic drugs. The administration of a second dose of SOI results in vomiting in virtually all remaining patients. The mean time from administration of SOI to the onset of emesis is about 20 minutes. Most patients experience three or four episodes of vomiting in the first few hours after administration.

The efficacy of SOI in preventing poison absorption under controlled conditions (i.e., human volunteers taking nontoxic doses of drugs and animals given overdoses of drugs and other chemicals) averages 57% (range, 28% to 73%) if it is given within 5 minutes of poison ingestion, and 30% (range, 2% to 45%) if administration is delayed 30 to 60 minutes. In comparative studies, SOI is less effective than charcoal. It is probably equal in efficacy to lavage. In overdose patients, SOI offers no advantage over charcoal alone (when both treatments are potentially effective), and its use is associated with more complications.

SOI is given orally in a dose of 30 mL for adults, 15 mL for children aged 1 to 12 years, and 10 mL for infants aged 6 to 12 months. The coadministration of water, another clear drinkable liquid, or milk in an amount of 5 to 10 mL/kg is recommended. The incidence, time of onset, and number of episodes of emesis are independent of the amount of fluid given. The effect of fluid volume on the efficacy of drug removal has not been studied.

Advantages of SOI include ease of administration, widespread availability, and a relatively low incidence of complications. Disadvantages are that vomiting is noxious and delayed in onset, and prevents the administration of charcoal and other oral treatments. Vomiting lasts for more than 1 hour (sometimes as long as 8 hours) in 8% to 17% of patients, and may result in electrolyte and fluid imbalances. Giving nothing by mouth for 1 to 2 hours after the onset of vomiting may decrease the incidence of protracted vomiting. Rare but sometimes fatal complications of emesis include tears and perforations of the esophagus and stomach, pneumomediastinum, diaphragmatic rupture, and cerebral hemorrhage in the elderly. Delayed onset of action allows time for pill dissolution, gastric emptying, and drug absorption. Hence, SOI given before charcoal negates the therapeutic advantage of the latter. Aspiration can occur if the patient becomes comatose or has a seizure while vomiting. This complication has been reported in up to 5% of emergency department patients given SOI. Atypical lethargy is a side effect noted in 12% of children given SOI.

SOI is contraindicated in patients with an increased risk of GI perforation (e.g., recent GI surgery, corrosive ingestions) or aspiration (e.g., coma, seizures, ingestion of low-viscosity hydrocarbons and rapidly acting CNS poisons). It should be used with extreme caution, if at all, in patients with altered mental status, pronounced hypertension, or significant cardiovascular or cerebrovascular disease, and in women who are in the third trimester of pregnancy. Because of its prolonged effects, it is not recommended in those with acetaminophen overdoses who are likely to require antidotal therapy.¹⁶

Ipecac poisoning may occur in patients with bulimia or anorexia nervosa who chronically abuse SOI. In addition to complications of vomiting, cardiac dysrhythmias and conduction disturbances, myocardial infarction, myocarditis, and generalized myopathy may occur.

Other methods of inducing emesis include apomorphine, copper sulfate, liquid dishwashing detergent, mechanical stimulation of the pharynx, mustard powder, and salt water, but these are either ineffective or associated with significant toxicity and are not recommended.

Gastric Lavage. GL is a process that removes ingested poisons from the stomach.⁴ Fluid is repeatedly instilled by a nasogastric or orogastric tube, then aspirated or siphoned off. Experimentally, GL decreases the absorption of potential poisons an average of 69% (range, 54% to 84%) if performed within 5 minutes of ingestion, 31% (range, 26% to 38%) if performed at 30 minutes, and 11% (range, 8% to 13%) at 60 minutes. In comparative studies, its efficacy is similar to that of SOI but less than that of charcoal.

GL is performed with the patient in both a left lateral decubitus and a Trendelenburg position. It can be safely performed in nonobtunded patients without an endotracheal tube. Conversely, the presence of a cuffed endotracheal tube does not preclude aspiration if correct patient positioning is neglected. Although it is recommended that the lavage tube be as large as possible (40F for adults, 28F for children) to increase the efficacy of particulate matter removal, no studies support this practice. On the contrary, lavage with a 16F tube was found to be just as effective in removing dissolved drugs as lavage with a 32F tube. Even with the largest tubes, simply comparing the size of the pill with that of the tube's openings and internal diameter will show that removal of intact pills is physically impossible for many drugs. Mercury-weighted, thumb-sized (46F) tubes may overcome this obstacle but are not generally available.

If a large-bore tube is used, it should be inserted orally to avoid nasal trauma. Because of potentially serious complications, only a physician should insert the tube, and struggling patients must be carefully restrained during the procedure. If restraints are necessary, the use of a short-acting sedative such as midazolam is preferable to physical measures. After the tube is inserted, gastric contents should be aspirated before fluid is instilled.

Aliquots of 50 to 250 mL of fluid are recommended. Saline solution should be used in infants to avoid iatrogenic fluid and electrolyte disturbances; for others, tap water is safe. A reusable plastic funnel can be inserted into the lavage tube for fluid instillation and removed during drainage. Gravity (raising and lowering the lavage tube) is preferable to the use of pressure and suction for fluid administration and recovery. Gastric lavage should be continued until the effluent is clear. The use of more than 5 L of fluid is usually not helpful.

Suggestions for increasing the efficacy of GL include epigastric massage (to enhance the mixing and suspension of gastric contents), the use of warmed fluids (to increase pill dissolution), and the instillation of air (to prevent stomach collapse and obstruction of lavage tube openings by gastric mucosa). Experimentally, the

administration of a dose of charcoal before, as well as after, GL is more effective than the usual practice of giving charcoal only after lavage is completed. Charcoal is also a readily visible marker that can be used to assess the completeness of GL.

The main advantage of GL is that it can be used in obtunded patients. The disadvantages are that it is an invasive, noxious, and skilled procedure, with the risk of significant complications if incorrectly performed. Although significant fluid and electrolyte derangements are uncommon, aspiration occurs in up to 10% of patients. The incidence of serious complications, such as esophageal and gastric perforation and inadvertent tracheal insertion and pulmonary lavage, may be as high as 1%. In one series, complications of GL were thought to have contributed to death in over one-third of lavaged patients who subsequently died.²⁰ Due to an increased risk of complications, GL is generally contraindicated in patients with low-viscosity hydrocarbon and corrosive ingestions. The use of alternative decontamination measures should strongly be considered before resorting to gastric lavage, particularly in patients who are not seriously ill or who present more than 1 to 2 hours after ingestion.

Activated Charcoal. AC is an odorless, tasteless, insoluble, fine, black carbon powder that is produced (activated) by the pyrolysis and oxidation of carbon-containing materials such as petroleum and wood. Each particle of AC has an extensive internal network of branching, irregular, interconnecting channels (pores) ranging from 10 to 105 nm in diameter. Pores account for the large surface area—950 to 2,000 m²/g for commonly used preparations.

The adsorption (adherence) of substances to the external and internal surfaces of AC occurs within 1 to 2 minutes of contact and is reversible. Increasing the ratio of AC to poison decreases the amount of free (unadsorbed) poison. At an AC–poison ratio of 10:1 or greater, *in vitro* studies indicate that 90% or more of most drugs is adsorbed to AC. The maximum amount of a chemical that can be adsorbed by AC (the binding capacity) varies from a few milligrams to more than 1,000 mg/g of AC.

The greater the surface area of AC and the greater the molecular size, dissolution rate (only molecules in solution are adsorbable), lipid solubility, and electrical neutrality of the poison, the greater the binding capacity. Hence, small, highly charged (ionized), readily dissociable inorganic molecules, such as those of mineral acids, alkalis, and salts of cyanide, fluoride, iron, and lithium, are poorly adsorbed by AC.

AC prevents the absorption of ingested poisons by binding them within the gut lumen, allowing the AC–poison complex to be evacuated per rectum.⁵ Cathartics are often used concurrently to enhance the rectal evacuation of the complex and to prevent constipation. Experimentally, AC decreases the absorption of potential poisons an average of 68% (range, 14% to 99%) when given within 5 minutes of poison administration, 50% (range, 17% to 75%) when given at 30 minutes, and 50% (range, 9% to 78%) at 60 minutes. Analogous to the results of *in vitro* studies, an AC–poison ratio of 10:1 or greater decreases the absorption of most agents by more than 90%. Diluting charcoal in large volumes of lavage fluid is less effective than giving the same dose in a concentrated bolus, probably due to mass action effects on the binding equilibrium.

The ability of AC to prevent poison absorption usually correlates directly with its ability to adsorb drugs *in vitro*. However, cyanide, malathion, and tolbutamide are poorly adsorbed to charcoal *in vitro*, yet their absorption or activity is significantly reduced by AC *in vivo*. Conversely, ethanol (and probably other low-molecular-weight hydrocarbons), ipecac, and *N*-acetylcysteine are relatively well adsorbed by AC *in vitro*, yet AC has minimal effects on their *in vivo* absorption and activity. Hence, antidotal efficacy should ultimately be determined by *in vivo* testing and clinical studies.

Experimentally, AC is equal or superior to SOI and GL in preventing poison absorption. Analogous results are noted in clinical studies. In awake overdose patients, AC is equal or superior to SOI when improvement or deterioration in clinical status, length of stay in the emergency department, and complications of treatment are used to measure efficacy. In obtunded patients, AC alone is as effective as GL followed by AC in patients who present more than 1 hour after overdose. It is unclear whether it is equally or less effective than combined treatment in those who present within 1 hour of ingestion.

AC is given as a suspension in water, using 8 mL of diluent per gram of AC powder if a premixed formulation is unavailable. Commercial preparations may contain propylene glycol and carboxymethylcellulose as lubricants and sorbitol as a cathartic. The recommended dose is at least ten times the weight of the ingested poison, or as much as possible if the amount ingested is unknown. Because of volume constraints, the maximum amount of AC that can be given as a single dose is limited to 1 to 2 g/kg. Hence, large-surface-area charcoals are theoretically preferable, particularly for large ingestions (5 to 10 g or more).

AC can be given by a drinking glass, nipples bottle (for infants), or gastric tube. Acceptability and palatability may be increased by giving it through a straw from a covered opaque container. Adding a sweetener or flavoring agent may improve palatability but decreases the absorptive capacity.

The advantages of AC are its safety, ease of administration, rapidity of action, and lack of contraindications. The main disadvantages are limited patient and staff acceptability because of its color, gritty taste, and ability to stain clothing and its low binding capacity for some poisons. Side effects include nausea, vomiting, abdominal cramps, diarrhea, and constipation. It is unclear whether these effects are due to charcoal itself, excessive fluid volume, the ingested poison, or coadministered cathartics. Because charcoal is inert and nonabsorbable, complications are mechanical in nature and include aspiration pneumonitis and mechanical obstruction of the airway and bowel due to inspissated charcoal. Because of pH changes, acidic agents such as aspirin may become ionized and desorb from AC and be absorbed from the small intestine; the use of large or multiple doses of AC may prevent such occurrences. AC may also prevent the enteral absorption (or enhance the elimination) of therapeutically administered agents, necessitating the use of larger-than-usual doses.

Although AC may not be beneficial in patients who have ingested agents that it adsorbs poorly, it should be given to those who have an equivocal history or who have ingested multiple agents. It is not recommended for pure ingestions of nonabsorbable corrosives (e.g., most acids and alkalis) because it may obscure endoscopic assessment of damage to the GI tract.

Whole-Bowel Irrigation. WBI prevents poison absorption by enhancing its rectal evacuation.⁷ Although experimental data are limited, WBI is more effective than either SOI or GL and more or less effective than AC in preventing poison absorption. It may be advantageous in patients who have ingested potentially toxic foreign bodies, drug packets, iron, and enteric-coated or sustained-release medications. Continuous WBI may also be effective in enhancing the elimination of drugs that are already absorbed by dialyzing the GI tract.

WBI is performed by giving a bowel-cleansing solution that contains electrolytes and polyethylene glycol (e.g., Colyte, GoLYTELY), orally or by a gastric tube, until the rectal effluent is clear. The patient must be in a sitting position. The recommended rate of fluid administration is 0.5 L/h in children and 2 L/h in adults. Fluid and electrolyte derangements are potential complications.

Endoscopy and Surgery. The absorption of poisons may also be prevented by removing them from the stomach by endoscopic snares and baskets or from anywhere along the GI tract by surgery. Endoscopy may be indicated when a potentially toxic foreign body fails to pass beyond the pylorus, when pill bezoars or concretions are present in the stomach, or when a potentially lethal dose of a heavy metal such as arsenic, iron, mercury, or thallium is radiographically visible in the stomach. Endoscopy should not be used for the removal of ingested drug packets, because the endoscope may rupture them.

Immediate surgical intervention is indicated in patients who ingest large numbers of cocaine packets and become toxic due to leakage or rupture of the packaging. Surgery should also be considered for the same situations as endoscopy when the latter is unsuccessful.¹⁶

Cathartics. Cathartics include osmotically active salts such as magnesium citrate, magnesium sulfate (Epsom salt), and sodium sulfate (Glauber's salt) and saccharides such as mannitol and sorbitol, which promote the rectal evacuation of GI contents by causing fluid retention, and hence increased bowel motility.⁶ They are primarily used as an adjunct to AC to enhance its evacuation. When used alone or with SOI or GL, they have little, if any, benefit.

Sorbitol, the preferred agent, is the most effective cathartic in terms of shortening the GI transit time of bowel contents. Sorbitol is available as a 70% solution and with AC in premixed suspensions. The recommended dose is 1 to 2 g/kg. Saline cathartics are available in various concentrations and are given in a dose of about 250 mg/kg. Castor, mineral, and vegetable oil; phenolphthalein; and disodium phosphate (Fleets salt) are not recommended.

Side effects include nausea, abdominal cramps, vomiting, and excessive diarrhea. Dehydration and electrolyte abnormalities may result from repeated dosing and are sometimes fatal. Hypermagnesemia with lethargy, weakness, loss of reflexes, and even coma may occur with multiple doses of magnesium-containing salts. Hypocalcemia and hypernatremia may also occur. Cathartics are contraindicated in patients with corrosive ingestions or spontaneous diarrhea, and should be used with extreme caution in patients with congestive heart failure or renal failure.

Dilution. Dilution is used to decrease the local effects of ingested corrosives by lowering their concentration. It is accomplished by having the patient drink up to 5 mL/kg of water or another clear, drinkable liquid. Greater amounts of fluid may precipitate emesis due to gastric distention and should be avoided. To be effective, dilution must be accomplished immediately (within minutes) but is generally given “as soon as possible.” As with cathartics, dilution alone is ineffective in preventing poison absorption; in fact, dilution may facilitate the dissolution of pills and drugs, thus enhancing absorption.

Supportive Care

The goal of supportive therapy is to maintain physiologic homeostasis until detoxification is accomplished. It is also necessary to prevent or treat secondary complications, such as aspiration, bedsores, cerebral and pulmonary edema, rhabdomyolysis, sepsis, and generalized organ dysfunction. Although supportive care is not specific to the management of poisoned patients, aspects of special relevance are discussed subsequently. The reader is referred to poison-specific chapters for further details.

The need for oxygenation and mechanical ventilation is best determined by arterial blood gas analysis. Although this need may be obvious in patients with severe CNS depression or excitation, clinical assessment of these parameters is not always reliable. In addition, because aspiration is a preventable complication of treatment (e.g., GI decontamination), as well as of poisoning, prophylactic endotracheal intubation is often required for airway protection. The gag reflex alone is not a reliable indicator of the need for intubation: Many healthy people have an absent gag reflex, and many comatose patients will gag with sufficient stimulation. Similarly, patients may be able to maintain a patent airway while being stimulated but not if left unattended. Hence, those who cannot respond to and by voice, or who cannot sit up and drink fluids without assistance, are best managed by intubation. A short-acting sedative or muscle relaxant is useful in facilitating intubation in patients with low-grade coma. Patients with high-grade physiologic excitation may require intubation for airway protection and to allow the pharmacologic control of seizures or behavioral agitation, to prevent or limit the extent of complications (e.g., hyperthermia, acidosis, rhabdomyolysis).

The initial treatment of pulmonary edema in poisoned patients should also include early endotracheal intubation. Because many cases are noncardiac in etiology (e.g., acute respiratory distress syndrome due to inhalational injury, prolonged apnea, or shock), the use of positive end-expiratory pressure is often beneficial. Iatrogenic fluid overload and myocardial depression often contribute to pulmonary edema in hypotensive patients. In such cases, an inotropic vasopressor (e.g., dopamine) is the treatment of choice. Only when the blood pressure has been normalized should a diuretic be given.

Supraventricular tachycardia associated with generalized physiologic stimulation is usually not hemodynamically compromising and requires only observation or nonspecific sedation (e.g., a benzodiazepine). However, if extreme hypertension, chest pain, or ECG evidence of ischemia is present, specific therapy is indicated. The use of a nonselective adrenergic blocker (e.g., labetalol) or both a beta blocker and a vasodilator (e.g., esmolol or propranolol and nitroprusside) is preferred for patients with sympathetic hyperactivity. Physostigmine is the treatment of choice for those with a purely anticholinergic cause.

Lidocaine is generally safe to use for ventricular tachyarrhythmias of any etiology. Procainamide and other class IA antiarrhythmics should be avoided in patients with poisoning by membrane-active agents because of their similar (and hence additive) electrophysiologic effects. Sodium bicarbonate may be therapeutic for dysrhythmias caused by cyclic antidepressants and other membrane-active agents. Patients with torsades de pointes and digitalis poisoning may respond to magnesium. Overdrive pacing (by isoproterenol or electricity) may be necessary in those with prolonged Q-T intervals. Antibody therapy as well as pacing should be considered for dysrhythmias caused by digitalis.

Bradycardias associated with hypotension should initially be treated with atropine, isoproterenol, and intravenous fluids. In patients with beta-blocker and calcium-channel blocker poisoning, the administration of calcium and glucagon may obviate the need for cardiac pacing. The treatment of bradycardia secondary to hypertension or increased intracranial pressure should be directed at the primary cause. In patients with a dysrhythmia, underlying metabolic abnormalities and extremes of temperature must be corrected.

Hypotension in poisoned patients is more often due to loss of vascular tone than to cardiac depression. It should initially be treated with crystalloids. If vasopressors are subsequently required, direct-acting agents (e.g., norepinephrine, high-dose dopamine) are preferred, because some chemicals (e.g., cyclic antidepressants) deplete endogenous catecholamines. Advanced cardiovascular and pulmonary supportive measures, such as extracorporeal membrane oxygenation, intraaortic balloon pump counterpulsation, and partial cardiopulmonary bypass pump assistance, should also be considered in severe but reversible poisoning.

Seizures caused by central excitatory neuroreceptor stimulation (e.g., those caused by sympathomimetics, hallucinogens, or drug withdrawal) or inhibitory neuroreceptor depression (e.g., the antagonism of gamma-aminobutyric acid [GABA] and glycine receptor activity by isoniazid and strychnine, respectively) are best treated with a GABA “agonist,” such as a benzodiazepine or a barbiturate. Pyridoxine, which is converted to a cofactor required for GABA synthesis, is usually necessary to stop seizures caused by isoniazid, because this agent inhibits GABA synthesis and because GABA agonists act, at least partially, by causing GABA release from presynaptic nerve endings.

In contrast, seizures caused by agents that stabilize neuronal membranes (e.g., beta blockers, cyclic antidepressants) are best treated with phenytoin, a membrane-active agent. For neurobehavioral hyperactivity resulting from central dopaminergic stimulation (e.g., phencyclidine poisoning), the dopamine antagonist haloperidol is preferred. Specific antidotes may be necessary in certain cases, such as anticholinergic, cyanide, or opioid poisoning.

Regardless of the cause, it is always prudent to give dextrose. Because prolonged convulsions can lead to rhabdomyolysis and severe acidosis (each resulting in additional complications), the use of paralyzing neuromuscular blocking agents is indicated in refractory cases. Continued seizure treatment, as indicated by electroencephalographic monitoring, is necessary to prevent permanent neurologic damage. In all patients, contributing metabolic and physiologic abnormalities (e.g., cerebral edema or ischemia) should be corrected.

Antidotal Therapy

Antidotes are chemicals that counteract the effects of poisons. They act by a variety of mechanisms: neutralization by antibody–antigen reactions, chelation, or chemical binding; physiologic antagonism by blocking or reversing the interaction of a chemical and its target site; activation or inhibition of an opposing division of the nervous system; and altered disposition by enhancing or inhibiting metabolism, excretion, or secretion. Although antidotes can reduce morbidity and mortality, relatively few poisons and toxic syndromes have antidotes ([Table 309.7](#)). Antidotes can themselves be toxic, so their indiscriminate use should be avoided. Details regarding the use of antidotes are provided in the appropriate poisoning chapters.

Acetaminophen	Cholinergics	Hypoglycemics
Anticholinergics	Cyanide	Isoniazid
Anticoagulants	Digitalis	Methanol
Benzodiazepines	Ethylene glycol	Methemoglobinemia
Beta blockers	Envenomations	Opioids
Calcium channel blockers	Fluoride	Sympathomimetics
Carbon monoxide	Heavy metals	Vacor (PNU)
	Hydrogen sulfide	

TABLE 309.7. Chemicals and Related Syndromes with Specific Antidotes

Enhancement of Elimination

Although the elimination of many chemicals can be accelerated by various therapeutic interventions ([Table 309.8](#)), the clinical efficacy of such interventions is often

insignificant. Pharmacokinetic efficacy requires that a significant fraction of a chemical dose be eliminated at a rate significantly greater than that accomplished by intrinsic mechanisms. Clinical efficacy implies a shortened duration of toxicity and improved patient outcome. In most instances, if vital signs can be adequately supported, the poison will be intrinsically detoxified and full recovery will follow. Hence, the decision to use an active removal procedure should be based on the actual or predicted maximal severity of the poisoning and the risk (i.e., invasiveness, complications) of the procedure. In addition, invasive procedures are expensive and require technical expertise and specialized equipment. Diagnostic certainty, usually by way of laboratory confirmation, is therefore a prerequisite.

Chelation therapy	Forced diuresis
Extracorporeal techniques	Gastrointestinal dialysis
Peritoneal dialysis	Hyperbaric oxygenation
Hemodialysis	Multiple-dose activated charcoal
Hemoperfusion	Urine pH manipulation
Hemofiltration	
Plasmapheresis	
Exchange transfusion	

TABLE 309.8. Methods of Enhancing Chemical Elimination

The use of extracorporeal procedures should be limited to patients who would not otherwise have a favorable outcome: those with severe clinical or laboratory toxicity who do not respond to supportive care and noninvasive elimination therapy; those with blood levels predictive of a significant risk of severe, irreversible, or prolonged toxicity, particularly if an invasive procedure is the only or most effective method of enhancing elimination; those who lack the capacity for self-detoxification because of liver or kidney failure; and those who have serious underlying illnesses or complications of poisoning that would adversely affect recovery.

Chelation therapy is covered in the chapters on heavy-metal poisoning. Hyperbaric oxygenation is discussed in the chapters on carbon monoxide, hydrogen sulfide, and cyanide poisoning and methemoglobinemia. Intestinal dialysis has been discussed in this chapter.

Multiple-Dose Activated Charcoal

When given in repeated doses, AC can enhance the elimination of absorbed poisons by adsorbing them in the gut lumen as they undergo biliary excretion, intestinal secretion, or passive diffusion from higher concentrations in blood perfusing intestinal surfaces to low concentrations in luminal fluids (i.e., enterocapillary exsorption).⁸ The efficacy of multiple-dose AC (MDAC) therapy depends on the adsorbability of the poison to AC and its pharmacokinetic properties but is independent of the initial route of poison absorption (e.g., orally versus intravenously). As with other dialysis techniques, efficacy is probably greatest with agents that have relatively low molecular weights, small volumes of distribution, low protein binding, and high lipid and water solubility. Experimentally, MDAC therapy is effective in enhancing the elimination of most substances tested, but its clinical efficacy (i.e., shortened duration of toxicity) remains to be proven. For some agents (e.g., phenobarbital, theophylline), its efficacy approaches that of hemodialysis.

In patients with normal bowel activity, MDAC in a dose of 0.5 g/kg of AC every 4 hours is usually well tolerated. Increasing the cumulative dose of AC by giving it in larger individual doses or at more frequent intervals increases efficacy. In patients with decreased GI motility or vomiting, MDAC may be better tolerated if given in smaller doses at more frequent intervals or by slow, continuous nasogastric infusion. The dosage of AC should be reduced or eliminated in the event of regurgitation or gastrostasis. Although the coadministration of cathartics is recommended, magnesium-containing agents should not be used, and the dose must be carefully titrated to bowel activity to avoid excessive diarrhea with fluid and electrolyte losses.

Enhanced Urinary Excretion

Diuresis and ion trapping by altering the urinary pH may prevent the passive renal tubular reabsorption of chemicals that enter the urine by glomerular filtration and active tubular secretion, and thus increase their excretion.¹¹ Because biologic membranes are more permeable to un-ionized molecules than to their ionized counterparts, acidic (low pK_a) chemicals are ionized and trapped in an alkaline urine, and basic chemicals are ionized and trapped in an acid urine. Saline diuresis can enhance the excretion of bromide, calcium, lithium, potassium, and isoniazid. Alkaline diuresis is effective for acidic herbicides (i.e., 2,4-D and 2,4,5-T), chlorpropamide, phenobarbital (and probably other long-acting barbiturates), and salicylates. Acid diuresis, although it enhances the excretion of amphetamines, cocaine, phencyclidine, quinine, quinidine, and strychnine, is not recommended, because the risks are significant and clinical efficacy has not been established.

The goal of diuresis is a urine flow of at least 3 mL/kg/h; that of alkalization is a urine pH of 7.5 or greater. An intravenous alkaline diuresis solution can be prepared by adding one to three ampules (44 to 132 mEq) of sodium bicarbonate to 1 L of appropriately hypotonic fluid so that the final solution is roughly isotonic. The carbonic anhydrase inhibitor acetazolamide should not be used to alkalize the urine, because it may produce a concomitant acidemia and enhance the tissue distribution of acidic chemicals. Acid–base, fluid, and electrolyte parameters as well as clinical response must be carefully monitored during therapy. Contraindications include congestive heart failure, kidney failure, and cerebral or pulmonary edema.

Extracorporeal Elimination

Extracorporeal techniques (see [Table 309.7](#)) theoretically can remove any diffusible chemical from the bloodstream.¹² Dialysis is most effective in enhancing the elimination of agents with a low molecular weight (less than 500 daltons), high water solubility, low protein binding, small volume of distribution (less than 1 L/kg), slow intrinsic elimination (i.e., long half-life), and high dialysis clearance relative to total body clearance. The efficacy of other extracorporeal procedures is not limited by molecular weight, water solubility, or protein binding.

Chemicals considered dialyzable with respect to both kinetic and clinical efficacy include bromide, chloral hydrate, ethanol, ethylene glycol, isopropyl alcohol, lithium, heavy metals, methanol, and salicylate. Although hemoperfusion may be more effective in removing some of these poisons, it does not readily correct associated acid–base and electrolyte abnormalities. Hemoperfusion is the preferred technique for enhancing the elimination of chloramphenicol, disopyramide, sedative–hypnotics (e.g., barbiturates, ethchlorvynol, glutethimide, meprobamate, methaqualone), phenytoin, and theophylline. Both techniques require central venous access and systemic anticoagulation, and may cause hypotension and bleeding complications. Hemoperfusion may also result in hemolysis, hypocalcemia, and thrombocytopenia.

Peritoneal dialysis is less effective, but it may be used when other extracorporeal procedures are unavailable, contraindicated, or technically difficult (e.g., in infants). Exchange transfusion is also less effective, but it may be used in the same situations, as well as for poisons that cause severe hemolysis or methemoglobinemia. The role of other extracorporeal techniques has not been defined. After the termination of any invasive elimination procedure, clinical relapse or a rebound increase in the blood level of a chemical may occur as it undergoes tissue redistribution.

DISPOSITION

After evaluation, treatment, and an appropriate observation period, asymptomatic patients may be discharged from the emergency department. The disposition of symptomatic patients depends on the actual or predicted severity and the need or potential need for therapeutic interventions. Most patients develop only mild toxicity and can be observed in the emergency department or comparable facility until asymptomatic. Those with significant (grade 3 or 4) physiologic stimulation or depression, hypoxia, hypercarbia, acid–base disturbances, metabolic abnormalities, extremes of temperature, and cardiac conduction or rhythm abnormalities should be admitted to an intensive care unit.^{10,14} Patients who require close monitoring of antidotal therapy or high-risk elimination procedures, those showing progressive clinical deterioration, and those with significant underlying medical problems are also candidates for the intensive care unit.

Patients with moderate toxicity can be admitted to a general medical floor, intermediate care unit, or emergency department observation area, depending on the anticipated duration of toxicity and the level of monitoring needed (e.g., intermittent clinical observation versus continuous clinical, cardiac, and respiratory monitoring). Lack of resources for the constant behavioral observation of suicidal patients may require a higher level of care than is medically necessary.

Consultation with a poison control center or toxicologist is recommended whenever the treating physician is not completely familiar with the specific chemical(s) involved in a given exposure or poisoning. Consultation with other specialists is dictated by the nature of the injury and its actual or potential severity.

The possibility of reexposure and its prevention must be addressed before discharge. Suicidal patients require psychiatric assessment, disposition, and follow-up. Prescriptions given to depressed or psychotic patients should be written for a limited amount of the drug and a limited number of refills. Such patients also require close monitoring for compliance with and response to therapy. Drug abusers should be referred for counseling and given the opportunity for rehabilitation.

The environment of all children must be poison-proofed. Parents and other caretakers should be instructed to store alcoholic beverages; medications; all automotive, cleaning, cosmetic, fuel, painting, and pet care products; nonedible plants; vitamins; and toiletries above or out of the child's reach or in cabinets with locks or childproof latches. Safety caps are always advisable, but are not necessarily sufficient to prevent access by children.

Adults with accidental home exposures should be instructed regarding the safe use of drugs and other chemicals. They should be advised to read the instructions on the label carefully and to avoid circumstances that caused the current problem. In environmental or workplace exposures, the appropriate governmental agency (e.g., EPA, OSHA, NIOSH, local health department) should be notified. Unsafe working conditions should also be brought to the attention of the employer. Assistance with the administration of medications should be arranged for confused patients with accidental exposures due to dosing errors. Preventive education is particularly important in cases of dosing errors committed by health-care providers.

COMMON PITFALLS

- Failure to consider the diagnosis of poisoning in patients with unexplained signs and symptoms of any nature
- Failure to appreciate the limitations of toxicology screening
- Failure to initiate routine and advanced supportive care when clinically indicated
- Failure to treat the patient, not the poison (or, with few exceptions, its blood level)
- Using ipecac syrup in patients who have ingested hydrocarbons, corrosives, or rapidly acting CNS and cardiovascular poisons
- Failure to appreciate that activated charcoal is the most effective and least hazardous method of GI decontamination
- Failure to address preventive measures before discharge

CHAPTER 310 Acetaminophen Poisoning

Jeffrey Brent

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Acetaminophen (*N*-acetyl-*p*-aminophenol, or APAP) is one of the most common over-the-counter medications used in the United States. Given its widespread use and availability, it is an extremely common overdose. Because many laypeople underestimate its toxicity, suicide gestures may result in actual suicides. In 1998, over 100,000 potential APAP poisonings were reported in the American Association of Poison Control Centers' annual report. These are undoubtedly only a fraction of the total number of cases.

Acetaminophen itself is a nontoxic molecule. It is almost entirely metabolized in the liver by the pathways shown in [Fig. 310.1](#). About 94% of an ingested dose of APAP is metabolized to glucuronide (42%) or sulfate (52%) conjugates and excreted as such in the urine. ⁷ Of the remaining APAP, about half is excreted unchanged in the urine and a similar amount is metabolized by the hepatic P-450 mixed-function oxidase (MFO) system to form a highly reactive intermediate. ⁷ With therapeutic doses, this intermediate is conjugated to glutathione and excreted as the inactive mercapturate conjugate plus other minor metabolites. ^{7,17} Toxicity occurs when stores of glutathione are depleted by about 70%, thus rendering the cell vulnerable to the effects of the MFO product. ^{7,10} Histologically, necrosis occurs at centrilobular (or perivenular) portions of the hepatic lobule. ⁵

Figure 310.1. Proposed metabolic pathways for acetaminophen metabolism in children. (From Peterson RG, Rumack BH. Hgc as a variable in acetaminophen overdose. *Arch Intern Med* 1981;141:391, with permission.)

Although the clinical picture of APAP overdose is predominantly one of hepatotoxicity, some patients also have nephrotoxicity. ²⁰ This is probably most commonly due to renal APAP metabolism by kidney MFOs. In addition, renal failure is an occasional concomitant complication of severe APAP-induced hepatotoxicity due to the hepatorenal syndrome.

The first stage of APAP poisoning is a relatively subtle period in which APAP is being absorbed and metabolized, glutathione stores are being consumed, and hepatotoxicity is beginning. This phase typically lasts less than 24 hours. Interventions to blunt the evolving hepatotoxicity are most effective during this early phase.

The second phase is entirely different. During this period, which usually begins late on the day of the ingestion, there is little APAP in the plasma. The hepatotoxic effects of MFO metabolites that have not been inactivated by glutathione become manifest during this time. The predominant clinical picture becomes one of hepatotoxicity.

There is a clear relation between the plasma level of APAP and the potential for toxicity, as demonstrated by the nomogram developed by Rumack and Matthew ([Fig. 310.2](#)).¹⁴ The nomogram stratifies patients into risk categories of “probable” or “possible” hepatotoxicity. The validity of this nomogram was confirmed in a national multicenter study.¹⁸ The “possible risk” category actually is a region in which toxicity would not be expected to occur, but it represents a 25% margin of error to account for possible errors in establishing the time of ingestion. The value of treating low-risk patients in the “possible toxicity” region of the nomogram has been questioned.¹ The nomogram begins at 4 hours after ingestion. Plasma APAP levels obtained before this time—during the absorption and distribution phases—are difficult to interpret. However, early APAP levels of less than 100 µg/mL predict a lack of risk for toxicity. ³

Figure 310.2. Rumack–Matthew nomogram for acetaminophen poisoning. Relation between plasma APAP levels and toxicity correlated with time after exposure. (From Rumack BH. *Pediatr Clin North Am* 1986;33:691, with permission.)

The APAP nomogram is based on presenting levels. Repeat levels offer no further useful information and should not be routinely obtained. Based on the known volume of distribution of APAP of 0.9 to 1.0 L/kg, an ingestion of 10.5 g APAP in a 70-kg adult, or 150 mg/kg in a child, may cause toxic levels. The current nomogram is derived from adults. Although children with toxic plasma levels appear to be less susceptible to APAP toxicity than are adults, ¹³ the same nomogram should be used.

Patients who have ingested a potentially toxic amount of APAP and have a history of alcoholism, chronic liver disease, or malnutrition may be more susceptible to APAP hepatotoxicity because of decreased glutathione stores. Conversely, patients with liver disease, and, consequently, poorly functioning MFOs, may be relatively protected because of inability to generate the toxic metabolite. These patients should also be evaluated using the standard nomogram. Alcoholics without liver disease, who have both induced MFO systems (which generate the toxic metabolite) and depressed hepatic glutathione stores, and patients with acute illnesses associated with poor oral food intake (i.e., acute starvation) appear to be more susceptible to the hepatotoxic effects of APAP. However, given the large therapeutic

index for APAP, this population would not be expected to be at enhanced risk when normal therapeutic doses are used.

CLINICAL PRESENTATION

The evolution of APAP toxicity can be divided into four sequential stages ([Table 310.1](#)). In the first 24 hours, patients may experience only nausea, vomiting, and malaise. Patients who present in stage II or III may have right upper quadrant pain, nausea, vomiting, jaundice, bleeding, encephalopathy, and symptoms of fulminant hepatic failure. Associated with this is a progressive increase in bilirubin, alanine aminotransferase (ALT), and aspartate aminotransferase (AST) levels, and prothrombin time. These liver function abnormalities can be dramatic in their magnitude, with ALT and AST levels of 10,000 to 20,000 not uncommon. In most cases, these abnormalities peak in 48 to 96 hours (stage III) and gradually resolve. Liver function test results usually return to normal within days after they peak (stage IV).

Stage	Time after Ingestion	Characteristics
I	0–24 h	Anorexia, nausea, vomiting, malaise, pallor, diaphoresis
II	24–48 h	Resolution of above; right upper quadrant abdominal pain and tenderness; elevated bilirubin, prothrombin time, hepatic enzymes; oliguria
III	72–96 h	Peak liver function abnormalities; anorexia, nausea, vomiting, malaise may reappear
IV	4 d–2 wk	Resolution of hepatic dysfunction or fulminant hepatic failure

Modified from Linden CH, Rumack BH: Acetaminophen Overdose. *Emerg Med Clin North Am* 1982;13:3.

TABLE 310.1. Stages in the Clinical Course of Acetaminophen Toxicity

The occasional patient with severe, untreated APAP toxicity exhibits a pattern of rising prothrombin time and bilirubin and ammonia levels as the AST and ALT decline. This pattern signifies severe hepatic failure. However, most patients, even those with severe hepatotoxicity, eventually recover, with normal livers.

DIFFERENTIAL DIAGNOSIS

In the earliest stage of APAP poisoning, the diagnosis is made by a history suggestive of overdose. No consistently reliable or pathognomonic signs or symptoms can be expected. Hence, the physician must consider the possibility of occult APAP poisoning when confronted with any overdose patient. The finding of any APAP in the plasma must alert the clinician to the possibility of a toxic APAP ingestion.

The patient who presents in stage II, III, or IV of APAP toxicity is another kind of diagnostic challenge. By this time, there may be little detectable APAP in the serum, so the diagnosis depends on the history and clinical suspicion.

The differential diagnosis of hepatic injury includes, most commonly, viral or chemical etiologies. Virtually any drug can cause hepatotoxicity as an idiosyncratic reaction. The correct diagnosis requires an astute history supplemented by laboratory studies. One particularly difficult diagnostic quandary is distinguishing between Reye syndrome and APAP toxicity in the child given acetaminophen for an antecedent viral syndrome. The chemistry profiles typically seen with the different types of hepatitis are shown in [Table 310.2](#). As shown in [Fig. 310.3](#), liver function test results may not rise dramatically until a day after the ingestion.

Hepatotoxic	Acute Viral		
	Studies	AST (IU/L)	ALT (IU/L)
Viral	Usually positive	Hundreds to low thousands	Variable but less than AST
Alcohol	Negative	Usually <100 or 10 × normal	Usually 100 and ALT/AST >2
APAP	Negative	May be very high	Much less than AST

AST, aspartate aminotransferase; ALT, alanine aminotransferase.

TABLE 310.2. Laboratory Values in the Common Acute Hepatitides: Viral, Alcoholic, Acetaminophen

Figure 310.3. Dotted line: the course of those who received acetylcysteine. Solid line: those with natural course. Dotted-dashed line: those with a severe course. (From Rumack BH, et al. Acetaminophen overdose. *Arch Intern Med* 1981;141:380, with permission.)

EMERGENCY DEPARTMENT EVALUATION

In all overdose patients, excessive APAP ingestion should be ruled out by a nontoxic APAP level. For patients who have detectable plasma APAP levels, the time of ingestion must be determined as accurately as possible. If this cannot be done, the possibility of a toxic ingestion at an unknown time must be considered. Therefore, if there is detectable APAP and an unknown time of ingestion, or if the patient has abnormal liver function tests, possibly resulting from an APAP overdose, *N*-acetylcysteine (NAC) therapy should be instituted ([Table 310.3](#)). If the patient needs treatment, baseline liver function tests (AST, ALT, and total bilirubin levels and prothrombin time) and renal function tests (blood urea nitrogen and creatinine levels and urinalysis) should be obtained.

Length	Administration	Loading Dose	Subsequent Doses	FDA Approval	Reference
I 72 h	Oral	140 mg/kg	70 mg/kg q6h for 17 doses	Yes	15
II 24 h	IV	150 mg/kg over 15 min	50 mg/kg over 4h, followed by 100 mg/kg over 16 h	No	12
III 48 h	IV	140 mg/kg	70 mg/kg q6h	No	19

TABLE 310.3. Protocols for N-Acetylcysteine Administration

EMERGENCY DEPARTMENT MANAGEMENT

After advanced life-support measures are performed, if necessary (e.g., for coingested agents), treatment of the patient with an acute APAP overdose includes stopping absorption and administering NAC when indicated.

Patients who have overdosed on APAP should receive activated charcoal if they present within 4 hours of ingestion. Because charcoal therapy does not have a clinically significant effect on NAC levels, it is unnecessary to increase the NAC dose when the patient is receiving both of these therapies.² However, charcoal and NAC should not be mixed together before administration. The routine use of gastric emptying, by syrup of ipecac or lavage, appears to have little role and should be avoided.

If an APAP level is unavailable by 8 hours after ingestion, a history (or suspicion of APAP overdose) is sufficient to warrant the initiation of NAC therapy until the plasma APAP levels are known.

The most efficacious treatment for APAP overdose is the administration of NAC.^{12,15,18,19} NAC is metabolized by hepatocytes to cysteine, a precursor of glutathione. NAC also enhances APAP sulfation, potentially leaving less APAP available to the MFO system (see [Fig. 310.1](#)). NAC therapy is almost 100% effective in preventing APAP toxicity if it is started within 8 hours of the ingestion, independent of the plasma APAP level.¹⁸ Delay in starting therapy beyond this time results in a progressive diminution of the effectiveness.^{15,18}

Three protocols are in use for the treatment of APAP overdose (see [Table 310.3](#)). The only one approved by the Food and Drug Administration (FDA) is the 72-hour oral protocol. Preliminary evidence shows that the 48-hour intravenous protocol is at least as efficacious, and it is hoped that FDA approval for this will be forthcoming.¹⁹

The use of intravenous NAC has other advantages. Giving oral NAC can be challenging. Because it tastes and smells like rotten eggs, it is poorly tolerated. Emesis after NAC ingestion is common; if it occurs within an hour of the dose, the dose should be repeated in full. NAC is available as the mucolytic agent Mucomyst in a 10% or 20% solution. Before administration, it should be diluted to 5% in a soft drink to increase its palatability. It is also helpful to have the patient drink it through a straw from a closed container to prevent the unpleasant vapors from causing emesis. If emesis occurs during NAC administration, droperidol (Inapsine; 1.25 to 2.5 mg [0.5 to 1.0 mL] in adults, 0.1 to 0.15 mg/kg [0.04 to 0.06 mL] in children), metoclopramide (Reglan; 0.1 to 1.0 mg/kg), or ondansetron (Zofran, 0.15 mg/kg intravenously) may be given and repeated as necessary. There are no known adverse effects of giving these agents in association with an APAP overdose. If these measures fail, NAC may be given as a drip through a nasogastric tube over about 1 hour for each dose. Standard Mucomyst preparations are not approved for intravenous use. However, the practice of giving the oral preparation intravenously through an in-line filter is widespread and generally considered to be acceptable practice by most medical toxicologists and poison control centers.^{4,11}

APAP crosses the placenta, so when a pregnant patient overdoses on APAP, fetal hepatotoxicity is possible. NAC may not cross the placenta.⁶ The advantage, if any, of immediate delivery of a preterm infant, so that NAC therapy can be given, is questionable.⁹ If spontaneous delivery occurs while the mother is receiving NAC, a full course of NAC should be given to the newborn.

A particularly perplexing group of patients are those who have taken a potentially toxic cumulative amount of APAP but have done so by ingesting multiple nontoxic doses over a period of time.¹⁶ One approach would be to treat for potential APAP toxicity any patient who has ingested more than 10.5 g or 150 mg/kg during the preceding 24 hours. However, this strategy would result in many patients being treated who would not require this therapy. All patients with a toxic plasma level according to the nomogram, based on the time since the last dose of APAP, should be treated with NAC.

The management of patients with APAP-induced hepatic or renal failure consists of NAC and supportive care.⁸ Patients who appear to have fulminant hepatic failure are candidates for transplantation. However, transplantation should not be done simply on the basis of an elevated transaminase level, because this does not portend a poor prognosis. Transplant teams should be considered necessary for patients with prothrombin times greater than 100 seconds, renal failure, and coma. Persistent metabolic acidosis should also be considered grounds for transplantations.

DISPOSITION

Any patient who is potentially APAP toxic by the nomogram requires admission and treatment. All intentional overdose patients should have a psychiatric evaluation before discharge. Patients who present more than 24 hours after ingestion, with abnormal liver function test results, should receive NAC therapy until the hepatotoxicity resolves.⁸

COMMON PITFALLS

- Failure to consider an occult APAP overdose in all patients with intentional overdose or unexplained hepatitis
- Withholding activated charcoal because of concern about its effect on NAC therapy
- Delaying NAC treatment beyond 8 to 10 hours while waiting for APAP levels

CHAPTER 311 *Anticholinergic Poisoning*

Jeffrey Brent and Kenneth W. Kulig

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The toxic effects that result from inhibition of normal cholinergic transmission are collectively known as the anticholinergic syndrome (ACS). The manifestations of this syndrome can be divided into those secondary to central or to peripheral nervous system effects. Some of the many toxins capable of causing the ACS are listed in [Table 311.1](#).

MEDICATIONS	
Aerosolized bronchodilators	Mydriatic eye drops
Anticholinergics	Neuroleptics
Antiparkinsonian agents	Orphenadrine
Belladonna alkaloids	OTC cough and cold remedies
Cyclohexamine	OTC sleep aids
Drugs for motion sickness	Tricyclic antidepressants
Glutethimide	
PLANTS	
Angel's trumpet (<i>Solaneum aviculare</i>)	Jimson weed (<i>Datura stramonium</i>)*
Black henbane (<i>Hyoscyamus niger</i>)	Jerusalem cherry (<i>Solanum pseudocapsicum</i>)
Black nightshade (<i>Solanum elaeagnifolium</i>)	Madagascar periwinkle (<i>Cathartus occidens</i>)
Blue belladonna (<i>Atropa belladonna</i>)	Night-blooming jasmine (<i>Cestrum nocturnum</i>)
Blue belladonna (<i>Atropa belladonna</i>)	Nutmeg (<i>Myristicaceae</i>)
Butterbean (<i>Lycium alatum</i>)	Potato (<i>Solanum tuberosum</i>)
Deadly nightshade (<i>Atropa belladonna</i>)	Wild sage (<i>Lantana camara</i>)
Ground cherry (<i>Physalis peruviana</i>)	Wild tomato (<i>Solanum carolinense</i>)

* Also known as Jamestown weed, stinkweed, thorn apple, and devil's apple.
 † OTC = over-the-counter.

TABLE 311.1. Agents That Cause Anticholinergic Syndrome

The peripheral sites of cholinergic transmission are shown in [Fig. 311.1](#). The major effects associated with the inhibition of cholinergic transmission are given in [Table 311.2](#). Only at high doses do these drugs have any nicotinic blocking effects, such as sympathetic ganglionic blockage, resulting in cutaneous vasodilatation (“atropine flush”). Even at extremely high doses, the neuromuscular junction is relatively spared. Quaternary ammonium anticholinergic compounds, such as glycopyrrolate, have more pronounced antinicotinic effects but, being charged, are poorly absorbed and therefore ineffective when taken orally. ³

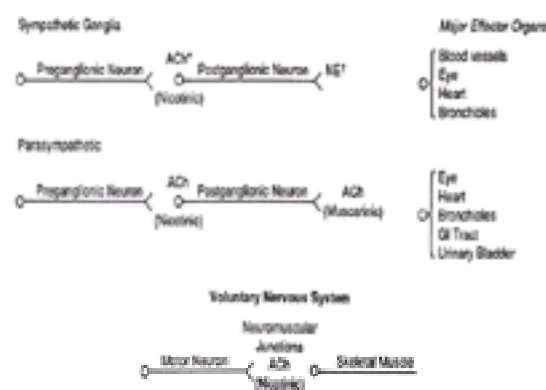

Figure 311.1. Peripheral sites of cholinergic transmission. *ACh, acetylcholine; †NE, norepinephrine.

Site of Blockade	Effects
Peripheral muscarinic synapses	Tachycardia Dilated pupils Loss of accommodation Dry skin and mucous membranes Flushed skin Decreased bowel motility Urinary retention Fever
Central nervous system	Delirium Seizures Coma Agitation Psychotic behavior Extrapyramidal signs Respiratory depression Cardiovascular collapse

TABLE 311.2. Anticholinergic Effects

Acetylcholine is a ubiquitous neurotransmitter in the central nervous system (CNS), and the central effects can be a significant or, occasionally, a predominant feature of the ACS.^{6,17} Because of the altered sensorium produced, these agents are occasionally deliberately abused.^{5,11} In the past, the antiparkinsonian agent trihexyphenidyl (Artane) had been among the most popular, probably because of its euphoric properties. The practice of ingestion of jimson weed (usually the seeds or flowers but sometimes a tea brewed from other plant parts), a widely available and free-for-the-picking intoxicant, is common, particularly among teenagers.^{6,12}

CLINICAL PRESENTATION

The patient with the ACS may present with peripheral or central manifestations, or both. Usually the former predominates, with some component of the latter. Commonly seen as a result of cholinergic receptor blockade are mydriasis, tachycardia, dry skin and mucous membranes, fever, and altered mentation.^{1,8} These features provide the basis for the mnemonic “hot as a hare, mad as a hatter, red as a beet, dry as a bone.” Although this describes many of the features of the ACS, it ignores tachycardia, one of the most consistent and reliable clinical findings.⁹ However, in infants, the elderly, alcoholics with autonomic neuropathy, and patients taking beta blockers or calcium channel blockers, tachycardia may be absent. Hence, the absence of tachycardia does not rule out the ACS.

Cardiac conduction delays are occasionally reported following very large overdoses.^{10,15,18} It is unknown whether these are consistent features of massive anticholinergic poisonings or relate to other actions of the agents ingested. The presence of significant cardiac conduction abnormalities in the setting of anticholinergic poisoning should always prompt an evaluation for alternative causes of these effects.

Central effects vary with the ability of an agent to penetrate the CNS. Central manifestations have been colorfully described in patients who were found confused and inappropriately and scantily dressed after ingesting alcoholic beverages adulterated with scopolamine eye drops.⁸

Patients with a severe ACS can present with such extreme findings as seizures, hypotension, rhabdomyolysis, and respiratory or cardiac arrest.²⁰ It is unclear whether these complications are direct anticholinergic effects, are the end result of severe physiologic stimulation, or are due to other pharmacologic properties of the agents involved. Most patients have a self-limited course, the extent and duration of which are determined by the amount and nature of the agent.

Although tricyclic antidepressants can predominantly cause the ACS when taken in small overdoses, the clinical presentation of large overdoses of these agents is usually dominated by hypotension, seizures, and dysrhythmias resulting from nonanticholinergic effects.

DIFFERENTIAL DIAGNOSIS

The ACS should be included in the differential diagnosis of any patient who presents with altered mental status, fever, urinary retention, tachycardia, or seizures. The history and physical examination are often crucial in ascribing a patient's symptoms to the ACS. The history should focus not only on prescribed medications, but also on over-the-counter agents, plant or mushroom ingestions, anticholinergic eye drops, antihistamine-containing skin lotions, or circumstances in which illegitimate use of these agents may be a possibility. However, the history alone can often be misleading, and it may be left to the astute clinician to diagnose an ACS without a supporting history. For example, there have been well-documented instances of street heroin being cut with significant amounts of the anticholinergic alkaloid scopolamine. Patients using this heroin presented to emergency departments with a history of only heroin use but a clinical picture of an ACS, causing considerable initial confusion.² It is also important to remember that seemingly minor, and therefore historically ignored, exposure to anticholinergic agents, such as to over-the-counter medications, drops to treat infantile colic,¹³ or even anticholinergic eye drops used as mydriatics for funduscopic examinations,⁴ can cause life-threatening anticholinergic toxicity. The physical examination should look for features of anticholinergic poisoning, namely delirium and hallucinations, tachycardia, mydriasis, dry skin, decreased bowel sounds, and a distended bladder.

Although several *Amanita* mushrooms (*A. muscaria*, *A. pantherina*, *A. gemmata*) have been implicated in causing an ACS, the toxidrome they usually induce is clinically and physiologically distinct (see [Chapter 355](#)). Because mydriasis and altered mentation occur during this toxidrome, it is often mistaken for an ACS. This toxidrome should, however, be included in the differential diagnosis.

Often, the clinical characteristics of an intoxication are a combination of anticholinergic features and other manifestations of the additional pharmacology of the ingested agent. For example, phenothiazines can cause an ACS complicated by the sedating and alpha-adrenergic blocking properties (e.g., coma, hypotension) of these drugs.

Given the clinical features of the ACS, it may easily be misdiagnosed as a CNS infection, dehydration, psychiatric disorder, or sepsis.

EMERGENCY DEPARTMENT EVALUATION

A detailed history and complete physical examination are essential. The physical examination should specifically search for the features of an ACS. Flushing of the skin may also be present as a result of excessive ingestion of anticholinergic agents, but this occurs infrequently. Cardiac monitoring and a 12-lead electrocardiogram (ECG) should be obtained on all patients, particularly in the presence of tachycardia. If seizures or altered mentation are present, particularly with fever, a full neurologic evaluation, including a computed tomography (CT) study of the head and a lumbar puncture, is required if it cannot be proven that these effects are secondary to anticholinergic poisoning. Physostigmine (discussion follows) can be helpful in quickly distinguishing between an ACS and a CNS infection.

If there is any question of the diagnosis, a toxicology screen for common anticholinergic agents should be obtained. If a particular drug is suspected of causing the syndrome, this should be communicated to the laboratory personnel. However, because many of the medications and all of the plants that cause the ACS are not detected by many toxicology screens, the diagnosis is made predominantly by the history and physical examination.

If an ACS is suspected to be due to misuse of drugs, through either intent or misunderstanding, the possibility of an occult simultaneous acetaminophen overdose should be ruled out by a quantitative acetaminophen level. If the patient has ingested a plant, it may be helpful to have the ingestant identified by a botanist. Medical toxicologists and regional poison control centers are usually aware of local resources available for help in this regard.

EMERGENCY DEPARTMENT MANAGEMENT

After any necessary advanced life-support measures have been performed and a preliminary history and physical examination have been completed, attention should be directed to preventing further drug absorption. Activated charcoal is the preferred method of gastrointestinal decontamination and should be administered to patients with recent ingestions. Eye drop exposure is treated by irrigation of the conjunctival recesses.

Most patients with an ACS can be treated supportively. The specific antidote for the ACS is physostigmine salicylate (Antilirium), a reversible inhibitor of acetylcholinesterase derived from the West African vine *Physostigma venenosum*. Because of physostigmine's ability to penetrate the CNS, it can reverse both central and peripheral anticholinergic effects.¹⁶ However, the cholinergic effects of physostigmine can be profound. Although such effects are rare, physostigmine may induce seizures, heart block, bradyarrhythmias, and asystole.^{14,19} Most of these adverse effects occur with patients who have ingested tricyclic antidepressants.^{7,14,19} Because of these effects, physostigmine should be reserved for extreme extrapyramidal movement disorders, recurrent or refractory seizures, severe agitation or hallucinations (causing patients to be dangerous to themselves or others and unresponsive to sedating medications), or ventricular or hemodynamically significant supraventricular tachyarrhythmias unresponsive to standard management, or if the diagnosis is in doubt. Both central and peripheral ACS manifestations should also be present to ensure a correct diagnosis. Because of its significant cholinergic effects, physostigmine is considered to be contraindicated in patients with bowel obstruction, significant cardiac or peripheral vascular disease, asthma, chronic obstructive pulmonary disease, cardiac conduction abnormalities on the ECG, or urinary tract obstruction. It is also contraindicated when excessive doses of tricyclic antidepressants have been ingested. The latter can be ruled out by an ECG. In the absence of a large R wave in lead AVR, it is very unlikely that the patient is experiencing any significant toxic effects of a cyclic antidepressant.

Due to its potential adverse effects, physostigmine should be given with cardiac monitoring, resuscitation equipment at the bedside, and in the presence of a physician. The cholinergic effect of physostigmine is expected to cause a reduction in heart rate. Because most patients with an ACS have sinus tachycardia, the syndrome itself provides an extra margin of safety for the use of physostigmine. This agent should be used with great caution, if at all, in patients without tachycardia. The adult dose of physostigmine is 1 to 2 mg intravenously, repeated every 5 to 20 minutes until the life-threatening features of the ACS resolve. Although no pediatric dose has been formally established, children have been treated with 0.02 mg/kg intravenously (up to 1 to 2 mg per dose), repeated as needed.¹⁶ Physostigmine has unpredictable intramuscular absorption patterns, and thus should not be given by that route. Doses of physostigmine should be given over no less than 2 minutes; however, because of its short half-life, it is ineffective if given over a period longer than a few minutes. Because it is a cholinergic agent, the treatment of physostigmine-induced complications is atropine. The dose of atropine is half of the amount of physostigmine administered.¹⁶ Atropine has a longer duration of action than physostigmine and must be used very cautiously in this setting. If standard doses of physostigmine are given and contraindications heeded, it is unlikely that significant complications will arise. Because the pharmacologic effects of physostigmine last from 30 minutes to 2 hours, it may be necessary to repeat treatment if life-threatening manifestations of an ACS reappear. In true anticholinergic poisoning, dramatic resolution of the syndrome is expected to occur within minutes of physostigmine administration. Thus, a lack of definitive response to physostigmine should cause the diagnosis of ACS to be questioned.

Benzodiazepines may be useful in patients with mixed signs and symptoms of the central ACS. Neuroleptic agents such as phenothiazines or butyrophenones should be avoided in the ACS because of their associated anticholinergic effects.

DISPOSITION

Any patient with a significant ACS should be observed until the clinical signs, including tachycardia, resolve and the patient has normal mentation. Often, this requires admission to a monitored unit.

In accidental poisoning, the physician must review the genesis of the ACS with patients or their caretakers so that a repetition can be avoided. Any patient who has deliberately overdosed on an anticholinergic substance needs emergency psychiatric evaluation or referral for substance-abuse treatment after their mentation has normalized.

Patients who have had a seizure caused solely by the ACS do not require chronic anticonvulsant medications.

If the physician is unfamiliar with the evaluation, management, or disposition of patients with the ACS, a medical toxicologist should be consulted.

COMMON PITFALLS

- Failure to consider the diagnosis of the ACS in patients with unexplained confusion, hallucinations, tachycardia, urinary retention, fever, or seizures
- Using physostigmine to treat minor manifestations of the ACS
- Failure to get an ECG and check for contraindications before giving physostigmine
- Using physostigmine without adequate monitoring and resuscitation capability
- Using neuroleptics to treat behavioral effects (agitation and hallucinations) of the ACS

CHAPTER 312 Antidysrhythmic Drug Poisoning

S. Rutherford Rose and James E. Cisek

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The antidysrhythmic agents discussed here are those used exclusively for the treatment of dysrhythmias, specifically those in Vaughn-Williams classes IA, IC, and III (Table 312.1). Those from other classes have additional uses and activities and are covered in separate chapters.

Class	Action	Classic Drugs	New Drugs
I	Sodium channel inhibition		
A	Increased APD Increased ERP Slowed conduction	Quinidine Disopyramide Procainamide	Clonidine Flecanide
B	Little/no decrease in APD Increased ERP in diseased tissue May increase conduction velocity	Lidocaine Tocainide Phenytoin	Ethacrynol sotalolol
C	Variable effect on APD Small increase in ERP Markedly slowed conduction	Flecainide Encainide	Propafenone
II	Beta-adrenergic blockade	Atenolol Metoprolol Propranolol	Acetaminophol Sotalolol
III	Prolonged repolarization	Amiodarone Beryllium Sotalol	N-acetylprocainamide
IV	Calcium channel inhibition	Diltiazem Nifedipine Verapamil	Bepridil Gallopamil

APD, action potential duration; ERP, effective refractory period.

TABLE 312.1. Classification of Antidysrhythmic Drugs

Class I agents decrease the influx of sodium through fast channels in myocardial cell membranes during depolarization (phase zero of the action potential), thereby slowing the rate of rise of the action potential (V_{max}) in myocardial cells. This action results in decreased conduction velocity and increased QRS duration. Class I drugs are divided into A, B, and C subclasses based on their respective rates of dissociation from fast sodium channels. Class IC agents dissociate slowly and therefore produce the greatest degree of QRS prolongation, even at therapeutic doses. They also prolong the JT interval. Class IB drugs quickly dissociate from binding sites and produce no QRS prolongation at therapeutic concentrations. Class IA drugs have intermediate dissociation constants and cause mild QRS prolongation with therapeutic dosing.

Class IA drugs also have variable alpha-adrenergic blocking effects, and disopyramide has relatively potent negative inotropic effects. Propafenone has relatively weak beta-adrenergic activity, which may be clinically important in patients on high doses or in approximately 7% of patients who poorly metabolize propafenone to an active metabolite, which has class IC-like properties.

Class III drugs prolong repolarization (i.e., the refractory period) in all cardiac tissue. In addition, amiodarone has vasodilating and weak beta-adrenergic blocking properties; however, intravenous administration results in pharmacologic effects consistent with all four Vaughn-Williams classes. Sotalol is a nonselective beta-adrenergic blocker that also prolongs the refractory period throughout the conduction system, including bypass tracts.

Class IA drugs are used to treat a wide variety of dysrhythmias of both ventricular and supraventricular origin, including reentry tachycardias and Wolff-Parkinson-White syndrome. The efficacy of these drugs in preventing reentry dysrhythmias is probably due to a change from unidirectional to bidirectional block resulting from slowed conduction. Class IC drugs have very narrow therapeutic windows and are primarily used for maintenance of sinus rhythm in patients with atrial fibrillation. The Cardiac Arrhythmia Suppression Trial study demonstrated increased mortality in patients given encainide or flecainide after myocardial infarction. Encainide was subsequently withdrawn from the U.S. market in 1991; however, it may be obtained directly from the manufacturer for patients with life-threatening dysrhythmias who have previously responded to the drug. Flecainide is typically reserved for treatment of refractory supraventricular tachycardias. The class III drugs (amiodarone, sotalol) are assuming more prominent roles as initial therapy for both ventricular and supraventricular rhythm disturbances.

Overdose with antidysrhythmic drugs is rare, compared with other cardiovascular drugs (e.g., beta blockers or calcium channel blockers). Most overdoses occur in adults and are accidental. Adverse effects are common and occur in 20% to 50% of patients on chronic therapy.

Pertinent pharmacokinetic parameters are summarized in Table 312.2. The salt forms of these drugs are well absorbed orally. Peak plasma levels following ingestion of immediate-release dosage forms usually occur within 1 to 3 hours, except with amiodarone (4 to 6 hours, but up to 10 hours) and with disopyramide (due to its anticholinergic effects). Elimination from the body follows first-order (rate proportional to concentration) kinetics. Metabolites of quinidine, encainide, propafenone, and amiodarone have varying degrees of pharmacologic activity and probably contribute to overall effects. These metabolites are not monitored clinically. The principal metabolite of procainamide, N-acetylprocainamide (NAPA), is approved under orphan drug status for patients with procainamide-induced lupus, and most closely resembles class III drugs because of its ability to prolong repolarization. Amiodarone is unique in that it has a very prolonged elimination half-life (50 days), and serum levels may continue to rise for a month after starting therapy.

Parameter	Quinidine	Disopyramide	Procainamide	Flecainide	Propafenone	Amiodarone	Beryllium	Sotalol
Protein binding (%)	80	5-67	5-20	88	91	95	5-6	Low
Distribution volume (L/kg)	25-30	0.8	18-24	4-10	2-3	2-3	4-10	15
Half-life (hr)	4-8	5-6	3-4	16-20	4-8	30-60	7-12	7-10
Route of elimination (%)								
Hepatic metabolism	80-90	15-20	30-40	30-40	30-40	95	10	8-20
Renal excretion	15-20	80-85	60-70	60-70	60-70	5	90	75-80
Usual maximum adult daily dose (mg)	1,800	800	3,000	400	600	400-500	300	320
Therapeutic serum level (mg/L)	2-11	2-5	4-12	0.1-0.3	0.1-0.3	10-20	1-2	0.1-0.3

*Binding increases with increasing protein.

TABLE 312.2. Summary of Pharmacokinetic Parameters

All antidysrhythmic agents have relatively narrow therapeutic ranges, and therefore low margins of safety between efficacy and toxicity. Therapeutic ranges are estimates based on population averages and do not apply to all patients; some patients, in fact, must suffer some mild yet annoying side effects to achieve a desired therapeutic effects. Serum drug levels of quinidine and procainamide or NAPA are easily measured by most hospital laboratories and are reasonably correlated with clinical and, to some extent, toxic effects. Serum levels of the other compounds are not routinely monitored but could be obtained to document toxicity.

The toxic effects of antidysrhythmics result from exaggerated therapeutic activity. Dose-dependent delays in conduction lead to varying degrees of atrioventricular block and, eventually, asystole. High drug levels also result in myocardial depression (classes IA, IC, and III) and peripheral vasodilatation (classes IA and III), which can result in profound hypotension. Central nervous system (CNS) effects appear to be independent of cardiac effects unless shock is present.

There are insufficient data to determine the minimum toxic doses for most antidysrhythmic drugs. For class IA drugs, toxicity may be expected after acute ingestions of 1 g or more. Ingestions of more than 2.5 to 3.0 g may result in serious toxicity. Survival has been reported following acute doses of up to 20 g and peak serum levels of 21.4 µg/mL (quinidine) and 77 µg/mL (procainamide).^{7,9,19,20} However, death has been reported in adults following estimated doses as low as 3.6 to 6.8 g and serum levels of 8.3 µg/mL (disopyramide), illustrating the variability in doses, plasma drug levels, and degree of toxicity. A 2-year-old boy died 28 hours after ingesting 600 mg of disopyramide, and a 16-year-old girl required 75 minutes of cardiopulmonary resuscitation after a reported ingestion of 2 g of disopyramide.^{1,10}

Class IC drugs appear to be more toxic than class IA drugs. Severe toxicity has been reported in a 6-month-old child who ingested a 25-mg encainide tablet.¹⁶ A healthy 46-year-old man ingested 3.0 to 3.5 g of encainide and suffered seizures, hypotension, bradycardia, and coma.¹⁸ Ingestion of 1.8 g of flecainide was fatal in an 18-year-old, and 1.5 g produced seizures and polymorphous ventricular tachycardia.¹¹ An acute overdose of 1.8 g (133 mg/kg) of propafenone in a 2-year-old child resulted in hypotension, seizures, and a prolonged QT interval.¹⁵ Ingestion of 8.1 g of propafenone caused seizures, coma, hypotension, and prolonged QRS in an adult with a propafenone serum level of 3.2 µg/mL.¹² An overall mortality of 22.5% was reported in a retrospective review of propafenone, flecainide, ajmaline, and prajmaline toxicity.¹³ About half of the patients became nauseated within 30 minutes of ingestion, and severe cardiac toxicity (atrioventricular block, bradycardia, pulseless electrical activity, asystole) occurred within 30 to 120 minutes after ingestion.

There is considerably less information about the acute toxicity of class III drugs. Amiodarone doses of 2.6 to 8.0 g have produced mild bradycardia, prolonged QT interval, and a brief episode of nonsustained ventricular tachycardia, all with a delayed onset of 12 to 48 hours.⁵ An inadvertent bolus of 30 mg/kg of bretylium resulted in significant hypertension (310/90 mm Hg) and subsequent hypotension (90/40) in a 58-year-old man being treated for recurrent ventricular tachycardia–fibrillation after a cardiac arrest.² A syndrome resembling clinical brain death was reported in a neonate who received a 12-fold (dosing error) increase in bretylium infusion and had a serum bretylium level (not peak) of 17 µg/mL. Sotalol poisoning is discussed in [Chapter 320](#).

Excessive dosing or impaired excretion of these compounds frequently leads to toxic levels during chronic therapy. Clinical toxicity at a relatively lower serum concentration may be expected during chronic therapy due to prior saturation of tissue stores and the likelihood of preexisting cardiac disease.

CLINICAL PRESENTATION

The onset of symptoms following acute overdose usually occurs within 4 hours, and often within 1 to 2 hours. However, drug absorption may continue for many hours following the ingestion of massive amounts, sustained-release preparations, or agents with anticholinergic effects. Delayed onset of toxicity has been observed following amiodarone overdose.⁵

Extracardiac manifestations of acute toxicity include dizziness, visual disturbances, psychosis, anticholinergic symptoms (disopyramide), hypoglycemia (disopyramide), hyperglycemia (encainide), hypokalemia, and hypersensitivity reactions (e.g., fever, rash, urticaria).^{9,19} Thrombocytopenia and a lupus-like syndrome (arthralgias, fever, myocarditis) with antinuclear antibodies have been well documented during chronic quinidine and procainamide therapy. The use of amiodarone is increasing despite the risk of numerous adverse effects, including corneal microdeposits, photosensitivity, hepatic dysfunction, myopathy, pulmonary fibrosis, hypo- or hyperthyroidism, and peripheral neuropathies.

Hypotension, bradycardia, CNS depression, seizures, metabolic acidosis, and cardiovascular collapse can occur in severe poisoning. Patients with disopyramide overdose may demonstrate early loss of consciousness, apnea, or cardiac failure. Seizures appear to be more prevalent with class IC drugs. Disopyramide has resulted in acute congestive heart failure at therapeutic doses in patients with heart disease. Clinical effects associated with quinidine include seizures, immune-mediated hemolytic anemia, syncope, and cinchonism. Syncope is due primarily to torsades de pointes (discussion follows), but may also be associated with adrenergic blockade (orthostasis) or, rarely, idiosyncratic reactions. Cinchonism (see [Chapter 315](#)) is associated with chronic therapy and does not appear to be dose-related. Procainamide and quinidine can predictably produce hypotension if given by too-rapid intravenous infusion. Death can result from refractory dysrhythmias or cardiovascular collapse.

Disturbances in cardiac conduction and rhythm are the electrocardiographic (ECG) hallmarks of poisoning. Excessive prolongation of the QT interval is almost always present in severe poisoning. With class IA agents, this results from prolongation of both the QRS and JT intervals, whereas with class IC and III agents, it is due primarily to QRS and JT prolongation, respectively. In general, an increase of the QRS or QT interval by 25% is considered therapeutic, and widening by 50% or more suggests toxicity. The PR interval may also be prolonged if there is sinus activity. Conduction disturbances and myocardial depression contribute to a host of supraventricular and ventricular dysrhythmias, including sinus bradycardia, atrioventricular dissociation, ventricular tachycardia or fibrillation, slow idioventricular rhythm, and asystole. Torsades de pointes is a triggered (early after depolarization) polymorphous ventricular tachycardia resulting from excessive JT prolongation, most commonly associated with class IA and III drugs (e.g., quinidine, amiodarone, high levels of NAPA).

All antidysrhythmic drugs can aggravate existing dysrhythmias or induce new ones (e.g., proarrhythmic effect) in patients being treated for supraventricular or ventricular dysrhythmias. The incidence of proarrhythmia is estimated at 5% to 20% and most often is associated with initiation of therapy or a dosage increase.¹⁴ The induction of dysrhythmias should always be suspected in patients on antidysrhythmic drugs who present with syncopal episodes.

Patients with preexisting renal, hepatic, or cardiac disease are at increased risk for toxicity. Although impairment of renal function does not appear to alter appreciably the elimination rate of quinidine, propafenone, or amiodarone, the elimination half-lives of procainamide and NAPA, flecainide, and sotalol are prolonged. Similar changes may occur when blood flow to the kidneys is reduced (i.e., congestive heart failure). Reduced biotransformation may be expected for quinidine, procainamide, propafenone, amiodarone, and, possibly, encainide and flecainide in the presence of hepatic dysfunction.

The correlation of serum levels with clinical effects depends on previous exposure to the drug, the presence of heart disease, and the degree of absorption, metabolite formation, and elimination. In general, serum levels exceeding 7, 8, and 15 µg/mL for quinidine, disopyramide, and procainamide (NAPA), respectively, should be considered toxic. Flecainide levels of 1.48 to 3.7 µg/mL have been observed in patients with prolonged QT intervals, ventricular dysrhythmias, and seizures, and levels of 13.0 to 16.3 µg/mL have been reported in fatal cases. Lower levels may result in toxicity in patients who coingest other cardiovascular agents. Patients on chronic therapy who take an acute overdose appear to be at greater risk for severe intoxication.

DIFFERENTIAL DIAGNOSIS

Similar bradyarrhythmias may be caused by beta blockers, calcium antagonists, cholinergic agents (carbamate and organophosphate insecticides), digitalis, clonidine, lithium, and cyclic antidepressants. QRS and QT interval prolongation may result from poisoning with antihistamines, phenothiazines, cyclic antidepressants, lithium, magnesium, or potassium. Ventricular tachyarrhythmias may occur in poisoning with sympathomimetics and drugs that cause QRS and QT prolongation.

EMERGENCY DEPARTMENT EVALUATION

The history should include the exact product and strength (immediate- or sustained-release), the amount ingested, the time ingested, and treatment before arrival. Any history of cardiovascular disease must be elucidated. Mechanisms for chronic toxicity, such as excessive dosing, exacerbation of congestive heart failure, or change in renal function, should be investigated.

The physical examination initially focuses on vital signs, with attention to cardiovascular stability and respiratory and neurologic status. A detailed examination should be performed after vital signs or rhythm abnormalities are stabilized.

A 12-lead ECG should be obtained as soon as possible. Laboratory work should include a blood glucose level; electrolyte analysis; blood urea nitrogen, creatinine, and magnesium measurement; liver function tests; and appropriate serum drug levels. Requests for NAPA should always accompany requests for procainamide

levels. Chest radiography and arterial blood gas analysis are included for patients with depressed levels of consciousness or serious dysrhythmias.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures should be instituted, as necessary. All patients suspected of antidysrhythmic drug toxicity should have an intravenous line, continuous cardiac monitoring, and pulse oximetry. Supplemental oxygen is given to symptomatic patients. Unstable patients must have close hemodynamic monitoring. Acid–base, electrolyte, and magnesium derangements should be corrected. Potassium should be replaced cautiously, because hypokalemia may protect against cardiotoxicity due to quinidine (and possibly other agents). Seizures are treated with standard doses of intravenous diazepam or lorazepam, or phenobarbital.

Hypotension is initially treated with intravenous normal saline. Infusions of sodium bicarbonate can reverse hypotension associated with class IA and IC drugs. Patients with compromised left ventricular function must not be overly fluid resuscitated. Hypotension refractory to volume expansion may require the use of vasopressors or inotropes (epinephrine, norepinephrine, dopamine), aortic balloon counterpulsation, or cardiopulmonary bypass pump support. ^{9,19,20}

As in cyclic antidepressant toxicity (see [Chapter 313](#)), increasing the serum sodium level, the serum pH, or both, by administering sodium bicarbonate (1- to 2-mEq/kg bolus doses, as needed) can also reverse conduction delays and dysrhythmias due to class IA and IC drugs. ⁶ Symptomatic bradycardia or atrioventricular dissociation will probably require ventricular pacing if there is inadequate response to atropine or sodium bicarbonate. Successful pacemaker capture may require concomitant epinephrine therapy. ¹²

After sodium bicarbonate, lidocaine is the drug of choice for ventricular ectopy. Other antidysrhythmic drugs in the same class are obviously contraindicated for treatment of dysrhythmias. Torsades de pointes usually responds to isoproterenol infusion (1 to 6 µg/min) and atrial or ventricular overdrive pacing. ^{8,16} A heart rate of 150 beats/min is usually required. Intravenous magnesium sulfate (1 to 4 g over several minutes to 1 hour, depending on the hemodynamic stability) may also be effective.

Activated charcoal is the preferred method of gastrointestinal decontamination. Repeat doses may be indicated when prolonged absorption is observed (increasing serum drug levels) and bowel sounds are present. Syrup of ipecac is not recommended, owing to its long duration of action and the potential for deterioration while the patient is still vomiting. Gastric lavage is of questionable benefit and should be reserved for patients with large overdoses who present soon after ingestion. Vagal effects secondary to passing a lavage tube could worsen conduction disturbances.

Patients whose vital signs can be supported during endogenous drug elimination usually recover fully. Efforts to enhance elimination of these compounds have had variable success. Patients should be adequately hydrated to maintain renal perfusion. Forced diuresis, however, is not recommended, due to potential problems of fluid overload and pulmonary edema. Urinary acidification is marginally effective in increasing quinidine excretion and is no longer recommended. Quinidine is poorly removed by hemodialysis, charcoal hemoperfusion, and peritoneal dialysis. Although disopyramide's pharmacokinetic profile would suggest success with extracorporeal removal, only small amounts of drug have been removed with charcoal hemoperfusion and resin hemoperfusion. ^{7,9} Hemodialysis and hemoperfusion both failed to remove a significant amount of flecainide in a patient with renal failure and chronic flecainide intoxication.

Extracorporeal elimination may have a role in the treatment of procainamide and NAPA toxicity. In the presence of renal failure, hemodialysis can increase the clearance of NAPA fourfold and procainamide twofold. Procainamide serum levels were halved, and clinical improvement was observed following a 6-hour treatment. ¹⁷ However, NAPA levels in a patient on chronic hemodialysis halved after 4 consecutive days of dialysis, perhaps due to extensive tissue stores and redistribution following each treatment. ⁸ Drug redistribution from tissues to serum may also have contributed to the success of continuous arteriovenous hemofiltration ($t_{1/2}$ of 3.1 days), compared with intermittent 4-hour hemodialysis ($t_{1/2}$ of 4.1 to 7.0 days) in the removal of NAPA. ⁴ Another case report documented a decrease of 19 µg/mL in the NAPA serum level following 4 hours of resin hemoperfusion. ³

DISPOSITION

Patients who remain asymptomatic and have a normal ECG after 6 hours of observation can usually be safely discharged. A 12-hour observation period is recommended if a sustained-release preparation is involved. Patients with amiodarone overdose probably should be admitted for prolonged observation. Patients who are symptomatic or exhibit ECG evidence of cardiotoxicity from either acute or chronic intoxication need admission to a monitored bed. Those with cardiovascular instability should be admitted to an intensive care unit. A cardiologist should be consulted. A regional poison center or toxicologist can help with disposition and management decisions. Patients with severe toxicity should be admitted or transferred to a facility with cardiopulmonary bypass and aortic balloon counterpulsation capabilities. Patients presenting after intentional overdose should undergo psychiatric evaluation before discharge.

COMMON PITFALLS

- Failure to appreciate that severe toxicity can result from therapeutic doses of antidysrhythmic agents
- Failure to consider the possibility of drug-induced dysrhythmias as a cause of syncope and weakness in patients taking antidysrhythmic agents
- Failure to appreciate that sudden deterioration can occur without warning and to immediately initiate continuous cardiac monitoring in patients with antidysrhythmic overdose
- Failure to appreciate that drug-induced dysrhythmias may resemble the ones for which the drug was prescribed and to check drug levels before treating them with more drug
- Failure to consider sodium bicarbonate and magnesium for the treatment of dysrhythmias
- Giving syrup of ipecac to patients who may rapidly deteriorate
- Failure to consider invasive cardiovascular supportive therapies, such as pacing, aortic balloon counterpulsation, and cardiopulmonary bypass in patients with severe poisoning

CHAPTER 313 Antidepressant Poisoning

Keith K. Burkhart

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The availability of cyclic antidepressants (CAs) has provided a major therapeutic adjunct for the successful treatment of depression since the 1950s. Additional therapeutic indications have included chronic pain, migraine headaches, enuresis, and peptic ulcer disease. The term *cyclic antidepressants* refers to a family of drugs that have similar pharmacology and toxicity ([Table 313.1](#)).

Class	Drug	Trade Name(s)
TERTIARY AMINES		
Tertiary Amines	Amitriptyline	Amitril, Amitril, Elavil
	Clomipramine	Anafranil, Anafranil, Anafranil
	Desipramine	Desipramine, Desipramine, Desipramine
	Imipramine	Imipramine, Imipramine, Imipramine, Imipramine, Imipramine, Imipramine, Imipramine
Secondary Amines	Desipramine	Desipramine, Desipramine, Desipramine
	Nortriptyline	Nortriptyline, Nortriptyline, Nortriptyline
	Protriptyline	Protriptyline, Protriptyline, Protriptyline
TETRACYCLICS		
Tetracyclics	Meprobamate	Meprobaral, Meprobaral, Meprobaral
	Alprazolam	Alprazolam, Alprazolam, Alprazolam
IMIPRAMINE		
Imipramine	Imipramine	Imipramine
SELECTIVE SEROTONIN REUPTAKE INHIBITORS		
SSRIs	Fluoxetine	Prozac, Prozac, Prozac
	Paroxetine	Paroxetine, Paroxetine, Paroxetine
	Citalopram	Citalopram, Citalopram, Citalopram
INVESTIGATIONAL SSRIs		
Investigational SSRIs	Escitalopram	Lexapro, Lexapro, Lexapro
	Venlafaxine	Effexor, Effexor, Effexor

TABLE 313.1. Antidepressant Agents

Antidepressant overdoses continue to account for approximately 20% of the fatalities reported to the American Association of Poison Control Centers.¹⁰ Worldwide, CAs are a leading cause of life-threatening drug poisoning. The ingestion of just one tablet may produce serious toxicity in pediatric patients.

A newer group of antidepressants, selective serotonin reuptake inhibitors (SSRIs), were introduced in the 1980s. This class of antidepressants offers a wider margin of safety, with less central nervous system (CNS) and cardiovascular toxicity, compared with the CAs.¹ Now SSRIs have taken a large share of the antidepressant-prescribing market.

The pharmacologic properties of the CAs contribute to their toxicity in overdose. CAs are highly lipophilic, with large volumes of distribution (VD) (10 to 50 L/kg). They are rapidly absorbed and quickly distributed to the target organs, thereby manifesting a characteristic rapid onset of toxicity. Delayed absorption, however, may result from the anticholinergic action that can prolong gastric emptying and decrease gastrointestinal motility. In addition to a large VD, CAs are more than 95% protein bound.

Most CAs are tertiary or secondary amines. Tertiary amines (e.g., amitriptyline and imipramine) are metabolized to their respective secondary amines (e.g., nortriptyline and desipramine), which are also active drugs. Tertiary amines block norepinephrine and serotonin reuptake, while secondary amines primarily block norepinephrine reuptake. Tertiary amines have more anticholinergic and antihistaminic effects than the secondary amines.

CAs have half-lives greater than 24 hours. Early reports described prolonged and delayed toxicity. Improved supportive care, including alkalinization therapy and the administration of activated charcoal (AC), is probably responsible for a better outcome today. Enterohepatic and possibly entero-entero recirculation may contribute to the long half-life, but may not have a significant effect on the duration of toxicity. Most CA-poisoned patients that are provided with good supportive care make a full recovery within 2 to 3 days.

SSRIs share some of the pharmacologic properties of CAs. Peak levels occur 4 to 8 hours after therapeutic dosing. SSRIs also have a large VD and are highly protein bound. Like CAs, SSRIs are eliminated extensively by hepatic metabolism. Fluoxetine and citalopram have active metabolites.

Therapeutic doses of CAs are typically less than 5 mg/kg. Tolerance does develop in chronically dosed patients. Toxicity is generally seen with ingestion greater than 10 mg/kg, while greater than 15 mg/kg may result in severe, potentially fatal ingestions.

The CNS and cardiovascular toxicity of CAs result from quinidine-like cardiac conduction disturbances, sympathomimetic and sympatholytic actions resulting from the blockade of the reuptake of norepinephrine, and anticholinergic effects. Antihistaminic and α -blocking properties may also contribute to toxicity. Some CAs produce predominantly CNS or cardiac toxicity. Amoxapine produces seizures, including status epilepticus, but cardiac conduction disturbances do not generally occur. The relative absence of quinidine-like effects, catecholamine reuptake blockade, and anticholinergic effects of the SSRIs is responsible for their increased margin of safety.

Serotonergic hyperstimulation may produce a symptom complex involving autonomic, motor, and CNS hyperactivity that has been termed the *serotonin syndrome* (see [Chapter 370](#)).¹² Excess stimulation of 5-HT_{1A} receptors appears to be responsible. In most cases, the serotonin syndrome results from the addition of a second drug that further enhances serotonergic tone. Metabolic interactions involving cytochrome-P450 metabolism may also be involved in some cases.²

CLINICAL PRESENTATION

The presentation of CA poisoning may range from asymptomatic to cardiopulmonary arrest.⁵ Most importantly, a patient who is alert on arrival may become comatose, have seizures, or develop hemodynamic and cardiac instability within minutes.

Patients may initially be tachycardic and mildly hypertensive (due to the blockade of norepinephrine reuptake and anticholinergic effects), or they may be hypotensive (from α_1 blockade). As norepinephrine is metabolized, a catecholamine depletion state may also develop and lead to hypotension, bradycardia, and, finally, cardiogenic shock.

Patients often develop absent bowel sounds, ileus, and urinary retention. Other anticholinergic effects, such as dilated pupils; flushed, hot skin; and dry mucous membranes, however, are not common. Central anticholinergic findings vary from agitation to psychosis to coma. Additional neurologic manifestations include choreoathetosis and ataxia. Despite coma unresponsive to painful stimuli, patients may develop severe myoclonus and status epilepticus.

Cardiac dysrhythmias may include supraventricular tachydysrhythmias and ventricular arrhythmias. Intraventricular conduction disturbances often make it difficult to distinguish a ventricular tachycardia from a supraventricular tachycardia with aberrant conduction. Polymorphous ventricular tachycardia (torsades de pointes) has been reported. Aspiration pneumonia is relatively common, and adult respiratory distress syndrome may occur. Coma-induced rhabdomyolysis and compartment

syndromes are additional potential complications.

SSRI overdoses have proved to have a much better safety record when compared with CA overdoses. With a few exceptions, patients present asymptomatic and have benign clinical courses. Symptoms, when they occur, may include mild tachycardia, hypertension, orthostatic hypotension, tachypnea, dizziness, drowsiness or lethargy, tremor, diaphoresis, and vomiting. Fatality reports are rare and often lack a postmortem evaluation, including drug screening. ^{1,6,9}

Seizures have occasionally occurred following SSRI overdoses. ¹⁷ They have usually been self-limited, often not requiring specific treatment. Electrocardiographic changes and seizures, however, were common in a retrospective series of citalopram overdoses at Swedish hospitals. ¹⁶ Six patients ingesting greater than 600 mg developed widened QRS complexes. Premature ventricular complexes and ST-T wave changes were noted, but no serious arrhythmias occurred. Thirty-three percent of patients in this group developed seizures, but all patients fully recovered. ¹⁶ QTc prolongation and widened QRS intervals have rarely been reported with other SSRIs.

The serotonin syndrome usually presents with mild cognitive, neuromuscular, and autonomic symptoms (see [Chapter 370](#)). ¹⁵ Rarely have severe life-threatening presentations or fatalities been suggested to have resulted from the serotonin syndrome. ^{12,19}

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of coma, seizures, and cardiac dysrhythmias includes hypoxia, metabolic abnormalities, intrinsic neurologic and cardiac disease, and poisoning by antidysrhythmics, antihistamines, antimalarials, beta blockers, calcium channel blockers, carbamazepine, phenothiazines, and propoxyphene. Anticholinergic, camphor, cocaine, chloral hydrate, isoniazid, lithium, and sympathomimetic poisoning and drug withdrawal should also be considered.

EMERGENCY DEPARTMENT EVALUATION

The potential for rapid deterioration requires that intravenous access and continuous cardiac and oxygenation monitoring be initiated immediately. Vital signs and neurologic status should initially be evaluated every 15 minutes, and a limb lead QRS duration (discussion follows) should be checked every 30 minutes.

The history should be obtained from the patient, family, friends, or prehospital personnel. If possible, the time, amount, and identity of all agents ingested should be determined. When known, the amount of CA ingested often helps anticipate the potential for deterioration.

Early into the evaluation, an electrocardiogram (ECG) should be performed. A QRS duration greater than 100 milliseconds is associated with seizures, while a QRS duration greater than 160 milliseconds is associated with ventricular dysrhythmias. More subtle, early ECG changes include a widening of the terminal 40 milliseconds of the QRS in the right frontal plane. This manifestation can be quickly assessed by looking for the presence of a widened S wave in leads 1 and AVL, and an R wave in lead AVR ([Fig. 313.1](#)). These terminal 40-millisecond changes are good indicators for CA poisoning, but they do not absolutely confirm or exclude the diagnosis. ²⁰

Figure 313.1. Terminal QRS changes in CA poisoning.

Other than a lactic acidosis secondary to seizures or shock, CAs are not known to produce biochemical disturbances. However, standard care of any patient with altered mental status or cardiotoxicity requires an assessment of electrolytes, blood urea nitrogen, creatinine, serum glucose, and serum osmolality. An arterial blood gas, creatine phosphokinase, calcium, magnesium, liver chemistries, and a chest x-ray should be considered in patients with abnormal vital signs, significant CNS depression, seizures, or an abnormal ECG.

Drug screening for CAs has very little impact on the management of the CA-poisoned patient. Qualitative screens may identify the presence of CAs in urine, while quantitative screens provide drug levels. Although serum levels greater than 1,000 ng/mL generally correlate with significant toxicity, levels do not assist in emergency management. Monitoring the changes on the ECG and the patient's mental status may actually be better indicators of CA toxicity. Serum levels of SSRIs are not routinely available, and no study has correlated these measurements with clinical manifestations.

EMERGENCY DEPARTMENT MANAGEMENT

The management of the CA-poisoned patient may need to begin with prehospital care directives. Field resuscitation of a patient with coma, seizures, hypotension, and arrhythmias includes endotracheal intubation; administration of anticonvulsants, crystalloids, and lidocaine; and serum alkalization with parenteral sodium bicarbonate boluses.

While CA-induced seizures tend to be short-lived, they may deteriorate into status epilepticus. ⁴ A parenteral benzodiazepine such as diazepam or midazolam (5 to 10 mg), or lorazepam (2 to 4 mg), typically produces a rapid response and is the agent of choice. Higher doses may be required. Seizures will rapidly produce a lactic acidosis that may further compromise the cardiac and hemodynamic status. Hence, a bolus of sodium bicarbonate is recommended as adjunctive treatment for seizures. Neuromuscular paralysis with a short-acting agent should be considered for cases that do not respond. When intubation is required, parenteral administration of benzodiazepines may be useful for their anticonvulsant as well as sedative effects. If benzodiazepines do not completely control seizures, phenobarbital or propofol should be considered. ¹³ In the intubated patient, a phenobarbital loading dose of 18 mg/kg is usually sufficient. Status myoclonic activity is seen with severe poisoning. Benzodiazepines are often not effective for myoclonus.

Hypotension should be treated with crystalloid boluses up to 20 mg/kg. This treatment should overcome hypotension secondary to alpha blockade and mild dehydration. For more seriously poisoned patients, pressors may be needed. Dopamine and norepinephrine have been used successfully. However, some cases have been refractory to dopamine. Because dopamine partially acts as an indirect-acting sympathomimetic agent, by causing catecholamine release when norepinephrine stores are depleted following CA poisoning, it may lose some of its effectiveness. High infusion rates of dopamine may be tried initially, but if there is an inadequate response, norepinephrine should be given (substituted for or added to dopamine). In patients unresponsive to these measures, the insertion of a Swan-Ganz catheter and measurement of pulmonary artery pressures may be useful to guide additional management. Cardiac dysrhythmias can be terminated with the administration of sodium bicarbonate. ^{11,15} Many reports have described the important prophylactic and treatment role for serum alkalization therapy in the management of CA poisoning. Sodium and bicarbonate have proven to be beneficial treatments for toxins that have quinidine-like, sodium-channel blocking actions. In experimental models of amitriptyline toxicity, sodium loading and pH elevation improved cardiac conduction, but both treatments together produced the greatest improvement. ^{11,18} In refractory ventricular dysrhythmias, lidocaine and bretylium should be considered, but type 1A antidysrhythmics, such as procainamide and beta blockers, should be avoided.

Dysrhythmias should be treated with at least one or two ampules of sodium bicarbonate (1 mEq/kg for pediatric patients). Sodium bicarbonate has acutely terminated ventricular tachycardia and wide complex tachycardia. The QRS duration shortens, and the terminal 40-millisecond changes become less evident. Respiratory

alkalosis is advocated by many clinicians, but the pH elevation is not as instantaneous as with bolus bicarbonate administration and sustained respiratory alkalosis, which will lead to compensatory renal bicarbonate excretion, resulting in a relative deficiency state. The target pH for alkalization is 7.45 to 7.55. Caution is also needed when sodium bicarbonate is given because of the potential to overshoot the desired pH and cause hypernatremia and ionized hypocalcemia. Additionally, the administration of large amounts of bicarbonate for a number of hours may lead to respiratory acidosis and hypoventilation.

Gastrointestinal decontamination should be accomplished following the institution of any necessary life-support measures. Syrup of ipecac is contraindicated in the setting of CA poisoning. Patients may become comatose, lose their gag reflex, and have seizures before or during emesis, resulting in airway compromise or aspiration pneumonitis. Gastric lavage probably benefits patients who present early (within an hour) after the ingestion, but its clinical utility beyond the first hour has not been proved.

AC should be administered in a dose of 1 g/kg. Because usually only a few grams of CAs are ingested, even in the most seriously poisoned patients, a single dose of AC represents a sufficiently large AC-to-drug ratio to theoretically prevent drug absorption. A clinical benefit from multiple doses of AC has not been clearly demonstrated.

The administration of Fab antibody fragments specific for CAs has resulted in hemodynamic improvement and decreased mortality in animal models.^{3,8} Human clinical trials are now underway. Extracorporeal removal techniques play no role in the management of the CA-poisoned patient. Because benzodiazepines are therapeutic, flumazenil is contraindicated for patients with coma and a history or ECG suggestive of CA poisoning. Similarly, physostigmine, although it may be effective in reversing anticholinergic toxicity (see [Chapter 312](#)), has resulted in asystole when used to treat cardiac arrhythmias due to CA poisoning. It is therefore contraindicated for patients with a prolonged QRS interval or arrhythmias suggestive of CA cardiotoxicity. Anticholinergic symptoms may persist for days. Physostigmine in this recovery phase may be beneficial.

The management of the SSRI overdose is based on providing general supportive care with cardiac monitoring and intravenous access. Seizures are usually self-limited and usually terminate without therapy.

Management of the serotonin syndrome is described in detail in [Chapter 370](#). Discontinuation of the inciting agent(s) is often all that is required.¹⁴ Serotonin antagonists such as cyproheptadine,⁷ methysergide, propranolol, chlorpromazine, and metoclopramide have been found to be of benefit in animal studies and some case reports. Benzodiazepines appear to lessen the severity without relieving the symptoms. Dopamine antagonists such as haloperidol and dantrolene have also been recommended but remain of unproven benefit. Bromocriptine increases serotonin levels and should be avoided. In severe, life-threatening syndromes, the early institution of anesthetic doses of propofol or phenobarbital may blunt neurotransmission and be protective until the clearance of the offending agent(s) can occur.

DISPOSITION

The maximal severity of a CA poisoning is usually apparent within 2 to 6 hours of an overdose. Patients who develop coma, hypotension, seizures, or arrhythmias require intensive care unit admission. A patient that remains or becomes asymptomatic after 6 hours of observation has not had a significant ingestion. These patients can be medically cleared for discharge or psychiatric evaluation (a requirement for all intentional ingestions). Patients that develop less severe symptoms, such as lethargy or tachycardia, will require prolonged monitoring and observation. Emergency department observation units or intermediate care units are appropriate.

Observation medicine is usually appropriate for serotonin overdoses and mild-to-moderate cases of the serotonin syndrome. Severe cases, however, may warrant intensive care unit admission.

A regional poison information center or toxicologist can be consulted for treatment and disposition decisions. Critically ill and complicated poisoned patients are best served at a regional poison treatment center or tertiary care facility. When indicated, transfer requires either an air ambulance or an advanced cardiac life support–equipped crew, accompanied by a nurse or physician.

COMMON PITFALLS

- Failure to appreciate that patients with recent CA overdose who are awake and appear stable may rapidly deteriorate
- Failure to administer AC
- Failure to aggressively treat seizure activity and correct the resultant metabolic acidosis
- Failure to alkalinize the serum in patients with coma, seizures, hypotension, arrhythmias, and cardiac conduction disturbances
- Failure to recognize the serotonin syndrome and to avoid prescribing multiple medications with serotonergic effects

CHAPTER 314 Antihistamine Poisoning

Andis Graudins

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Histamine receptor antagonists (H₁ and H₂ blockers; [Table 314.1](#)) are a large group of drugs with wide consumer availability and multiple uses. H₁ blockers are used to relieve the symptoms of allergy and the common cold; as sedatives, antipruritics, and antiemetics; to prevent motion sickness; and to reverse dystonic reactions. These agents are available in their pure forms or combined with multiple other drugs (e.g., analgesics, sympathomimetics, caffeine, anticholinergic compounds), which can significantly alter the clinical presentation in overdose. ³ H₂ blockers are used to treat peptic ulcers and gastroesophageal reflux disease; they have also been used to treat allergic conditions.

Agent	Dose (mg)
FIRST-GENERATION H₁ BLOCKERS	
Brompheniramine	4–8
Chlorpheniramine	4
Clemastine	1–3
Cyproheptadine	8
Diphenhydramine	50–100
Hydroxyzine	25–50
Meclizine	2.5–25
Triproleamine	80–160
Triproleamine	25–50
Triproleamine	25–50
SECOND-GENERATION H₁ BLOCKERS	
Azetizole	10
Cetirizine	10
Levocetirizine	10
Fexofenadine	60
Loratadine	10
Terfenadine	60
H₂ BLOCKERS	
Cimetidine	300
Ranitidine	150
Famotidine	40
Esomeprazole	40

TABLE 314.1. Therapeutic Oral Adult Doses of Common Antihistamines

The incidence of antihistamine overdose increased markedly following the approval of over-the-counter sale for brompheniramine, chlorpheniramine, and diphenhydramine in 1983. In 1997, antihistamines represented 4.9% of all exposures reported to poison control centers in the United States. ¹⁴ This number appears to be rising with each year and may be related to the increasing availability of these agents over the counter. Half of all exposures occurred in children under 6 years of age. Half of the ingestions were with over-the-counter medications, and half involved the use of diphenhydramine. There were 25 reported deaths with H₁-receptor antagonist ingestions but none from H₂-receptor antagonists. ¹⁴

H₁ blockers are reversible competitive pharmacologic antagonists of histamine at H₁ receptor sites. They decrease vascular permeability, reduce pruritus, and relax smooth muscle in the respiratory and gastrointestinal (GI) tracts. The older, or first-generation, H₁ blockers are lipophilic, readily penetrate the blood–brain barrier, and cause sedation. These agents may also have anticholinergic, antiserotonergic, and alpha-sympathetic receptor blocking effects, which can become more apparent in overdose. Some of the newer second-generation agents also reduce the release of mediators of inflammation from mast cells. They are much less sedating because they are less penetrating of the central nervous system (CNS) and lack many of the unwanted side effects of the older agents. ¹⁹

H₁ blockers can also block sodium channels in excitable tissues and have local anesthetic effects and antiarrhythmic effects similar to those of class IA antiarrhythmics (e.g., quinidine, procainamide, disopyramide; see [Chapter 311](#)). In particular, diphenhydramine and cyproheptadine are notable for prolonging the duration of cardiac muscle action potential. ⁴ Astemizole and terfenadine may prolong repolarization by blockade of potassium rectifier currents during myocardial repolarization, resulting in QT-interval prolongation on the electrocardiogram (ECG) and a risk of polymorphic ventricular tachycardia. ^{1,20} Drugs blocking terfenadine metabolism, such as ketoconazole and erythromycin, may result in accumulation of the parent compound and an increased risk of cardiac toxicity. ^{9,16} Fexofenadine, an active metabolite of terfenadine, is now available as an antihistamine agent. It does not possess any cardiac toxic effects in therapeutic doses or in animal studies of overdose. To date, there are no reports in the literature of human overdose. ¹⁵

The first-generation H₁ blockers all have the basic structure of histamine. They can be divided into subgroups based on substitutions on the imidazole ring: ethanolamines (e.g., diphenhydramine, dimenhydrinate, doxylamine, clemastine); ethylenediamines (e.g., pyrilamine, methapyrilene, tripeleminamine); piperazines (e.g., chlorcyclizine); alkylamines (e.g., brompheniramine, chlorpheniramine); phenothiazines (e.g., promethazine, trimetopazine); cyclizines (e.g., meclizine, hydroxyzine, cyclizine); and cyproheptadine. The second-generation H₁ blockers are less readily classifiable.

H₂ blockers primarily inhibit gastric acid secretion and have much less sedative and anticholinergic activity than the H₁ antagonists. In overdose, these agents appear to have an extremely high therapeutic index, with reported cases of ingestion of up to 15 g without clinical effect. ¹² The main toxicity of these agents, particularly cimetidine, which inhibits hepatic P-450–mixed function oxidase activity, results from their interaction with the metabolism of other drugs.

Antihistamines are rapidly and extensively absorbed from the GI tract, with peak levels occurring in 2 to 4 hours. In overdose, peak levels may be delayed because of anticholinergic gastric stasis. All antihistamines are affected by extensive first-pass metabolism, with bioavailability of 40% to 60%. Some of these agents may form active metabolites; for instance, hydroxyzine is metabolized to cetirizine, a second-generation agent. ¹⁹ Protein-binding is highly variable, ranging from 20% for cimetidine to 99% for diphenhydramine. Volumes of distribution range from 1 L/kg for cimetidine to 3 to 7 L/kg for diphenhydramine. First-generation H₁ blockers are quite lipophilic and readily cross the blood–brain barrier. Most agents are metabolized in the liver, and the metabolites are excreted renally. Some of the newer agents are excreted unchanged in the urine (cetirizine, a metabolite of hydroxyzine) or fecally (astemizole). ¹⁹ Elimination half-lives are variable for the antihistamines. Most of the first-generation H₁ antagonists have half-lives of 2 to 6 hours. The half-lives of the second-generation H₁ blockers tend to be longer, allowing once-daily dosage. ¹⁹ In the elderly, those with hepatic dysfunction, and patients with overdoses, elimination may be slower.

Antihistamines have a high margin for safety, but massive overdoses of H₁ blockers have led to deaths in adults and children. Drug interactions play a role in many intentional overdoses, with potentiation of toxicity by the concurrent use of barbiturates, benzodiazepines, alcohol, or opioids. Tripeleminamine may be injected in combination with pentazocine (“T’s and blues”) by intravenous drug users.

CLINICAL PRESENTATION

In about a third of reported exposures to H₁ blockers, there are no signs of toxicity. ¹⁴ Another third show signs of mild-to-moderate toxicity. ¹⁴ Symptoms and signs can be divided into CNS, cardiovascular, and anticholinergic effects. CNS depression (e.g., drowsiness, ataxia) is common in adults following overdosage of first-generation agents. ¹¹ There have also been reports of patients presenting with toxic psychosis (as evidenced by hallucinations) ¹¹ and coma (in severe overdoses). In children, CNS excitation is more common because of their sensitivity to the anticholinergic effects. Tremors, confusion, hyperpyrexia, agitation, and seizures are often seen with significant overdose and can progress to status epilepticus. ¹⁷ Children may develop anticholinergic toxicity or encephalopathy following exposure to

topical antihistamines.^{6,18} There have also been rare reports of anisocoria and diplopia as well as dystonias after diphenhydramine overdose.

The most common cardiovascular effect is sinus tachycardia, which is due to anticholinergic blockade. Conduction disturbances can occur with significant overdoses. Diphenhydramine can cause QRS-interval prolongation and ventricular dysrhythmias.^{4,17} Astemizole can cause QT prolongation, atrioventricular block, ventricular tachycardia, and fibrillation following overdose.^{8,13} Terfenadine has also been reported to produce QT prolongation and torsades de pointes, both in overdose and in normal doses, as a drug interaction in patients concomitantly ingesting erythromycin, ketoconazole, sotalol, or cimetidine. This effect may also be apparent in patients with underlying chronic liver impairment and those with congenital QT-interval prolongation. Torsades de point has also been reported in a previously healthy individual on therapeutic doses of terfenadine.¹⁰

Peripheral anticholinergic effects include dry, warm skin; flushing; dry mucous membranes; mydriasis; intestinal ileus; constipation; and urinary retention. These symptoms may persist for several days. Nontraumatic rhabdomyolysis has been reported in patients following H₁-antagonist overdose.

After large ingestions, coma and seizures may occur within 30 minutes of ingestion. Patients with these findings have an increased risk of death. In children less than 2 years old, seizures have occurred with doses as little as 150 mg of diphenhydramine. Fatal doses in adults may range from 20 to 40 mg/kg; in children, as little as 500 mg may result in death.

Significant toxicity following H₂-antagonist overdose is rare.^{12,14} Sinus bradycardia, atrioventricular block, and QT-segment prolongation have been reported in patients on oral or parenteral cimetidine and ranitidine.⁵ Blockade of H₂ receptors and enhancement of H₁-receptor stimulation in cardiac muscle may prolong atrioventricular conduction. These drugs may also produce confusion and disorientation in therapeutic doses.⁵

DIFFERENTIAL DIAGNOSIS

A history of exposure to antihistamines is helpful in the diagnosis of poisoning but is not always available. Antihistamines are widely available as over-the-counter preparations and, as such, are often abused or used in suicide gestures. The diagnosis of H₁-antagonist poisoning should be considered in any patient presenting with signs of anticholinergic blockade, CNS depression, psychosis, or encephalopathy. Other agents capable of producing similar toxicity include antiarrhythmics, cyclic antidepressants, neuroleptics, anticholinergic medications, and plant ingestions, such as jimsonweed, henbane, and deadly nightshade. Antihistamine poisoning must be differentiated from varicella encephalitis in children with altered mental status who have chickenpox and have been treated with topical or oral antihistamines.

EMERGENCY DEPARTMENT EVALUATION

The history includes the time, amount, and identity of all agents ingested; the time of onset, nature, and progression of any symptoms; and any prehospital interventions. The physical examination begins with an assessment of vital signs and cardiovascular and autonomic function. All patients should have cardiac monitoring, and a 12-lead ECG should be obtained in symptomatic ones. In patients with intentional overdoses, routine laboratory evaluation should include electrolyte measurements; blood urea nitrogen, creatinine, and glucose levels; and toxicology screening for coingestion of acetaminophen and salicylate. In patients with abnormal vital signs, full toxicologic screening and a chest radiograph are advised. Antihistamines are not detected by standard immunoassay tests for drugs of abuse. They can be detected by thin-layer and gas chromatography, but these techniques are unavailable in most hospital laboratories.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures are instituted, as necessary. Early airway control and assisted ventilation are important to maintain oxygenation and prevent aspiration pneumonia in obtunded patients. Intravenous access is established. Hypotension is treated with intravenous crystalloid. Seizure activity and agitation may be treated with intravenous benzodiazepines (e.g., lorazepam or diazepam). In refractory cases, barbiturates and chemical paralysis may be necessary. Phenothiazines should be avoided, as they may worsen anticholinergic effects and hypotension.

Ventricular tachyarrhythmias are initially treated with lidocaine. Wide-complex tachycardia associated with massive diphenhydramine overdose may respond to hyperventilation and intravenous sodium bicarbonate infusion.¹⁷ Torsades de pointes associated with astemizole overdose has responded to intravenous magnesium sulfate.¹³ Phenytoin and bretylium might be useful in refractory cases. Class IA antiarrhythmics (e.g., procainamide) and class III agents (e.g., sotalol) should be avoided, as they may promote dysrhythmias due to prolongation of cardiac muscle cell repolarization.⁷ Conduction disturbances and ventricular dysrhythmias seen with terfenadine and astemizole are often self-limiting and may require only ECG monitoring.

In patients with obvious anticholinergic toxicity, and with agitation, hallucinations, and hyperactivity refractory to benzodiazepines, the cholinesterase inhibitor physostigmine may be diagnostic and therapeutic. It may also avert unnecessary and extensive investigation of other potential causes of delirium.² Physostigmine should never be used in patients with ECG evidence of delayed cardiac conduction (see [Chapter 312](#)).

GI decontamination should be performed in adults who have ingested more than five therapeutic doses or in children who have ingested an adult dose. Activated charcoal orally or via a gastric tube is usually adequate in most cases. Gastric lavage should be considered only in those with massive, life-threatening ingestions, with appropriate airway protection in place. Ipecac is contraindicated in H₁-antagonist overdose because of the potential for rapid onset of coma and seizures. Antihistamines have high protein binding and large volumes of distribution, suggesting that extracorporeal methods of removal should be ineffective. A patient with cardiac toxicity resulting from diphenhydramine poisoning and refractory to serum alkalization and bicarbonate therapy had an apparent successful response to in-series hemodialysis and hemoperfusion.¹⁷

DISPOSITION

Patients who become or remain asymptomatic after a 4- to 6-hour observation period may be discharged. Patients with hallucinations, agitation, coma, seizures, or cardiovascular instability should be admitted to the intensive care unit. Patients with persistent but mildly depressed levels of consciousness and stable vital signs should be admitted to a telemetry unit until symptoms have resolved. All patients with intentional overdoses should have a psychiatric evaluation before discharge.

COMMON PITFALLS

- Failing to consider antihistamines as a cause of unexplained dysrhythmias and cardiac conduction disturbances
- Failing to consider antihistamines as a cause of altered mental status in children with varicella
- Inducing emesis in patients, who may rapidly develop CNS depression, seizures, and the inability to protect the airway
- Giving physostigmine to patients with conduction disturbances on ECG
- Using physostigmine to treat CNS depression
- Giving a class IA (e.g., procainamide), IC (e.g., flecainide), or III (e.g., sotalol, amiodarone) antiarrhythmic agent to patients with ventricular tachyarrhythmias due to antihistamines
- Failing to consider the use of sodium bicarbonate and magnesium sulfate in patients with ventricular tachyarrhythmias unresponsive to lidocaine

CHAPTER 315

Antimalarial Poisoning

J. Ward Donovan

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Agents used to treat malaria are derived from a variety of chemical compounds, and include quinolines, quinacrine, halofantrine, and dehydrofolate reductase inhibitors.¹² Of these, the quinoline derivatives quinine and chloroquine cause severe toxicity in overdoses.^{4,10,12}

Quinine is the principal alkaloid derived from the bark of the cinchona tree, and has been used as an antipyretic and for the treatment of malaria, nocturnal leg cramps, and myotonia.¹⁸ Quinine is also used as an adulterant for street cocaine and heroin, as an over-the-counter analgesic and muscle relaxant, and, in small amounts, in tonic water.² Quinoline derivatives have an undeserved reputation as abortifacients.^{2,18} Chloroquine is also used for the treatment of rheumatoid arthritis, parasitemia, and lupus erythematosus.¹⁷ For oral use, quinine is available as the sulfate salt, and chloroquine, as the phosphate salt. Both are available for parenteral use as the hydrochloride salt.

Most quinoline derivative poisonings are the result of attempted suicides and accidental childhood ingestions, but they may also be due to self-induced abortion attempts and to the use of street drugs. Chloroquine poisoning is associated with high fatality rates, but occurrences are infrequent in the United States.^{4,12}

Quinine has local anesthetic and irritant effects, has curare-like action on skeletal muscle, is a vasodilator, has oxytocic action on the uterus, and acts centrally on the chemoreceptor trigger zone to cause emesis.² Chloroquine shares these properties and is also a respiratory depressant. Quinoline derivatives have type 1A antiarrhythmic cardiac effects, including negative inotropism, slowing of depolarization and conduction, increased action potential duration, and lengthened effective refractory period.^{2,12}

Oral quinine and chloroquine are rapidly absorbed in the small intestine, with 80% to 90% bioavailability and peak levels occurring 1 to 3 hours after ingestion.¹⁹ The apparent volume of distribution is 1.6 to 1.8 L/kg for quinine and 116 to 285 L/kg for chloroquine, with plasma protein binding of 89% and 55%, respectively.¹⁹ The elimination of quinine is primarily by hepatic microsomal oxidation, but 20% is excreted unchanged in the urine.² Because it has a pK_a of 8.4, urinary quinine excretion increases as the pH falls, but urinary flow rate may be more important than pH in determining clearance.¹² The elimination half-life of quinine is 10 to 12 hours, but in malaria patients, it increases to 16 to 18 hours, owing to reduced hepatic elimination and an increase in drug distribution.¹² In overdose, the elimination half-life increases to 26 to 34 hours, probably because of decreased (saturable) metabolism.¹ Chloroquine is eliminated by slow hepatic degradation, and 55% is excreted in the urine as chloroquine and its metabolites.¹² The elimination half-life is 75 to 278 hours, with slower elimination seen with higher drug concentrations.¹²

The toxic effects of quinoline derivatives are caused by their antiarrhythmic, cytotoxic, and irritant properties. Oculotoxicity develops in 17% to 42% of patients with quinine poisoning, and appears to be caused by a direct toxic effect on the photoreceptor and ganglion cell layers of the retina.^{2,3} and ^{4,9} Constriction of retinal arterioles occurs secondarily and has been the focus of many unsuccessful therapies.^{1,10}

The toxic dose of quinine in adults ranges from 1.8 g to 4.0 g, but a lethal dose cannot be readily identified.^{1,12} Chloroquine has a narrow margin of safety, with toxicity occurring at doses as low as 1.0 g to 1.5 g, or 20 mg/kg, which is only twice the therapeutic dose.¹² Doses greater than 2 g in adults almost always produce toxic effects, and doses greater than 5 g are usually lethal.¹⁷ There is a good correlation between plasma quinine and chloroquine concentrations and the development of toxicity. Quinine levels of only 2 $\mu\text{g/mL}$ can cause mild, reversible hearing loss.⁶ Levels of 6 to 15 $\mu\text{g/mL}$ are normally associated with the development of toxic effects, although levels of 10 $\mu\text{g/mL}$ may be tolerated in malaria patients because of enhanced drug protein binding.^{1,10} Levels greater than 15 $\mu\text{g/mL}$ are often associated with cardiac arrhythmias, irreversible blindness, and death, but survival has occurred with levels as high as 23.5 $\mu\text{g/mL}$.^{1,4,10} Concentrations higher than 13 $\mu\text{g/mL}$ at 5 hours and 6 $\mu\text{g/mL}$ at 20 hours postingestion predict serious toxicity.^{1,4,10} Chloroquine levels greater than 3 $\mu\text{g/mL}$ are usually toxic, and death is likely if the level is greater than 8 $\mu\text{g/mL}$.^{12,17}

CLINICAL PRESENTATION

In quinine overdose, cinchonism is the most common early feature, and occurs in about 75% of patients.¹⁰ Symptoms usually begin within 4 hours of ingestion but may appear as early as 2 hours after ingestion or be delayed for 8 to 12 hours.^{4,10} Cinchonism is characterized by tinnitus, hearing loss, nausea, vomiting, vertigo, ataxia, diaphoresis, headache, flushing, lethargy, and hypotension.^{2,11,12} It may result from acute or chronic poisoning from any quinoline derivative.

Cardiac toxicity in quinine toxicity is typically mild, with sinus tachycardia and minor electrocardiographic (ECG) changes. However, ventricular arrhythmias, including torsades de pointes, conduction disturbances, and complete atrioventricular dissociation, may occur.² ECG abnormalities include prolonged P-R and Q-T intervals, ST- and T-wave changes, U waves, bundle-branch blocks, and QRS widening.^{4,10} Convulsions, coma, respiratory depression, adult respiratory distress syndrome, and cardiac arrest may occur in large overdoses.^{4,9,10}

Visual disturbances are often delayed for 6 to 24 hours after ingestion, and may present with progressive blurring of vision or sudden blindness.^{10,13} The pupils may become dilated and fixed before vision loss. Peripheral visual field defects, color misperceptions, diplopia, and poor dark adaptation can occur and either progress to total blindness or clear rapidly.^{2,11,13} The fundus usually is normal at the onset of visual defects, but retinal arteriole constriction, macular edema, and a cherry-red macular spot may develop within hours.¹³ Optic atrophy may be seen later in serious cases.² Laboratory findings may include hypoglycemia, hypokalemia, and thrombocytopenia.¹² Hypoglycemia may occur due to quinine-induced inappropriate insulin secretion by the pancreas.² Quinine is seldom successful in inducing abortion but frequently causes fetal abnormalities and maternal deaths.¹⁸

Chloroquine toxicity differs in that it produces a much more rapid onset of symptoms, severe cardiovascular effects, greater respiratory depression, marked hypokalemia, and milder and transient ocular and auditory toxicity.^{12,17} Cardiovascular collapse is common within 2 hours of ingestion and is due to marked myocardial depression and ventricular arrhythmias.¹² Toxicity can be predicted by the degree of hypokalemia, which is probably caused by intracellular shifts, and a QRS greater than 0.12 second.^{12,17} Toxic effects are usually short-lived, despite persistently high plasma levels of the drug.¹⁷

Other quinoline derivatives, such as primaquine, amodiaquine, and piperaquine, do not cause cardiovascular or other severe toxicities. They are associated with gastrointestinal distress, hemolytic anemia, and, at least in the case of primaquine, methemoglobinemia.¹² The acridine derivative, quinacrine, may cause nausea, vomiting, confusion, hallucinations, and seizures.¹² Halofantrine, a phenanthrenemethanol, causes only mild gastrointestinal distress.¹² Of the dehydrofolate reductase inhibitors, pyrimethamine is the most toxic and may cause ataxia, seizures, coma, blindness, and deafness, as well as folate deficiency with megaloblastic anemia.¹² Dapsone may cause acute methemoglobinemia and hemolytic anemia.¹²

DIFFERENTIAL DIAGNOSIS

Quinoline derivative toxicity may resemble the presentation from other agents that cause visual, auditory, or cardiac effects. Methanol, ergot derivatives, and heavy metals (e.g., lead and mercury) should be considered in the differential of visual disturbances from an unknown agent. Unlike the quinolines, methanol causes a marked anion gap acidosis and osmolal gap. Manifestations of cinchonism are similar to those of salicylate toxicity, but the latter causes an elevated anion gap,

acid–base imbalances, and no visual effects.⁴ Quinidine, an isomer of quinine, causes similar cardiac effects but no visual deficits.¹² Cyclic antidepressants cause similar cardiovascular and electrocardiographic effects but do not cause auditory or visual loss.

EMERGENCY DEPARTMENT EVALUATION

In the overdose patient who presents with visual, auditory, and cardiovascular symptoms of unknown cause, the history should include availability or antimalarial agents and drugs for leg cramps, lupus, and arthritis. Attempted abortion by quinine should be suspected in a pregnant patient with these complaints. Physical examination must be directed at the vital signs, cardiac rhythm, auditory and visual acuity, pupillary size and reaction, funduscopic findings, visual field testing, and cerebellar status. Studies to assist in the differential include determination of quinine, quinoline, salicylate, electrolyte, glucose, liver enzyme, blood urea nitrogen, and creatinine levels; complete blood count; platelets; serum osmolality; and ECG. If available, electroretinograms and visual evoked response testing may detect signs of retinal damage in quinine overdose.¹¹

EMERGENCY DEPARTMENT MANAGEMENT

A suspected ingestion of antimalarials requires immediate attention to the vital signs, cardiac monitoring, and gastric decontamination. Prevention of absorption is probably only effective in the first 2 to 3 hours, but it must be aggressively attempted because of the direct relation of peak plasma levels to toxicity. Activated charcoal binds very effectively to chloroquine and quinine, and its immediate use is likely to be more efficacious than induced emesis or gastric lavage.¹⁴ Gastric emptying procedures may be complicated by rapid onset of central nervous system (CNS) depression, particularly with chloroquine overdose.

Hypotension usually responds to fluids but may require a vasopressor (e.g., dopamine or norepinephrine) and powerful inotropes (e.g., epinephrine, isoproterenol, or dobutamine).^{2,5,12,17} Beta agonists (e.g., isoproterenol) or combined beta and alpha agonists (e.g., epinephrine) may be more beneficial in preventing ventricular arrhythmias than alpha agonists, by increasing heart rate and shortening the effective refractory period.⁵ Hypotension, ventricular arrhythmias, and cardiac conduction abnormalities are also likely to respond to serum alkalinization to a pH of 7.50.^{8,12} This may be accomplished by sodium bicarbonate administration, hyperventilation, or a combination of both. Lidocaine has been used but may potentiate the arrhythmias, like all class IA and IC antiarrhythmics. Torsades de pointes may require overdrive pacing.⁵

Benzodiazepines, combined with mechanical ventilation and inotropes, are of significant benefit in chloroquine toxicity.^{5,12,17} Diazepam at doses of 0.5 mg to 3.0 mg/kg may counteract the hemodynamic and ECG changes, perhaps by an antiarrhythmic effect or pharmacokinetic interaction.^{5,16,17} Alternatively, the benefit may derive from its anticonvulsant and sedating effects.⁵ The use of other sedating and anticonvulsant agents, such as barbiturates and thiopental, risk exacerbation of hypotension and have been both discouraged and proposed in severe chloroquine toxicity.^{5,7} The use of high doses of any sedating agent to induce coma and prevent seizures is probably more important than the agent selected. Because cardiac toxicity is similar to that caused by hyperkalemia, hypokalemia need not be corrected unless it is severe. In fact, potassium administration may be harmful and should initially be avoided.¹²

Repeated doses of activated charcoal have been reported to reduce the elimination half-life of quinine by passive diffusion of the drug into the gastrointestinal lumen. The half-life in healthy volunteers taking a therapeutic dose was reduced by 50%, and, in overdoses, was shortened from over 24 hours to 8 hours.¹⁵ Doses of activated charcoal should total 200 to 400 g, given as 25 to 50 gm every 2 to 4 hours.

Acidification of the urine, despite its theoretic potential for enhanced quinine elimination, is unproved, risks increased cardiotoxicity, and should not be used. Resin and charcoal hemoperfusion, hemodialysis, peritoneal dialysis, plasmapheresis, and exchange transfusion have all been tried in attempts to enhance drug elimination. However, because of their high volumes of distribution and plasma protein binding, these techniques remove only a small portion of the total body drug load, and clinical improvements are more likely due to the natural course of recovery.^{1,2,9,12}

Attempts at reversal of retinal arteriolar vasospasm by way of stellate ganglion block, anterior chamber paracentesis, retrobulbar injections, and systemic vasodilators have not been effective and can produce significant complications.^{2,4,9,10,12} Hyperbaric oxygenation therapy has been promoted on the premise that retinal hypoxia secondary to arteriolar vasoconstriction contributes to visual loss.²⁰ However, the reported benefit may well represent natural recovery.

Recovery from quinoline overdose is usually gradual and complete, but visual deficits from quinine may resolve only partially.^{2,4,10,13} Resolution of visual toxicity may occur within hours to months, but, often, the patient is left with peripheral field deficits, color impairment, and night blindness.

Specific therapies for other antimalarials are methylene blue for methemoglobinemia (see [Chapter 352](#)) and multiple-dose charcoal therapy to enhance dapsone removal.¹² Leucovorin and folic acid may be useful in patients with chronic dehydrofolate reductase poisoning.

DISPOSITION

Patients suspected of ingesting a toxic amount of a quinoline derivative should be observed for 6 to 8 hours. Symptomatic patients should be admitted to an intensive care unit. Consultation with a medical toxicologist or the regional poison center should be considered. An ophthalmologist should be consulted in patients with visual symptoms. If such services are not available, transfer to a tertiary center with complete toxicology, cardiac, and ophthalmologic services should be done rapidly and with full advanced life-support capabilities en route.

COMMON PITFALLS

- Failure to consider antimalarial poisoning in patients with auditory, visual, cardiac, and neurologic abnormalities of unknown cause
- Failure to appreciate and be prepared for very rapid neurologic and cardiac deterioration from chloroquine overdose
- Reluctance to administer the very large doses of sedatives to prevent arrhythmias and seizures in patients with chloroquine overdose
- Failure to perform prompt gastrointestinal decontamination and to administer repeated doses of activated charcoal
- Failure to recognize that invasive procedures are unlikely to be of benefit and may have significant complications

CHAPTER 316

Aromatic Hydrocarbon Poisoning

Jeffrey Tucker

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Aromatic hydrocarbons are a group of compounds derived from benzene, a six-membered ring compound that has alternating single and double bonds between its carbon atoms. Common aromatic hydrocarbons include naphthalene and the benzene derivatives, such as toluene (methylbenzene), xylene (dimethylbenzene), styrene, paradichlorobenzene, cresols, and phenols. Aromatic hydrocarbons are found in household and industrial products such as felt-tipped markers, glue, mothballs, shoe polish, solvents, degreasers, paints, paint removers, gasoline, preservatives, and pesticides.¹⁴ Styrene is used in the manufacturing of polystyrene plastics. Although *p*-dichlorobenzene has replaced the more toxic naphthalene in most deodorizers and mothballs, many old-fashioned preparations may still contain naphthalene or camphor. Differences in solubility and density can help differentiate these compounds. Turpentine can dissolve a *p*-dichlorobenzene mothball in 60 minutes, whereas at least 25% of a naphthalene mothball will remain after the same period. When placed in water and saturated-salt solutions (3 tablespoons NaCl per 4 oz H₂O), camphor and *p*-dichlorobenzene float and sink, respectively, in both solutions; naphthalene sinks in water but floats in the salt solution.

Toxicity from aromatic hydrocarbons most often follows intentional inhalation, although accidental industrial and household exposures, including ingestion may occur. Volatile substance abuse (VSA) or inhalant abuse refers to the intentional inhalation of aromatic and other volatile hydrocarbons for the purpose of achieving an euphoric state.^{4,7,9,14} VSA is a widespread problem among adolescents. Preteens and young teens have higher rates of abuse than do older adolescents.^{16,17} Volatile hydrocarbons are abused by “sniffing,” “huffing,” or “bagging.” Sniffing is direct inhalation of the volatile substance from an open container. Huffing involves the inhalation of the volatile substance from a piece of cloth after it has been soaked. In bagging, the volatile substance is placed in a paper or plastic bag. The user then breathes in and out of the bag. Such practices result in exposure to vapor concentrations hundred of times greater than the occupational standards for the safe use of solvents in industry.¹⁴

Inhalation results in the rapid distribution to the brain due to high volatility at room temperature, excellent absorption by the lungs, high lipid solubility, and bypass of first-pass hepatic metabolism. Clinical effects are seen within seconds to minutes and are related to the vapor concentration of the agent, cardiac output, and minute ventilation.

Aromatic hydrocarbons are central nervous system (CNS) depressants and neurotoxins. CNS effects are similar to those seen in ethanol intoxication, except for the presence of hallucinations, more rapid onset, and shorter duration.⁷ Euphoria results from depression (disinhibition) of higher cortical function. Although pharmacologic effects were believed to be due to alterations in membrane function, recent data suggest that binding to specific GABA and glutamate receptors may represent the mechanism of action.^{3,6}

Aromatic hydrocarbons are myocardial irritants and depressants. They can sensitize the heart to the dysrhythmic effects of endogenous as well as exogenous catecholamines. Sudden sniffing death results from ventricular fibrillation.²

They are also respiratory tract, skin, and mucous membrane irritants. Exposure to very high vapor concentrations can lead to pulmonary edema. Ingestions may be accompanied by aspiration pneumonitis. Cresols and phenols are corrosives.

CLINICAL PRESENTATION

Patients may present with altered mental status, gastrointestinal (GI) complaints, respiratory symptoms, trauma, weakness, syncope, or cardiac arrest.^{2,5,7,8,10,14,15,18} Early effects include euphoria, agitation, and hallucinations. Visual hallucinations are more common than auditory hallucinations. With increasing toxicity, depressant effects predominate, with manifestations progressing from slurred speech, ataxia, and impaired manual dexterity, response, speed, and coordination to delirium and coma. Inhalational abusers may have glazed eyes and a vacant expression, and they may appear drunk. Workers exposed to styrene may develop drowsiness, dizziness, nausea, and headache (“styrene sickness”). CNS effects usually last less than an hour after a single acute exposure.

Patients with VSA will usually not seek treatment in the emergency department (ED) unless there has been a complication. They are typically brought in by friends, relatives, ambulance, or police. Findings suggestive of VSA include glue or paint on the hands and face, solvent odor on the breath, and a “glue sniffer’s rash” (erythematous spots around the nose and mouth).

The typical history in a patient with sudden sniffing death is sudden collapse occurring during a period of excited behavior or exertion (e.g., running) shortly after an acute inhalation.² Dysrhythmias have been reported during the use of phenols for removing skin wrinkles (“facial peels”). Toluene abuse has also been associated a myocardial infarction.¹¹

Acute exposure to concentrated cresols and phenols can result in corneal, skin, and GI burns. All aromatics can cause an irritant dermatitis. Children with unintentional mothball ingestions rarely become symptomatic. In contrast, the ingestion of other aromatics is often accompanied by choking, cough, dyspnea, cyanosis, and other manifestations of pulmonary aspiration, along with nausea, vomiting, abdominal cramps, and diarrhea. Systemic effects may ensue.

Chronic inhalational abuse and occupational exposure may result in neurologic, cardiac, hematologic, and renal toxicity. Neurologic effects include cognitive impairment, encephalopathy, dementia, corticospinal tract dysfunction, oculomotor abnormalities, tremor, peripheral neuropathy, parkinsonism, and deafness.^{8,10,19} Subjective symptoms include fatigability, irritability, memory difficulty, changes in personality or mood, and impaired intellectual function. Dilated cardiomyopathy has been reported.

Chronic exposure to benzene is associated with a number of hematologic effects, including leukemia, aplastic anemia and multiple myeloma. Other aromatic hydrocarbons have been reported to cause similar hematologic effects, but this is probably due to contamination with benzene. The oxidative metabolites of naphthalene, alpha-naphthalene and naphthol, can cause methemoglobinemia and hemolytic anemia. Infants and patients with G6PD are at increased risk. Chronic or massive exposure to *p*-dichlorobenzene can lead to aplastic anemia, renal dysfunction, and hepatotoxicity.

Chronic exposure to toluene can cause distal renal tubular acidosis (i.e., bicarbonate wasting), Goodpasture syndrome, formation of urinary calculi, and reversible renal failure.^{14,15} Patients with renal tubular acidosis may present with diffuse weakness associated with hypokalemia and hypophosphatemia, often with accompanying rhabdomyolysis. Either a high-anion-gap metabolic acidosis or a hyperchloremic nonanion-gap acidosis may be seen. Toluene is oxidized to benzoic acid and conjugated with glycine to form hippuric acid, crystals of which may be seen on urinalysis. Chronic toluene abusers may also present with abdominal pain, vomiting, and dehydration. Toluene abuse during pregnancy has been associated with an embryopathy similar to that of fetal alcohol syndrome.^{1,12,20}

Laboratory evaluation may reveal evidence of rhabdomyolysis, blood dyscrasias, normal or high-anion-gap metabolic acidosis, renal failure, and profound hypokalemia. The urine may turn brown following exposure to cresols and phenols.

DIFFERENTIAL DIAGNOSIS

The diagnosis of aromatic hydrocarbon intoxication is made on the basis of history and clinical findings. Laboratory studies may be supportive if abnormal. An ethanol

level should be determined because of the similarity in clinical presentations. Patients may be mistakenly triaged for psychiatric evaluation. The differential diagnosis includes other causes of altered mental status and weakness, such as drug intoxication, trauma, infection, neurologic disorders, and metabolic abnormalities of other causes. Similar metabolic abnormalities may be seen in poisoning caused by salicylates, methanol, ethylene glycol, and ethanol (ketoacidosis). Toxicologic analysis of blood and urine may be necessary to exclude these possibilities.

EMERGENCY DEPARTMENT EVALUATION

The history should include the identity of the offending agent(s) and the details surrounding the exposure (e.g., amount, time, duration, intent). The physical examination should focus on the vital signs and neurologic and cardiorespiratory functions. A detailed mental status and neurologic examination should be performed. The presence or absence of muscle tenderness should be noted. Because intoxicated patients may not perceive pain, the history and physical must also address the possibility of occult trauma.

Ancillary evaluation should include oxygen saturation measurement or arterial blood gas analysis, a complete blood count, electrolytes, blood urea nitrogen, creatinine, glucose, creatinine phosphokinase, urinalysis (for pH, crystals, and myoglobin), and electrocardiogram. Liver function tests should also be obtained in patients with chronic exposures. A chest radiograph should be obtained in patients with respiratory symptoms or abnormal breath sounds. Symptomatic patients with ingestions of cresols and phenols should be evaluated for the presence of oral, esophageal, and GI burns (see [Chapter 330](#)). A computed tomography scan or magnetic resonance imaging of the head may be useful in patients with chronic exposures and neurologic complaints. ^{4,13}

EMERGENCY DEPARTMENT MANAGEMENT

In industrial or environmental accidents, prehospital personnel should not enter an area of potential exposure without adequate respiratory and skin protection.

Management of aromatic hydrocarbon intoxication is supportive. Advanced life-support measures should be instituted, as necessary. Activated charcoal, with or without antecedent gastric aspiration via nasogastric tube, is recommended for patients with recent ingestions. However, if signs and symptoms of corrosive ingestion are present (e.g., with cresols and phenols), aspiration alone is preferred. Seizures, cardiac dysrhythmias, and coma are managed with standard therapy. Epinephrine and beta agonists should be used with caution, as they could precipitate or worsen dysrhythmias. Patients with metabolic acidosis should be treated with intravenous sodium bicarbonate as an infusion, not as a bolus. Volume replacement with normal saline and potassium may be necessary. Rhabdomyolysis should be treated with fluids and, possibly, bicarbonate.

Patients with acute psychiatric symptoms should be reassured and observed in a calm, protective environment. Physical or pharmacologic restraint may be required.

DISPOSITION

Patients with syncope, coma, or dysrhythmias should be admitted to a monitored bed. Those with altered mental status or metabolic abnormalities that persist after 4 to 6 hours of ED observation and treatment should also be admitted.

A neurologist should be consulted for patients with persistently abnormal mental status or peripheral neuropathy. A nephrologist should be consulted for patients with rhabdomyolysis, metabolic abnormalities, or renal dysfunction. Patients with persistent psychiatric symptoms may be referred to a psychiatrist or detoxification center if they are otherwise healthy. Those with hematologic abnormalities should be referred to a hematologist.

Long-term follow-up is usually necessary in patients with chronic aromatic hydrocarbon exposure, particularly to benzene, which may cause leukemia. All patients should be advised to avoid reexposure. VSA patients should be referred for substance-abuse treatment.

COMMON PITFALLS

- Misdiagnosing aromatic hydrocarbon poisoning as psychiatric illness, alcohol intoxication, gastroenteritis, Guillain-Barré syndrome, or dehydration
- Failing to examine blood and urine for hematologic, metabolic, electrolyte, and renal function abnormalities
- Failing to refer patients for appropriate evaluation and follow-up
- Failing to warn patients that they should avoid reexposure and that sudden death may occur during solvent inhalation
- Failing to perform GI decontamination after ingestions for fear of causing aspiration
- Failing to monitor for cardiac dysrhythmias and for hypoxia

ACKNOWLEDGMENT

[Common Pitfalls](#)
[Chapter References](#)

Barbiturates are barbituric acid derivatives that reversibly depress excitable tissues, particularly those of the central nervous system (CNS). The term *short-acting barbiturates* (SABs) includes the pharmacologic categories of short-acting (less than 3 hours) and intermediate-acting (3 to 8 hours) barbiturates, and distinguishing between the two has no clinical relevance in overdose.^{9,10} Barbiturates are available as tablets, capsules, or elixirs for oral use and as parenteral products for intravenous or intramuscular use.

SABs are sedative–hypnotic prescription drugs (Drug Enforcement Administration [DEA] schedule II) with elimination half-lives of usually less than 40 hours ([Table 317.1](#)). SABs used to be widely prescribed as sleeping pills and were the leading cause of coma from drug overdose. Although their abuse has markedly declined in recent years, SABs are still available on the street and remain popular with drug abusers. Most SAB overdoses are suicide attempts, but some are recreational. The usual route of intoxication is oral ingestion; rarely, tablets are dissolved in water and injected intravenously.⁹

Generic Name	U.S. Trade Name	pKa	Protein-Binding (%)	Volume of Distribution (L/kg)	Therapeutic Half-Life (h)
SHORT-ACTING BARBITURATES*					
Amobarbital	Amoyal	7.9	29	0.9–1.4	11–40
Aprobarbital	Abaral	8.1	35–79	0.6–0.7	14–34
Barbital	Barbitol	7.9	—	—	34–42
Phenobarbital	Phenobarbital	7.9	45	0.5–1.0	20–30
Secobarbital	Seconal	7.9	46–79	1.6–1.9	23–29
Thibarbital	Thibarbitol	8.4	—	—	19
LONG-ACTING BARBITURATES					
Barbital [†]	—	7.9	25	0.4–0.6	40
Mephobarbital	Melbaral	7.9	40–60	2.4	40–52
Metharbital	Concord	8.3	—	—	—
Phenobarbital [‡]	—	7.2	30	0.5–0.6	40–144
Primidone	Mysoline	—	8–20	0.5–1.0	6–22
PEMA [§]	—	—	8–20	—	24–48

*Other short-acting barbiturates include butobarbital (used in analgesic/active preparations such as Sagar and Formal) and fenobarbital (not available in United States).
[†]Metabolite of metharbital.
[‡]Metabolite of mephobarbital and primidone.
[§]Phenylethylmalonamide, metabolite of primidone.

TABLE 317.1. Barbiturate Classification and Kinetic Data

Long-acting barbiturates (LABs) are anticonvulsant prescription drugs (DEA schedule IV) with elimination half-lives of usually more than 40 hours (see [Table 317.1](#)). Although LABs have sedative effects, they are used primarily to treat tonic, clonic, and partial seizures. Some intoxications occur because of excessive therapeutic dosage, but most are suicidal ingestions of phenobarbital, taken by epileptic patients or their family members. Most LABs have active metabolites: Mephobarbital is metabolized to phenobarbital (15%); primidone is metabolized to phenobarbital (15% to 25%) and phenylethylmalonamide (PEMA; 50% to 70%).

Barbiturates act by enhancing gamma-aminobutyric acid (GABA) inhibition in excitable tissues of the CNS, skeletal muscle, smooth muscle, and heart.^{11,12} GABA increases chloride flow from the chloride channel to cell membranes, thereby inhibiting depolarization. In addition, phenobarbital decreases the paroxysmal firing of nerve cells by a mechanism that is unknown but different from GABA inhibition.

Barbiturates enhance the metabolism of many drugs by interacting with cytochrome P-450, which binds substrates of the hepatic microsomal drug-metabolizing enzyme system. Although phenobarbital is a strong inducer of cytochrome P-450, it does not induce its own metabolism and appears to have a longer half-life after chronic use.¹⁹ Barbiturates also increase the production of delta-aminolevulinic acid, a precursor of porphobilinogen, and may precipitate an attack of acute intermittent porphyria in patients with porphyria. Ethanol and barbiturates are synergistic: Coingestion of ethanol and an SAB significantly decreases the LD₅₀ of the barbiturate in rats.

Chronic use of barbiturates leads to tolerance, physical dependence, and withdrawal symptoms.

The therapeutic effects of SABs—decreased motor activity (sedation), followed by induction of sleep (hypnosis)—occur at doses of 0.5 to 3.0 mg/kg, begin within 30 minutes, and last for 3 to 8 hours. Therapeutic serum concentrations are 6 to 14 µg/mL.⁹

The maximum recommended anticonvulsant loading dose of phenobarbital is 20 mg/kg; the sedative dose is much lower (30 to 60 mg). Maintenance anticonvulsant doses of LABs are 200 to 600 mg/d for mephobarbital, 100 to 800 mg/d for metharbital, 60 to 200 mg/d for phenobarbital, and 750 to 1000 mg/d for primidone. The therapeutic serum concentration of phenobarbital usually ranges from 15 to 40 µg/mL, but levels up to 50 µg/mL may be necessary to control seizures in some patients. Therapeutic serum levels are 5 to 12 µg/mL for primidone; concomitant metabolite levels average 10 to 20 µg/mL for phenobarbital and 15 µg/mL for PEMA. Therapeutic serum levels for other LABs are not well defined. They are less than 5 µg/mL for mephobarbital and metharbital, with concurrent barbital and phenobarbital metabolite concentrations of 10 to 30 µg/mL. Because their lipid solubility is lower than that of SABs, LABs accumulate more slowly in tissue, and peak effects may not be seen for several hours with therapeutic dosing. Their duration of action ranges from 6 to 24 hours after a single dose.

Barbiturates are well absorbed from the intestinal tract, except for mephobarbital, which is about 71% to 75% absorbed. Food in the stomach decreases the rate of absorption but not the total amount absorbed. Barbiturates are distributed to all tissues and body fluids and concentrate in the brain, liver, and kidneys. SABs are almost entirely metabolized in the liver to inactive metabolites that are excreted in the urine as glucuronides. However, 7.5% to 17.5% of a dose of aprobarbital is excreted unchanged in the urine over 4 days.¹⁷

Liver metabolism of barbital, phenobarbital, primidone, and PEMA is limited because of the lower lipid–water partition coefficients. Hence, urinary excretion accounts for 95% of barbital, 25% to 33% of phenobarbital, 15% to 42% of primidone, and 95% of PEMA elimination. In addition, phenobarbital undergoes enterohepatic recirculation, which contributes to its long half-life.

Because phenobarbital is a weak acid, it is markedly enhanced by alkalization of the urine. Increasing the urine pH increases the fraction of ionized drug in the urine, and thus decreases the amount of un-ionized drug available for passive tubular reabsorption, a process known as *ion trapping*. With alkalization of the urine, the renal clearance of phenobarbital may be increased up to ten times and its half-life shortened by one-half to two-thirds. Although not proven, alkalization of the urine would be expected to have similar effects on LABs that are excreted unchanged in the urine. The elimination of phenobarbital is enhanced by multiple oral doses of activated charcoal.³

Although not studied, a similar effect on SAB elimination would be expected. The relatively low volume of distribution, protein binding, and lipid solubility of barbiturates makes them amenable to removal by extracorporeal techniques. Elimination half-lives for phenobarbital are roughly 30 to 60 hours with alkaline diuresis, 8 to 14 hours with hemodialysis, 6 to 8 hours with hemoperfusion, and 6 to 45 hours with multiple-dose activated charcoal.

The benzodiazepine antagonist CGS 846 has shown some antidotal activity against phenobarbital in animals.¹¹

Barbiturate kinetics in overdosage are largely unknown. There is some evidence that SAB elimination is constant (zero-order) at high concentrations and exponential (first-order) at lower concentrations, indicating saturable (Michaelis-Menten) metabolism. ¹⁶

Toxic effects of barbiturates result from intensification of GABA inhibition. The cerebral cortex and reticular activating system are affected first, producing generalized CNS depression. Skeletal muscle and smooth muscle of the gastrointestinal (GI) tract, urinary bladder, and uterus may lose their tone. Depressed tissue metabolism may result in hypothermia. As the intoxication intensifies, the respiratory and vasomotor centers in the brainstem become depressed. In severe overdoses, depressive effects may extend to cardiac muscle. Cardiac dysrhythmias are unusual, but congestive heart failure may occur. ⁹ Hypotension may result from vasodilatation, fluid loss, or low cardiac output. In most cases, hypotension is due to hypovolemia associated with arterial constriction and normal or low central venous pressure. ¹⁴

For nonaddicts, the acute fatal oral dose of SABs is about 3 to 6 g. Barbiturate addicts may tolerate higher doses. One adult survived a reported ingestion of 20 g. ¹⁸ Serum SAB levels correlate with the severity of intoxication (Table 317.2). For a given level of consciousness, serum SAB concentrations are higher than those listed in addicted patients and lower in those who have coingested other CNS depressants or who have medical complications such as anoxia. The highest reported serum concentration with lack of significant toxicity occurred in an SAB addict, who was drowsy when his serum SAB level was 42 µg/mL. ⁹

Stage	Definition	Serum Level (µg/mL)
Alert	No signs of CNS depression	6
Drowsy	All degrees of CNS depression between alert and stupor	8 ± 2
Stupor	Markedly inhibited; responds but does not awaken to verbal or tactile stimuli	14 ± 3
Coma-1	Responsive to painful stimuli but not to verbal or tactile stimuli, with no disturbances in respiration or blood pressure	18 ± 2
Coma-2	Unconscious, not responsive to painful stimuli, with no disturbances in respiration or blood pressure	22 ± 2
Coma-3	Unresponsive, or abnormally responsive to painful stimuli, with spontaneous respirations that are slow, shallow, or rapid, or with low but adequate blood pressure, or both	26 ± 2
Coma-4	Unresponsive, or abnormally responsive to painful stimuli, with apnea or inadequate respirations, inadequate blood pressure, or both	34 ± 6

TABLE 317.2. USC Coma Scale and Short-Acting Barbiturate Serum Concentrations

The acute fatal oral dose of phenobarbital is about 6 to 9 g in nonaddicted patients. As with SABs, addicts may tolerate larger doses. The correlation between LAB concentrations and level of consciousness has not been precisely defined. Coma (as defined in Table 317.2) may occur with therapeutic levels in patients not previously exposed to LABs who have coingested other CNS depressants (e.g., ethanol). In contrast, patients who chronically use or abuse LABs may have levels of 100 µg/mL without manifesting coma. The highest reported serum phenobarbital level with survival was 580 µg/mL in a patient who survived after hemodialysis and alkaline diuresis, during which 11.4 g of phenobarbital was recovered in the dialysis fluid and urine. ⁵

Some patients, especially the elderly, become excited, depressed, and confused after taking relatively small doses of barbiturates. Patients with hypothyroidism, myasthenia gravis, or impaired cardiac, renal, or respiratory function are sensitive to the effects of barbiturates. Except for phenobarbital and primidone, quantitative serum barbiturate measurements may not be routinely available.

CLINICAL PRESENTATION

The diagnostic signs are CNS depression, decreased motor activity, and some degree of hypothermia. About 40% of patients who present with severe toxicity have aspiration pneumonia. ⁹ One report described a patient who presented with shallow respirations, no obtainable pulse or blood pressure, and a rectal temperature of 69.8°F (21.0°C) after ingesting 3 g phenobarbital; his serum SAB was 27 µg/mL. ⁸ He recovered after peritoneal dialysis with warm fluids. Urinary retention and GI atony with acute gastric dilatation may occur. Patients with SAB intoxication may initially have a high output of almost colorless (dilute) urine. In severe cases, coma with apnea and hypotension may be present. “Barbiturate burns”—erythematous areas over pressure points that blister and heal with a black eschar—may be seen in deeply comatose patients. ¹ Complications include rhabdomyolysis and renal failure. Permanent brain damage and multiple organ failure may result from anoxia. Nonocclusive intestinal infarction requiring ileostomy has been reported during phenobarbital coma. ¹³ Inadvertent intraarterial injection of barbiturates may result in arterial spasm and tissue necrosis. ⁷

Common laboratory abnormalities include hypoglycemia and electrolyte disturbances. Alterations in acid–base and fluid balance may be present. A chest radiograph may show aspiration pneumonia or pulmonary edema. The electrocardiogram (ECG) is usually normal. The electroencephalogram (EEG) shows diffuse slowing during barbiturate-induced coma. Three patients with isoelectric EEGs had complete recovery of cerebral function. ^{6,15}

In SAB overdose, symptoms usually begin less than an hour after ingestion, and toxicity is usually well established by 4 to 6 hours. In LAB overdose, initial symptoms appear within an hour or two of ingestion, but toxicity may not peak for more than 10 hours.

The severity of barbiturate poisoning is judged by the degree of CNS depression and the vital signs (see Table 317.2). Expected serum SAB concentrations at the seven states of intoxication in Table 317.2 apply to patients who have taken only SABs, have no medical complications that would affect the level of consciousness, and are not addicted to barbiturates. Patients with multiple drug ingestions or medical complications such as anoxia have lower serum levels. Patients addicted to the drug have higher serum levels.

The usual clinical course for patients with drowsiness to stage 3 coma is gradual improvement within a day or two for SABs and recovery in 3 to 7 days for LABs. For patients with stage 4 coma from SAB or LAB, intractable shock and adult respiratory distress syndrome or other pulmonary complications may lead to death.

DIFFERENTIAL DIAGNOSIS

A similar clinical picture may be produced by overdosage of other sedative–hypnotics, benzodiazepines, alcohol, narcotics, clonidine, phenothiazines, or carbon monoxide, and, sometimes, phencyclidine, cyclic antidepressants, or methyl bromide. Drug-induced coma must be differentiated from hypoglycemia and other medical causes, head trauma, cerebrovascular insults, and CNS infections.

EMERGENCY DEPARTMENT EVALUATION

The history includes the identity of the drug, time of ingestion, treatment at the scene, known medical or psychiatric illnesses, and current drug therapy, especially use of sleeping pills or treatment for epilepsy. The physical examination focuses on the vital signs, including rectal temperature. The classification of coma includes vital signs, eye opening, best verbal response, best motor response, muscle tone, and deep tendon and central reflexes, such as gag, eyelash, corneal, and oculocephalic reaction. The skin is examined for redness or blisters over pressure points. A succussion splash elicited in the left upper quadrant is a sign of acute gastric dilatation; absent bowel sounds signify GI atony. Suprapubic percussion may reveal a distended urinary bladder.

Routine laboratory tests should include a complete blood count; determination of serum levels of electrolytes, blood urea nitrogen, creatinine, and glucose; and urinalysis. Serum alcohol and barbiturate concentrations should be quantified, if possible. If the history is unobtainable or unreliable, full toxicology screening should be done. Stuporous or comatose patients should have a chest radiograph, ECG, and arterial blood gas and serum chemistry analyses, including liver function tests and muscle enzymes. Patients in stage 3 or 4 coma and those with focal neurologic findings should have a computed tomography scan of the head to rule out cerebral edema and structural causes of coma. A lumbar puncture may be necessary to rule out meningitis.

EMERGENCY DEPARTMENT MANAGEMENT

The treatment of acute barbiturate poisoning is primarily supportive, including an intravenous line, administration of oxygen, cardiac monitoring, intubation, and mechanical ventilation, as necessary. Patients with CNS depression are given intravenous glucose and naloxone. For patients with significant hypotension, assessment of the central venous or pulmonary artery and pulmonary capillary (wedge) pressure is necessary. Those with normal or low pressures and no evidence of pulmonary edema require fluid resuscitation. Fluid administration in patients in stage 3 or 4 coma should be carefully monitored by a Swan-Ganz catheter. Patients with cardiogenic pulmonary edema, high central venous or pulmonary artery pressure, or adult respiratory distress syndrome are treated with dobutamine or dopamine. Furosemide may be given slowly intravenously in small doses (20 to 60 mg). The goal of therapy is to maintain a systolic pressure of 90 mm Hg with adequate tissue perfusion. Mild or moderate hypothermia is treated with blankets to prevent further heat loss; core rewarming is necessary for severe hypothermia.

After resuscitation and stabilization, all patients should undergo GI decontamination. Activated charcoal absorbs barbiturates quite well; repeated oral doses of activated charcoal are recommended for all stuporous and comatose patients with bowel sounds.

In LAB intoxication, the urine should be alkalinized in the absence of renal failure and cerebral or pulmonary edema. Therapy should not be started until fluid and acid–base balances have been restored. One method for alkalinizing the urine is to add 1.5 mEq/kg sodium bicarbonate to 1 L dextrose 5% in 0.45% sodium chloride solution and infuse it at a rate of 200 to 250 mL/h until a urine pH of 7.5 to 8.0 and a volume of 100 to 150 mL/h are attained. If the urine pH has not increased sufficiently after 4 hours, additional doses of bicarbonate in increments of 0.5 mEq/kg may be needed. Treatment continues until the patient regains consciousness.

In addition to vital signs and the cardiovascular measurements noted, the amount of fluid given, urine output, acid–base balance, and oxygenation status must be carefully monitored to prevent fluid overload and alkalosis. These parameters should initially be checked hourly.

Alkalinization of the urine is not indicated for SAB intoxication, because SABs are not significantly excreted in the urine as active drugs.

A major controversy in the treatment of barbiturate intoxication concerns the use of hemoperfusion or hemodialysis. Many experts advocate extracorporeal drug removal only when the patient has failed to respond to supportive measures. Because mortality in comatose patients is related to the presence of apnea, shock, hypothermia, pulmonary complications, and the duration of coma,²⁰ I recommend charcoal or resin hemoperfusion for patients in stage 4 coma with high serum concentrations of either SABs or LABs, and for patients with lesser degrees of coma from LAB toxicity, to shorten the duration of coma. Patients treated with hemoperfusion are usually conscious at the end of the procedure, and rebound toxicity is not expected.⁴

If the patient has pulmonary edema, renal failure, or severe electrolyte imbalance, hemodialysis may be a better choice, although it is not as effective as hemoperfusion in removing barbiturates. Peritoneal dialysis is not as effective as hemodialysis or hemoperfusion.²

Serial barbiturate levels should be obtained to assess the efficacy of all forms of therapy.

DISPOSITION

A regional poison control center or toxicologist should be consulted if the treating physician is not completely familiar with the management of barbiturate intoxication. Nephrology consultation should be obtained when hemodialysis or hemoperfusion is being considered. Psychiatric consultation is required for all suspected suicide attempts as soon as the patient is alert enough to be interviewed.

Awake patients who have ingested SABs may be observed for 4 to 6 hours and then discharged if symptoms are mild and the serum barbiturate level is low. For patients who have ingested LABs, the observation period should be 10 hours. Barbiturate levels should be repeated before discharge to ensure they are not increasing. All stuporous or comatose patients should be admitted to an intensive care unit.

Patients who require intensive care monitoring or hemoperfusion may need to be transferred if such facilities are unavailable. A patient should not be transferred until advanced life-support measures have been instituted and GI decontamination has been performed.

COMMON PITFALLS

- Failing to consider head trauma and barbiturate withdrawal in patients with seizures
- Misinterpreting an isoelectric EEG as evidence of brain death if the patient has very high serum levels of barbiturates
- Failing to perform GI decontamination, regardless of the time of ingestion. Pills can remain in an atonic stomach for many hours.
- Failing to use crystalloids to treat hypotension initially if the patient has normal or low central venous pressure. Vasoconstriction associated with shock may be aggravated by administering dopamine or norepinephrine.
- Failing to monitor fluid and acid–base balances and respiratory status scrupulously during therapy to avoid iatrogenic complications
- Failing to treat patients with LAB overdose with alkaline diuresis and multiple-dose activated charcoal
- Failing to consider extracorporeal drug removal in patients with severe poisoning

[Common Pitfalls](#)
[Chapter References](#)

Arsenic is found in rodenticides, insecticides, herbicides, paints, veterinary medicinals, and folk remedies. It is also present in drinking water and seafood and is used in the production of glass and metals (e.g., computer chips). An estimated 1.5 million exposures to arsenic occur each year. It is the most common cause of acute heavy-metal poisoning and is second only to lead as a cause of chronic intoxication. Arsine gas is formed when arsenic compounds interact with acids.

Arsenic most commonly exists in trivalent (arsenite) and pentavalent (arsenate) forms. The average dietary intake is about 2 mg/d in adults. The trivalent form exhibits rapid gastrointestinal (GI) absorption, with more than 80% of the ingested dose absorbed. The pentavalent form is even more readily absorbed. Blood arsenic levels may be as high as 60 µg/L in normal people, with urine arsenic concentrations ranging from 10 to 300 µg/L. A seafood dinner can transiently elevate arsenic urine levels to 20 to 1,700 µg/L.

Arsenic is an intracellular toxin that appears to act by combining with sulfhydryl groups of enzymes and proteins involved in the Krebs cycle, thereby interfering with oxidative phosphorylation processes. It has also been postulated that arsenic is capable of substituting itself for the phosphate moiety in many cellular reactions, resulting in the loss of high-energy bonds. The pentavalent form appears less toxic than the trivalent form but may be converted to it at the cellular level. An acute dose of 100 to 200 mg is potentially fatal, whereas larger cumulative doses can be tolerated when exposure is chronic.

In poisoned patients, blood arsenic levels usually exceed 100 µg/L, with urine concentrations ranging from several hundred to several thousand micrograms per liter. Arsenic levels tend to remain elevated with chronic exposure but decrease rapidly over a period of several days after acute exposure.

The major route of arsenic elimination is renal excretion, with small amounts excreted in bile, feces, and saliva. The elimination curve is biphasic, apparently because of protein binding and redistribution of arsenic into the extravascular compartment.

Mercury was used as a folk remedy for GI problems, an antiseptic, an antisiphilitic, an unguent, a purgative, and a cure for adynamic ileus during the latter half of the nineteenth century. It is still used medically in dental amalgam and as a germicide, bactericide, diuretic, and laxative. In industry, it is used as a chemical intermediate, in the manufacture of electrical apparatus, and as an antifouling agent, a paint pigment, an instrument fluid, a fungicide, and a catalyst in the production of plastics and paper.

Mercury is found in elemental, inorganic, and organic forms. Toxic effects vary considerably with the chemical form of the metal, as well as the duration and intensity of exposure. There is evidence that *in vivo* conversion exists between the various forms of the metal, and that these forms may accumulate in tissue by binding to proteins. Mercury crosses the placenta and can be secreted into breast milk. Normal blood mercury levels may be 20 µg/L or higher as a result of its presence in dietary fish. Urine concentrations are normally less than 50 µg/L.

Elemental mercury exposure commonly results from the accidental ingestion of the contents of a broken thermometer (0.1 mL), suicidal ingestion, rupture of mercury-containing balloons used for GI procedures, inhalation of mercury vapor, or intravenous or subcutaneous injection.¹⁸ Although mercury is present in dental amalgam, there is little evidence that mercury-containing restorations are hazardous to health.^{4,17} Elemental mercury volatilizes slowly at room temperature (more rapidly with heat), producing mercury vapor that is absorbed through the lungs. It is poorly absorbed from the GI tract but may be absorbed through the skin if applied in a suitable vehicle. The solubility of the lipophilic elemental form, and therefore its potential to cause toxicity, depends on its oxidation to the mercuric ion. This conversion is enhanced with exposure to heat, acids, and strong oxidants. As is true of arsenic, the ionic form of mercury combines with the sulfhydryl groups of various proteins, leading to the inhibition of enzyme systems. Excretion is primarily through the urine and feces, with a half-life of up to 60 days. What constitutes a toxic dose is poorly defined.

In general, bivalent inorganic mercuric salts (e.g., sulfide, chloride, and oxide) are more soluble and more toxic than monovalent ones (e.g., mercurous chloride or calomel). They are irritating, occasionally producing dermatitis with or without vesication, discoloration of the nails, and burns of mucous membranes. The potentially fatal acute oral dose is about 100 mg. Percutaneous absorption can also result in systemic toxicity.²⁰ Once absorbed, inorganic salts are converted to the mercuric form and are concentrated in the kidneys. They do not penetrate the blood–brain barrier to any significant extent, consistent with its limited CNS effects. Excretion is mainly through the urine and feces, with a half-life of about 40 days.

Exposure to organic mercury compounds (merbromin, Merthiolate, thimerosal, methylmercury, ethylmercury, and phenylmercuric salts) is most often due to the ingestion of contaminated fish, shellfish, or grain and to the inhalation of vaporized organomercurials. Consumption of seafood from Minamata Bay, which contained high levels of methylmercury, resulted in an outbreak of chronic organic mercury poisoning (Minamata disease). Mass poisoning has also resulted from the ingestion of grain treated with methylmercury fungicide. Organic forms of mercury are well absorbed by the GI and respiratory tracts, but the potential for dermal absorption appears low.

Alkyl mercury compounds (e.g., methyl and ethylmercury) are highly lipid-soluble, become distributed widely throughout the body, become concentrated in the blood and central nervous system (CNS), and easily pass the placental barrier. Long-chain aryl and alkyl compounds (e.g., phenyl and methoxyethyl mercury) are converted *in vivo* to the inorganic form. The shorter chain alkyl agents undergo enterohepatic recirculation, with final excretion in the feces and a half-life approaching 70 days. The potentially fatal acute oral dose of organic mercurials is about 1 g.

CLINICAL PRESENTATION

Manifestations of acute arsenic poisoning begin 30 minutes to 2 hours after ingestion and usually consist of violent gastroenteritis, with vomiting, profuse diarrhea, colicky abdominal pain, and, in severe cases, GI hemorrhage. Rapidly progressive toxicity, with hypotension, renal failure, Q-T prolongation with ventricular dysrhythmias (e.g., torsades de pointes), rhabdomyolysis, and CNS depression may occur.² Severe, generalized capillary damage can lead to massive third-spacing, resulting in cardiovascular collapse, adult respiratory distress syndrome, and massive proteinuria.

Delayed neurologic, dermatologic, and hematologic effects can occur after acute arsenic poisoning and are similar to the manifestations of chronic intoxication. Symmetric polyneuropathy, involving both sensory and motor nerve fibers, is common. Symptoms can resemble those of the Landry-Guillain-Barré syndrome.⁷ Histologic studies demonstrate axonal degeneration of large myelinated fibers. However, recent evidence supports a demyelinating polyradiculopathy, evolving to an axonal degeneration neuropathy.¹⁵ Recovery is slow (as long as 6 years) and often incomplete. An encephalopathy resembling Wernicke's or one characterized by prominent disinterest and anosognosia of peripheral neurologic deficits can be seen. Dermatologic manifestations may include diffuse exfoliative dermatitis, palmar hyperkeratosis, and Mees lines (transverse white bands on the nails). Normochromic, normocytic anemia, leukopenia, and thrombocytopenia may develop. Chronic exposure may also cause edema, sore throat, stomatitis, pruritus, coryza, alopecia, lacrimation, salivation, weakness, and restrictive or obstructive lung disease.¹³

Symptoms of arsine gas inhalation include abdominal pain, headache, weakness, malaise, nausea, and vomiting. Laboratory manifestations include hemolysis, renal failure, hyperkalemia, and anemia. These findings may be delayed up to 24 hours after milder exposures.

Elemental mercury is relatively nontoxic when ingested, due to poor GI absorption and slow oxidation to a more absorbable form. The oral LD₅₀ for humans has been reported to be in the range of 1,429 mg/kg, or about 100 g in a 70-kg adult.²⁰ With ileus or leakage of mercury into the peritoneal cavity, mercuric oxide or sulfide salts

may form, be absorbed, and cause systemic inorganic mercury poisoning. Without an ileus or GI perforation, systemic absorption is unlikely, and the elemental mercury usually passes uneventfully per rectum.

Aspiration of elemental mercury into the lungs can cause acute respiratory distress, pneumonitis, hemoptysis, cyanosis, tachycardia, hypotension, hematuria, and bloody diarrhea. This type of exposure may also lead to chronic respiratory and systemic problems.¹¹

Intravenous injection of elemental mercury has caused abscess and granuloma formation at the injection site, hemoptysis, pulmonary embolization of mercury with consequent pulmonary dysfunction, and elevated blood and urine mercury levels.¹⁸ Systemic manifestations include weeping dermatitis, leukopenia, anemia, diarrhea, salivation, liver damage, and kidney damage. Subcutaneous injection has also caused local inflammation, abscess and granuloma formation, and elevated mercury concentrations.¹⁴

Exposure to elemental mercury within a confined space may cause toxicity as a result of inhalation of fumes. Heat and oxidative processes accelerate the formation of mercury vapor (mercuric oxide). Symptoms usually begin within a few hours of exposure and include cough, dyspnea, chills, fever, weakness, salivation, nausea, vomiting, diarrhea, and a metallic taste. Respiratory symptoms may subside or progress to interstitial pneumonitis with patchy bilateral infiltrates, pulmonary edema, atelectasis, pneumothorax, necrotizing bronchiolitis, and, possibly, death. Systemic effects similar to those of inorganic mercury poisoning and CNS depression can occur. Fumes can also cause skin and mucous membrane irritation, with manifestations similar to the mucocutaneous lymph node syndrome (Kawasaki disease).¹

Chronic exposure to mercury vapor can result in mild-to-moderate CNS dysfunction, including increased irritability, emotional instability, memory loss, and insomnia.¹⁷ GI complaints, renal failure, chronic pneumonitis, constriction of visual fields, discoloration of the lens capsule, dermatitis, anorexia, and tremor may also be present. Hyperthyroidism and autonomic findings similar to those seen with pheochromocytoma have been described.^{10,14} Findings typically associated with chronic inorganic mercury poisoning (acrodynea) have also been reported.

Acute exposure to the inorganic mercury salts may cause tachycardia, hypotension or hypertension, and sudden cardiovascular collapse. The corrosive nature of such salts often causes nausea, vomiting, abdominal pain, bloody diarrhea, edema, and necrosis of the GI tract. Symptoms may progress over 1 to 3 days to include mercurial stomatitis (glossitis and ulcerative gingivitis), loosening of teeth, jaw necrosis, proximal renal tubular necrosis resulting in transient polyuria, albuminuria, cylindruria, hematuria, anuria, and acidosis.²⁰ Hepatic necrosis can also occur.

Chronic exposure to inorganic mercury salts may result in acrodynea ("pink disease"). Originally reported in children exposed to elemental mercury or teething powders containing calomel, it is characterized by redness of the palms and soles, edema of the hands and feet, rashes, diaphoresis, tachycardia, hypertension, photophobia, irritability, and anorexia.

Poisoning by organic mercurials is usually much more insidious than that which results from inorganic mercury. Symptoms may not occur for as long as several weeks after exposure. Nausea, vomiting, diarrhea, and abdominal pain are common GI complaints. Phenylmercury (and other aryl compounds), however, can cause acute malaise and myalgias, and the alkylmercurials (methylmercury and ethylmercury) are irritating to skin and mucous membranes, possibly resulting in burns and dermatitis. Neurologic effects range from paresthesias, confusion, hallucinations, irritability, sleep disturbances, ataxia, memory loss, slurred speech, auditory defects, narrowing of the visual fields, emotional instability, and inability to concentrate to stupor, coma, and death. Chronic exposure to organic mercurials can result in similar neurotoxicity.

DIFFERENTIAL DIAGNOSIS

Arsenic or mercury poisoning should be suspected in patients with acute or chronic GI and neurologic symptoms and multiple organ dysfunction of unknown etiology. Similar GI symptoms may be caused by viral or bacterial pathogens or the ingestion of other heavy metals (e.g., iron, thallium), food-borne toxins, and a variety of plants, mushrooms, and toxic agents (e.g., theophylline, ricin, abrin, cholinergics, corrosives, lithium, laxatives, alcohol, hydrocarbons, and fluoride). Solvents, hydrocarbons, other heavy metals, alcohol, and vitamins, as well as the possibility of organic disease, should be considered in the differential diagnosis of neurotoxicity. Multiple organ failure can occur after the ingestion of antimetabolites, colchicine, or other heavy metals and exposure to carbon monoxide or cyanide.

EMERGENCY DEPARTMENT EVALUATION

The history should include identification of the product and the route, dose, and duration of exposure. For ingestions, the physical examination should focus on vital signs, assessment of hydration, the abdomen, the cardiovascular system, and neurologic function. The mucosa should be checked for corrosive injury, and airway patency should be confirmed. For mercury inhalation or injection, the examination should also focus on respiratory function.

Ancillary studies include cardiac monitoring, electrocardiogram, chest radiograph, abdominal radiographs (for ingestions), and routine blood work (oxygen saturation or arterial blood gas analysis; complete blood count; serum levels of electrolytes, blood urea nitrogen, creatinine, and glucose; liver function tests; prothrombin time; partial thromboplastin time; creatine phosphokinase; and urinalysis). Blood and 24-hour urine arsenic or mercury levels (with or without chelation, depending on the presence or absence of acute symptoms) should be obtained.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures are instituted, as necessary. Patients with acute ingestions of arsenic or inorganic mercury salts and those with arsine gas inhalation commonly require aggressive intravenous fluid resuscitation. Maintenance fluids should be sufficient to sustain a brisk urine output. Central venous pressure monitoring and bladder catheterization with urine-output monitoring may be necessary. Exposure to elemental mercury fumes may necessitate endotracheal intubation.

For acute ingestions of arsenic and inorganic or organic mercurials, gastric aspiration and lavage are preferred initial methods of GI decontamination, with consideration given to the corrosive effects of the inorganic mercury salts. Activated charcoal should also be given for arsenic and inorganic mercury salt ingestions, and continued until charcoal stool is noted. Whole-bowel irrigation should also be considered for large ingestions or cases in which abdominal radiographs show the persistent presence of radiopaque material in the GI tract. In patients with progressive toxicity and persistent metal present on x-ray despite these interventions, endoscopic or surgical removal may be warranted. GI decontamination is not recommended for acute elemental mercury ingestion or chronic exposures. The patient exposed to arsine gas should have dermal decontamination.

Chelation therapy is warranted in acutely symptomatic patients and possibly in asymptomatic patients who present to the emergency department early after a significant exposure to arsenic and inorganic or aryl mercury compounds. Dimercaprol (BAL in peanut oil) should be initiated with an intramuscular loading dose of 3 to 5 mg/kg and followed by doses of 2.5 to 3.0 mg/kg every 4 to 6 hours during the first 2 days, then every 8 to 12 hours thereafter. If the integrity and function of the gut are intact, D-penicillamine (Cuprimine) or succimer (dimercaptosuccinic acid [DMSA]; Chemet), both oral chelators, may also be given. The dose of D-penicillamine is 100 mg/kg/d (maximum, 2 g/d) in four divided doses, and that of succimer is 10 mg/kg every 8 hours for 5 days, and then the same dose every 12 hours. Some investigators have advocated an optimal adult succimer dose of 30 mg/kg/d for 5 days.^{3,5,9} The duration of the initial chelation course varies, depending on the severity of the exposure. A 5- to 7-day course may be adequate in mild intoxications, but it seems prudent with severe exposures to continue the initial course for 10 to 14 days. Thereafter, 24-hour urine arsenic levels should be followed, with repeat 5- to 14-day courses of chelation therapy prescribed until the 24-hour urine arsenic or mercury level falls below 50 µg/L. Courses of therapy should be interrupted by a 5- to 10-day abstinence period to allow for redistribution of arsenic from peripheral tissues into the blood and more effective subsequent chelation.

Hemolysis caused by arsine gas exposure is usually not responsive to dimercaprol therapy, but exchange transfusion or blood replacement may help. Alkalinization of the urine may benefit patients with significant rhabdomyolysis and hemoglobinuria. The use of chelation therapy in organic and elemental mercury poisoning is controversial, although succimer has shown some promise in the treatment of elemental mercury exposures.

D-penicillamine or succimer therapy is also indicated for asymptomatic patients with an elevated arsenic or mercury body burden (as indicated by blood and urine levels) or for patients exhibiting very mild symptoms who can be treated on an outpatient basis. They may be given in the same dosages described previously. The course may be repeated on the basis of the measurement of urine arsenic or mercury excretion after a 10- to 14-day abstinence period. With prolonged D-penicillamine treatment courses, some authorities have recommended decreasing the dosage to 35 mg/kg/d. Dimercaprol should be used instead of D-penicillamine

if the latter cannot be taken orally, if significant renal impairment is evident, or if the patient is allergic to penicillin or succimer.

Dimercaprol can cause a dose-dependent rise in blood pressure accompanied by tachycardia. Other adverse reactions include pain at the injection site, urticaria, hyperpyrexia, CNS stimulation, headache, nausea, vomiting, conjunctivitis, a burning sensation around the mouth and throat, blepharospasm, and diaphoresis. Because dimercaprol undergoes biliary excretion, it can be used in patients with renal impairment.

D-penicillamine administration has been associated with generalized pruritus, fever, rash, leukopenia, eosinophilia, thrombocytopenia, and other symptoms consistent with penicillin allergy. Nausea, vomiting, diarrhea, nephrotoxic reactions, bone marrow suppression, and a pyridoxine-responsive optic neuritis have also been reported. Due to the possibility of cross-reactivity, D-penicillamine should be avoided in patients with a documented penicillin allergy. It should not be used in renal failure unless concurrent hemodialysis is planned. Complete blood count and renal function should be monitored during therapy.

Although succimer is approved by the Food and Drug Administration (FDA) only for the treatment of lead poisoning in children, it is now advocated for the management of mercury or arsenic toxicity in children or adults.^{3,5,8,9,16} Succimer has the advantage of being relatively nontoxic. GI complaints are among the most common adverse effects. Mild and transient elevations in serum transaminase levels have been reported, so it is prudent to monitor liver function tests during therapy. Thrombocytosis, eosinophilia, and dysrhythmias occur infrequently. Pharyngitis, rhinorrhea, nasal congestion, rash, and mucocutaneous eruptions have also been reported. Because it is primarily eliminated in the urine, it should be used with caution in patients with renal impairment.

N-acetyl-D, L-penicillamine, an investigational oral chelator, appears to be more specific for chelating mercury than is D-penicillamine. It has been effective in reversing neurotoxicity due to chronic elemental and inorganic mercury exposures.¹² The dosage regimen is similar to that for D-penicillamine: Adults receive 250 to 500 mg four times a day (children, 30 mg/kg/d) for 6 to 10 days.

Dimercaptopropane sulfonate (DMPS) is an effective chelator of arsenic, elemental mercury, and inorganic mercurial salts. It is used in Europe and is also available (without FDA approval) in the United States. It can be given by a variety of parenteral routes (intravenous, intramuscular, subcutaneous) as well as orally. For chronic arsenic chelation, an oral regimen of 100 mg, administered three times a day for 3 weeks, has been used for up to 9 months. For the management of mercury exposures, 5 mg/kg of a 5% solution has been administered intramuscularly or subcutaneously three to four times within the first 24 hours, two to three times a day on day 2, and then one to two administrations daily on subsequent days.

N-acetylcysteine has also shown some promise in the treatment of arsenic and inorganic mercury salt exposures.^{6,19} It could be used in the same doses as for acetaminophen poisoning. Limited experience suggests that hemodialysis (in conjunction with chelation therapy) performed within the first 24 hours of acute arsenic or mercury poisoning may remove a significant percentage of the ingested toxin before distribution into tissues, possibly averting, or at least minimizing, the toxic effects. It is ineffective later in the course, when there is relatively little metal in the blood. Hemodialysis is, however, indicated for the removal of chelated mercury or arsenic when renal dysfunction impairs its clearance.

DISPOSITION

Patients with acute poisoning after ingesting inorganic arsenic or mercury salts and long-chain aryl organic mercurials, or inhaling arsine or elemental mercury should be admitted. Patients with significant chronic toxicity should also be admitted for initial therapy. The level of care (intensive care unit or floor bed) should be dictated by the clinical presentation. The asymptomatic patient should be observed for 6 to 8 hours before discharge, with arrangements made for next-day follow-up. Patients who present with asymptomatic exposures or mild-to-moderate chronic toxicity may be treated as outpatients.

Consultation with a regional poison control center or a clinical toxicologist and a nephrologist should be part of the treatment plan. Although chelation therapy is not technically difficult, the details of treatment must be individualized, and optimal management requires the guidance of an experienced consultant. If antidotes and experts are not available locally, transfer of the patient to a tertiary care facility may be necessary. Patients with intentional exposures require psychiatric evaluation prior to discharge.

COMMON PITFALLS

- Failure to consider the possibility of acute arsenic or mercury poisoning in patients with intense abdominal pain and violent gastroenteritis of unknown cause
- Failure to appreciate that acute poisoning by inorganic arsenic or mercury salts can be rapidly progressive and that cardiovascular collapse may ensue if vigorous fluid resuscitation is not undertaken
- Failure to appreciate that the effects of mercury vary considerably with the form of the metal and the route, duration, and intensity of the exposure
- Failure to appreciate that the ingestion of liquid elemental mercury is usually benign, whereas inhalation of elemental mercury vapor may result in severe acute toxicity
- Failure to treat poisoning by long-chain aryl organomercurials the same as for inorganic salts, because the former is converted to the latter *in vivo*
- Failure to appreciate that the type of exposure, clinical severity, GI and renal function, and potential side effects of therapy influence the choice of chelating agent
- Failure to seek expert advice regarding treatment, particularly chelation

TABLE 319.1. Benzodiazepines: Dosage and Kinetics

Although the incidence of abuse and overdose is second only to that of alcohol, serious toxicity and fatalities are seldom encountered unless benzodiazepines are combined with other central nervous system (CNS) depressants.⁷

Benzodiazepines (BZDs) potentiate gamma-aminobutyric acid (GABA) neurotransmission at all levels of the neurologic axis and increase the efficacy of GABA synaptic inhibition at the postsynaptic GABA subtype A (GABA-A) receptor sites.¹⁹ Potentiation of GABA molecules increases the rate at which chloride ion channels open, remain open, and allow chloride influx. Enhanced chloride ion permeability renders the postsynaptic sites less excitable. Several BZD receptor sites have been identified in the CNS that modulate anxiolytic, hypnotic, neuroleptic, and anticonvulsant properties. Receptor antagonists, such as the imidazodiazepine flumazenil, may be useful in the treatment of BZD poisoning.

The gastrointestinal tract rapidly and completely absorbs most of the BZDs, but absorption by the intramuscular route is sometimes erratic and delayed. The rate of absorption from the gastrointestinal tract, rather than lipophilicity, determines the onset of action. Diazepam, alprazolam, and triazolam are the most rapidly absorbed oral agents; prazepam is the slowest. Peak levels occur in 1 to 3 hours, but ethanol enhances absorption and may cause the peak level to be doubled at 1 hour.

The volume of distribution (V_D) for diazepam is 0.95 to 2.0 L/kg; for lorazepam, 1.3 L/kg; and for chlordiazepoxide, 0.3 to 6.0 L/kg. The range for other drugs in the class is 0.26 to 6 L/kg (see [Table 319.1](#)). The more lipophilic BZDs, such as diazepam and midazolam, have a shorter duration of action after a single dose than do less lipid soluble derivatives, such as lorazepam and chlordiazepoxide, because increasing lipophilicity enhances drug distribution into peripheral sites (adipose tissue). This leads to the rapid egress of the drug out of blood and brain into inactive storage sites, thus diminishing its effects on the CNS. The BZDs are highly protein bound (85% to 99%). Hepatic metabolism is their primary route of elimination. The two principal pathways involve either hepatic microsomal oxidation (*N*-dealkylation or aliphatic hydroxylation) or glucuronide conjugation ([Fig. 319.1](#)).

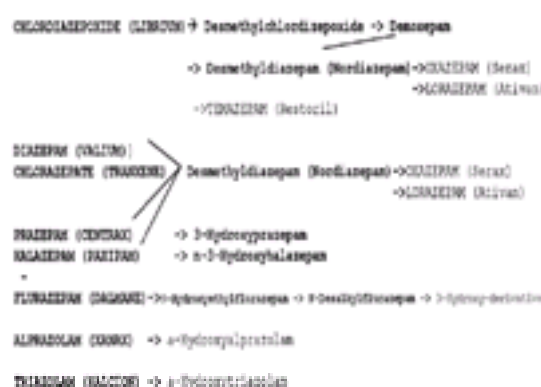

Figure 319.1. Metabolism of benzodiazepines. Compounds in boldface capitals have active metabolites. Compounds in regular-face capitals are active drugs without active metabolites. Compounds in lowercase bold are active metabolites. Compounds in regular-face letters are clinically insignificant in active metabolites.

BZDs are substrates for CYP 2c19 and CYP 3A4 hepatic enzymes. CYP 3A4 is the predominant P-450 enzyme for xenobiotic metabolism, and is inducible by a variety of drugs, including rifampin, phenobarbital, and phenytoin. Elimination half-life can be increased by microsomal enzyme inhibitors, thus producing a potentially hazardous interaction, especially with midazolam. Examples of inhibitors include clotrimazole, erythromycin, estrogens, isoniazid, and ketoconazole. The elimination half-life is prolonged in elderly men, owing to unknown mechanisms. The elimination half-life is also prolonged in obese patients because of an increased V_D and in patients with hepatic dysfunction because of impaired metabolism. Pharmacokinetic parameters and duration of action of the various BZDs are listed in [Table 319.1](#).

Massive overdoses of BZDs of up to 2,000 mg of chlordiazepoxide and 1,400 mg of diazepam have minimal toxic effects, and recovery is rapid and complete.⁸ A lethal dose for BZDs has not been established; other CNS depressants enhance sedation and respiratory depression. Intravenous diazepam and midazolam are more toxic than the oral forms, and rapid administration may result in apnea and hypotension, because propylene glycol is used as a vehicle.⁹ Concern about the ability to produce abuse, dependence, and delayed withdrawal reaction has led to restricting the range of indications for dispensing these agents.^{5,13} Dependence on diazepam is produced by a dosage of 60 mg/d for 40 days; dependence on chlordiazepoxide is produced by a dosage of 200 mg/d for 60 days.

Flunitrazepam (trade name, Rohypnol; street names, “roofies,” “Mexican Valium,” “parachute,” “roach 2”) is a long-acting BZD agonist sold by prescription in over 60 countries worldwide, but it is not legally available in the United States. It has anxiolytic, anticonvulsant, and sedative effects; it also causes amnesia, muscle relaxation, and sleep induction. Flunitrazepam is sold illegally in the United States and is abused as a “date rape” drug because of the anterograde amnesia associated with its use.¹

Flunitrazepam readily mixes with alcohol-containing beverages, although the manufacturer (Roche) has produced tablets that will break down into particles and turn

the beverage blue. It is touted as a remedy for the depression that often follows a stimulant high, hence the street name “parachute.” The pharmacokinetics include an onset of 1.5 to 2.0 hours, an oral peak of 2 hours and a duration of action of 8 hours or more after a 2-mg dose.

Flunitrazepam can be identified in urine from 4 to 30 days after ingestion. Although routine drug screens check for BZDs, they usually do not identify flunitrazepam. However, Hoffman-LaRoche has made available a free testing service for cases in which “date rape” drugs are suspected. For testing authorization, emergency departments, rape crisis centers, and law enforcement agencies can call 1-800-608-6540. National Medical Services, at 1-800-522-6671 or 1-215-657-4900, also has a date-rape drug-testing service. They test for flunitrazepam, ketamine, or gamma-hydroxybutyric acid (GHB). There is a fee charged for this service.

Zolpidem (Ambien) is a non-BZD, imidazopyridine sedative–hypnotic drug. Imidazopyridines are thought to interact with the same GABA receptor–chloride channel complex as the BZDs by high affinity with the “central-type” BZD receptors.¹¹ Zolpidem is approved only for short-term treatment of insomnia. Its metabolism is prolonged in the elderly.

Like the BZDs, zolpidem overdose usually does not produce severe respiratory depression unless other agents are coingested. However, caution should be exercised in patients with obstructive sleep apnea. Adverse effects are headache, nausea, diarrhea, miosis, and next-day drowsiness. Confusion in the elderly can occur at doses over 20 mg. Cases of withdrawal and tolerance have been reported.^{8,12}

CLINICAL PRESENTATION

Manifestations of acute BZD poisoning include ataxia, lateral nystagmus, hypotonia, drowsiness, slurred speech, and coma.³⁶ Even when BZD is given in large doses, a resultant deep coma, causing cardiorespiratory depression and loss of deep tendon reflexes, is rare. The ultrashort-acting agents are important exceptions, however. Triazolam has been reported to produce apnea and coma within 1 hour of a dose of 2 to 5 mg.¹⁴ Two fatal poisonings have also been associated with temazepam overdose. The toxic dose of flunitrazepam for a child is 0.1 mg/kg.¹⁷

Paradoxical excitement, including hallucinations, hostility, and seizures, has been reported to result from BZD overdose.³ A sensitivity to triazolam in the healthy elderly has been reported. Triazolam has been noted to produce delirium and psychosis. Nitrazepam also has been associated with swallowing disturbances in children, which may result in aspiration.¹²

The elderly and very young children are more susceptible to the CNS depressant action of BZDs. In rare instances, the adult respiratory distress syndrome has developed after a 30-mg intravenous dose of chlordiazepoxide and a massive flurazepam ingestion.^{16,18}

Long-term use of high therapeutic doses of BZDs produces manifestations of anxiety, insomnia, anorexia, headache, muscle spasm, and weakness. A spectrum of affective disorders (psychosis, agitation, confusion, hallucinations, and delirium) and motor dysfunction (tremors, restlessness, myoclonic jerks, and seizures) may develop on withdrawal when diazepam has been taken in daily doses of 60 to 300 mg.

Seizures are rare, and most commonly develop 7 to 8 days after withdrawal (range, 2 to 12 days). Withdrawal symptoms develop in an average of 3 to 4 days after discontinuation (range, 1 to 11 days), peak in 5 to 6 days, and resolve by 4 weeks, but minor symptoms may persist for months.^{9,13} Earlier onset and peak and shorter duration of withdrawal may be seen with shorter acting agents.

Most patients with acute BZD poisoning recover without sequelae within 24 hours. Patients with preexisting medical conditions, such as hepatic disease, may be more susceptible to toxicity. Chronic BZD use may cause mild leukopenia and abnormal liver function tests.

Quantitative plasma BZD levels are useful only for diagnostic confirmation, not for evaluation or management. Tolerance, drug coingestion, active metabolites, and distant tissue-binding sites result in poor correlation between blood concentrations and clinical effects. Although diazepam levels of 5 to 20 mg/mL are often associated with toxicity and levels over 20 mg/mL may be seen in lethal cases, chronic daily consumption of large doses may result in blood concentrations of 5 to 6 mg/mL without signs of toxicity.

DIFFERENTIAL DIAGNOSIS

The presence of deep coma, apnea or significant respiratory depression, hypotension, multiple organ involvement, or a prolonged time for recovery should prompt a search for coingestants (i.e., sedatives, narcotics, sympatholytics, cholinergics, or alcohols) or another cause (i.e., CNS lesions, trauma, infection, or metabolic disturbances).

EMERGENCY DEPARTMENT EVALUATION

The history should include the time and intent of all agents ingested and the amount and duration of chronic daily BZD use. Concomitant medications and medical history should also be documented. The physical examination should focus on vital signs and neurologic and cardiorespiratory function and the ability to protect the airway.

Except for measurement of oxygen saturation, routine laboratory tests are not necessary in the verbally responsive patient. Hematologic and metabolic profiles, urinalysis, and arterial blood gas analysis are recommended for those who are unresponsive to voice. Qualitative or semiquantitative BZD analysis of the blood and urine by immunoassay or thin-layer chromatography may confirm the presence of the drug but does not guide clinical management. It should be noted, however, that immunoassay screening techniques will only detect BZDs that are metabolized to desmethyldiazepam or oxazepam and that most BZDs are not detected in thin-layer chromatography of the urine due to low drug concentrations. Immunoassays show cross-reactivity, such that false-positive results can occur with nonsteroidal antiinflammatory drugs (NSAIDs). Thin-layer chromatography, gas chromatography, and mass spectroscopy successfully discriminate between BZDs and NSAIDs.^{28,29}

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures should be instituted, as necessary. Supportive therapy is usually all that is necessary when a BZD is the sole agent involved.²⁰ Gastrointestinal decontamination is indicated for patients who present within 1 hour of ingestion.^{1,36} Forced diuresis and hemodialysis are ineffective in enhancing BZD elimination because of high protein binding and V_D . Full recovery can be expected within 12 to 24 hours.

Flumazenil (Romazicon) is available in 5-mL and 10-mL vials containing 0.1 mg/mL. It is a specific competitive BZD receptor antagonist that blocks the effect of inhibitory neurotransmitters (GABA) and reverses BZD-induced CNS depression. It also appears to be effective in reversing the sedative effects of zolpidem and endogenous BZD receptor agonists associated with hepatic encephalopathy. It does not antagonize other portions of the GABA receptor (e.g., barbiturate, ethanol, general anesthetic-binding sites) and does not affect the bioavailability, plasma concentration, or elimination half-life of BZDs. Most importantly, it may not reverse BZD-induced hypoventilation.¹⁰ Airway protection and mechanical ventilation are definitive treatment for respiratory distress or failure.

In intravenous doses of 0.1 to 0.2 mg, flumazenil is partially antagonistic. In doses of 0.4 to 1.0 mg, onset of action and reversal of the CNS effects are evident within 1 to 2 minutes. An 80% response occurs within 3 minutes, and the peak effect is noted within 6 to 10 minutes. Duration and degree of reversal are related to the dose and the plasma concentration of BZD. In general, flumazenil has a short duration of action. Because flumazenil has a shorter duration of action than most BZDs, the effects from the exposure may recur. A 1-mg bolus usually lasts about 60 minutes but can last as long as 6 hours.¹⁰

Indications for flumazenil include reversal of the sedative effect of BZDs when they have been used therapeutically (e.g., for conscious sedation, see [Chapter 413](#)) and for the management of accidental or intentional BZD overdose. In overdose situations, flumazenil is best reserved for patients with pure, acute BZD overdose who are verbally unresponsive and have no history of long-term BZD use or recent treatment of a medical condition (e.g., seizures) with BZDs. The use of flumazenil as a diagnostic and therapeutic tool in patients in coma of uncertain etiology is controversial, and generally not recommended.

Studies suggest that there is an increase in GABA-ergic tone in hepatic encephalopathy. BZD has been detected in the cerebrospinal fluid of patients with hepatic

encephalopathy, and the use of flumazenil has led to the improvement of clinical as well as electrophysiologic responses in such patients. While the response rate in case studies is approximately 65%, additional research is necessary to further characterize the role of flumazenil in hepatic encephalopathy.

The suggested treatment protocol for using flumazenil in patients with known or suspected BZD overdose is shown in [Fig. 319.2](#). An initial dose of 0.1 mg is recommended for patients who are potentially addicted to BZDs and at risk for withdrawal. Patients who do not use BZDs chronically can be given an initial dose of 0.2 mg. For the reversal of therapeutic sedation, the initial dose in adults is 0.3 mg intravenously, followed by 0.1 mg every minute until the patient is awake or a total dose of 2 to 5 mg has been administered. It may be repeated in boluses of 0.1 mg or administered as an infusion of 0.1 to 0.5 mg/h, if necessary.

Figure 319.2. Flumazenil dosing for benzodiazepine

Patients who respond to flumazenil must be continuously monitored for re-sedation. Furthermore, because flumazenil does not reverse hypoventilation, patients who awaken must often be repeatedly “reminded” to breath (e.g., they must be prompted to “take a deep breath”), and the adequacy of ventilation must be frequently reassessed. Emergence reactions following flumazenil administration (e.g., anxiety, agitation, confusion) are relatively common, particularly when flumazenil is given in higher doses or more rapidly than recommended.

Flumazenil has no significant intrinsic pharmacologic activity. It may cause withdrawal and seizures in BZD-dependent patients, however, and it should be used in such patients with extreme caution, if at all. Lower-than-recommended doses and slower administration should be used if the benefits outweigh the risks. Seizures have also been reported in patients with CNS trauma and cyclic antidepressant, cocaine, and isoniazid intoxication who were given flumazenil. Because BZDs have therapeutic roles (i.e., as anticonvulsants) in these conditions, flumazenil should not be given to such patients. Serious cyclic antidepressant poisoning is an absolute contraindication to the use of flumazenil. QRS-interval prolongation on an electrocardiogram is a sensitive indicator of cyclic antidepressant toxicity (see [Chapter 313](#)); this finding in a patient with an unknown or mixed overdose should be considered a contraindication to flumazenil administration. A flumazenil-related dystonic reaction has also been reported. There is no role in the treatment of BZD poisoning for stimulants such as aminophylline–theophylline, naloxone, or physostigmine.

Stopping the use of BZDs in any patient who has been maintained on these drugs longer than 6 weeks should be done gradually over a minimum of 3 weeks and up to 2 to 3 months, depending on previous dosage and duration of treatment. BZD withdrawal is managed by institution of oral diazepam (10 to 60 mg) for several days, followed by tapering the dose by 10% daily, usually over several weeks. Physician visits every 5 to 7 days are necessary to assess both physical symptoms and coping mechanisms.

DISPOSITION

Consultation with a specialist is rarely indicated, because most BZD overdoses alone do not produce significant toxicity. Psychiatric evaluation is necessary before discharge, unless the exposure is accidental.

Patients with mild clinical toxicity (i.e., they are lethargic or asleep but respond to verbal stimuli) can often be observed in the emergency department until they recover. Those who respond only to painful stimulation, regardless of whether flumazenil is given, probably require 12 or more hours of monitoring and treatment. If emergency department observation is not possible, these patients should be admitted to an intensive care unit.

Outpatient referral and follow-up are required for patients who have evidence of chronic abuse, dependence, or psychological problems, such as depression.

Transfer is indicated only if the initial facility lacks the equipment or personnel to deliver the level of support needed to maintain the patient or to provide the appropriate specialized evaluation and treatment of sequelae or complications of the overdose.

COMMON PITFALLS

- Failure to consider concomitant poisoning or other causes, especially in patients with severe CNS depression
- Failure to administer oxygen, glucose, thiamine, and naloxone to comatose patients
- Failure to appreciate that patients with poisoning from BZDs alone usually only require 6 hours of observation, not hospital admission.
- Failure to appreciate that many BZDs are not detected by immunoassay screening techniques
- Administering large initial doses of flumazenil to patients with a history of chronic BZD use, thereby precipitating withdrawal and possibly seizures
- Use of flumazenil in overdose patients with seizures or conduction delays on their electrocardiogram and in those who have coingested agents known to cause these conditions

[Chapter References](#)

Beta blockers are used to treat a wide variety of conditions, including angina pectoris, pheochromocytoma, thyrotoxicosis, hypertension, aortic dissection, congestive cardiomyopathy, dysrhythmias, glaucoma, tremors, stage fright, mitral valve prolapse, migraine headache, portal hypertension, and alcohol withdrawal, and to prevent reinfarction and sudden death after myocardial infarction. These agents competitively inhibit the binding of norepinephrine and epinephrine to b-adrenergic neurohumoral receptors. This, in turn, inhibits the production of cyclic adenosine monophosphate (cAMP) by adenylate cyclase and decreases the physiologic effects resulting from the stimulation of b1 and b2 receptors ([Table 320.1](#)). Decreased levels of cAMP also inhibit sodium and calcium influx during phase zero (depolarization) of the action potential. This latter effect defines beta blockers as class II antidysrhythmics.

Receptor Type	Organ	Response to Receptor Stimulation
Beta-1	Eye	Aqueous humor production
	Heart	Increased automaticity, conduction velocity, contractility, refractory period
Beta-2	Kidney	Renin production
	Blood vessels	Smooth muscle contraction
	Bronchioles	Smooth muscle contraction
	Fat	Lipolysis
	Liver	Gluconeogenesis, glycogenolysis
	Pancreas	Insulin release
	Skeletal muscle	Increased tone, potassium uptake
Uterus	Smooth muscle relaxation	

TABLE 320.1. Beta Receptors and Their Activity

While all beta blockers block one or both subtypes of b receptors, their pharmacologic profiles differ in other respects ([Table 320.2](#)). So-called first-generation agents are nonselective and inhibit both b₁ and b₂ receptors. The second-generation, or cardioselective, beta blockers act primarily on b₁ receptors, and third-generation agents have additional alpha-adrenergic receptor blocking activity. Some beta blockers also have partial agonist (sympathomimetic) activity, and others have quinidine-like myocardial membrane-stabilizing effects. Carvedilol has antioxidant activity and sotalol has electrophysiologic properties similar to class III antidysrhythmic agents. Especially in high concentrations, sotalol prolongs the duration of the action potential in the ventricle and Purkinje fibers, which, in turn, results in a prolonged Q-T interval.¹⁵

Drug	Pharmacologic Activity					Pharmacokinetics				
	Dose (mg)	Cardio-selective	Partial Agonist	Membrane-stabilizing	Absorption (%)	First-Pass Metabolism (%)	Protein Binding (%)	Volume of Distribution (L/kg)	Route of Elimination	Half-Life (h)

TABLE 320.2. Pharmacology of Beta Blockers

Most beta-blocker preparations are racemic mixtures of the d and l isomers, with the l isomer responsible for most of their activity. They are available as immediate- and sustained-release pills for oral use and as solutions for intravenous and ocular use. All beta blockers are well absorbed, and peak effects occur 1 to 2 hours after a single therapeutic dose. Although most have relatively short durations of action (less than 6 hours), extended-release formulations allow for once-daily dosing. Beta blockers differ markedly in protein binding, elimination, absorption, and first-pass hepatic metabolism ([Table 320.3](#)). There is a rough correlation between volume of distribution, lipid solubility, and membrane activity.

Agent	Absorption (%)	First-Pass Metabolism (%)	Protein Binding (%)	Volume of Distribution (L/kg)	Route of Elimination	Half-Life (h)
Acetazolamide	70	Yes	25	2.3	Renal	6
Alprenolol	50	No	15	6.7	Renal	6-8

Timolol	>100	No	10	1.2	Renal	4-6

TABLE 320.3. Pharmacokinetics of Beta Blockers

After overdose, the cardioselectivity of second-generation agents may be lost, and membrane effects may occur with all agents.^{7,9,12,20} Excessive beta-receptor blockade and membrane depression are responsible for cardiovascular, central nervous system (CNS), and metabolic toxicity. Drugs with similar activity, such as quinidine and calcium channel blockers, synergistically add to the cardiovascular toxicity when used concurrently. Patients with underlying heart, kidney, or liver disease are at increased risk for toxicity.¹²

Chronic use of beta blockers results in an increased density of adrenergic receptors and a supersensitivity to catecholamines on drug withdrawal. Hence, large doses of beta blockers are usually well tolerated when the drug dose is gradually increased, but the same dosage can result in toxicity if the patient is not accustomed to beta blockers. In addition, receptor supersensitivity may result in a sympathomimetic withdrawal syndrome after the abrupt termination of beta-blocker therapy. ¹³

The minimal dose necessary to produce toxic effects varies with the particular agent. In general, toxicity may result from the ingestion of an adult dose by a child or a high therapeutic dose by a previously unexposed adult. The ingestion of more than 1 g of any beta blocker may cause serious or fatal toxicity.

CLINICAL PRESENTATION

Manifestations of toxicity usually begin within 30 minutes and peak within 2 hours of an acute oral overdose. ^{7,9,20} Exceptions to this are sustained-release preparations and sotalol, which may produce severe dysrhythmias up to 20 hours after ingestion. ^{2,14,15} Factors that influence the severity of poisoning include the type and amount of beta blockers ingested, the patient's age, the presence of underlying cardiovascular disease, tolerance to beta blockers, and the concurrent ingestion of other cardiodepressants, such as calcium channel blockers and quinidine.

The level of consciousness and the degree of hypotension reflect the severity of the intoxication. ^{7,9,20} In mild and moderate poisoning, symptoms include nausea, vomiting, bradycardia, and normal or slightly decreased blood pressure. The patient may be alert or slightly confused and lethargic. Hypotension can occur in the absence of bradycardia. In severe overdoses, marked bradycardia, hypotension, coma, respiratory depression, and convulsions may be present. Electromechanical dissociation, asystole, ventricular tachycardia, and ventricular fibrillation have also been reported. ^{5,14,16} The skin is often pale and clammy; cyanosis, both central and peripheral, has been reported. Pulmonary edema, congestive heart failure, and bronchospasm may also be seen, particularly in patients with underlying cardiac or pulmonary disease. Oliguric renal failure and mesenteric ischemia are rare complications. Beta blockers with high lipid solubility and membrane-stabilizing effects (e.g., propranolol) produce more pronounced CNS disturbances. Agents with partial sympathomimetic activity (e.g., pindolol) may cause hypertension and tachycardia. ⁹

Metabolic abnormalities include hypoglycemia and hyperkalemia. Diabetics and children are at greatest risk for hypoglycemia. Metabolic (lactic) acidosis may be present in patients with shock. With increasing severity of poisoning, ECG manifestations include sinus bradycardia, progressive atrioventricular block, loss of P waves, early repolarization, increased QRS duration with either a nonspecific or bundle-branch block pattern, and asystole. Early repolarization and ST-segment elevation have also been reported. ⁶ Interventricular conduction delays are more common with agents that have greater membrane-stabilizing activity. Sinus tachycardia, prolongation of the Q-T interval, ventricular tachycardia (including torsades de pointes), ventricular fibrillation, and asystole may be seen with sotalol poisoning. ¹⁵ Labetalol (and probably carvedilol) may cause severe hypotension, presumably due to its concomitant alpha-blocking activity. The chest radiograph may demonstrate pulmonary edema with or without cardiomegaly. Dilated cardiomyopathy may be seen on echocardiogram. ¹³ Angina pectoris, myocardial infarction, and a hyperadrenergic state may result when longstanding beta-blocker therapy is abruptly discontinued. ¹² Beta blockers are not detected by enzyme immunoassay toxicology screening tests, and are variably detected by thin-layer chromatography. Quantitative blood levels are not routinely available and serve only to confirm an overdose.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis is that of cardiovascular collapse and includes anaphylaxis, cardiogenic shock, pulmonary emboli, hypovolemia, sepsis, and other overdoses. Beta-blocker poisoning should be suspected in patients who suddenly develop hypotension, bradycardia, or seizures that are resistant to standard therapies. Agents that may cause similar toxicity include antidysrhythmic agents, calcium channel blockers, carbamate and organophosphorus insecticides, centrally acting antihypertensive drugs, cyanide, digitalis, narcotics, sedative-hypnotics, and tricyclic antidepressants. The serum glucose level may be helpful in differentiating beta-blocker poisoning from calcium channel-blocker poisoning. Hypoglycemia may be present in the former, and hyperglycemia in the latter. Hyperkalemia is another diagnostic clue.

EMERGENCY DEPARTMENT EVALUATION

The history should include the time, type, and amount of beta blocker (and any other agents) ingested; current medications; and a medical history. The physical examination should focus on vital signs, the cardiopulmonary system, and the neurologic status. All patients should have cardiac monitoring, frequent monitoring of vital signs, and an initial rhythm strip, as well as a 12-lead ECG. In symptomatic patients, the physician should also obtain serum electrolyte measurements; glucose, blood urea nitrogen, and creatinine levels; a complete blood count; oxygen saturation or arterial blood gas analysis; and a chest radiograph. Severely poisoned patients should also have liver function tests. In unclear cases, toxicology screening tests may be useful in identifying beta blockers or coingestants.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures should be instituted as necessary. Prehospital personnel should follow advanced cardiac life-support (ACLS) guidelines for the treatment of symptomatic bradycardia, hypotension, and dysrhythmias. Endotracheal intubation and assisted ventilation may be necessary in patients with CNS or respiratory depression. Patients with altered mental status, particularly those with coma or seizures, should be given intravenous dextrose 50% in water and naloxone. Dextrose is particularly important, because beta-blocker poisoning may cause hypoglycemia. For severe cases of known etiology that are unresponsive to standard ACLS measures, prehospital personnel should also give glucagon and calcium, if available.

Patients with bradycardia and a normal blood pressure need only close monitoring. Bradycardia with hypotension should be treated initially with pharmacologic measures such as intravenous fluids, atropine, beta agonists (e.g., epinephrine, isoproterenol), glucagon, calcium, and vasopressors (e.g., dopamine, norepinephrine). Combined therapy with multiple agents may be effective when a single agent is not. Dobutamine may be useful for patients with concomitant pulmonary edema or congestive heart failure. Glucagon is the most consistently effective single agent for treating cardiovascular toxicity. Atropine usually reverses bradycardia but does not necessarily reverse hypotension. ¹⁰

The utility of beta agonists and vasopressors is often limited: A therapeutic response often requires doses three to four times the normal levels, and toxic reactions may occur. ^{7,9,20} Invasive (peripheral and pulmonary artery pressure) monitoring may be necessary to optimize the treatment of persistent hemodynamic instability.

All severely poisoned patients should be given glucagon, either alone or in combination with other agents. Glucagon effectively increases the heart's contractility, as well as the heart rate and blood pressure, by activating adenylate cyclase, which, in turn, stimulates nonadrenergic membrane receptors. ¹⁷ Glucagon is more effective in reversing hypotension (86%) than either epinephrine (50%) or isoproterenol (22%), even when it occurs in the absence of concomitant bradycardia. ⁴ It is given as an initial bolus of 5 to 10 mg intravenously (50 to 150 µg/kg in children), diluted in 10 mL of saline, followed by an infusion of 1 to 5 mg/h (10 to 50 µg/kg/h in children).

Intravenous calcium, given in the same dose as for poisoning by calcium channel blockers (see [Chapter 321](#)), may also reverse hypotension. ^{8,16} Preliminary data suggest that the glucose-insulin-potassium regimen used for calcium channel blocker poisoning may also be effective for beta blockers.

Theophylline, which stimulates endogenous catecholamine release and inhibits the enzymatic inactivation of cAMP by phosphodiesterase, has a synergistic effect with glucagon in canine studies, but its clinical effectiveness is not well substantiated. ¹⁹

Prenalterol, a cardioselective beta agonist, has been successful in reversing both bradycardia and hypotension but is not yet approved for use in the United States.

Amrinone produces an inotropic effect that is not inhibited by alpha- or beta-receptor blockade. It has been used successfully in conjunction with glucagon to treat hypotension caused by a calcium channel poisoning and is effective in canine beta-blocker poisoning. The dosage of amrinone for heart failure is a slow intravenous bolus of 0.75 mg/kg, followed by a continuous infusion of 5 to 10 µg/kg/min. If necessary, the bolus dose may be repeated 30 minutes after beginning therapy.

If pharmacologic therapy fails to restore hemodynamic stability, the physician should consider invasive measures such as cardiac pacing (transcutaneous or

transvenous), intraaortic balloon pump, cardiopulmonary bypass, and extracorporeal membrane oxygenation. ^{10,11,14}

Patients with hypertension and sinus tachycardia due to sotalol poisoning usually require only close monitoring. If the blood pressure or heart rate is dangerously high, or if there is evidence of organ ischemia, short-acting agents (e.g., nitroprusside and esmolol) should be used. Ventricular dysrhythmias, including torsades de pointes, may result from the prolonged Q-T interval as well as the bradycardia, which lends itself to the R-on-T phenomenon. Treatment of ventricular tachyarrhythmias includes lidocaine, magnesium (2 to 4 g intravenously over several minutes to an hour, depending on patient stability), phenytoin, or overdrive pacing with either isoproterenol or electricity. ^{2,15,18} Prophylactic magnesium may be useful for patients with a prolonged Q-T interval. Sodium bicarbonate (see [Chapter 311](#)) should also be considered in the treatment of ventricular tachyarrhythmias and conduction disturbances caused by membrane-active agents. ⁵ Class IA antidysrhythmics, such as procainamide, and class III agents, such as bretylium, should be avoided.

Seizures that are not caused by hypoglycemia or responsive to glucose should be treated with diazepam, phenytoin, or a barbiturate. Bronchospasm may require the use of inhaled beta agonists, subcutaneous epinephrine, and intravenous aminophylline, alone or in combination. Exacerbation of hypotension is a potential side effect of these agents.

Gastrointestinal (GI) decontamination should be done as soon as possible. Activated charcoal is the preferred method. Whole-bowel irrigation may have some benefit in the ingestion of sustained-released tablets. Ipecac should be avoided because of the potential for vagally mediated cardiovascular collapse secondary to vomiting and the risk of aspiration if coma or seizures develop. A prophylactic dose of atropine (e.g., 0.5 mg intravenously for adults and 0.01 mg/kg for children) may inhibit the detrimental vagal effects that may result from endotracheal or gastric intubation. Repeated doses of activated charcoal are recommended for symptomatic patients.

Although charcoal hemoperfusion has been used successfully in a case of metoprolol poisoning, pharmacokinetic efficacy has not been documented. ³ Except for atenolol and sotalol, extracorporeal measures are unlikely to remove significant amounts of beta blockers because of unfavorable kinetic parameters. ^{4,7,18,20}

Clinical toxicity seldom lasts longer than 24 to 48 hours. ^{1,7,9,16} If vital signs can be supported, most patients will completely recover. The treatment of withdrawal involves treatment of ischemic complications and reinstatement of beta-blocker therapy, with a slow tapering of the dose over a 2-week period.

DISPOSITION

Patients who ingest immediate-release formulations and have mild or absent toxicity can usually be discharged, or referred for psychiatric evaluation, if they remain or become asymptomatic and have a normal ECG after 4 to 6 hours of emergency department observation. Patients who ingest sustained-released formulations should be observed for 12 hours. Patients who manifest any symptoms or signs of poisoning during the observation period should be admitted for 24 hours of cardiac monitoring. Those with abnormal vital signs, nonsinus rhythm on ECG, coma, or seizures should be admitted to an intensive care unit. Physicians unfamiliar with beta-blocker poisoning should consult a poison center or toxicologist. The services of a cardiologist or vascular surgeon may be required if electrical pacing or invasive measures are needed for hemodynamic support. If intensive care and invasive treatments are necessary but unavailable, patients should be transferred to another institution by advanced life-support units and should be accompanied by personnel familiar with potential or required therapies.

COMMON PITFALLS

- Failure to appreciate that GI decontamination may increase vagal tone and worsen or precipitate cardiovascular toxicity
- Giving ipecac to patients who may rapidly deteriorate
- Failure to determine whether the preparation ingested was an immediate- or sustained-release preparation
- Failure to appreciate that beta blockers can cause hypoglycemia, and to give dextrose to patients with altered mental status, especially those with coma and seizures
- Failure to appreciate that glucagon is the treatment of choice for bradycardia and hypotension
- Failure to appreciate that combined drug therapy may be effective for cardiovascular toxicity when a single agent is not
- Failure to consider invasive measures for hemodynamic support when drug therapy is ineffective

Calcium channel blockers (CCBs) are a structurally diverse group of drugs that are used for the treatment of supraventricular arrhythmias, hypertension, angina, heart failure, and subarachnoid hemorrhage, and in the prevention of migraine headaches. Ten CCBs are currently approved for use in the United States: verapamil, diltiazem, nifedipine, nicardipine, felodipine, isradipine, amlodipine, nisoldipine, nimodipine, and bepridil.

Calcium channels are found in the membranes of many cells, especially those of vascular smooth muscle, the myocardium, and the specialized pacemaker and conducting fibers of the heart. Membrane depolarization leads to the influx of calcium ions by way of the calcium channels. As intracellular calcium concentration rises in muscle cells, actin–myosin interaction inhibition ceases and muscle contraction occurs. In the pacemaker cells of the sinoatrial and atrioventricular (AV) nodes, the influx of calcium by way of slow channels during phase 4 of the action potential accounts for spontaneous depolarization. In His-Purkinje cells, calcium influx by way of slow channels contributes to phase 2 (plateau) as well as to phase 4 of the action potential. CCBs act by depressing the activation, inactivation, and recovery of slow calcium channels, and are thus classified as class IV antiarrhythmics. Cardiovascular responses to therapeutic doses vary considerably ([Table 321.1](#) and [Table 321.2](#)). Serum calcium and ionized calcium levels remain normal in therapeutic use and overdose, and do not reflect the pharmacologic loss of calcium activity.

	Verapamil	Diltiazem	Nifedipine and Other Dihydropyridines	Bepridil
Heart rate (sinus node)	↑ or ↓	↓	↑	↓
Atrioventricular nodal conduction	↓↓	↓	↑	↓
Smooth-muscle tone	↓↓	↓	↓↓↓	↓
Blood pressure	↓	↓	↓↓	↓
Contractility (in vivo)	↓↓	↓	↑ or ↓	↓

TABLE 321.1. Cardiovascular Response to Drug Therapy

Drug	Trade name	Usual Dose	Therapeutic Range
Verapamil	Calan, Isoptin, Verelan		
Oral		80–160 mg t.i.d.	15–100 ng/mL
Intravenous		5–10 mg	
Diltiazem	Cardzem, Dilacor	30–90 mg q.i.d.	30–130 ng/mL
Nifedipine	Adalat, Procardia	10–40 mg t.i.d.	25–100 ng/mL
Nicardipine	Cardene	20–40 mg q.i.d.	20–50 ng/mL
Nimodipine	Nimotop	60 mg q8h	7–86 ng/mL
Felodipine	Plenil	5–20 mg qd	0.7–8.0 ng/mL
Isradipine	DynaCirc	2.5–10.0 mg b.i.d.	2–4 ng/mL
Nisoldipine	Solar	20–40 mg qd	
Amlodipine	Norvasc	2.5–10.0 mg qd	5–15 ng/mL
Bepridil	Viscor	200–400 mg qd	

TABLE 321.2. Therapeutic Doses of Calcium Channel Blockers

CCBs are well absorbed after oral administration. With verapamil, onset of action is noted within the first hour, and peak effects occur approximately 5 hours after ingestion. Nifedipine, nicardipine, and diltiazem, on the other hand, are more rapidly absorbed and show peak effects in 30 minutes to 2 hours after ingestion. Symptom onset and peak effects are usually delayed 6 to 18 hours after the ingestion of sustained-release preparations. CCBs are significantly protein-bound (80% to 98%), have a moderate volume of distribution (1.4 to 4.3 L/kg), are extensively metabolized by the liver, and are excreted in the urine and bile. Verapamil, diltiazem, and bepridil have active metabolites. The elimination half-life for most CCBs is 2 to 9 hours in therapeutic doses. Amlodipine and bepridil have longer half-lives, ranging from 24 to 60 hours. After overdose, the half-life of diltiazem remains unchanged; those of verapamil and nifedipine increase slightly. ^{4,9,11,15}

Most of the CCB clinical toxicology experience is based on three agents: verapamil, diltiazem, and nifedipine. Nicardipine, felodipine, nisoldipine, isradipine, amlodipine, and nimodipine are members of the same class as nifedipine (dihydropyridines) and can be expected to have similar toxicity. Bepridil is a unique agent, with actions both as a CCB and a type Ia antiarrhythmic (see [Chapter 311](#)). The toxic cardiovascular effects of CCBs are due to an exaggeration of their therapeutic effects. Peripheral vascular resistance is always decreased, but cardiac output may be normal, increased, or decreased. Central nervous system effects are secondary to hypoperfusion. Hypoperfusion may also lead to lactic acidosis. Inhibition of calcium-dependent insulin release may cause hyperglycemia. With overdose, the drug-specific effects noted in [Table 321.1](#) are often lost. ^{13,16}

Because people ingest drugs that are readily available to them, an unusually large percentage of CCB poisoning occurs in older people. Most of these are intentional, but some result from confusion or failing vision. Toxic doses are at least one to two times the usual total daily dose. ¹⁶ Significant toxicity has been reported after ingestion of a single tablet of by a child. ¹⁸ The elderly are susceptible to lower toxic doses. ¹⁶ Toxicity can also be seen when these agents are used in therapeutic doses with other myocardial depressants, such as b-adrenergic blockers and quinidine-like agents.

CLINICAL PRESENTATION

Signs and symptoms of toxicity usually develop within 30 minutes of ingestion but may be delayed as long as 16 hours after overdose of sustained-released preparations. Findings include hypotension, bradycardia, drowsiness, confusion, thready pulse, and peripheral cyanosis. Older patients may experience chest pain and myocardial ischemia and infarction. Inadequate perfusion may also result in cerebral, renal and bowel ischemia, or infarction in patients of all ages. In severe cases, coma, seizures, and respiratory distress associated with pulmonary edema are described. The electrocardiogram (ECG) often shows decreased rate and first-, second-, or even third-degree AV block, and may have changes indicative of ischemia or infarction. ¹⁶ Chest radiography may show pulmonary edema. Laboratory abnormalities include metabolic acidosis and hyperglycemia. Serum drug levels are not readily available and have not proved useful in the management of these patients.

Toxic effects typically last 24 to 36 hours. Duration may be longer after ingestion of bepridil, amlodipine, and sustained-release preparations. Complications have

required longer hospitalizations in many patients.

DIFFERENTIAL DIAGNOSIS

Patients with primary myocardial infarction, as well as those with overdosage of b-adrenergic blockers, digoxin, clonidine, guanabenz, imidazolines, angiotensin converting enzyme inhibitors, cholinergic agents (nicotine, organophosphate and carbamate insecticides, and myasthenic agents), tricyclic antidepressants, a-methyl dopa, and veratrum alkaloid-containing sneezing powders, may present similarly to those with CCB ingestion. b-Adrenergic blocking agents are more likely to cause hypoglycemia, and CCBs are more likely to cause hyperglycemia. With cholinergic agents salivation, nausea, vomiting, diarrhea, and weakness dominate the presentation. Tricyclic antidepressant overdosage infrequently presents with heart block and bradycardia. The QRS complex is often prolonged in tricyclic antidepressant ingestion but is usually normal with CCB overdosage.

EMERGENCY DEPARTMENT EVALUATION

The history should include time of ingestion and all other substances ingested or available to the patient. Physical examination should focus on the pulse, blood pressure, central nervous system function, heart, lungs, and peripheral perfusion. All patients should have cardiac monitoring, an ECG, and frequent monitoring of blood pressure. Those with symptoms, abnormal vital signs, or an abnormal ECG should have arterial blood gas analysis and determination of serum electrolytes, glucose, blood urea nitrogen, and creatinine. Continuous peripheral and pulmonary artery pressure monitoring may be necessary in patients with shock.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures should be initiated as necessary. Intravenous access should be established in all patients. Early management should include gastrointestinal decontamination. Activated charcoal is the preferred method.

Mild hypotension may respond to a fluid challenge with 1 to 2 L of saline solution (10 to 20 mL/kg in children). When bradycardia, with or without AV block, is also present, atropine (1.0 mg intravenously; 0.01 mg/kg in children) can be tried. Response is infrequent but may be improved following calcium administration. ^{8,16}

Hypotension and symptomatic bradycardia should also be treated with calcium chloride (1 g intravenous slow push; 10 to 20 mg/kg in children). ¹⁶ Calcium gluconate (3 g intravenous slow push; 30 to 60 mg/kg in children) may be given if calcium chloride is unavailable. This dose may be repeated several times in patients who show incomplete, transient, or no response. ^{2,5,13,14} Care must be taken to avoid extravasation, which can result in severe tissue damage. A continuous infusion at the rate of 1 g/h of calcium chloride or gluconate may be used to support heart rate and blood pressure in patients who relapse after an initial bolus. Doses as high as 30 g of calcium gluconate in 12 hours have been used with success. ² Calcium levels should be monitored in patients receiving more than two doses, but very high serum calcium levels are not a reason to discontinue treatment. Response and survival have been associated with dosing that resulted in a peak serum calcium level of 23.8 mg/dL. ² In another patient who responded to high-dose calcium, irreversible hypotension occurred when calcium gluconate was discontinued, solely because the serum calcium level had reached 17.7 mg/dL. ¹³

Hemodynamically compromising bradycardia or heart block unresponsive to atropine and calcium may respond to an infusion of glucagon or isoproterenol, but a pacemaker is often required. ^{3,16} Hypotension unresponsive to fluids and calcium should be treated with pressors. Pressors may be given without regard to the coincident presence of heart disease or acute myocardial infarction, because they are titrated to reverse the adverse pharmacologic effect of the calcium blocking agent. Dopamine, dobutamine, norepinephrine, isoproterenol, and combinations of these have been used with success. Beta-agonist (inotropic) activity may be more important than alpha-agonist (peripheral vasoconstricting) activity, particularly following verapamil and diltiazem ingestions. Glucagon may also be considered in this setting. Intravenous doses of glucagon, 5 and 10 mg, have each been reported to produce a significant response. ^{3,19} Amrinone has produced additive effects, with isoproterenol in one case report and glucagon in another. ^{5,20} The use of an intraaortic balloon pump should be considered in patients who are unresponsive to pharmacologic therapies. Cardiopulmonary bypass was also used to sustain a child until hepatic metabolism of verapamil occurred. ⁷

Hyperinsulinemia–euglycemia therapy, which facilitates myocardial metabolism and enhances myocardial contractility, significantly improved hemodynamics and survival over controls and epinephrine-treated, calcium-treated, and glucagon-treated dogs. ¹² Human experience is limited. Five humans with severe hypotension and bradycardia, considered unresponsive to conventional therapy, were treated with regular insulin (0.1 to 0.2 U/kg as a bolus, followed by 0.1 to 1.0 U/kg/h) along with glucose (25 g as a bolus, followed by 1 g/kg/h as a 20% infusion) and potassium sufficient to maintain euglycemia and normokalemia. ¹⁰ Blood pressure normalized in all five, and all five survived. Two had transient asymptomatic hypoglycemia.

Limited information exists regarding the use of multidose charcoal to enhance CCB elimination in the overdose setting, but when used, it has not been shown to be of benefit. ¹⁷ Although enhanced elimination using charcoal hemoperfusion was described in a patient with diltiazem overdose, ¹ it should not be regarded as standard therapy. If supportive measures can maintain a pulse and blood pressure sufficient to allow hemoperfusion, there is little to be gained from this procedure. Full recovery can be expected, unless prolonged shock has resulted in irreversible end-organ damage.

DISPOSITION

Asymptomatic patients should be observed for 4 to 6 hours after ingestion of standard formulations and 18 to 24 hours following ingestion of sustained-release ones. Those who remain asymptomatic may be discharged or referred for psychiatric evaluation. Symptomatic patients should be admitted to an intensive care unit. A regional poison center or a toxicologist should be consulted if the physician is unfamiliar with the management of CCB overdosage. Transfer may be necessary if an intensive care unit bed is unavailable and should be arranged as soon as the ingestion is recognized, because cardiovascular performance may rapidly deteriorate. The patient should be transferred in an advanced life-support unit with an adequate supply of cardiovascular drugs, including calcium chloride and glucagon, on hand.

COMMON PITFALLS

- Failure to consider CCB poisoning in patients with hypotension, bradycardia, or AV block, particularly when hyperglycemia is present
- Failure to observe asymptomatic patients with overdoses of sustained preparations for an extended period of time
- Failure to administer calcium, a specific antidote, for hypotension or bradycardia
- Failure to administer chronotropic agents and pressors to patients with myocardial ischemia secondary to hypoperfusion
- Failure to appreciate that refractory hypotension and bradycardia may respond to glucagon or high-dose insulin and glucose therapy
- Failure to consider invasive hemodynamic monitoring and cardiovascular support in patients with shock

Carbamazepine (CBZ) is an anticonvulsant drug widely used for the management of epilepsy, trigeminal neuralgia, chronic pain syndromes, and affective disorders. Its main actions are to reduce the permeability of neuronal membranes to sodium and potassium ions, and to block norepinephrine reuptake. CBZ is an iminostilbene derivative, structurally related to the tricyclic antidepressants. Despite the structural resemblance between CBZ and the tricyclic antidepressants, there is only partial overlapping in their toxicity after overdose. Notably, the therapeutic index of CBZ is much greater than the tricyclic antidepressants.

CBZ is available in 100- and 200-mg tablets and as a 100-mg/5 mL suspension. Although CBZ is almost completely absorbed, the rate of absorption can be erratic. Peak concentrations, usually found 4 to 8 hours after therapeutic dosing, may be delayed 24 to 72 hours after massive ingestions. At therapeutic concentrations (4 and 10 mg/L), CBZ is 75% bound to plasma proteins, with a volume of distribution of 0.8 to 1.2 L/kg and a total body clearance of about 1.3 mL/kg/min (adult). CBZ is predominantly metabolized to CBZ 10,11 epoxide (CBZE), which, in turn, is metabolized and excreted principally as glucuronides in the urine.⁵ CBZE is pharmacologically active, possessing both anticonvulsant and toxic properties. Concentrations of CBZE are usually about 20% of those of CBZ, but can be as high as 50% after overdose. CBZE is less protein-bound (50%) and has a smaller volume of distribution (0.74 L/kg) and a shorter half-life than CBZ, but it has a comparable total body clearance.

Within weeks of therapeutic use, CBZ induces its own metabolism by hepatic P-450 enzymes, especially CYP 3A3 and 3A4. Consequently, patients naive to CBZ eliminate it with a half-life of 20 to 65 hours, much slower than that of the chronic user (8 to 17 hours). The half-life of CBZE is 8 to 14 hours. Other anticonvulsants, such as phenobarbital, phenytoin, valproic acid, and felbamate, may further increase the metabolism of CBZ by heteroinduction. CBZ metabolism is inhibited by erythromycin, propoxyphene, isoniazid, calcium channel blockers, cimetidine, fluvoxamine, ketoconazole, and other CYP 3A3 and 3A4 inhibitors, at times resulting in toxicity despite therapeutic CBZ dosing.

After overdose, significant toxicity can be expected after ingestion of 20 to 30 mg/kg in an adult patient not regularly taking CBZ,¹⁴ and life-threatening effects may occur after ingestion of 140 mg/kg.³ Ingestions of greater than 20 g have been associated with fatal outcome.¹⁶ In a patient regularly taking CBZ, and thus with induced metabolism, survival has been reported after acute ingestion of 640 mg/kg.¹⁵ One patient survived an ingestion of 80 g.¹⁴ After an overdose, even in patients on chronic therapy, the half-life of CBZ is prolonged to about 19 hours.⁸ This may be due to saturation of the rate-limiting epoxidation to CBZE as well as ongoing gastrointestinal (GI) absorption.

CLINICAL PRESENTATION

The clinical manifestations of CBZ toxicity involve four main areas: central nervous system (CNS), ocular, cardiac, and motor.^{11,16} Although a sequential progression is classically described, individual patients may present at any stage and may, at times, progress rapidly to profound coma and cardiac instability.¹³ Initial symptoms include restlessness, confusion, excitation, and aggression. Dizziness, ataxia with nystagmus and diplopia, nausea, and vomiting are often present. As toxicity progresses, drowsiness, coma, and respiratory depression may occur, often after some hours.²⁰ Hypotension (preceded by hypertension) and rhythm disturbances may be seen in severe poisoning.¹³ Loss of P waves, premature ventricular beats, QRS prolongation, and complete atrioventricular block have been described, and tend to occur in the elderly or patients with underlying cardiac disease.^{9,10} In severe poisoning, the pupils may be fixed and dilated and the gaze disconjugate.

Abnormal motor findings include tremor, choreoathetoid movements, and hemiballismus. Reflexes may initially be hyperactive with clonus. Seizures can occur, usually in patients with underlying seizure disorder.¹⁷ The electroencephalogram may be helpful in such patients, and may show occipital delta activity (usually suggestive of a brainstem disorder), which regresses as plasma CBZ concentrations subside.⁷ In the deeply comatose patient, adynamic ileus, hypothermia, and pulmonary edema may be present. Complications include aspiration and sequelae of hypoxia and seizures. Hyponatremia may result from an antidiuretic effect.^{4,16} Older patients may develop bradycardia or atrioventricular block, at times progressing to Adams-Stokes syncope or ventricular standstill.⁹ Chronic intoxication may result in hypokalemia as well as hyponatremia.

Confusion, lethargy, and ataxia are usually associated with peak plasma CBZ concentrations of 15 mg/L; coma may be seen with concentrations higher than 20 mg/L. Coma, cardiovascular disturbances (hypotension, dysrhythmias), seizures, and death typically occur in patients with peak plasma concentrations higher than 40 mg/L.^{6,11,17,18,20} It is important to note that these concentrations represent peak concentrations, which may occur hours or days after ingestion. Initial drug levels correlate only weakly with clinical course, and they are imperfect prognosticators of outcome.^{11,16} Because of the long half-life after overdose, continued absorption over many hours, and the additive effects of the active metabolite CBZE, the clinical course is typically prolonged.⁸ Severely poisoned patients may require more than a week to make a full recovery. Cyclic coma, in which partial recovery is followed by a relapse into a coma, presumably due to resumption of absorption as the "gut wakes up," has been described.^{6,17,19}

DIFFERENTIAL DIAGNOSIS

Mild poisoning may present in a manner similar to that of hypoglycemia, neurologic disease, serotonin syndrome, or intoxication by ethanol. In severe poisoning, the clinical picture may mimic that of overdose with tricyclic antidepressants, anticholinergic agents, or other anticonvulsants. Other physiologic depressants, coexistent trauma, and coingestions should also be considered. A prolonged postictal state in a patient with a history of seizures should raise suspicion for poisoning with CBZ or another anticonvulsant.

EMERGENCY DEPARTMENT EVALUATION

A directed history should be obtained from the patient, prehospital care providers, or available friends and family members. Attempts should be made to ascertain recent dosing changes or whether the patient has been prescribed other medications that may inhibit CBZ metabolism. The physical examination should include a full set of vital signs pupil position, size, and reactivity; bowel sounds; and a focused neurologic examination, including level and content of consciousness, responsiveness to stimuli, reflexes, motor tone, and cerebellar function. A 12-lead electrocardiogram (ECG), cardiac monitoring, and serum electrolyte and glucose determinations are indicated in symptomatic patients. Comprehensive toxicology testing and computed tomography scanning of the head should be performed when there is diagnostic uncertainty.

Frequent measurements of CBZ concentrations are mandatory to detect continued absorption in patients with acute overdose. Serial levels should be obtained until the patient is asymptomatic and levels have clearly peaked and fallen below 10 mg/L. Rebounds in levels coinciding with clinical deterioration are well described. Serum CBZ and CBZE concentrations can be separately determined by high-performance liquid chromatography. A CBZ/CBZE ratio above 2.5 suggests ongoing absorption of CBZ from the GI tract. Many centers, however, use immunologic assays, which cannot distinguish between CBZE and the parent compound.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures should be instituted, as necessary. As always, stabilization of the airway has the highest priority. Most deaths from CBZ overdose are secondary to complications such as pulmonary aspiration and respiratory depression. Level of consciousness and vital signs should be monitored. Hypotension

should be managed with intravenous fluids and, if necessary, invasive pressure monitoring and pressors such as norepinephrine. Fluids, however, should be carefully monitored to avoid fluid overload, an inherent risk due to CBZ's antidiuretic effect. Arrhythmias should be treated as described for cyclic antidepressants.

Activated charcoal is the preferred method of GI decontamination and is recommended for all symptomatic patients (regardless of time to presentation) and for those with significant ingestions by history. Multiple-dose charcoal therapy enhances the elimination of CBZ and should be instituted for patients with significant symptoms or CBZ levels above 20 mg/L.^{1,12,18} This treatment should be continued until levels have fallen into the therapeutic range or lower (based on whether the patient is dependent on the anticonvulsant properties of CBZ).

Forced diuresis, peritoneal dialysis, and hemodialysis are of no value in CBZ poisoning. Although CBZ is effectively cleared from the blood during charcoal hemoperfusion,^{2,10,14} only a small proportion of the CBZ ingested can be removed, and hemoperfusion is difficult to obtain in a timely fashion in most centers. Hemoperfusion should be considered only for those with significant dysrhythmias, hypotension, or prolonged coma and extremely elevated CBZ levels despite multiple-dose activated charcoal.

DISPOSITION

Patients who are symptomatic or who have a CBZ level that is rising or higher than 20 mg/L should be admitted. Those with moderate or severe clinical toxicity, rising drug levels, or an abnormal ECG should be treated in an intensive care unit. A regional poison center or clinical toxicologist should be consulted if the physician is unfamiliar with CBZ poisoning. Psychiatric evaluation should be obtained for patients with intentional overdose.

COMMON PITFALLS

- Failure to appreciate that CBZ absorption is slow and erratic and that peak levels may not be seen for many hours or days after acute overdose
- Being falsely reassured by a low CBZ concentration shortly after ingestion and failure to obtain serial drug levels after acute overdose
- Failure to appreciate that although CBZ is an anticonvulsant, overdose can cause or exacerbate seizures
- Failure to appreciate that CBZ is structurally similar to tricyclic antidepressants and can cause similar CNS and cardiovascular toxicity
- Failure to appreciate that activated charcoal may be useful, even many hours after ingestion
- Failure to consider the use of multiple-dose charcoal therapy for enhancing CBZ elimination
- Failure to appreciate that CBZ has active metabolites and that clinical toxicity may take days to resolve

CHAPTER 323

Carbon Monoxide Poisoning

Kent R. Olson

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Carbon monoxide (CO) is a colorless, odorless gas produced by the combustion of any carbon-containing material. It is found in automobile exhaust and in gas and coal heaters, and it is an important toxin in smoke inhalation victims of fires (see [Chapter 396](#)).^{5,14} CO is also produced *in vivo* by the metabolism of inhaled methylene chloride.⁶ In the 10-year period from 1979 through 1988, a total of 56,133 deaths in the United States were attributed to CO poisoning. Of these, 25,889 were suicides, 15,523 were associated with severe burns or house fires, and 11,547 were classified as unintentional.¹ By most statistics, CO is one of the leading agents of fatal poisoning in the United States.

CO produces toxicity by three possible mechanisms: hypoxemia, ischemia, and cellular asphyxia.⁹ It combines with hemoglobin with an affinity approximately 250 times greater than that of oxygen. Thus, at even low levels, significant saturation of hemoglobin-binding sites may occur, decreasing the oxygen-carrying capacity of the blood. In addition, CO binding to hemoglobin alters the shape of the oxygen-hemoglobin dissociation curve, effectively shifting it to the left, resulting in further lowering of intracellular oxygen concentrations. CO may also produce toxicity by decreasing cardiac output and causing hypotension, resulting in ischemic organ damage.⁴ Finally, it has been proposed that CO may bind to intracellular cytochromes, interfering with oxygen utilization.^{13,20}

The dose required to produce toxicity varies, depending on the rate of ventilation, the underlying health of the victim, and the presence of other toxins. Equilibrium is reached more rapidly in people who perform vigorous physical activity. As little as 0.1% CO (1,000 ppm) may produce potentially fatal 50% saturation of hemoglobin at equilibrium. The exposure limit in the workplace is 25 ppm as an 8-hour time-weighted average. The level considered immediately dangerous to life or health is 1,200 ppm. People with underlying pulmonary or cardiovascular disease may not be able to tolerate hypoxia produced by even mild or moderate CO levels. Infants and fetuses are more susceptible to CO poisoning, because fetal hemoglobin has an even higher affinity for CO.¹¹

CO is rapidly absorbed from the lungs. After removal from exposure, CO slowly desaturates hemoglobin, with an apparent half-life in room air of about 4 to 5 hours.^{9,13} The apparent half-life of CO produced by methylene chloride metabolism is substantially longer.

CLINICAL PRESENTATION

The signs and symptoms of CO poisoning are highly variable and nonspecific. At low levels, headache, dizziness, nausea, vomiting, and diarrhea are common. With higher levels, confusion, syncope, shortness of breath, and angina pectoris may occur. Severe poisoning may cause coma, seizures, hypotension, cardiac arrhythmias, and death ([Table 323.1](#)).^{4,8,9,13} Although the severity of intoxication usually parallels the CO-hemoglobin level, there are reports of patients with severe intoxication with relatively low levels and of patients with high levels but minimal symptoms.² Survivors of severe poisoning are often left with permanent neurologic injury, which may be gross (blindness, deafness, seizures, parkinsonism, or vegetative state) or subtle (memory loss or personality changes).^{4,8,9,13,19}

Carbon Monoxide-Hemoglobin Level (%)	Signs and Symptoms
0-10	Usually none
10-20	Headache, dyspnea with minimal exertion, angina in patients with coronary disease
20-30	Moderate headache, dyspnea, nausea, dizziness
30-40	Severe headache, vomiting, fatigue, poor judgment
40-50	Confusion, syncope, tachypnea, tachycardia
50-60	Syncope, seizures, coma
60-70	Coma, hypotension, arrhythmias, death
>70	Rapidly fatal

TABLE 323.1. Signs and Symptoms of Carbon Monoxide Poisoning

The physical examination may reveal cherry-red coloration of the skin, mucous membranes, and venous blood, owing to the bright red color of the CO-hemoglobin complex. This finding is inconsistently noted in patients with CO poisoning, and its presence or absence cannot be considered diagnostic.⁹ Retinal hemorrhage may be present. Neurologic examination usually reveals altered mental status, which may rapidly improve after the patient is removed from the poisoned atmosphere and oxygen is administered. Arterial blood gas analysis and serum electrolyte levels often reveal metabolic acidosis, which is caused by tissue hypoxia-ischemia. The arterial P_{O_2} , and hence the calculated oxygen saturation, are usually normal, because dissolved oxygen in the serum is not affected by CO. Although the oxygen saturation measured directly by co-oximetry is less than that calculated from the P_{O_2} (by an amount roughly equal to the percent CO-hemoglobin), the oxygen saturation measured by pulse oximetry is falsely normal.¹⁶ Signs of myocardial ischemia are frequently present on the electrocardiogram (ECG), and, occasionally, myocardial infarction occurs.

DIFFERENTIAL DIAGNOSIS

Other causes of coma and altered mental status should be sought, such as hypoglycemia, head trauma, meningitis, and drug or alcohol intoxication. Many suicidal patients ingest medications and alcohol as they poison themselves with CO. Other toxic gases should be considered in any patient with smoke inhalation. Cyanide, hydrogen sulfide, agents that cause methemoglobinemia, and other toxins may produce symptoms and signs of systemic hypoxia that are similar to those of CO.^{4,9,14}

EMERGENCY DEPARTMENT EVALUATION

Immediate evaluation in the emergency department should include rapid neurologic assessment and determination of the specific carboxyhemoglobin saturation (this may be performed on a venous or arterial sample). History that may be helpful in raising suspicion of CO poisoning includes being found in a car with the engine running, riding in the back of a pick-up truck, multiple victims found in a common room, smoke inhalation, and use of paint strippers or solvents that contain methylene chloride in a poorly ventilated area. Depending on severity, arterial blood gas analysis (using a co-oximeter), routine laboratory evaluation, ECG, and chest radiography may be indicated. Patients with suspected trauma should have a computed tomography scan of the head.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures should be instituted as needed. Oxygen (100%) should be provided through a tight-fitting mask or a nonrebreather mask with oxygen reservoir, or by way of an endotracheal tube. If the patient is hypotensive, 1 to 2 L of crystalloid solution should be administered. ECG, arterial blood gases, and the carboxyhemoglobin level should be monitored. Mild-to-moderate metabolic acidosis (i.e., serum pH 7.2 to 7.3) should not be treated, because acidosis may facilitate

oxygen delivery to the tissues by moving the oxygen–hemoglobin dissociation curve to the right.

Decontamination is performed by removing the victim from the toxic environment; the rescuer should take care not to become exposed during the rescue (a self-contained breathing apparatus is recommended). Administer 100% oxygen, which shortens the half-life of CO to 40 to 80 minutes. Hyperbaric oxygen (HBO), 100% oxygen provided under pressures greater than 1 atm, may further speed removal of CO to a half-life of 20 minutes or less.^{9,13,18} Some clinicians believe that HBO may also drive CO from intracellular sites, although this has not been proved. Animal studies suggest a potential protective effect of HBO against CO-induced postischemic reperfusion injury, although this benefit may be nonspecific and could have broader application for other anoxic–ischemic injuries.

Controversy remains about which patients should receive HBO treatment. Most hospitals do not have ready access to a chamber, which means that unstable patients may require transport over long distances at a time when arrhythmias and hypotension are more likely to occur. Because the half-life of CO–hemoglobin in 100% oxygen at 1 atm is less than 1 hour, in most cases, the level has already dropped to low levels by the time the HBO chamber is ready. Despite numerous case reports and uncontrolled case series supporting the use of HBO, its value has not been settled. Proponents of HBO argue that it may provide protection against late neurologic sequelae, but this claim has never been proved.^{13,15,18} Up until recently, no randomized controlled studies were available to compare HBO with normobaric oxygen (NBO). In a study that failed to show a benefit of HBO compared with 100% oxygen at normal pressure, only patients without a reported loss of consciousness were randomized, a subgroup that has an expected good outcome anyway.¹⁰ Although a greater incidence of delayed neuropsychiatric sequelae was observed in patients who received NBO compared with HBO, all patients reportedly had resolution of their symptoms within 77 days.¹³ Moreover, this and other previous studies did not blind patients and health-care providers to the treatment received.

Recently, two double-blind, randomized, and placebo-controlled (“sham” HBO) studies were completed, and both found no difference in outcome between HBO and NBO.^{12,17} Both studies randomized all patients regardless of severity. In one, extensive follow-up neuropsychiatric testing was performed.¹⁷

Pregnant women and infants pose a special problem in CO poisoning, because fetal hemoglobin has a greater affinity for CO than does normal hemoglobin.^{11,13} Prolonged oxygen therapy and a lower threshold for HBO are often recommended, although, once again, studies are lacking.

The prognosis after severe CO poisoning is unpredictable but grim. As many as 40% of victims have permanent neurologic injury. Patients with an abnormal computed tomography, SPECT scan, or magnetic resonance imaging scan on admission appear to be at higher risk for permanent sequelae.^{3,19}

DISPOSITION

All patients with loss of consciousness or with seizures should be admitted to the hospital, as should those with evidence of myocardial infarction or ischemia. Similarly, infants, young children, and pregnant women require intensive or prolonged treatment and should be admitted. Most authorities would also automatically admit any patient with a CO–hemoglobin level greater than 25%, regardless of symptoms. One investigator has developed a neuropsychiatric screening protocol to help determine which patients with low CO levels should be admitted for aggressive therapy.⁷

Despite the lack of conclusive scientific data, many experts recommend HBO therapy for patients with any of the following: coma (including a history of loss of consciousness), cardiovascular dysfunction (including ECG evidence of ischemia), pulmonary edema, significant acidosis, CO–hemoglobin level greater than 30% to 40%, symptoms that persist despite NBO therapy, or delayed-onset neuropsychiatric complaints. Patients with mild symptoms who become asymptomatic after several hours of oxygen therapy and who have a CO level less than 10%, a normal physical examination, and normal arterial blood gas parameters may be discharged.

A regional poison center or medical toxicologist may provide assistance with the decision to use HBO and may also know the location of nearby HBO chambers. If the patient is experiencing cardiac arrhythmias or hypotension, a critical care nurse or physician should accompany the patient during transport to an HBO facility. Once the acute episode of poisoning has resolved, patients should be referred for follow-up neuropsychiatric evaluation. Those discharged from the emergency department should be instructed to return immediately if any signs of neurologic dysfunction develop.

COMMON PITFALLS

- Failure to appreciate that signs and symptoms of CO poisoning are often nonspecific and that the diagnosis may be missed if there is no accompanying history of exposure
- Failure to consider CO the diagnosis of CO poisoning in patients presenting with a severe headache. Despite common belief, the victim's skin is seldom noted to be cherry-red.
- Failure to appreciate that the arterial blood gas P_{O₂}, calculated oxygen saturation, and pulse oximetry oxygen saturation are usually normal despite severe CO poisoning
- Failure to consider the ingestion of alcohol or other drugs in patients with suicidal exposure to carbon monoxide

CHAPTER 324

Centrally Acting Antihypertensive Agent Poisoning

James R. Roberts and Sharona Bryant

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Centrally acting antihypertensives include clonidine, guanabenz, guanfacine, methyldopa, and reserpine. Clonidine hydrochloride is available in tablet form (Catapres: 0.1 mg, 0.2 mg, 0.3 mg), in combination with the diuretic chlorthalidone (Combipres), or as a transdermal patch (Catapres TTS) designed to be worn for a week and slowly release 0.1 mg, 0.2 mg, or 0.3 mg per day. Significant amounts of clonidine may remain in used patches, and children have mistaken discarded patches as Band-Aids or stickers, resulting in clonidine toxicity from transdermal absorption, oral ingestion, or mouthing of patches. Although it has no known teratogenicity in humans, clonidine use in pregnancy has been associated with transitory hypertension in neonates and hyperactivity and sleep disturbances in children; therefore, this drug is not recommended for use during pregnancy. Maintenance therapy (0.2 to 0.8 mg/d) may be associated with side effects, most commonly dry mouth, fatigue, sedation, constipation, sexual dysfunction, and nonpostural dizziness. In addition to its use as an antihypertensive agent, clonidine has been used to ameliorate the symptoms associated with alcohol, narcotic, and nicotine withdrawal; as an adjunct to sedation and pain management; to reduce postmenopausal flushing; as migraine headache prophylaxis; and for acute pancreatitis.^{1-5,6} Clonidine has been increasingly used to treat attention deficit disorder in children.

Clonidine, an imidazole first used as a nasal decongestant, is the prototype of a group of centrally acting agents (including guanabenz and methyldopa) that produce their antihypertensive effect by stimulation of presynaptic α_2 -adrenergic receptors in the medulla oblongata, resulting in a decreased sympathetic outflow from the central nervous system (CNS).^{2,14} Although clonidine is primarily a central α_2 -adrenergic agonist, it also possesses some peripheral α_1 -adrenergic receptor agonist properties. The therapeutic effect of clonidine is attributed primarily to a reduction in heart rate and cardiac output rather than to a significant reduction in total peripheral resistance.

Guanabenz and guanfacine are structurally and pharmacologically similar to clonidine and produce similar toxicity.⁷ Proprietary preparations may also contain thiazide diuretics. Mild withdrawal symptoms have been noted after abrupt cessation of maintenance therapy. As in clonidine overdose, there are no specific laboratory studies that are helpful in the diagnosis or treatment of guanabenz overdose. Guanabenz is not detected in standard toxicologic analysis, and quantitative levels are usually unavailable. If ingestion has been recent and significant, gastrointestinal decontamination, with oral activated charcoal alone, should be accomplished. There is no known benefit of hemodialysis, charcoal hemoperfusion, or forced diuresis. There are no known antidotes. Neither naloxone nor tolazoline has been reported to be useful. Cardiovascular and respiratory derangements are treated supportively.

After efficient absorption from the gastrointestinal tract, clonidine is 20% to 40% protein bound and highly lipid soluble, with excellent CNS penetration. Forty percent to 60% of the drug is excreted unchanged in the urine, and the remainder undergoes hepatic metabolism. Onset of action is 30 to 60 minutes, peaking in 2 to 3 hours. The elimination half-life is 5 to 13 hours, with minimal accumulation in renal failure. There are no known pharmacologically active metabolites. The volume of distribution is 3.2 to 5.6 L/kg.

After abrupt cessation of long-term clonidine therapy, a well-described withdrawal syndrome may occur, producing varying degrees of rebound hypertension, tachycardia, tremulousness, insomnia, anxiety, sweating, and palpitations.⁴ The syndrome is usually mild and not life-threatening; however, significant cardiac arrhythmias and hypertensive crises have been reported, as well as one case of myocardial infarction thought to have resulted from acute clonidine withdrawal.¹³ The withdrawal syndrome results from an unbalancing of central adrenergic activity; as clonidine's inhibitory effect at a α_2 -adrenergic receptors is removed, upregulated α_1 -adrenergic receptors and elevated catecholamine levels operate to increase sympathetic outflow.

Except for one poorly documented fatality attributed to a massive ingestion in a child, deaths have not been reported from clonidine poisoning alone. Clonidine overdose can result in significant respiratory and cardiovascular instability and CNS depression. Deaths have been reported when clonidine has been taken with other drugs in suicide attempts.¹⁵ A combined overdose of clonidine and methylphenidate, drugs used to treat attention deficit disorder, has anecdotally been associated with sudden death.

Guanfacine (Tenex) and guanabenz (Wytensin) are structurally and pharmacologically similar to clonidine and produce similar toxicity.⁷ The usual adult dose is 1 to 2 mg for guanfacine and 2 to 4 mg for guanabenz. Proprietary preparations may also contain thiazide diuretics. Mild withdrawal symptoms have been noted after abrupt cessation of maintenance therapy. There are no known deaths related to a pure guanabenz or guanfacine overdose.

Methyldopa (Aldomet) is metabolized α -methylnorepinephrine, which may stimulate α_2 -adrenergic receptors, indirectly reduce plasma renin activity, or act as a "false" (i.e., inactive) neurotransmitter.¹⁷ Peripheral vascular resistance is decreased, while cardiac output is maintained. The usual adult dose is 250 to 500 mg, which can be given intravenously as well as orally. Methyldopa preparations commonly include a thiazide diuretic. Sedation is a prominent side effect encountered during methyldopa therapy. A positive direct Coombs' test develops in about 25% of patients taking methyldopa, but hemolysis is seldom a clinical problem. Hepatitis occurs in 6% of patients using methyldopa. A mild rebound syndrome (mainly hypertension) has been associated with the abrupt cessation of maintenance therapy.

The pharmacologic effects of reserpine (and other rauwolfia alkaloids) are attributed to a depletion of catecholamine and serotonin in the brain and adrenal medulla. The usual adult dose of reserpine ranges from 0.1 to 0.25 mg. Most preparations also contain a thiazide diuretic. Depression and other adverse side effects, such as increased gastrointestinal motility, nasal congestion, and parkinsonian-like effects, have limited its current use. No fatalities have been reported after overdose.

CLINICAL PRESENTATION

In adults, significant clinical toxicity occurs after the ingestion of 1 to 2 mg of clonidine. A specific lethal dose has not been determined. Children seem to be particularly susceptible to even small doses of clonidine, and serious symptoms have been precipitated by ingestion of a single adult therapeutic dose (0.1 to 0.3 mg).^{9,18} Toxicity has been reported in children who have sucked on a used transdermal patch containing residual clonidine.⁸ Signs and symptoms of toxicity usually occur within 30 to 60 minutes after ingestion, producing a clinical scenario that resembles a narcotic overdose, consisting of bradycardia, respiratory depression, coma, and miosis. With serious toxicity, hypotension, hypothermia, and hyporeflexia are common. A peculiar intermittent apnea, responsive to physical or auditory stimuli, has been noted in children. Clonidine interacts with other CNS depressants, such as alcohol and barbiturates, and the concomitant ingestion of these substances or sedative-hypnotics can increase CNS depression. Seizures are rare after overdose and are likely related to hypoxia rather than a direct effect.

Hypertension may be seen in the initial phases of clonidine overdose and is associated with high plasma drug levels. It is due to vasoconstriction resulting from the stimulation of peripheral α_1 -receptors. This phase is transient, resolves spontaneously, and is quickly and precipitously followed by prolonged or serious hypotension. Rebound hypertension and other withdrawal symptoms may subsequently develop 2 to 4 days after an overdose if the patient has been on maintenance clonidine therapy.

There are few reports of serious guanabenz or guanfacine overdose in the literature, but significant ingestion may produce lethargy, bradycardia, and hypotension. With methyldopa overdose, a benign clinical course is generally seen.¹¹ Drowsiness, lethargy, bradycardia, hypotension, and atrioventricular conduction abnormalities have been reported. Significant reserpine ingestion may cause drowsiness, lethargy, hypotension, and bradycardia.¹²

DIFFERENTIAL DIAGNOSIS

Clonidine, guanabenz, and guanfacine poisoning may be clinically indistinguishable from toxicity caused by naphazoline, oxymetazoline (Afrin), tetrahydrozoline (Visine), and xylometazoline. These compounds are found in nasal decongestant and topical ophthalmic preparations. In children, the ingestion or topical application of such preparations has resulted in signs and symptoms that are identical to clonidine poisoning. Centrally acting antihypertensive agent poisoning may also resemble overdose from other substances, particularly narcotics, β -adrenergic blockers, calcium channel blockers, digitalis, and sedative-hypnotics. Hypoglycemia, sepsis, hypothermia, cerebrovascular accident, and head trauma should also be considered in the differential diagnosis.

EMERGENCY DEPARTMENT EVALUATION

Patients with known or suspected centrally acting antihypertensive agent overdose should be treated in a facility with capabilities for close clinical observation, frequent vital sign determinations, and continuous electrocardiographic (ECG) monitoring. Special attention should be directed toward the clinical assessment of airway and breathing abnormalities, cardiovascular status, and evaluation for concomitant trauma.

The diagnosis of poisoning is based on the history and clinical findings. There are no laboratory or clinical tests that are of specific diagnostic or therapeutic value. These agents are not detected on routine drug screening. Quantitative levels are unavailable in the clinical setting and are of no value in management. If the diagnosis is certain, ancillary studies will be of no additional value. Radiographic imaging, routine laboratory tests, and toxicologic analysis are useful only to rule out or confirm concomitant pathology.

EMERGENCY DEPARTMENT MANAGEMENT

Prehospital care is supportive. The routine administration of naloxone and evaluation for hypoglycemia are warranted in symptomatic patients. Because of the rapidity of onset of clonidine toxicity, prehospital use of ipecac should be avoided. Activated charcoal alone is the preferred form of gastrointestinal decontamination. Continuous ECG monitoring and intravenous access should be maintained during the prehospital care and emergency department evaluation.

Treatment is primarily supportive and symptomatic, with therapy aimed at reversing specific derangements in cardiovascular and respiratory status. Hypotension usually responds to crystalloid infusion. Occasionally, vasopressors, such as dopamine and norepinephrine, are required. Bradycardia secondary to clonidine usually responds to intravenous atropine, with repeated doses titrated against heart rate and blood pressure. Dopamine, epinephrine, and cardiac pacing are of theoretic benefit, but their use in clonidine poisoning has not been described. Respiratory depression is a serious consequence of clonidine overdose, and tracheal intubation and assisted ventilation may be required. In the unusual case in which transient hypertension is noted, antihypertensive treatment should generally be avoided because of the potential for subsequent serious and prolonged hypotension.³ Hypertension usually requires only observation, although, occasionally, a short-acting antihypertensive such as nitroprusside may be warranted. Hypothermia and coma are treated with supportive care. Clinical recovery is usually noted within 24 to 48 hours. Hemodialysis, charcoal hemoperfusion, and forced diuresis are of no proven value. Because clonidine is excreted unchanged in the urine, adequate urine output should be assured. Antacid therapy has been recommended to counter hyperchlorhydria during reserpine overdose.

There are no proven antidotes for centrally acting antihypertensive agent overdose. Naloxone has been used to reverse clonidine toxicity, but the response is inconsistent. The improvement in mental status and hemodynamic parameters noted after naloxone has been explained on the basis of a reversal of clonidine's opiate-like activity in the CNS. Its use is acceptable as a therapeutic trial in patients with depressed mental status. The optimal dose is unknown, but doses similar to those used for narcotic poisoning have been suggested. Both hypertension and hypotension have been temporally associated with the use of naloxone to reverse clonidine overdose. Patients who are given naloxone should be closely observed for potential hemodynamic deterioration.

Tolazoline, a central and peripheral α -adrenergic blocking agent, was once touted as an antidote for clonidine toxicity.¹⁶ Because its efficacy is based on sporadic case reports and it has potentially serious side effects (e.g., hypotension, tachycardia, and arrhythmia), its use is not recommended.

Yohimbine, a centrally acting α_2 -adrenergic antagonist, may be expected to have clinical activity opposite that of clonidine. Yohimbine has been suggested as a possible antidote for clonidine overdose, but little evidence is available to support its use, and no clinical guidelines are available.

The clonidine withdrawal syndrome is best treated by the reinstatement of clonidine therapy that is tapered over 5 to 10 days. Clonidine may be used to supplement standard therapy for the inpatient or outpatient treatment of alcohol, narcotic, and nicotine withdrawal. The drug is titrated to control symptoms, particularly tremor, tachycardia, and agitation; a suggested starting dose is 5 to 8 $\mu\text{g}/\text{kg}/\text{d}$ (divided into three to four doses), tapered over 5 to 10 days. Excessive sedation and orthostatic hypotension are the main side effects, limiting outpatient use.

DISPOSITION

If vital signs are normal and the patient remains or becomes asymptomatic within 4 to 6 hours of ingestion, he or she may be discharged from the emergency department with appropriate psychiatric or social service follow-up. Symptomatic patients require admission to the hospital for observation and monitoring. A toxicology consultant or the drug and poison information center may be helpful in providing advice regarding the use of particular antidotes or final disposition. There is no known cyclical nature to clonidine overdose, and improvement is not followed by relapse. Patients may be safely transferred to another facility with paramedic-level transportation.

COMMON PITFALLS

- Failure to render the correct or complete diagnosis, either by attributing the clinical scenario to other agents or diseases or by failing to recognize coexisting trauma or concomitant ingestions
- Failure to appreciate that clonidine poisoning may result in respiratory depression
- Misdiagnosis of clonidine poisoning as narcotic overdose because of clinical similarities
- Overly aggressive treatment of early but transient hypertension, especially with long-acting agents
- Reliance on unproved antidotes rather than supportive care in the treatment of toxicity
- Failure to consider the possibility of child abuse or attempted homicide in children with overdose and to address psychiatric issues in patients with suicide attempts

Exposure to chemical and biologic agents may occur intentionally following terrorist or military attack or accidentally during the manufacture, transportation, storage, and deployment of these weapons. Lacrimating agents are currently used by civilians for personal protection and by law enforcement personnel for crowd dispersal and incapacitation of criminal suspects.

Chemical and biologic agents can be delivered in multiple ways. They may be aerosolized as a spray from hand-held or vehicle-mounted pressurized tanks, low-flying aircraft, crop-dusters, cruise missiles, or spray bottles. These agents may also be dispersed as liquid droplets or vapor from low-flying aircraft, artillery, missiles, detonated bombs, and hand-held devices. The geographic area affected by warfare agents typically depends on prevailing weather conditions and the method of delivery used. In the Tokyo terrorist incident, Sarin was dispersed by evaporation from punctured plastic bags that were left on subway cars.¹² If an agent is highly toxic, it may be added to the enemy's water supply or food source. In 1984, the intentional contamination of restaurant salad bars in Oregon by a religious cult resulted in 751 cases of salmonellosis.¹⁸ Bioagent contamination of most United States water supplies is unlikely to be successful due to the excessively large amounts of bioagent required and water purification techniques currently used.¹⁶ The aerosolized dispersal of both chemical and biologic agents is the mode most likely to result in the maximum number of casualties and is thus the method most likely to be used by terrorists and military groups.^{3,4,16,20} Unexpected and uncontrollable spread of these agents by wind, water, or humans may affect unintended populations.

CHEMICAL TOXINS

Blood Agents

Incorrectly labeled "blood agents" by the military, these agents include the systemic asphyxiant gases cyanogen chloride and hydrogen cyanide (see [Chapter 331](#)), hydrogen sulfide (see [Chapter 344](#)), and the hemolytic gas arsine, derived from arsenic (see [Chapter 318](#)). Sodium monofluoroacetate (see [Chapter 366](#)) is another cellular asphyxiant proposed for military use. As a chemical warfare agent, the efficacy of cyanide is limited due to its high volatility, resulting in nonpersistence in open air, and its relatively low toxicity compared with nerve agents.

Choking Agents

Introduced in World War I, the choking agents chlorine, phosgene, and diphosgene act principally as pulmonary irritants (see [Chapter 346](#)). Chlorine, a dense, low to moderately water soluble, yellow-green gas that smells like concentrated bleach, is toxic to all tissue surfaces it contacts—skin, eyes, and respiratory and gastrointestinal (GI) tracts. The injury is proportional to the gas concentration, duration of contact, and water content of exposed tissue. Chlorine reacts with tissue water to form hydrochloric acid and oxygen free radicals, which produce corrosive and cytotoxic effects to the lung and other tissues.

Phosgene (carbonyl chloride), which replaced chlorine, is thought to have been responsible for more than 80% of all chemical agent fatalities in World War I.²⁰ It is a colorless gas that is heavier than air and smells like freshly mown hay. Odor is not a reliable indicator of exposure. Phosgene's propensity to settle into low-lying areas, such as trenches, led to its tactical success. Phosgene vapor is poorly soluble in water and is only mildly irritating to the eyes and upper respiratory tract on initial contact; exposure may temporarily go unnoticed. Phosgene hydrolyzes with terminal bronchial and alveolar mucosal water to produce hydrochloric acid. This and other toxic by-products of phosgene stimulate the synthesis of leukotrienes and other inflammatory products, which leads to pulmonary edema. The rate and extent of pulmonary injury depend on the concentration and duration of exposure, but it typically occurs slowly over hours.

Diphosgene (trichloromethyl chloroformate) was created shortly after World War I and is simply phosgene with chloroform attached to it. The chloroform moiety allowed diphosgene to penetrate the crude chemical filters of the day, with the phosgene moiety being responsible for its toxicity. Diphosgene causes a more immediate irritation to the eyes, nose, and respiratory tract than does phosgene, due to its higher chlorine content.

Vesicating Agents

Vesicating agents cause blistering of exposed surfaces and include mustard gases and organic arsenicals. Sulfur mustard (2,2-dichlorodiethyl sulfide) is the most well known and extensively used agent. It was used in World War I and in the Iran–Iraq war.^{4,13,20} Sulfur mustard is not immediately lethal but has several properties that make it useful for warfare. It is simple to produce, easily disseminated, and difficult to protect against, and it effectively incapacitates its opponents. Sulfur mustard has a low volatility and persists for several days in temperate climates, thereby restricting enemy use of contaminated equipment and terrain.⁴

Sulfur mustard is an oily amber liquid that smells like burning garlic or mustard. It becomes aerosolized by spraying or volatilized by an exploding military shell or high ambient temperature and is rapidly absorbed on inhalation or contact with the skin or eye. Mustard irreversibly binds with tissue cellular components within 2 minutes of exposure.^{1,13} Its cellular toxicity results from the spontaneous formation of highly reactive and unstable episulfonium compounds, which irreversibly alkylate nucleic acids and cellular proteins. This leads to DNA strand breaks and inhibition of DNA replication, protein synthesis, and enzyme function. In the process of cellular DNA repair, depletion of nicotinamide adenine dinucleotide (NAD⁺) occurs, glycolysis is inhibited, cellular proteases are released, and cell death occurs. Additionally, cellular toxicity may result from mustard agent binding to cellular glutathione and resultant depletion of this free radical scavenger. Depletion of glutathione results in an inactivation of sulfhydryl-containing enzymes, loss of calcium homeostasis, lipid peroxidation, cellular membrane breakdown, and cell death. The nitrogen mustards [HN] have identical cytotoxicity. They are used medically in the intravenous form as alkylating chemotherapeutic agents and can cause severe local tissue damage if, inadvertently, intravenous extravasation occurs.

Because mustards are alkylating agents, they may be mutagenic and carcinogenic.^{1,13} The mortality rate from mustard injuries during World War I was less than 2%; rates of 3% to 4% were reported in the Iran–Iraq war.^{1,13,17} Death results from respiratory failure or bone marrow suppression. Most of the mustard injuries in World War I were nonfatal but disabling; nearly all of the victims suffered skin burns, 86% suffered eye burns, and 75% sustained respiratory injury.^{1,20} Although the lethality of sulfur mustard is considerably less than that of other chemical agents, dermal exposure to as little as 1.0 to 1.5 teaspoons of liquid is potentially lethal to a 70-kg adult.²⁰

Lewisite (2-chlorovinylchloroarsine) is the best known of the organic arsenicals. It was developed in 1918 to complement sulfur mustard as a semipersistent blistering agent. Many countries have generated large stockpiles of lewisite, but its actual use in combat is not well documented.^{17,20} It may have been used by Iraq in the Iran–Iraq war. Lewisite is an amber, oily liquid that smells like geraniums. It persists in the environment for up to 24 hours under temperate conditions due to low water solubility.⁴ Under normal conditions, lewisite is moderately volatile, making inhalational toxicity a concern. Its vapor is about seven times heavier than air and will flow into lower terrain.²⁰

Lewisite enters the body most rapidly through vapor inhalation or liquid absorption through breaks in the skin. It penetrates intact skin within 15 minutes, more rapidly than mustard agents, due to its moderate lipid solubility.²⁰ In the dermis, it hydrolyzes to hydrochloric acid and chlorovinylarsenious oxide, the vesicating agent. Its organic arsenical moiety has additional systemic toxicity (see [Chapter 318](#)). Arsenicals also increase capillary permeability and cause extensive interstitial fluid losses, resulting in hypovolemia; this phenomenon is called "lewisite shock."²⁰ Lung capillaries are particularly sensitive to lewisite, and inhalation may result in severe pulmonary edema.²⁰

Nerve Agents

Nerve agents are similar in structure and function to commonly used organophosphorus pesticides (see [Chapter 361](#)) but are more potent and typically have a more rapid onset and shorter duration of clinical symptoms. The first three nerve agents, the "G" (short for "German") agents Tabun (GA), Sarin (GB), and Soman (GD), were developed in Germany between 1936 and 1944.²² The fourth, VX, with the "V" standing for "viper," was synthesized in 1952 in England.

Although commonly referred to as nerve gases, these agents are colorless, odorless liquids under temperate conditions. They are dispersed as vapors or liquid aerosols by spraying or explosive blasts and are significant vapor hazards at higher ambient temperatures. Vapors are heavier than air and, thus, will concentrate closer to the ground. The G agents are moderately volatile, evaporate within several hours, and are environmentally nonpersistent.¹⁵ Sarin is the most volatile, with a volatility similar to that of water. Vapor inhalation causes symptoms within seconds to several minutes.^{5,15,20} The human lethal inhaled dose of the G agents is estimated to be 1 mg.^{15,20} VX is an oily compound that is much less volatile and persists for several weeks after dispersion.²⁰ It is not a major inhalation hazard (unless

ambient temperatures are high) and exhibits most of its toxicity by skin absorption. It is the most potent of the nerve agents on a weight basis. All the agents rapidly penetrate skin and clothing, with onset of symptoms within 30 minutes to 18 hours after skin exposure.^{5,20} The time of onset is determined by the dose and the agent. VX has the most efficient percutaneous absorption, with a 10-mg dose applied to the skin expected to be lethal to 50% of unprotected individuals.²⁰

Toxicity results primarily from phosphorylation and inactivation of acetylcholinesterase (AChE) at its serine active site (see [Chapter 361](#)). Acetylcholine accumulates at nerve terminals, initially stimulating, then paralyzing, cholinergic neurotransmission. Once inactivated, AChE may undergo three processes. The phosphorylated enzyme may spontaneously reactivate via endogenous hydrolysis, be reactivated by nucleophilic oximes, or become incapable of reactivation. Endogenous hydrolysis is insignificant, due to tight binding of nerve agents to AChE. Reactivation of AChE occurs if an oxime binds the phosphate moiety of the nerve agent more avidly than the serine residue of AChE. Reactivation is impossible once dealkylation (“aging”) of the phosphorylated cholinesterase occurs, and *de novo* AChE synthesis is required for enzyme replenishment. The rate of aging varies among the nerve agents. It occurs within 2 minutes after Soman exposure, 5 to 8 hours after Sarin exposure, and more than 40 hours after Tabun or VX exposure.²⁰

AChE inhibition is not solely responsible for nerve agent toxicity. Tabun, Sarin, and Soman are direct partial agonists at nicotinic receptor sites, and VX blocks nicotinic receptor ionic channels.^{5,20} They also bind directly to cardiac muscarinic receptors, antagonize GABA neurotransmission, and stimulate glutamate *N*-methyl- α -aspartate receptors. These latter actions may contribute to nerve agent-induced seizures and central nervous system (CNS) neuropathology.¹⁵ Some compounds that are protective in nerve agent toxicity do not reactivate AChE. CNS-active oximes (e.g., Pro-2-PAM) are no more efficacious in nerve agent treatment than oximes that do not reactivate brain AChE. There is poor correlation between clinical toxicity and levels of AChE activity.⁵

Vomiting Agents

The vomiting agents are typically nonlethal, arsenic-based compounds used for riot control.²⁰ These agents are normally solids that vaporize on heating and then condense to form aerosols. Vomiting agents were developed near the end of World War I but were not frequently used. They produce rapid irritation of the eyes, skin, and respiratory and GI tracts. Features of systemic arsenic toxicity are discussed in [Chapter 318](#).

Lacrimating Agents

Lacrimating agents (tear gases), also known as riot-control and harassing agents, are pulmonary irritants (see [Chapter 346](#)) and mild corrosives (see [Chapter 330](#)). They were introduced in World War I and have since been used regularly for the temporary incapacitation of criminals, civilian crowds, and enemy armies. Most of the original compounds have become obsolete. Agents currently in common use include *o*-chlorobenzylidenemalonitrile (CS), *w*-chloroacetophenone (CN or Mace), and capsaicin (pepper spray). The noxious effects of lacrimating agents are typically transient, but lethal toxicity may occur.

Before CS was developed in the 1950s, CN was the agent most widely used by civilian and military authorities. CN is typically dispersed as a smoke of suspended particles or liquid aerosol. It is more toxic than CS and, at high concentrations, can result in permanent corneal epithelial damage, contact dermatitis with skin blistering, and noncardiogenic pulmonary edema.²⁰ At least five deaths from CN grenades have been reported when CN was used in confined spaces.²⁰ Persistent toxic effects are unlikely if CN is used in open spaces. CN effects usually last less than 20 minutes.

CS is now the riot-control agent of choice in the United States. It is about ten times more potent as a lacrimator than CN but is much less toxic to tissues.²⁰ Symptoms begin within 20 seconds of exposure; long-lasting ocular effects are uncommon. Chemical pneumonitis and fatal pulmonary edema have been reported. CS is delivered as a vapor or cloud of suspended solid particles (a smoke) produced by a thermal grenade. Newer CS formulations consist of an unheated micropulverized powder (CS1, CS2) that can remain active in the environment for several weeks. CS powders were used by the U.S. military during the Vietnam war.

Capsaicin, a chemical irritant found in many plants of the genus *Capsicum*, can produce cutaneous, GI, and respiratory irritation in humans. The oleoresin of capsicum is used frequently by civilians for personal protection and by law enforcement personnel for immobilization of assailants. “Pepper Mace” can contain CS, oleoresin of capsicum, or both. It is a lipid-soluble alkaloid that first stimulates release of substance P from nociceptive neurons and then blocks its synthesis and transport. Substance P depolarizes neurons to produce dilatation of blood vessels, stimulation of smooth muscle, and activation of sensory nerve endings that mediate pain. With repeated application, nociceptive fiber response and number are decreased (desensitization). This forms the basis for the medicinal use of capsaicin as a topical analgesic (counterirritant).

BIOLOGIC TOXINS

Biologic toxins are the poisonous by-products of microorganisms, plants, and animals. Toxins tend to be more stable than microorganisms, because they are not living. To be most effective as biowarfare agents, toxins need to be disseminated to target populations in the form of respirable aerosols. These agents are neither volatile nor dermally active.

Of all biologic toxins, the exotoxin formed by the anaerobic, spore-forming, gram-positive bacillus, *Clostridium botulinum*, poses the most credible threat as a biologic warfare agent.^{4,20} Although unsuccessful in producing disease, the Aum Shinrikyo cult aerosolized botulinum toxin in Japan on several occasions before the Tokyo Sarin attack.⁴ Botulinum toxin is relatively easy to manufacture and the most lethal toxin known, with an LD₅₀ of 0.001 mg/kg.²⁰ It is 15,000 times more toxic than VX and 100,000 times more toxic than Sarin. Botulinum toxin is actually eight distinct protein by-products of *C. botulinum* metabolism.³ Types A, B, E, and F are toxic to humans. Botulism may result from the inhalation, ingestion, or wound contamination of either the microbial spores or preformed toxin (see [Chapter 205](#)). It is characterized by progressive descending paralysis. Botulinum toxin inhibits the release of acetylcholine from presynaptic neurons at the neuromuscular end-plate and cholinergic autonomic neurons.

Other potent biotoxins include the naturally occurring trichothecene mycotoxins. Nivalenol and T2, the best known, are derived from wheat and corn contaminated by the fungi *Fusarium nivale* and *Fusarium tricinctum*, respectively. Since 1976, there have been claims that the Soviet and Vietnamese governments used trichothecenes against Indochinese refugees in Southeast Asia.²⁰ “Yellow rain” is allegedly due to small yellow particles of trichothecenes released from low-flying planes.

Trichothecene mycotoxins are potent inhibitors of protein synthesis and electron transport.²⁰ Rapidly proliferating tissues are affected most. T2 toxin is well absorbed orally, achieving peak tissue levels by 1 to 4 hours. The highest mycotoxin concentration is reached in the liver. Elimination half-life is about 22 hours, with 50% excreted as metabolites in the feces.

Other possible toxins (see [Table 325.2](#)) include those derived from plants (e.g., ricin, abrin), marine organisms (e.g., saxitoxin, tetrodotoxin), and snake venoms (e.g., bungarotoxins).

INFECTIOUS AGENTS

Of the biologic agents, anthrax, smallpox, and plague represent the greatest potential for use as weapons.^{4,7,20} Anthrax is caused by *Bacillus anthracis*, an aerobic, spore-forming, gram-positive bacillus found ubiquitously in soil. Spores of *B. anthracis* are easily disseminated by military munitions and can persist in the environment for decades.²⁰ Anthrax is normally acquired by human skin contact with infected livestock. The spores are inoculated via skin breaks and produce cutaneous black eschars. The mortality rate for cutaneous anthrax is less than 1% with early penicillin therapy. The aerosolized delivery of anthrax spores will result in inhalational exposure and is the most likely means of military and terrorist attack.^{1,20} Anthrax spores are of ideal size (1 to 5 μ m) to reach alveoli. Inhalational anthrax, as contrasted to cutaneous anthrax, is a highly fatal disseminated infection. The lethal potential of aerosolized anthrax was demonstrated in 1979, when accidental release of anthrax spores from a Soviet military facility in Sverdlovsk resulted in 79 cases of inhalational anthrax, with 68 being fatal.⁹ Following inhalation, spores of *B. anthracis* are phagocytized by alveolar macrophages and transported to mediastinal lymph nodes.³ After a variable latency period (2 to 60 days), spores germinate into bacilli, which release toxins that lead to hemorrhage, edema, and necrosis.^{3,9,20} Anthrax bacilli can also seed the general circulation and lead to overwhelming septicemia.

Smallpox (variola) virus is highly infectious by aerosol, environmentally stable, and associated with high mortality and secondary spread rates.^{3,4,20} The virus can

survive for 24 hours or more in the environment. Currently, the majority of the United States population has no immunity, and there is little available vaccine and no effective treatment for the disease. Release of the virus into any major metropolitan area would have devastating consequences. Although the virus was globally eradicated in 1980 and is currently retained in only two approved laboratories (in the United States and Russia), clandestine stockpiles may exist. Humans are infected by inhaling the virus, which enters the respiratory tract and multiplies locally. After an incubation period of 7 to 17 days, virions are hematogenously transported within macrophages (primary viremia) to regional lymph nodes, where additional multiplication occurs. Secondary viremia subsequently occurs, during which the virus localizes to small dermal blood vessels. This leads to endothelial swelling and infection of epidermal cells. Intraepidermal vesicles form in the skin and mucous membranes. Smallpox infection is usually incapacitating and frequently fatal, with mortality occurring in 30% of unvaccinated individuals.

Plague is caused by the gram-negative, bipolar-staining coccobacillus, *Yersinia pestis*. *Y. pestis* is usually spread to humans from infected rodents by a flea vector. Following skin inoculation by the bite of a flea, bacteria migrate to local lymph nodes, are phagocytized but not killed by mononuclear cells, replicate locally, and result in enlarged suppurative lymph nodes (buboes) after 1 to 8 days.^{3,20} Bacteria subsequently spread by lymphatics and blood to distant sites. Secondary spread to the lung (secondary pneumonic plague) occurs in 10% of patients. In the United States, 85 to 90% of plague that occurs naturally is the bubonic form, with only 1% being the primary pneumonic form.²⁰ As a biowarfare agent, however, it would be deployed as an infectious aerosol and result in primary pneumonic plague. Pneumonic plague is readily spread person to person by respiratory droplets and, untreated, has a mortality rate approaching 100%.

Numerous other microorganisms, including bacteria, rickettsiae, viruses, and fungi, have been investigated as possible agents for use in biologic warfare. Biologic engineering makes it possible to alter current strains of these microorganisms so that they are resistant to known forms of treatment.

CLINICAL PRESENTATION

Choking Agents

Clinical symptoms begin within minutes after significant chlorine exposure and include lacrimation, conjunctival irritation, rhinorrhea, cough, sore throat, chest burning, dyspnea, sputum production, nausea, headache, and respiratory failure. Corneal abrasions and cutaneous burns may result from eye and skin exposure, respectively. Following significant chlorine exposures, pulmonary edema may develop within 2 to 4 hours and peaks at 12 to 24 hours.²⁰ The chest radiograph may be normal or may display noncardiogenic pulmonary edema. After a typical latency period of 4 to 6 hours (range, 1 to 24 hours), patients with significant phosgene exposure present with dyspnea, chest tightness, cyanosis, hemoptysis, hypotension, and pulmonary edema. Chest radiographic findings of pulmonary edema are rather late and nonspecific, occurring 6 to 8 hours after exposure. Diposgene produces identical signs and symptoms. Following significant pulmonary agent exposure (e.g., chlorine gas), patients may subsequently develop reactive airways dysfunction syndrome, a chronic asthma-like condition.

Vesicating Agents

After mustard exposure, there is typically a latency period of 4 to 12 hours before the onset of symptoms. The latency period is shorter with high concentrations and long exposures, with increased ambient temperature and humidity, and in victims previously exposed to or innately susceptible to mustard.^{1,13,17,20} Sites of injury principally involve the skin, eye, and respiratory tract and may follow vapor or liquid exposure. Heavy exposure may lead to systemic effects such as bone marrow depression and sloughing of intestinal mucosa.

Cutaneous injury resulting from mustard exposure ranges from erythema to vesication and skin necrosis. The moist, thinner skin of the neck, axilla, and groin is more severely affected. After an asymptomatic period of 4 to 12 hours, erythema and edema develop. Vesication typically starts within 24 hours and evolves over several days. Vesicles coalesce into blisters, and skin necrosis occurs over 24 to 72 hours.^{17,20} Blister fluid does not contain active mustard and is not toxic. Skin denudation occurs over 6 to 9 days, and healing may take 4 to 10 weeks.

The eye is the organ most sensitive to sulfur mustard. Tissue injury occurs rapidly, but symptoms develop gradually over 4 to 8 hours and include eye pain, lacrimation, photophobia, and blurred vision. Physical findings include blepharospasm, eyelid edema, conjunctival injection and edema, chemosis, anterior chamber cellular infiltrates, and decreased vision. Corneal edema begins within 1 hour after exposure, and the corneal epithelium vesicates and sloughs within 4 to 36 hours.^{13,17,20} Resolution of injury depends on the severity of exposure and typically takes 1 to 2 weeks. About 90% of victims are visually disabled for 10 days with conjunctivitis, photophobia, and corneal swelling. The remaining 10% are severely affected and are at risk for permanent blindness from corneal opacification, scarring, and ulceration.

Respiratory epithelial damage occurs several hours after exposure. Victims may develop rhinitis, nasal bleeding, sinus discomfort, hoarseness, sore throat, cough, sputum production, and dyspnea of increasing severity. Hemorrhagic inflammation and erosions of the upper airway mucosa are followed by fibrinous pseudomembrane formation and sloughing of necrotic, ulcerated mucosa. Bronchospasm and partial airway obstruction result. After high-dose exposures, severe bronchitis, secondary bronchopneumonia, and respiratory failure may develop within 24 to 48 hours.^{1,13,20} Pulmonary edema is not a characteristic finding, as mustard does not typically affect the pulmonary parenchyma.

In the presence of high concentration or prolonged exposure, bone marrow and GI mucosal toxicity may be seen. Leukopenia develops within 5 to 7 days, with the white cell nadir occurring 10 days after exposure. Thrombocytopenia and anemia typically follow. The development of hematologic effects from mustard poisoning is a grave prognostic sign.^{13,20}

The clinical manifestations of lewisite poisoning are similar to those of sulfur mustard, although lewisite causes immediate severe pain on contact with the skin, eyes, and nasal mucosa. Vapor condensing on the skin causes erythema within 30 minutes and blister formation within 2 to 3 hours.^{17,20} The eyes are very sensitive to lewisite, and permanent blindness from corneal destruction may result if decontamination is not initiated within 1 minute. Inhalation of lewisite vapor can result in death within 10 minutes from rapid respiratory mucosal sloughing and bleeding, leading to asphyxiation.

Nerve Agents

Clinical manifestations of nerve agent exposure are described in detail in [Chapter 361](#). Toxicity may occur after inhalation of vapor, skin contact with vapor or liquid, or ingestion. The rate of onset and severity of effects are determined by the route of exposure and dose.⁵ At high ambient temperature, skin absorption is rapid, and increasing amounts of the agent are volatilized, leading to increased inhalation.¹⁵ A small amount of vapor affects the eyes, nose, and lungs, causing miosis, rhinorrhea, mild dyspnea, cough, and wheezing.^{5,15,20} This can occur within seconds to minutes. Symptoms of mild poisoning include eye pain, blurred and dim vision, headache, and dizziness.¹² As the dose of vapor increases, nausea and vomiting, increased respiratory difficulty, progressive muscular weakness, and agitation develop. A high vapor concentration causes rapid loss of consciousness, seizures, flaccid paralysis, and respiratory arrest within seconds to minutes. In the Tokyo Sarin gas attack (vapor exposure), the most prominent signs and symptoms for patients with moderate-to-severe poisoning included miosis (99%), headache (75%), dyspnea (63%), nausea (60%), eye pain (45%), blurred vision (40%), and vomiting (37%).¹² Tachycardia and hypertension were common, but bradycardia and bronchorrhea were not. Victims of vapor exposure are unlikely to deteriorate once removed from exposure.^{5,12} In contrast, those with dermal exposure may subsequently worsen. Skin absorption of a lethal dose may occur within 1 to 2 minutes, yet symptoms are commonly delayed and develop after a latency period of 30 minutes to 18 hours.^{1,5,20} Skin exposure may result in local sweating and twitching or fasciculations before systemic toxicity. In contrast to vapor exposure, miosis is absent early following skin exposure.⁵

Ingestion of food or water contaminated with a nerve agent may produce symptoms within 30 minutes.²⁰ Death from nerve agent exposure is primarily due to respiratory failure secondary to depression of the central respiratory drive.^{5,20} Respirations cease before significant neuromuscular blockade or bronchoconstriction occurs.

Lacrimating Agents

Tear agents cause intense eye discomfort, blepharospasm, lacrimation, stinging and burning of the mouth and nose, salivation, rhinorrhea, irritation of the respiratory tract and stomach with coughing and vomiting, and skin irritation leading to burning pain and erythema within seconds to minutes of exposure.²⁰ Tear agents are miscible in sweat, and skin irritation is amplified in areas of increased sweat, such as the axilla, popliteal and antecubital areas, inguinal region, and buttocks. Skin effects are heightened in warm, moist environments. Prolonged exposure may produce malaise, skin blistering, chest tightness, shortness of breath, and a feeling of

suffocation.

Biologic Toxins

The clinical manifestations of inhalational botulism are identical to those following ingestion of tainted food. Symptoms are likely to appear 1 to 4 days following exposure and are described in detail in [Chapter 205](#).^{3,20} Signs and symptoms begin within minutes to hours of oral, dermal, or inhalational exposure to trichothecene mycotoxins. Toxic effects include corneal, cutaneous, and mucous membrane inflammation and necrosis; GI inflammation and hemorrhage; petechiae; ecchymosis; and hematologic and immunologic suppression. Southeast Asian victims exposed to Yellow Rain experienced painful burning, irritation, rash, and blistering of the skin; vomiting; diarrhea; lightheadedness; and dyspnea. Some experienced rapid onset of asphyxiation, hemorrhage, and death.²⁰ Survivors developed a radiation-type illness. Trichothecene exposure may also result in alimentary toxic aleukia, a condition similar to radiation toxicity. Manifestations include fever, fatigue, weakness, headache, dizziness, nausea, vomiting, diarrhea, leukopenia, diffuse bleeding, and sepsis. Routine laboratory analysis does not aid in diagnosis. Leukopenia, thrombocytopenia, and anemia take 2 to 4 weeks to develop.

Infectious Agents

Inhalational anthrax has a typical incubation period of 1 to 6 days, but fatal human disease has occurred with a latency as long as 43 days.^{3,6,9} Initial manifestations are nonspecific and “flu-like” and include headache, low-grade fever, nonproductive cough, malaise, and myalgias. After 2 to 3 days, the disease progresses rapidly and is characterized by high fever, diaphoresis, dyspnea, stridor, hypoxia, hemoptysis, and cyanosis. Bacteremia, mediastinitis, meningitis, and septic shock frequently occur. Most patients die within 24 hours despite antibiotic therapy. Characteristic findings on the chest radiograph are mediastinal widening, indicative of hemorrhagic mediastinitis, and pleural effusions. Pneumonia, however, is not present.

Smallpox is characterized by an incubation period of 7 to 17 days, followed by the abrupt onset of high fever (102°F to 106°F), headache, malaise, myalgias, rigors, abdominal pain, back pain, and vomiting.^{3,20} Two to 3 days later, these prodromal symptoms subside and macules develop on the face, hands, forearms, and legs. At this juncture, patients are infectious to others and shed virus from oropharyngeal and respiratory secretions. Over the next 3 to 7 days, the lesions increase in number, spread centrally, and evolve to vesicles, then pustules. Greater numbers of lesions are found on the face and extremities, and lesions are in similar stages of development on each body region. In the second week of illness, skin lesions scab over and may subsequently leave depigmented scars. Bacterial pneumonia and superinfection of skin lesions may occur. Laboratory findings include leukopenia and thrombocytopenia during the prodromal illness and leukocytosis during the pustular stage.

Pneumonic plague is characterized by an incubation period of 2 to 3 days, followed by the abrupt onset of high fever, malaise, fatigue, chills, headache, myalgias, and cough productive of blood-tinged sputum.^{3,20} Sputum is loaded with *Y. pestis* and is highly contagious when aerosolized by coughing. Chest radiography commonly reveals a patchy or consolidated multilobar pneumonia. Patients develop rapidly progressive respiratory failure, shock, cyanosis, and disseminated intravascular coagulation.

DIFFERENTIAL DIAGNOSIS

Chemical or biologic warfare agent poisoning should be suspected when an increased number of patients present with a disseminated disease with fulminant course and high mortality in a compressed time frame, particularly if the disease is rare, not endemic to the area, or presents in an unusual pattern (e.g., predominance of respiratory symptoms, associated with infected or dead animals).^{4,16} Prompt recognition that an attack has occurred enables health-care personnel to implement measures to protect themselves and others from secondary illness and plan an appropriate medical and public health response.

It is also important to recognize the differences between chemical and biologic exposures. Following a chemical attack, clinical effects will occur within minutes to hours, and large numbers of symptomatic patients will present to medical facilities within a short period of time.^{2,4} Although the nature of the exposure may not be immediately known, the release site of the weapon (“hot zone”) is quickly discoverable and may be cordoned off. The distribution of affected patients is rapidly ascertained. Decontamination is an important aspect of treatment. In contrast, following a bioagent attack, clinical effects are delayed due to the incubation period of the illness.^{3,6,7,16} After several days, patients will present insidiously, often with nonspecific signs and symptoms. It is often difficult to identify the release site of the weapon, and the geographic distribution of patients may be wide by the time symptomatic disease develops. Decontamination of patients is not usually necessary.^{4,7}

Familiarity with the clinical syndromes associated with various chemical and biologic agents and their differentiation from other illnesses are equally important. The diagnosis is made by history, physical examination, and initial diagnostic testing.

Irritant or corrosive gas inhalation, hydrocarbon aspiration, and vesicating agent and high-dose lacrimating agent exposures may produce pulmonary signs and symptoms similar to those caused by choking agents. Exacerbations of asthma and chronic obstructive pulmonary disease and allergic or infectious pneumonitis may present similarly. The vesiculobullous skin lesions that result from vesicating agents may mimic those resulting from Stevens-Johnson syndrome, toxic epidermal necrolysis, pemphigus vulgaris, bullous pemphigoid, scalded skin syndrome, thermal and chemical burns, and hypersensitivity reactions. Nerve agent poisoning is nearly identical to organophosphate and carbamate pesticide poisoning. Other agents and conditions that can produce similar clinical effects are botulism; nicotine; cholinergic drugs such as bethanechol, carbachol, edrophonium, methacholine, neostigmine, pilocarpine, physostigmine, pyridostigmine, and succinylcholine, and muscarine-containing mushrooms. Nerve agents or cyanide should be suspected if victims of a suspected chemical weapons incident become comatose or seize within minutes of exposure.^{15,20} Lacrimating agents cause effects similar to those of irritant gas and lewisite exposure.

Botulism must be differentiated from other conditions that produce generalized paralysis, such as Eaton-Lambert syndrome, neurotoxic snake envenomation, Guillain-Barré syndrome, myasthenia gravis, tick paralysis, diphtheria, familial periodic paralysis, shellfish poisoning, organophosphate or nerve agent poisoning, poliomyelitis, and transverse myelitis. Trichothecene mycotoxicosis is similar to radiation, chemotherapeutic, and vesicant toxicity and sepsis. The acute fulminant pneumonitis resulting from *Y. pestis* may be clinically indistinguishable from that caused by numerous bacterial pneumonias. Anthrax may present similarly to Legionnaire disease, Q fever, tularemia, and overwhelming bacterial or viral infections. Anthrax should be suspected if chest radiography reveals a widened mediastinum in a previously healthy patient with an overwhelming flu-like illness.⁶ Unlike pneumonic plague, inhalational anthrax is not characterized by pneumonia. Conditions resembling smallpox are chickenpox, herpes zoster, disseminated herpes zoster, herpes simplex virus infection, monkeypox, other disseminated viral infections, drug eruptions, Stevens-Johnson syndrome, and eczema herpeticum. Smallpox is distinguished from chickenpox by the centrifugal distribution of its rash and the presence of lesions that remain synchronous in their stage of development.³ Fulminant hemorrhagic smallpox may closely resemble meningococemia. Anxiety and hysterical reactions must also be considered in the differential diagnosis of patients exposed to warfare agents.

EMERGENCY DEPARTMENT EVALUATION

An attempt should be made to document the amount, time, nature, and duration of exposure. The color and odor of the toxic agent may provide clues to its identity. The time of onset, nature, progression, and severity of symptoms should be noted. If numerous patients have been affected, the epidemic should be characterized similarly. A case definition should be established, the number of cases identified, and the attack rate determined.

Physical examination should first focus on vital signs and an assessment of neuromuscular and cardiopulmonary function, and then on the eyes, skin, and GI tract. Ideally, all patients should have continuous cardiac and oxygen saturation monitoring, but priority must be given to the most severely affected patients in mass casualty situations. The initial evaluation of numerous victims from a mass casualty incident will require rapid implementation of a hospital- and community-wide disaster plan (see [Chapter 399](#)).

If signs and symptoms of choking, vesicating, or lacrimating agent toxicity are present, ancillary studies should include a chest radiograph, electrocardiogram (ECG), and arterial blood gas analysis, depending on the severity of symptoms. There are no specific diagnostic tests for choking agents. Additional laboratory evaluation after exposure to a vesicating agent should include baseline complete blood count and serum electrolyte, blood urea nitrogen, creatinine, and glucose levels. Patients with eye symptoms should have fluorescein and slit-lamp examinations.

Patients with signs and symptoms of nerve agent toxicity should have a chest radiograph, ECG, arterial blood gas analysis, routine admission laboratory studies, and measurement of peak expiratory flow rate and plasma or erythrocyte cholinesterase activity (see [Chapter 361](#)). Routine toxicology testing will not identify nerve

agents in serum or urine. Treatment decisions should be clinically based, particularly because the results of cholinesterase activity will not be readily available and do not always correlate with the severity of disease.^{5,20} In the Tokyo Sarin attack, 27% of patients with clinical manifestations of moderate poisoning had plasma cholinesterase levels in the normal range.¹²

Patients with suspected botulism from the ingestion of contaminated food should have blood and feces samples sent for bioassay identification of botulinum toxin. Following inhalational exposure, however, the diagnosis is made by enzyme-linked immunosorbent assay (ELISA) detection of toxin from swabs obtained from nasal and oral mucosa within 24 hours of exposure.^{3,20} Spirometry and arterial blood gas analysis should also be performed. Routine laboratory studies are not helpful in the diagnosis.

With trichothecene exposure, ancillary studies should include a complete blood count and a coagulation profile. Although trichothecene mycotoxins can be identified in human tissue samples, the technology is not readily available.

Patients with suspected inhalational anthrax should have a chest radiograph, arterial blood gas analysis, routine admission laboratory studies, blood cultures, serology, and Gram-staining of unspun peripheral blood. New rapid diagnostic tests to detect *B. anthracis* and its proteins have been developed and include polymerase chain reaction, ELISA, and direct fluorescent antibody testing.^{3,6,20} Currently, these tests are available only at national reference laboratories. The definitive diagnosis of anthrax is made by culturing bacteria from blood. Blood cultures from patients with systemic infection are almost always positive. Results are usually available by 24 hours. Microbiology personnel should be informed when anthrax is suspected so that *B. anthracis* is correctly identified. Antibiotic-susceptibility testing should be performed on all bacterial isolates, because strains may be deliberately modified by terrorists to enhance antibiotic resistance.

Ancillary studies in suspected smallpox depend on the clinical appearance. A chest radiograph, complete blood count, electron microscopic analysis of vesicle scrapings, and culture are recommended.^{2c} Acute and convalescent serologic analysis should also be performed. Polymerase chain reaction techniques have been developed and promise more rapid and accurate diagnosis. Currently, definitive diagnosis of smallpox involves viral isolation from skin lesions, the oropharynx, or urine or serology.

Patients with suspected pneumonic plague should have a chest radiograph, arterial blood gas analysis, routine admission laboratory studies, blood cultures, serology, and Gram-staining of unspun peripheral blood and sputum. Disseminated intravascular coagulation screening should be performed for patients that are critically ill. A preliminary diagnosis can be made if gram-negative coccobacilli with bipolar, safety-pin morphology are detected in the blood, sputum, or other body fluids.^{3,20} The diagnosis of plague is confirmed when *Y. pestis* is detected by direct fluorescent antibody staining or culture of blood and sputum. Polymerase chain reaction techniques have been developed and can facilitate rapid diagnosis.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced cardiac and trauma life-support measures are instituted, as necessary. Important facets of treatment include self-protection of health-care workers, patient decontamination, supportive care, and specific antidotal and antimicrobial therapy.

In the event of a suspected chemical weapon attack, emergency field personnel will be responsible for performing on-scene triage, decontamination, and initial treatment prior to patient transport. Emergency field personnel must be equipped with the appropriate personal protective equipment (PPE) until patients can be decontaminated and the threat of secondary exposure is no longer present. If the hazardous substance is unknown, this consists of an encapsulated, vapor-impermeable, and chemical-resistant suit; chemical-resistant gloves and boots; and a self-contained breathing apparatus (level A PPE).² The importance of first-responder personal protection was illustrated in the Matsumoto and Tokyo Sarin gas attacks in which 10% to 35% of rescuers developed mild toxicity.^{10,12} In each incident, patients were not decontaminated, and rescuers wore standard work clothing without respiratory protection.

Initial victim management includes establishing and maintaining the airway, breathing, and circulation, and gross decontamination (brushing off chemical powder, removal of clothing and jewelry and of the patient from the contaminated environment). Clothing should be discarded in impervious plastic bags, particularly leather items (e.g., shoes and watchbands), which absorb chemicals and act as a depot. The next priorities are further medical stabilization and decontamination. If exposed, the eyes are irrigated with copious amounts of water or saline. A topical anesthetic may be used, if available. Skin should be decontaminated with a triple wash, which includes initial irrigation with tepid water, followed by 0.5% hypochlorite solution (household bleach diluted 1:10 with water) or alkaline soap, and then repeated, thorough water rinsing.^{2,7,20} The waste water should be collected and isolated, if possible. For inhalation exposure, initial treatment includes administration of 100% humidified oxygen, assisted ventilation, as necessary, and removal from the vapor source. Once the patient is decontaminated, more definitive field supportive care and antidotal therapy can be delivered while the patient is taken to the hospital.

Police, fire department, emergency medical, and HAZMAT (hazardous materials) personnel should inform hospital personnel of the nature and magnitude of exposure, the number and severity of casualties, and the manifestations of illness. On recognition of a mass casualty incident, emergency physicians must implement the hospital disaster plan as well as establish a well-demarcated decontamination area outside the emergency department for patients that arrive without prior decontamination.² Details of disaster planning and management are discussed in [Chapter 399](#). Emergency department personnel performing initial decontamination should wear a nonencapsulated, chemically resistant body suit, gloves, and boots, and a full-face mask with air purifier (level C PPE) until threat of secondary exposure is no longer viable.² Rapid dermal decontamination is critical following exposure to the liquid or aerosolized form of an agent but less important following exposure to vapor.^{2,5} Patient decontamination was inadequately performed in the Tokyo Sarin gas exposure (vapor), yet secondary injury to hospital staff was minimal and did not necessitate treatment.¹¹

Following a bioagent attack (exposure by aerosol), decontamination of patients is not likely necessary unless gross contamination of the skin is evident. In a publicized attack, asymptomatic victims should be instructed to remove their clothing and place it in well-sealed plastic bags, wash their hands, and shower thoroughly with soap and water.⁷ This may be performed at home or in a preestablished decontamination area of the emergency department. For patients who present with symptomatic illness after a covert attack, decontamination is likely unnecessary, but health-care provider protection is critical. Standard infection control precautions (gown, mask with eyeshield, and gloves) provide adequate protection from most agents.⁷ Of the potential biologic agents, only smallpox, plague, and viral hemorrhagic fevers are spread person to person and require airborne, contact, and droplet precautions.^{3,7} If patients present with respiratory symptoms or a rash, they should be placed in a private negative-pressure room, and medical personnel caring for the patient should wear N95 high-efficiency particulate air filter respirators pending the results of a more complete evaluation.⁷

Choking Agents

Treatment of choking agent poisoning is primarily supportive and consists of copious saline irrigation of exposed skin and eyes, humidified oxygen, bronchodilators, ventilatory support, intravenous crystalloids for hypotension, and antibiotic administration for secondary infection.^{2c} Although sometimes recommended for chlorine and phosgene exposure, corticosteroids have no proven benefit. Preliminary animal studies suggest that tomelukast, a leukotriene-receptor antagonist, and *N*-acetylcysteine, an antioxidant, may limit the development of pulmonary edema following phosgene exposure. Preliminary human evidence suggests that nebulized 2% sodium bicarbonate may provide symptomatic relief following acute chlorine gas exposure.

Vesicating Agents

Treatment of sulfur mustard victims focuses on rapid decontamination, followed by symptomatic therapy. Mustard reacts irreversibly with tissue macromolecules within minutes of exposure; immediate removal of mustard from the skin is the best form of treatment.^{1,13,20} Decontamination prevents further absorption and tissue damage, but only supportive care can be given once mustard is tissue-bound. Street clothing offers no protection, but military protective garments (chemical-resistant suit) can provide up to 6 hours of protection following exposure.¹

The recommended method of decontamination is to wash with standard 5% household bleach, diluted 1:10, or copious amounts of soap and water. Water alone is ineffective, as mustard is relatively water-insoluble. Bleach produces "free" chlorine, which inactivates the mustard compound. Dry decontamination can be performed by applying absorbent powders (flour, baking soda [sodium bicarbonate], talcum powder, activated charcoal, or Fuller's earth) to the skin and wiping off with moist paper towels.¹ Skin can also be decontaminated by irrigating with 10% sodium thiosulfate. Copious water or saline irrigation is the favored method of ocular

decontamination.

General supportive care focuses on the skin, eyes, and respiratory system. Skin care involves aggressive burn management of skin lesions with irrigation when appropriate, application of topical agents such as silver sulfadiazine, and surgical debridement of blisters and necrotic skin. Ocular injury requires urgent ophthalmologic consultation. Treatment may include topical anesthetics, antibiotic ointment to prevent infection, and mydriatic or cycloplegic medication to prevent adhesions between iris and cornea.^{1,20} Respiratory toxicity is managed by aggressive pulmonary toilet, supplemental oxygen, inhaled bronchodilators, antibiotics for superinfection, and mechanical ventilation with positive end-expiratory pressure, when indicated.

Preliminary studies have identified several potential antidotes for sulfur mustard toxicity including mustard scavengers (glutathione, N-acetylcysteine, thiosulfate), antioxidants (vitamin E), NAD⁺-level stabilizers (niacin and nicotinamide), antiinflammatory drugs (corticosteroids), and nitric oxide synthase inhibitors (L-nitroarginine methyl ester).^{13,20} Bone marrow suppression may respond to granulocyte colony-stimulating factor.

Treatment of lewisite exposure involves washing the skin with water, soap and water, or solutions of dilute chlorine bleach (0.5%) or baking soda (sodium bicarbonate).²⁰ Dry decontamination may also be efficacious. Neither scrubbing nor hot water is appropriate, because both enhance lewisite absorption and toxicity. Blisters, shown to contain arsenic, should be opened and drained of fluid. Management is otherwise identical to that of thermal burns.

The systemic manifestations of lewisite poisoning can be effectively countered by its chelator antidote, British antilewisite (BAL, 2,3-dimercaptopropanol, or dimercaprol). BAL is given intramuscularly for systemic treatment (see [Chapter 318](#)). It has also been used topically as a 5% ointment for skin lesions and as a 5% to 10% oil solution for ocular symptoms. Newer, less toxic dithiol analogs of BAL have been developed that can be given orally or intravenously. These agents include 2,3-dimercapto-1-propan-sulfonic acid (DMPS) and meso-dimercaptosuccinic acid (DMSA, marketed as Succimer or Chemet; see [Chapter 318](#) and [Chapter 348](#)). These agents have lower mammalian toxicity than BAL and equal efficacy.

Nerve Agents

The first priority in nerve agent treatment is self-protection and decontamination. Self-protection minimally involves a well-sealed respirator with a charcoal filter and heavy-butyl rubber gloves.⁵ Use of a chemical-resistant suit and self-contained breathing apparatus provides the best protection. Victims of vapor exposure manifest maximal toxicity rapidly and will not worsen after hospital arrival.^{5,12} They pose little threat to hospital personnel following removal of the clothing. Patients with liquid contamination of skin and clothing, however, may develop toxicity insidiously and pose a significant vapor and skin contact risk to rescuers.^{5,20} Patient clothing should be removed rapidly and the skin decontaminated. Skin can be decontaminated with a triple wash—irrigation with tepid water, followed by 0.5% hypochlorite solution or alkaline soap, and repeated, thorough water rinsing.^{2,5,15,20} The U.S. military decontamination kits contain towelettes impregnated with a hypochlorite solution. The skin should not be scrubbed, because abrading the skin will increase absorption. Water alone does not hydrolyze the nerve agents but does serve to dilute the poison. Eye decontamination involves copious saline irrigation. Hypochlorite should not be used in the eye.

Intubation, mechanical ventilation, and the use of atropine and pralidoxime antidotes may be necessary. The use of succinylcholine to assist intubation is discouraged, as it may result in prolonged neuromuscular blockade due to nerve agent–induced plasma cholinesterase inhibition.⁵ Antidotal therapy is discussed in [Chapter 361](#). Cumulative atropine doses of 10 to 20 mg are usually adequate over the first 2 to 3 hours, with little or no therapy required thereafter.^{5,12,15,20} This differs from organophosphate pesticide poisoning, which frequently requires significantly greater amounts and a longer duration of atropine therapy. In the Tokyo Sarin attacks, only 19% of poisoned patients required more than 2 mg of atropine.¹² Severely poisoned patients required 1.5 to 15.0 mg of atropine (mean, 6 mg).^{1011 and 12} Atropine therapy is dictated by symptoms and titrated to the desired clinical effect. Heart rate and pupil size are poor clinical indicators of adequate atropinization. U.S. soldiers carry three atropine autoinjectors, each containing 2 mg, for rapid intramuscular self-injection. Topical mydriatic–cycloplegic eye drops (e.g., tropicamide) may be used for patients with intractable eye pain due to ciliary spasm. Eye drops are not recommended for those patients with miosis as their only ocular finding. Because nerve agents age extremely rapidly, pralidoxime must be given as soon as possible after exposure to be effective. Toxicity from pralidoxime includes hypertension and tachycardia. U.S. soldiers also carry three pralidoxime autoinjectors, each containing 600 mg of the oxime to be injected intramuscularly along with each atropine injection.²⁰ In the Tokyo Sarin attacks, severely poisoned patients required 1 to 36 g pralidoxime (mean 11 g).^{1011 and 12}

Seizures resulting from nerve agent exposure are treated with high-dose benzodiazepines, such as diazepam 10 mg intravenously (0.2 to 0.4 mg/kg). Experimental animal data suggest that prophylactic diazepam reduces the incidence of seizures and pathologic brain injury following nerve agent exposure.^{5,20} Military physicians recommend diazepam prophylaxis for all severely exposed victims.^{17,22} During Operation Desert Storm, military personnel carried 10-mg diazepam autoinjectors for intramuscular use following nerve agent exposure. Recent evidence suggests that glutamate antagonists are also effective treatment for nerve agent–induced seizures. In primates poisoned with Sarin, the administration of the glutamate antagonist, GK-11 (gacyclidine), prevented seizures, mortality, and delayed neuropathology and accelerated clinical recovery.⁸

An additional approach to limit nerve agent toxicity is to pretreat at-risk personnel with a reversible (carbamate) AChE inhibitor, such as physostigmine or pyridostigmine. Nerve agents cannot bind cholinesterase that is carbamylated (bound to carbamate), which spontaneously reactivates or is regenerated with oxime therapy, leaving the victim with enough AChE to function normally. Pyridostigmine pretreatment carbamylates 20% to 40% of erythrocyte AChE. Soman exposure results in such rapid aging that standard atropine and pralidoxime therapy is unlikely to significantly increase survival. The addition of pyridostigmine pretreatment to the treatment regimen greatly reduces Soman lethality.²⁰ Pretreatment does not enhance protection from Sarin and VX exposures, wherein the aging phenomenon is more prolonged. Pralidoxime is useful therapy for these exposures. Pyridostigmine does not afford any protection by itself without the use of antidotes.²⁰ Carbamates have direct nicotinic receptor, ionic channel actions, which may contribute to their efficacy independent of AChE carbamylation.

During the Persian Gulf war, soldiers at risk for nerve agent exposure were given pyridostigmine bromide in blister packs containing twenty-one 30-mg tablets.²⁰ Pyridostigmine was taken orally every 8 hours without causing impaired performance. Side effects were reported to be minimal, but they can mimic those of mild nerve gas poisoning. Pyridostigmine does not cross the blood–brain barrier and offers no protection from CNS nerve agent toxicity.¹⁵ Physostigmine, which does cross the barrier, has proved too toxic for pretreatment.

Conventional oximes (pralidoxime preparations, obidoxime, trimedoxime) are not clinically useful against Soman. Newer H-series oximes (named after their inventor, Inge Hagedorn) are superior in their ability to reactivate unaged Soman-inhibited AChE. Their greater efficacy is partly due to greater oxime group potency and enhanced reactivation of phosphorylated AChE. H-series oximes also have direct antimuscarinic and antinicotinic (ganglia-blocking and nondepolarizing neuromuscular-blocking) actions but do not protect from nerve agent–induced seizures.^{14,20} Although they do not readily cross the blood–brain barrier and do not regenerate CNS AChE in animal studies, they provide some CNS protection, presumably from a direct cholinolytic action.

HI-6, the most well-studied agent, is the only oxime clinically efficacious against Soman. It also provides protection against other agents, and no significant side effects from its use have been reported in human studies.¹⁴ HI-6 is given intramuscularly at an adult dose of 250 to 500 mg every 6 hours. Animal studies have shown that HI-6 use alone after Soman exposure protects from lethality.^{14,20} Efficacy was enhanced when it was used with atropine. Animal studies suggest that the bispyridium dioxime, HLö 7, is more efficacious than HI-6.¹⁹

Promising treatments are being researched. Human monoclonal antibodies to the various nerve agents may provide passive protection before exposure.²⁰ Soman lethality is decreased when animals are preloaded with excess cholinesterase. The circulating cholinesterase presumably scavenges nerve agent and protects tissue AChE.

Lacrimating Agents

Medical treatment is frequently unnecessary after tear agent exposure, because the initial effects resolve quickly. Symptomatic patients, however, require prompt decontamination and supportive care. Health-care personnel should wear rubber gloves; if contamination is heavy, airway protection may also be necessary. The skin is washed thoroughly with soap and water or a mild alkaline solution such as 6% sodium bicarbonate or 1% benzalkonium chloride.²⁰ Ambulatory patients can be bathed in a shower. Contact dermatitis may respond to topical corticosteroids and antipruritics. Tearing usually irrigates the eyes adequately, but topical anesthetics and saline irrigation may be necessary. Chemical conjunctivitis may require symptomatic treatment with topical vasoconstrictors. Corneal injuries are treated with cycloplegics, topical antibiotics, and ophthalmologic referral (see [Chapter 99](#)). Some argue that patients exposed to high gas concentrations, as in enclosed spaces or

near exploding tear gas canisters, should be observed for several days because of delayed pulmonary effects.²⁰ Treatment of pulmonary toxicity consists of humidified oxygen, bronchodilators, and assisted ventilation, as needed. Powder may linger in clothing and hair and may repositon the patient at a later time.

Biologic Toxins

Treatment of suspected botulism involves close respiratory monitoring and supportive care. Mortality is less than 5% if assisted ventilation is provided in a timely manner.^{3,20} A trivalent (ABE) equine antitoxin (immunoglobulin) and investigational, heptavalent (A-G), equine, F(ab')₂ fragment antitoxin are available for emergent treatment of disease (see [Chapter 205](#)). After aerosol exposure, the F(ab')₂ fragment antitoxin is protective only if given before the onset of clinical symptoms. It will not bind toxin that has already entered nerve terminals. If there is no ileus and exposure was by ingestion, cathartics and enemas may be used to enhance elimination of unabsorbed toxin. An investigational, pentavalent (A-E) botulinum toxoid has been developed that prevents symptomatic disease following all routes of exposure. This vaccine was used to immunize Operation Desert Storm troops as a protective measure.

Treatment of trichothecene mycotoxicosis is entirely supportive. Skin decontamination with soap and water has prevented skin lesions up to 6 hours following exposure.²⁰ Superactivated charcoal binds T-2 toxin avidly and should be administered as soon as possible following inhalational and oral exposures. Monoclonal antibodies against T-2 toxin have been developed but are still investigational.

Infectious Agents

Treatment of inhalational anthrax includes supportive care, antibiotics, and postexposure vaccination for asymptomatic patients. Traditionally, high-dose intravenous penicillin G (2 million U every 2 hours) has been the preferred therapy.^{3,6} The threat of biologic terrorism brings with it the threat of resistant strains of *B. anthracis*. Experts currently recommend intravenous ciprofloxacin (400 mg every 12 hours for adults; 20 to 30 mg/kg/d, divided in two daily doses for children) as preferred initial therapy for symptomatic patients pending the results of susceptibility testing. Doxycycline is an acceptable alternative. Recommendations for pregnant women are no different. Chemoprophylaxis and vaccination are recommended for asymptomatic patients following known or suspected exposure to *B. anthracis*. The antibiotic regimen is the same as for symptomatic patients, but drug dosages are given orally and prophylaxis is continued for 60 days.⁶ Victims should be immunized with a licensed, inactivated, cell-free vaccine at 0, 2, and 4 weeks.^{3,6,20} Prophylactic antibiotic administration may be discontinued at 30 to 45 days for patients that have been immunized. U.S. troops in the Persian Gulf war were immunized against anthrax as a protective measure; no serious adverse effects have been associated with the vaccine.²⁰

Treatment of smallpox is mainly supportive. The antiviral, cidofovir, has demonstrated efficacy *in vitro* against variola virus and may have a therapeutic role in treatment.³ Strict quarantine with respiratory isolation is recommended for patients (until lesions are scabbed over) and their close contacts (for 17 days).²⁰ Immediate vaccination with the licensed, attenuated vaccinia virus vaccine is recommended for postexposure prophylaxis. Vaccination is highly effective if accomplished within a few days of exposure. Vaccinia immune globulin should be given to patients who are pregnant, are immunocompromised, have eczema, or experience severe vaccination reactions. The United States stock of vaccinia vaccine is maintained at the Centers for Disease Control and Prevention (CDC) in Atlanta.

Streptomycin (15 mg/kg every 12 hours) by intramuscular injection has been the traditional treatment of plague pneumonia. If streptomycin is not available, intravenous gentamicin (1.75 mg/kg every 8 hours) or doxycycline (200 mg initially, followed by 100 mg every 12 hours) may be given.^{3,20} For hemodynamically unstable patients and those with meningitis, intravenous chloramphenicol (50 to 75 mg/kg/d in four divided doses) is recommended. Treatment should be continued for 10 days. All patients with pneumonic plague should be isolated, with respiratory precautions. Postexposure prophylaxis is recommended for close contacts of infected patients and all asymptomatic exposure victims. Prophylaxis consists of oral tetracycline, doxycycline, or trimethoprim-sulfamethoxazole in standard doses for 6 days. A licensed, killed, whole-cell vaccine is available but will not protect against pneumonic plague.

Most U.S. military personnel are immunized against yellow fever, cholera, tetanus, typhus, typhoid fever, poliomyelitis, diphtheria, meningococcal meningitis, hepatitis A and B, and influenza. Vaccines against tularemia, Rift Valley fever, chikungunya, Q fever, Argentine hemorrhagic fever, Venezuelan equine encephalitis, Eastern equine encephalitis, and Western equine encephalitis have also been produced. Depending on the agent involved, treatment may include immune globulin and antibiotics, as described in other chapters.

DISPOSITION

Consultation with a toxicologist, regional poison control center, experienced military physician, infectious disease specialist, epidemiologist, and public health specialist is recommended for all chemical or biologic agent poisoning except civilian exposures to the lacrimating agents. The CDC (770-488-7100) and the United States Army Medical Research Institutes for Infectious Diseases (USAMRIID) (1-888-USA-RIID) have 24-hour hotline services to assist physicians with biologic agent inquiries. Any suspected or confirmed case of chemical or biologic agent poisoning should prompt an immediate call to local law enforcement authorities, the local Federal Bureau of Investigation field office, and local or state health department and laboratory. An ophthalmologist or plastic surgeon should be consulted for patients with corneal or skin burns.

Asymptomatic patients are observed and monitored for at least 6 hours after choking agent exposure. Mild to moderately symptomatic patients may be discharged safely after several hours of observation if symptoms have improved or resolved with treatment. Some argue that all patients with a history of phosgene exposure should be admitted and closely observed because of phosgene's varying latency period and high potential morbidity. Asymptomatic patients should be observed and monitored for 12 hours after vesicating agent exposure and 24 hours after skin exposure to nerve agent liquid or aerosolized droplets. Following exposure to nerve agent vapor, patients with signs and symptoms confined to the eyes may be discharged safely after a short period of observation.^{5,12} Victims of lacrimating agents may be treated and released if there is no significant pulmonary toxicity. The disposition of asymptomatic patients following biologic agent exposure depends on the agent. Patients exposed to *C. botulinum* are admitted and observed, those exposed to smallpox should be quarantined for 17 days, and those exposed to trichothecene mycotoxins, *B. anthracis*, and *Y. pestis* may be discharged following appropriate chemoprophylaxis. All patients with systemic symptoms, pulmonary toxicity, and severe or extensive dermal injury should be hospitalized. Patients with moderate-to-severe poisoning from chemical or biologic agents should be admitted, with the level of care dependent on clinical severity.

COMMON PITFALLS

- Failure to adequately protect rescuers and medical personnel from secondary contamination
- Failure to decontaminate victims of chemical agent exposure in a timely fashion
- Failure to appreciate the differences between chemical and biologic warfare agent exposures
- Lack of familiarity with chemical and biologic warfare agent toxidromes
- Failure to maintain appropriate isolation of infectious patients
- Failure to observe asymptomatic victims for appropriate periods of time

CHAPTER 326

Cocaine

Richard D. Shih and Judd E. Hollander

[Clinical Presentation](#)
[Emergency Department Evaluation](#)
[Differential Diagnosis](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Cocaine (benzoylmethylecgonine) has been used for social, religious, and medicinal purposes for many centuries. Over the past several decades, its illicit use as a drug of abuse has risen dramatically. An estimated 23 million Americans have used cocaine at least once, and approximately 5 million use it regularly.¹⁵ Further, among visits to emergency departments due to drugs of abuse, cocaine is the most commonly involved drug.¹²

Cocaine is well absorbed on contact with mucous membranes or by pulmonary inhalation. It is derived from the *Erythroxylon coca* plant, which is found in abundance in Central America, South America, the West Indies, and Indonesia. In the manufacturing process, leaves are initially dissolved in hydrochloric acid to form the cocaine hydrochloride salt. This is the form most often abused via nasal insufflation or intravenous injection. Crack cocaine or cocaine free base are the alkaloid forms of cocaine that are produced by an extraction process utilizing a basic solution, a solvent (usually ether), and heat. The free-base form is close to 100% purity, while crack approximates 75%. These forms are heat stable, and thus can be smoked and absorbed by the lungs.

By the intravenous or inhalational routes, cocaine is rapidly distributed throughout the body and central nervous system (CNS), with peak effects in 3 to 5 minutes. With nasal insufflation, absorption is slower and effects are delayed, peaking at approximately 20 minutes. Although not a typical route of abuse, oral ingestion delays absorption even further, with peak effects occurring at 40 to 60 minutes.

Cocaine has a half-life of 0.5 to 1.5 hours. It is predominantly metabolized to the active metabolites ecgonine methyl ester and benzoylecgonine (BE) by hydrolysis. These two metabolites account for approximately 80% of cocaine metabolism. They have half-lives of 4 to 8 hours and many effects similar to their parent compound, cocaine. Other metabolites include cocethylene, ecgonine, and norcocaine. Urine drug tests typically test for BE, and this cocaine metabolite is typically present for 48 to 72 hours after use.¹

Cocaine has a number of pharmacologic effects peripherally and in the CNS. It acts to augment the peripheral sympathetic system, producing such findings as tachycardia, hypertension, diaphoresis, arterial vasoconstriction, and dilated pupils. Additionally, cocaine has local anesthetic effects. In the amide group of topical anesthetic agents, it is the only one that has vasoconstrictive effects, which help control secretions and bleeding. Because of these properties, it has frequently been used for otolaryngology procedures and wound repair. The central effects of cocaine are very complex and not completely understood. It has effects on a number of neurotransmitters in the CNS. However, the net effect is the augmentation of the sympathetic nervous system.

“Body stuffers” and “body packers” are individuals who have ingested containers of an illicit drug (most commonly cocaine and heroin).⁵ These containers can be plastic bags, plastic vials, elastic wraps, elastic condoms, or other packaging material. A “stuffer” is someone who hastily ingests containers just prior to being arrested by police in order to conceal the evidence.¹⁷ A packer, or “mule,” is an individual who ingests a large number of carefully wrapped containers of highly pure drug as a means of concealing and smuggling it into the United States from a foreign country or into jail.

CLINICAL PRESENTATION

Cocaine toxicity can be manifested in a number of different organ systems. The most commonly seen manifestations in the emergency department involve the cardiovascular and neurologic systems.² Signs and symptoms of mild cocaine intoxication include normal or minimally increased blood pressure, pulse, respiratory rate, and temperature; agitation; anxiety; euphoria; headache; hyperreflexia; nausea; vomiting; mydriasis; pallor; diaphoresis; tremors; and twitching. Moderate intoxication may result in hypertension, tachycardia, dyspnea, tachypnea, hyperthermia, confusion, hallucinations, marked hyperactivity, increased muscle tone and deep tendon reflexes, abdominal cramps, formication, and generalized but brief tonic-clonic seizures. Severe intoxication is manifested by hypotension, tachycardia (or preterminal bradycardia), ventricular dysrhythmias, Cheyne-Stokes respirations, apnea, cyanosis, malignant hyperthermia, coma, flaccid paralysis, and status epilepticus.

Chest pain is the most common chief complaint. Myocardial infarction due to cocaine is well established^{7,8} and occurs in approximately 6% of patients presenting with this complaint. Cocaine causes coronary ischemia through coronary artery vasoconstriction,¹⁰ *in situ* thrombus formation, platelet activation, and inhibition of endogenous fibrinolysis, as well as triggering an increase in the myocardial oxygen demand through generation of tachycardia and hypertension.⁷ Chronic users develop premature atherosclerosis and left ventricular hypertrophy, which can further exacerbate the oxygen supply–demand mismatch that results from chronic use.⁷ Other less common but equally important cardiovascular complications of cocaine use include atrial and ventricular dysrhythmias, both systolic and diastolic congestive heart failure, coronary and aortic dissection, dilated cardiomyopathy, and ischemia in other vascular beds (e.g., intestinal, renal, etc.).

Euphoria, the impetus for the recreational use of cocaine, is typically short-lived and without serious sequelae. The stimulatory effects of cocaine can lead to seizures, both bland and hemorrhagic cerebral infarction, and subarachnoid hemorrhage. Severe, persistent lethargy with an altered mental status can occur following prolonged and intense cocaine usage and has been termed the *cocaine wash-out syndrome*. This diagnosis should be made only after exclusion of the aforementioned neurologic catastrophes (i.e., after a normal computerized tomography (CT) of the head and lumbar puncture, if indicated). The syndrome is thought to be due to such excessive cocaine usage that essential neurotransmitters are depleted. Symptoms will generally abate within 12 to 24 hours.

Rhabdomyolysis is another common manifestation of cocaine toxicity. Cocaine's stimulatory effects lead to severe agitation and marked muscular agitation and rigidity. Ischemia of the skeletal muscle beds may also contribute. Profound elevations in creatinine kinase (CK) may be seen. Concurrent development of severe hyperthermia and acute renal failure can be life-threatening.⁹ Hyperthermia is most commonly due to a combination of environmental exposure and heat production from excessive muscle activity. Renal failure is due to muscle breakdown and renal tubular precipitation of the released muscle myoglobin.

Cocaine has a number of direct and indirect effects on the lungs. Many of the effects of cocaine are due to the method of abuse rather than direct toxin effects. Asthma exacerbations have been frequently reported with crack cocaine usage. This is most likely due to particulate by-products of combustion. Further, crack usage is typically associated with deep Valsalva maneuvers to maximize drug delivery. This can cause pneumothorax, pneumomediastinum, and noncardiogenic pulmonary edema. Other less common effects on the lung include pulmonary infarction, bronchiolitis obliterans, pulmonary artery hypertrophy, and alveolar hemorrhage. Treatment of these conditions follows standard management protocols, whether they are related to cocaine, or not.

The intestinal vascular system is very sensitive to the effects of cocaine. Acute intestinal vascular infarction has been associated with all routes of administration.

The amount of drug released in the gastrointestinal (GI) tract in stuffers is relatively low and unlikely to cause serious toxicity.⁵

Although oral ingestion is not a common route of abuse, local intestinal and systemic effects can occur when containers of cocaine leak or rupture in body stuffers and packers. Body packers most often present asymptotically, having been discovered by customs officers.

Habitual cocaine usage during pregnancy is associated with low birth weight, small head circumference, developmental problems, and a number of birth defects. Acute toxicity can also cause the induction of premature labor, eclampsia, and abruptio placentae. After delivery, neonates exposed to cocaine *in utero* are at risk for the development of neonatal withdrawal. This diagnosis of exclusion is manifested as irritability, jitteriness, and poor eye contact.

EMERGENCY DEPARTMENT EVALUATION

The diagnostic evaluation of patients manifesting cocaine toxicity relies on a history of cocaine use, recognition of signs and symptoms consistent with sympathomimetic toxidrome, and evaluation of specific organ system complaints. The history should include the total amount and time of cocaine use in relation to symptom onset. Friends (or witnesses) of confused patients should be questioned about a history of seizures or syncope and antecedent activities. New-onset seizures, epistaxis, hypertension, myocardial infarction, intracranial hemorrhage, or psychiatric illness, especially in young patients, should suggest the possibility of cocaine use. Many patients deny cocaine use unless approached with reassurance and compassion or confronted with a positive urine test.

The physical examination should include a complete set of vital signs and a detailed examination of the cardiac, pulmonary, and neurologic systems. All patients should initially have continuous cardiac monitoring.

When the history is clear and symptoms are mild, laboratory evaluation is unnecessary. In contrast, if the history is absent or unreliable or the patient manifests moderate or severe toxicity, routine laboratory evaluation should include a complete blood count; determination of electrolyte, glucose, blood urea nitrogen, and creatinine levels; arterial blood gas analysis; urinalysis; and CK. Qualitative toxicologic analyses of blood and urine can confirm the diagnosis and rule out other intoxicants. Toxicology testing is indicated only when confirmation of drug use would change management, counseling, or referral patterns.

A chest radiograph and electrocardiogram (ECG) should be obtained in patients with chest pain or moderate-to-severe toxicity. Those with prolonged, unexplained pain should have serial ECG and cardiac enzyme measurements to rule out myocardial infarction. Many of the clinical parameters to assess ischemia or infarction are not as reliable as when they are used for patients with traditional coronary artery disease (CAD).⁴ The ECG is less sensitive and specific for identifying ischemia or infarction in this setting, the CK is often elevated due to associated rhabdomyolysis, and false elevations in the MB fraction can occur. Cardiac troponin I testing can help distinguish true-positive from false-positive CK-MB elevations.⁹

Persistent headache despite normalization of blood pressure requires evaluation by CT scan and lumbar puncture to rule out intracranial hemorrhage. Patients with abdominal or back pain must be evaluated for intestinal or renal infarction. The urine should be inspected and the CK level determined, because myoglobinuric renal failure may develop.

Occult infections must be excluded in patients with fever, even though fever can be due solely to cocaine toxicity. A brief seizure clearly related (temporally) to cocaine use in an otherwise healthy person should be evaluated with CT to exclude serious underlying pathology, but it does not require further workup, provided the patient is alert and coherent, has no headache, and has a normal neurologic examination. Patients suspected of body packing or stuffing should be evaluated by abdominal radiographs (including contrast imaging) and cavity searches (digital or visual examination of the rectum or vagina). Toxicity lasting for more than 4 hours suggests continued drug absorption and should prompt a similar workup.

The route of administration may influence the patient's chief complaint or which organ system is affected. Intravenous users may present with fever and malaise secondary to infectious complications such as cellulitis, endocarditis, hepatitis, pneumonia, and the acquired immunodeficiency syndrome. Chronic nasal use may lead to rhinitis, septal perforation, and epistaxis. Inhalational use may produce dyspnea, cough, or hemoptysis from reactive airway disease, "crack lung" pneumonitis, or pulmonary edema, or may result in pulmonary barotrauma (e.g., pneumothorax, pneumomediastinum, pneumopericardium) as a result of the Valsalva maneuver or from blowing smoke into the mouth of a partner. Patients with barotrauma may also complain of neck and chest pain and demonstrate tachypnea, subcutaneous emphysema, or Hamman's sign.

Behavioral disorders (e.g., agitation, combative behavior), headache, back pain (renal infarction or aortic dissection), abdominal pain (mesenteric ischemia), altered level of consciousness, or cardiopulmonary arrest are other common presentations that may follow the use of cocaine by any route. Patients may present as victims of trauma, because of the violent, irrational, and risk-taking behavioral associated with drug use. Delayed cardiovascular complications can sometimes occur. Myocardial ischemia can occur in the first few days after cocaine use. Intestinal and myocardial infarction have been reported 1 to 2 weeks after last use.¹⁴

Manifestations of chronic cocaine abuse include anorexia, insomnia, formication, depression, impotence, weight loss, paranoia, and psychosis. Halo vision (lights around objects) and "snow lights" (flashes in the peripheral fields) have also been described.

DIFFERENTIAL DIAGNOSIS

Similar toxicity can be caused by a variety of physiologic stimulants (see [Table 309.4](#)). A sympathomimetic toxidrome can also be seen with hypoglycemia, environmental and malignant hyperthermia, pheochromocytoma, psychiatric conditions, status epilepticus, and thyroid storm. Patients with persistent altered mental status need to be evaluated for possible meningitis and CNS lesions. [Table 326.1](#) lists the differential diagnosis of chest pain related to cocaine use.

Aortic dissection	Bacterial endocarditis
Bronchospasm	Esophageal illnesses
Gastrointestinal illnesses	Musculoskeletal injury
Myocarditis	Myocardial infarction
Myocardial ischemia	Pericarditis
Pleurisy	Pneumonia
Pneumothorax	Pneumomediastinum
Pulmonary emboli	Pulmonary infarction

TABLE 326.1. The Differential Diagnosis of Cocaine-Associated Chest Pain

EMERGENCY DEPARTMENT MANAGEMENT

Management depends on the specific complaint and presentation ([Table 326.2](#)). Patients presenting with a sympathomimetic toxidrome are at risk for hyperthermia and rhabdomyolysis. After initial attention to the airway and cardiovascular status, management should focus on lowering core body temperature (see [Chapter 209](#)), halting further muscle agitation and heat production, and giving intravenous fluids to ensure a good urinary output. The agents of choice for muscle relaxation in this setting are benzodiazepines.³ Supranormal cumulative doses may be necessary in severely agitated individuals.

TABLE 326.2. Treatment of Specific Cocaine-Related Medical Diseases

Patients with severe hypertension or tachycardia necessitating pharmacologic measures can usually be safely treated with benzodiazepines. When large doses of benzodiazepines are not effective, intravenous nitroprusside or phentolamine should be considered. Beta antagonists or compounds with partial beta-blocking effects are contraindicated. The use of beta antagonists in the setting of cocaine intoxication can lead to unopposed alpha stimulation, with resultant marked increases in hypertension and worsening coronary vasoconstriction.^{7,11,18}

Patients with suspected cocaine-induced ischemia or myocardial infarction should be treated similarly to those with traditional CAD, with some notable exceptions.^{7,11} Aspirin, nitroglycerin, and heparin remain important initial therapies. Intravenous benzodiazepines should be provided as early management. They will decrease the central stimulatory effects of cocaine, thereby indirectly reducing the cardiovascular toxicity of cocaine.^{3,7} Beta antagonists should not be used. They are contraindicated, as they exacerbate cocaine-induced coronary artery vasoconstriction.^{5,11,18} Another management difference in the setting of cocaine use relative to patients with traditional acute coronary syndromes is a preference for percutaneous interventions (angioplasty) over thrombolysis. Thrombolysis in the setting of cocaine-associated myocardial infarction has no proven efficacy, a possible reduced safety profile, and a high likelihood of being administered to patients who are not sustaining an acute infarction (because young patients with recent cocaine use have a high prevalence of early repolarization and “false-positive” ST-segment elevations on the ECG). Such therapy should, therefore, be used with caution. Finally, there are anecdotal reports of the safety and efficacy of phentolamine, an alpha antagonist, for treatment of cocaine-associated acute coronary syndromes.^{6,7} Verapamil reverses cocaine-induced vasoconstriction,¹⁶ but several animal experiments suggest that it exacerbates CNS toxicity. Therefore, it may have a role in patients with continued ischemia who do not have signs of central stimulation from cocaine.

Supraventricular dysrhythmias may be difficult to treat. Adenosine can be administered, but its effects may be temporary. Use of calcium channel blockers in association with benzodiazepines appear to be most beneficial. Beta blockers should be avoided.⁷

Ventricular dysrhythmias may be due to excess adrenergic tone or cocaine's sodium channel blocking effects. Management with benzodiazepines, lidocaine, and/or sodium bicarbonate appears to be most useful.^{7,19} Bicarbonate is preferred when patients have dysrhythmias directly following the use of cocaine. In this setting, the dysrhythmias are presumably related to the type I effects of cocaine. Bicarbonate reverses cocaine-associated QRS widening. Lidocaine can be used when dysrhythmias appear to be related to cocaine-induced ischemia. ECG evidence for the type I effects of cocaine has often disappeared by the time symptomatic ischemia develops.

Cocaine-induced seizures are typically brief and self-limited. For refractory cases, benzodiazepines and phenobarbital are the first- and second-line agents, respectively. Phenytoin is not recommended.

Patients with suspected cerebrovascular infarctions and hemorrhage should be treated the same as other patients with these conditions. Intracranial and systemic hypertension necessitating treatment is accomplished using standard therapies, except that beta blockers should not be utilized.

The main concern in asymptomatic body stuffers and packers is eliminating the packages out of the GI system. Whole-bowel irrigation with subsequent radiologic verification of passage of all drug-filled containers may be warranted.⁵

Body stuffers who manifest clinical signs of toxicity should be treated similarly to other cocaine-exposed individuals. In addition, GI decontamination with activated charcoal should be administered liberally.²⁰

Symptomatic body packers should be treated more aggressively, because rapid deterioration and severe toxicity can result from their potentially massive exposures. Immediate surgical removal of the ruptured package(s) may be lifesaving. Aggressive supportive care with activated charcoal and benzodiazepines is warranted as preparation for surgery occurs.^{5,13}

DISPOSITION

Patients with severe agitation, hyperthermia, and possible rhabdomyolysis need to be admitted. Those with cocaine-associated chest pain need admission if myocardial ischemia cannot be excluded. Patients with severe hypertension, hypotension, hyperthermia, and any dysrhythmias also need to be admitted. All of these patients should have cardiac monitoring. Those with behavioral or cardiovascular instability should be admitted to an intermediate or intensive care unit. Consultation with a cardiologist, medical toxicologist, or poison control center may be warranted for patients who do not readily respond to treatment. The disposition of patients with neurologic complications is the same as for other patients with these conditions. The likelihood of compliance with outpatient follow-up should be considered when contemplating the discharge of patients who may need further evaluation. If definitive care cannot be provided at the site of presentation, transfer may be necessary. Patients requiring transfer should be accompanied by personnel with advanced life-support training. All patients should be referred for substance abuse counseling and treatment.

COMMON PITFALLS

- Failure to recognize the dangers of using beta-adrenergic antagonists to treat any manifestation of cocaine toxicity
- Failure to utilize benzodiazepines as a first-line agent in treating all cocaine-related toxicities
- Failure to consider cocaine toxicity in the differential diagnosis of patients with chest pain, seizures, agitation, altered mental status, and arrhythmias
- Failure to recognize the limitations of the ECG in the evaluation of cocaine-related chest pain
- Failure to appreciate differences between the management of cocaine-related chest pain and that of traditional CAD
- Failure to ensure adequate passage of cocaine-filled packages in treating body stuffers and body packers

[Common Pitfalls](#)
[Chapter References](#)
[APPENDIX](#)

Few diseases or conditions are as pervasive, if not unavoidable, in the emergency department as is alcoholism. Although encountered frequently, *alcoholism*, *alcohol use*, *alcohol dependence*, and *alcohol abuse* remain nebulous terms, the definitions of which lack consensus among physicians. In 1992, the Joint Commission for the Diagnosis of Alcoholism, a subgroup of the National Council on Alcoholism and Drug Dependence, and the American Society of Addiction Medicine revised the definition of *alcoholism* as,

a primary chronic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. The disease is often progressive and fatal. It is characterized by impaired control over drinking, preoccupation with the drug alcohol, use of alcohol despite adverse consequences, and distortions in thinking, most notably, denial. Each of these symptoms may be continuous or periodic.¹²

The World Health Organization, instead, attempts to stratify a patient's drinking habits: "[H]azardous consumption" is present if the patient places himself or herself at physical or psychological risk through his or her drinking, and "harmful consumption" is present when drinking has resulted in physical or psychological complications.¹⁶

As of 1992, The National Longitudinal Alcohol Epidemiologic Study found that 44% of the adult population of the United States was currently drinking alcohol. The current prevalence of alcohol abuse and dependence is estimated between 7.4% to 9.7%, with a lifetime prevalence between 13.7% and 23.5%, with 43% of all adults reporting alcoholism in their families.^{13,17} Among college students, 45% admit to binge drinking.¹¹ It is unclear how many patients proceed unknowingly from social "binging" to pathologic drinking during these years.

Alcohol is associated with between 100,000 and 200,000 deaths annually, with a total economic burden of greater than \$100 billion each year in the United States alone. It is estimated to be responsible for 15% of the nation's annual health-care costs. Alcohol is involved with 64% to 70% of homicides, 75% of stabbings, 30% to 50% of all motor vehicle fatalities, 69% of beatings, and 56% of domestic violence cases. It also is a significant factor in fires, gunshot wounds, pedestrian accidents, falls, and suicides.^{3,11}

Alcohol is the leading contributor to death in people between ages 15 and 45 and contributes to 85% of the 11,000 deaths per year from liver disease.^{6,7,11} The disease has both a genetic and familial predisposition and is associated with immunosuppression, myocardial disease, and an increased propensity toward oral, pharyngeal, laryngeal, esophageal, and liver cancers.² Studies suggest that women are at an increased risk for ethanol-related morbidity at lower levels of ingestion than men, perhaps because ethanol has less presystemic metabolism and a lower volume of distribution in this population.

It can be difficult to recognize alcoholism. Despite the recent impetus to increase physician participation in recognition and treatment of the alcoholic patient, in the generalist's office, as many as 50% of patients with alcoholism go undiagnosed and untreated.¹³ Despite its role in trauma, 79% of trauma centers do not screen patients for alcohol abuse.³ Detection and treatment often are delayed for women—due perhaps to cultural and social value systems, in which it may be less acceptable for a woman to have an alcohol or substance abuse disorder.

Criteria mandating a diagnosis of alcoholism include alcoholic hepatitis, blackouts, drinking despite social contraindications, and withdrawal symptoms. A number of simple questionnaires can be used to rapidly identify high-risk patients in the emergency department (see Appendix, [Table 327.A1](#), [Table 327.A2](#), [Table 327.A3](#), [Table 327.A4](#) and [Table 327.A5](#)).⁸ High-risk groups include adolescents, patients involved in violent activity or trauma (one-car crashes), caretakers accused of child abuse, spouses of known alcoholics, suicidal patients, and those presenting with neuropsychiatric disturbances.¹⁶ Other risk factors include male sex, unemployment, homelessness, polysubstance use or abuse, and tobacco use.¹⁹ The vast preponderance of emergency department patients who present with ethanol levels of 300 mg/dL or greater score high in response to two or more CAGE questions (see [Appendix](#)). Yet even when the CAGE questionnaire is successfully utilized, it is often unclear what clinical approach to take with the patient identified at risk—beyond the chief complaint that brought him or her to the emergency department.¹⁷

Many of the metabolic problems caused by alcoholism result from the metabolism of ethanol. Ethanol oxidation to acetaldehyde is accomplished via three separate pathways.^{5,9,10} The simplest pathway, catalase, generates H₂O from H₂O₂. Metabolism through the microsomal ethanol oxidizing system oxidizes the reduced cofactor nicotinamide adenine dinucleotide phosphate (NADPH) to NADP⁺. This reaction generates free radicals, which then interact with glutathione, eventually leading to glutathione depletion and possibly contributing to hepatotoxicity (see [Chapter 309](#)).

The principal metabolic pathway involves alcohol dehydrogenase (ADH) and nicotinamide adenine dinucleotide (NAD⁺) as a cofactor. During this reaction, NAD⁺ is reduced to NADH. The conversion of NADH back to NAD⁺ requires large amounts of oxygen. When excessive amounts of ethanol are metabolized, oxygen requirements in the centrilobular areas of the liver exceed those delivered. The relative hypoxia that results in these areas is believed to contribute to hepatic damage.

Increased oxygen demand also shifts the redox potential of the cell. The result is both an increased ratio of lactate to pyruvate, and a favoring of the glycolytic pathway—depleting available glycogen stores. The increase in free hydrogen radicals (H[•]) tends to favor ketone formation and fatty acid generation. Excess H⁺ depresses the citric acid cycle and decreases the use of free fatty acids as an energy source. This favors hypercholesterolemia and fatty liver formation.^{5,14} Gamma glutamyl transferase, the most sensitive indicator of hepatic injury, rises in patients who have had more than five drinks a day for several weeks.¹ A carbohydrate-deficient transferrin test (if possible) is highly sensitive and specific for detecting alcohol abuse.¹³

Ethanol-induced metabolic derangements, especially in the setting of poor nutritional intake, increase the patient's risk of developing ketoacidosis and hypoglycemia. Renal magnesium wasting, secondary to ethanol's inhibitory effect on magnesium resorption, combined with intestinal malabsorption of magnesium, make the chronic alcoholic prone to hypomagnesemia. Thiamine, a water-soluble nutrient, has limited stores in the body. Lack of thiamine (usually secondary to poor nutrition) can lead to life-threatening lactic acidosis. Pyruvate, which is normally catalyzed to acetyl coenzyme A through thiamine cofactors, is converted instead to lactate, causing the acidosis.¹⁵

CLINICAL PRESENTATION

The clinical presentations suggestive of alcohol abuse are listed in [Table 327.1](#). Certain presenting complaints and background history should prompt the physician to consider an underlying ethanol problem.

blood alcohol level, further investigation is mandatory in order to exclude occult head trauma or another severe comorbidity. [3,4,9,11](#)

EMERGENCY DEPARTMENT MANAGEMENT

In the prehospital setting, the patient with altered mental status should receive 50 to 100 mL of 50% dextrose solution intravenously (or have a fingerstick blood sugar), 100 mg parenteral thiamine, and high-flow oxygen (or pulse oximetry). If opiate use is suspected, parenteral naloxone 0.1 mg to 2.0 mg should be given. Cervical spine and full spinal immobilization should be instituted if the possibility exists that there has been trauma to the head or neck or some other part of the body.

In the department, chronic alcoholics, particularly those who are malnourished, should also receive parenteral folate (1 mg) and magnesium (2 g), and be hydrated with an electrolyte solution containing glucose. Glucose is important, as many alcoholics have inadequate glycogen stores and will become hypoglycemic with stress.¹⁰ Oxygenation should be followed and maintained. The patient's temperature should be followed serially and treated aggressively if abnormal.

Intoxicated patients frequently are uncooperative, belligerent, or violent. Judicious use of chemical and physical restraints may be necessary to protect emergency department staff and other patients from such patients. The risks associated with chemical or physical restraint are far outweighed by the benefit of controlled, thorough, serial examinations that can assess for subtle injury or pathology. Concomitant medical or surgical problems are treated through standard measures. Treatment of withdrawal (see [Chapter 375](#)) may also be required.

DISPOSITION

The decision to admit or discharge the patient depends on the nature and severity of comorbid illness or injury as well as the patient's ability to care for himself or herself. If the patient is admitted, the potential for ethanol withdrawal needs to be considered.

Legal precedents suggest that the patient can be discharged when no longer drunk, although no specific criteria exist to determine clinical sobriety. Blood ethanol levels that define "driving under the influence" vary from state to state and range from 50 to 120 mg/dL. Even if the alcoholic patient is observed until his or her blood level is below such limits, there remains the risk of iatrogenically induced withdrawal. In general, however, if a patient is functionally sober and demonstrates no signs of injury or comorbidity, he or she can be safely discharged. It is important, as always, to accurately document all aspects of the physical and neurologic examination on the patient's chart.

The inebriated patient who wishes to leave the emergency department against medical advice (either before or after evaluation and treatment) should be considered analogous to a patient with altered mental status who requests discharge. It is the emergency department's responsibility to protect patients who do not have the capacity to make competent decisions for themselves. Documentation of a blood ethanol level greater than the state's legal limit offers support for the emergency physician's decision that the patient was not competent and left against medical advice. Psychiatric consultation may also be helpful if there is any question concerning the patient's competency. When in doubt, it is prudent to err on the side of safety by restraining the patient in the emergency department.

Prior to discharge, the patient should be offered any available social assistance, and arrangements should be made for medical follow-up. Patients should be offered medical detoxification or an appropriate referral. All such arrangements and discussions should be carefully documented on the patient's chart. If the patient consents to medical detoxification, transfer him or her directly, if possible, to the detoxification facility from the emergency department.

COMMON PITFALLS

- Failure to consider that an altered mental status may be due to something other than intoxication
- Failure to obtain a full set of vital signs, including core temperature
- Failure to fully disrobe and examine an alcoholic patient
- Failure to evaluate fully an agitated, combative, and uncooperative patient
- Failure to obtain a stat fingerstick glucose or to empirically give 50% dextrose and thiamine to the alcoholic patient with altered mental status
- Failure to consider cervical spine trauma and to appropriately immobilize the intoxicated patient with evidence of head trauma
- Failure to appreciate that intoxication in an adolescent may be a suicide attempt
- Failure to consider carbon monoxide poisoning in the obtunded and homeless alcoholic
- Failure to reevaluate the patient frequently and to document this
- Failure to evaluate the alcoholic with constitutional symptoms for metabolic abnormalities and occult infection
- Failure to detain an inebriated patient in the emergency department until functionally sober
- Failure to restrain an intoxicated but ill or injured patient who is attempting to leave against medical advice
- Failure to involve social services and to advise or arrange for detoxification services

CHAPTER 328

Complications of Injection Drug Use

James A. Feldman and Susan S. Fish

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

An estimated 1.1 to 1.8 million people in the United States currently use nonprescribed drugs by intravenous, subcutaneous, and other routes of injection, and another 2.5 million have self-injected drugs at least once. The lifestyle associated with drug use increases the risk of trauma, tuberculosis, and sexually transmitted diseases. Intravenous drug use (IDU) brings with it the risk of complications directly related to the local or systemic effects of the substances injected, the use of nonsterile methods of injection, and other aspects of injection practices ([Table 328.1](#)).

TABLE 328.1. Medical Complications of Injection Drug Use by Organ System

A history of IDU should be routinely obtained in all patients and considered carefully in medical decision making. While patients with IDU may accurately identify complications of injection drug use, they are *unlikely* to seek medical care for these complications. Hence, such patients should be presumed to have a serious medical condition until proven otherwise.

Cutaneous and superficial soft-tissue infections, particularly abscess formation at the site of injection, are common reasons for IDU patients to seek emergency care. The bacteriology of abscesses in IDU patients is more likely to be mixed aerobic–anaerobic infections than in non-IDU patients.¹⁶ Although *Staphylococcus aureus* is the most common organism (36% to 50%), flora of the oropharynx are often isolated. Bacteremia is infrequent, even with extensive cutaneous infections, but 19% had positive blood cultures in a recent case series.¹⁶ Cutaneous abscesses of the neck may lead to respiratory complications such as airway obstruction, laryngeal edema, and vocal cord paralysis.¹²

Clostridial toxin-mediated diseases and tetanus have been identified in chronic injection drug users. Wound botulism has been increasingly reported since 1982, with 35 cases identified in California during a recent 26-month study period.¹⁴ IDU-related tetanus has been increasingly reported. Of the 67 cases of tetanus reported in California from 1987 through 1997, 40% occurred in IDU patients.¹⁷ Skin lesions or small abscesses that appear innocuous may harbor *C. botulinum* or *C. tetani*. Injection drug users are also at risk for more serious and deeper soft-tissue infections, including necrotizing fasciitis (see [Chapter 181](#)).

Broken needles at the site of intravenous injection are usually an incidental finding noted on radiograph. Such retained needle fragments rarely embolize centrally. However, pericarditis with pericardial effusion secondary to central migration has been reported.⁹

Vascular complications related to IDU include unintentional intraarterial injection, with resultant vasospasm or thrombosis and limb ischemia; venous and arterial pseudoaneurysm formation; development of infected hematoma; and venous thrombosis and septic thrombophlebitis. Mycotic aneurysms involving central arteries, such as the hepatic, mesenteric, cerebral, and pulmonary arteries, as well as large vessel occlusive emboli may occur in the context of endocarditis and should be considered in the evaluation and treatment of patients with suspected endocarditis (see [Chapter 140](#)). The bacteriology of both arterial and venous mycotic aneurysm is polymicrobial in up to 40% of cases. *S. aureus*, frequently beta-lactam-resistant, is often cultured from the wound or blood. Anaerobic organisms have been reported in up to 20% of some series.

Pulmonary complications from IDU can result from mechanical injury to the lung during injection. “Pocket shooting,” or injection into the supraclavicular fossa to access the jugular, subclavian, or brachiocephalic veins, often leads to pneumothorax, hemothorax, hydropneumothorax, or pyopneumothorax. In one review of 525 cases of pneumothorax, 20% were related to IDU. Of these, 19% were complete collapse or tension pneumothorax (two were bilateral), 43% were large, 32% moderate or small, and 6% had only an apical cap.⁴

Injection of solubilized tablets and capsules can lead to pulmonary dysfunction from injected particulate matter that deposits in the lung. Tablets are usually crushed, dissolved in water or other liquid, sometimes heated. Then the solution is drawn up into a syringe either directly or filtered through cotton. The fillers in the tablet consist usually of talc, cornstarch, or cellulose. Talc is well known to induce granulomas in and around the arterioles and capillaries of the lung, and it can also deposit in retinal vessels; this condition is referred to as “talcosis.”¹³ Both restrictive and obstructive pulmonary dysfunction can be seen, as well as pulmonary hypertension and cor pulmonale. Although cornstarch is not associated with granuloma formation, the resultant bland pulmonary thromboses can lead to pulmonary hypertension.

Osteomyelitis and septic arthritis secondary to IDU may result from direct contamination or hematogenous spread. Vertebral osteomyelitis is the most common form of skeletal infection in IDU patients.¹¹ The sites of vertebral involvement reported are lumbar (54%), cervical (27%) and thoracic (4%). The increased frequency of cervical involvement noted in IDU patients is an important variation in the distribution of vertebral osteomyelitis, compared with the general population.

The sacroiliac, sternoclavicular, costochondral, and pubic symphysis synchondroses are frequent sites of septic arthritis in IDU patients. Although these axial fibrocartilaginous joints are the most common sites of septic arthritis in IDU patients,¹ other joints, including the knees, hips, and shoulders, may be involved. While *Pseudomonas aeruginosa* and *Serratia marcescens*, in the past, had been the most common cause of osteoarticular infections, *S. aureus* has more recently replaced gram-negative bacilli and *Candida* as the primary cause of these infections.³

Serious central and peripheral nervous system complications have been well described in the IDU population. These patients are at increased risk of central nervous system (CNS) infections, including fungal and bacterial meningitis, cerebritis, and spinal, epidural, and brain abscesses.⁶ *Candida* meningitis is usually associated with *Candida* endocarditis.¹⁰ Indolent CNS aspergillosis, cerebral mucormycosis, and anterior spinal artery syndrome with subsequent paraplegia have been reported. A syndrome of cerebral mucormycosis has been well described in IDU patients who were seronegative for the human immunodeficiency virus (HIV).⁷ Fungal endophthalmitis, caused by such organisms as *Aspergillus* and *Fusarium*, has been described in patients with IDU as the only identified risk factor for these uncommon infections.¹⁸ Peripheral nerve injuries may result from needle-induced trauma, extrinsic compression, and direct toxic or hypersensitivity reactions to injected materials.

Systemic infections may result from exposure to skin contaminants, contaminated apparatus, contaminated injection mixture, and blood-borne pathogens transmitted by the practice of needle sharing. HIV and hepatitis B, C, and delta infections are discussed in other chapters. Infection with the HTLV virus (types I and II) is associated with injection drug use.⁵ Hepatitis GB virus type C (HGBV-C), an important cause of fulminant non-A-E hepatitis, is also more commonly identified in IDU patients.¹⁸ The lifetime seroconversion rate for hepatitis B in IDU patients is 80% to 90%, and the incidence of bacterial endocarditis is 5%.² A number of uncommon infections have also been described. A syndrome of disseminated candidiasis, characterized by scalp, ocular, and osteoarticular involvement, was attributed to the use of lemon juice in the preparation of brown heroin for injection.³ Malaria, both falciparum and vivax, endophthalmitis, and tick-borne relapsing fever have been reported.

In IDU patients presenting with fever, 64% had readily identifiable major illnesses such as pneumonia, cellulitis, or endocarditis; another 4% of patients had major illnesses that were not clinically apparent on initial evaluation.¹⁵ "Cotton fever," an acute but self-limited pyrogenic reaction induced by intravenous injection of foreign material from cotton balls used to filter injected solution, may mimic sepsis. The history, physical examination, and laboratory testing were not able to reliably differentiate cotton fever or other minor conditions from more serious causes of fever.

CLINICAL PRESENTATION

Patients with superficial abscesses complain of localized pain. Fever and systemic complaints may also be present. The classic signs and symptoms of warmth, redness, tenderness, swelling, and fluctuance may be absent in IDU patients. As many as 25% of patients with cutaneous abscesses do not have fluctuance.

Patients with broken needle fragments at injection sites may be asymptomatic or have localized complaints of pain due to the needle itself or to infectious complications. Patients may present with concerns about the risks of a retained needle fragment. They may also be unaware of its presence or fail to mention it unless asked.

Inadvertent intraarterial injection causes immediate severe pain, hyperemia, numbness, weakness, distal swelling, cyanosis, and motor deficit and, often, sensory abnormalities. Distal ischemia may progress to gangrene, myonecrosis, and associated complications. The use of crushed oral medications and the lower extremity as a site of injection appears to be associated with more severe complications.

Patients with arterial mycotic aneurysms usually present with an indurated mass, local pain, and swelling. The mass is pulsatile in approximately 50%, and a bruit is often heard over the swelling.²⁰ Fever and leukocytosis are common, but bleeding, although occasionally massive, is usually intermittent, minor, or absent. Claudication, paresthesias, or compression neuropathy can occur. Signs and symptoms of distal embolic phenomenon, including cutaneous purpura, may be present and may precede systemic manifestations. While upper and lower extremity arteries are most commonly involved, mycotic aneurysms of the subclavian and carotid arteries have been reported following attempted central venous injections.

Venous pseudoaneurysms are most commonly noted in the groin. Pain, swelling, and purulent drainage may be noted. Some patients may appear clinically septic, with minimal localized complaints. In these patients, either pulmonary complaints or symptoms referable to sites of metastatic septic involvement may be more prominent.

Patients with pneumothorax typically present with a history of recent neck injection, dyspnea, and pleuritic chest pain.⁴ Patients with particulate-induced pulmonary dysfunction frequently complain of progressive dyspnea. Chest x-ray can show a micronodular pattern; over time, the pattern changes to show large homogenous opacities, usually in the perihilar regions and upper lobes.¹³ Retinoscopy can show talc depositions (small, whitish, glistening dots) and may have a higher diagnostic yield than either chest x-ray or pulmonary function tests.

Patients with skeletal infections often present with localized pain and tenderness. Almost 20% of patients with vertebral osteomyelitis related to IDU have had pain for more than 3 months at the time of diagnosis. About 15% report a history of minor blunt back trauma, such as a fall or kick, a factor that may contribute to delayed diagnosis. Fever is usually absent or of low grade. Neurologic signs and symptoms occur infrequently (less than 15%) and are usually transient. Routine laboratory studies are usually normal. The erythrocyte sedimentation rate (ESR) usually is elevated but can be normal. Plain x-rays may demonstrate disc space narrowing (82%) or paravertebral shadows, suggesting abscess (12%), but magnetic resonance imaging (MRI) is diagnostic.

Patients with septic arthritis associated with IDU are similar in presentation to other patients with septic arthritis, except for the prominence of fibrocartilaginous joint involvement. Local signs of inflammation as well as fever, leukocytosis, and elevated ESR are usually noted. Asymptomatic HIV infection has been reported in one-third of IDU patients with septic arthritis.¹

Patients with wound botulism usually present with neurologic complaints such as cranial palsies or descending symmetrical paralysis. Atypical signs, including asymmetric or unilateral cranial nerve weakness and peripheral motor weakness, may be present.⁸ Patients with atypical presentations and false-positive edrophonium tests have been misdiagnosed with Eaton-Lambert syndrome and myasthenia gravis, resulting in prolonged delays in appropriate therapy.

Patients with tetanus present with increased muscle tone, spasm or trismus. Patients with fungal endophthalmitis usually present with severe visual loss and pain, which develop rapidly in the affected eye.¹⁹ Patients with cerebral mucormycosis usually have headache, fever, and rapidly developing cranial nerve and motor deficits. Basal ganglia lesions on computed tomography (CT) scan should suggest this diagnosis. Patients with cotton fever may complain of dyspnea, palpitations, headache, and rigors.

Patients who inject drugs are also at risk for systemic drug or drug-contaminant toxicity (see [Chapter 326](#), [Chapter 360](#), and [Chapter 369](#)), withdrawal syndromes (see [Chapter 375](#)), and CNS infections (see [Chapter 184](#)).

DIFFERENTIAL DIAGNOSIS

The most important requirement for developing an appropriate differential diagnosis is obtaining the history of IDU. Biases can easily enter into the physician's decision to obtain this information. It may be necessary to consider the possibility of IDU, even if denied by the patient. In such cases, a urine screening test for drugs of abuse may be helpful. Unless the history of IDU is routinely obtained or considered, conditions such as vertebral osteomyelitis and epidural abscess may not be considered in the differential diagnosis of complaints such as back pain. The IDU patient who develops a fever or flulike symptoms is much more likely to have an infection requiring hospital admission than is a non-IDU patient who presents with similar complaints. It is very important to carefully consider clinical syndromes that are well described in patients with IDU when one is evaluating such patients.

EMERGENCY DEPARTMENT EVALUATION

The possibility of IDU, recent or remote, should be included in the standard "screening history." A nonthreatening question such as, "Do you smoke cigarettes, or use alcohol or other drugs?" should be routinely asked of all patients. Patients with IDU should be asked about the specifics of drug type, amount, needle sharing, preparation of materials (licking the needle, for example), and whether they have a history of hepatitis, endocarditis, HIV, pain at injection sites, recent fever, and nonprescribed antibiotic self-treatment.

The physical examination of a patient with recognized IDU should include a careful review of vital signs, particularly the temperature (tympenic or rectal). Examination of the skin for signs of endocarditis, jaundice, infection at injection sites, and markers of HIV infection, such as oral thrush, should be performed in addition to a complaint-oriented examination. Evidence of opiate withdrawal, such as diaphoresis, lacrimation, yawning, pupillary dilation, and piloerection, should also be sought.

Routine laboratory tests are of limited use. Drug screens provide little information that will affect decisions, except possibly to suggest drug use when it is denied. Although the complete blood count (CBC) and ESR lack sufficient sensitivity and specificity to guide disposition decisions, if infection is suspected or present, a very high or low white blood cell count might prompt admission, even for a simple abscess. The use of ultrasonography to identify occult abscesses that require drainage is an area of active research.

Patients with significant cutaneous abscesses or associated systemic complaints should have a culture of the abscess material. A radiograph should be routinely considered in patients with cutaneous complaints of pain and tenderness at injection sites in order to exclude retained needle foreign bodies as well as to identify gas-forming infections.

In IDU patients with fever, three sets of blood cultures, chest radiograph, urinalysis, and urine culture should be obtained. Patients with respiratory complaints should have a chest radiograph and oxygen saturation. Those with joint pain and effusion should have two sets of blood cultures and aspiration, Gram stain, and culture of affected joints. Septic synchondroses may be safely aspirated in the emergency department and should be evaluated similarly. Ultrasound may identify a perivascular abscess but is not very sensitive for detecting pseudoaneurysms. While digital subtraction angiography may be a useful diagnostic modality, color-flow duplex scans may be the diagnostic study of choice.^{2c} Arteriography may be necessary to confirm the diagnosis.

Two sets of blood cultures and an MRI should be obtained for suspected vertebral osteomyelitis or epidural abscess. A patient with IDU and complaints that suggest a CNS process (headache, weakness, ataxia) will require a detailed neurologic examination, CT scan or MRI, and a lumbar puncture in order to identify direct vascular complications of IDU use, opportunistic CNS infections, or malignancy (related or unrelated to HIV infection). Patients with complaints of visual loss will require a complete eye examination, usually dilation with indirect funduscopy.

EMERGENCY DEPARTMENT MANAGEMENT

Localized cutaneous abscesses without vascular involvement may be managed with routine incision and drainage. If there is a possibility of vascular involvement, needle aspiration should be performed first. Patients with localized infections involving the neck, groin, or vascular structures should be evaluated by a surgeon.

While antibiotics are not routinely required, patients with HIV infection or neutropenia may require parenteral antibiotics and hospitalization. Initial antibiotic therapy should include a penicillinase-resistant synthetic penicillin such as oxacillin. An antipseudomonal aminoglycoside (APAG) such as gentamicin should also be given if enteric organisms or *Pseudomonas* has been identified as part of the "IDU" flora.

In areas with methicillin-resistant *S. aureus*, vancomycin should be used until culture results are available. Extensive extremity infections should be evaluated by a surgeon and explored in the operating room, as inadequate drainage may prolong hospitalization. The treatment of septic thrombophlebitis involves antibiotic therapy, as described previously, as well as surgical consultation. Patients with gas-forming infections require immediate operative intervention and combination antibiotic therapy with clindamycin, high-dose penicillin G (cephalothin, if penicillin allergic), and an APAG (see [Chapter 181](#)).

In general, removal of fractured needle fragments should not be attempted by emergency physicians. Even if palpable, finding them may be difficult, important neurovascular structures nearby may be injured, and migration may occur despite the use of a proximal tourniquet. All of these reasons argue for surgical consultation and removal in the operating room.⁹

When associated with infection or vascular injury, needle fragments require urgent removal. Patients with retained needle foreign bodies without these complications may be given appropriate discharge instructions and referral to a surgeon for elective removal.

Patients with signs and symptoms of intraarterial injection require aggressive management because of the potential for distal limb ischemia. Treatment should include antibiotics and anticoagulation with heparin. Consultation with a general or vascular surgeon is essential. Measurement of extremity compartment pressures should be considered. Some authors suggest the use of intravenous dextran 40 (20 mL/h) and dexamethasone (4 mg every 6 hours) or the intraarterial injection of an arterial vasodilator such as papaverine (40 to 60 mg) or phentolamine (2 mg). Favorable results have been reported from the use of iloprost, a prostacyclin analogue, and intraarterial thrombolysis.²⁰

Patients with pseudoaneurysms require blood cultures, preoperative laboratory testing, including blood typing, and consultation with a general or vascular surgeon. Hospitalization is usually indicated. Hemorrhage control with direct pressure may be required. Local drainage should not be attempted in the emergency department, as life-threatening hemorrhage may result.

The management of pneumothorax is discussed in [Chapter 102](#) and [Chapter 149](#). Pulmonary dysfunction from other causes is treated by supportive measures.

Vertebral osteomyelitis and septic arthritis should be treated with vancomycin and an APAG. Consultation with an orthopedic surgeon, as well as an infectious disease specialist, should be obtained for patients with or suspected of having these complications.

Patients with cotton fever require only supportive care. This illness usually resolves within 12 to 24 hours. However, given the possibility that a serious medical condition is the etiology of fever, inpatient observation is recommended until the patient is well and the results of blood cultures are known.

DISPOSITION

Patients with cutaneous abscesses who are otherwise asymptomatic and healthy may be discharged with appropriate instructions and referral for follow-up in 24 to 48 hours. The ability of a patient to comply with outpatient therapy and follow-up should be considered. Most patients with other infectious complications require admission. Many "rule-out" diagnoses, including endocarditis, sepsis, and meningitis, will also require admission for observation pending culture results. Concomitant HIV infection may also modify the decision to admit or discharge a patient with IDU and a specific complaint.

Patients should also be educated about secondary prevention and "harm reduction," practices that have been shown to reduce the morbidity and mortality from injection drug use. These should be referred for substance abuse treatment and, if available, to needle-exchange programs. Patients who continue to use injection drugs may benefit from teaching practices, such as antiseptic skin preparation prior to injection, the use of bleach for cleaning needles and syringes, and the use of condoms to prevent sexually transmitted disease.

COMMON PITFALLS

- Failure to ask about IDU in all adolescent and adult patients
- Allowing a judgmental attitude toward patients who use injection drugs to interfere with a careful medical evaluation
- Labeling patients with IDU as "pain medication seekers" without performing a careful history and physical examination
- Failure to consider infectious etiologies in the differential diagnosis of musculoskeletal complaints in IDU patients
- Failure to appreciate that patients with vertebral infections may give a history of minor trauma and have a normal neurologic examination
- Attributing fever in an IDU to a trivial illness or to cotton fever
- Attempting to drain a soft-tissue mass in proximity to a major blood vessel. Incising a mycotic aneurysm or pseudoaneurysm that has been misdiagnosed as an abscess can lead to uncontrollable hemorrhage.
- Failure to consider the possibility of arterial injection, compartment syndrome, deep-space infection, or nerve injury in patients with limb complaints
- Attempting to remove an asymptomatic needle fragment in an anatomically sensitive area
- Failure to obtain a radiograph of sites of localized infection to identify the presence of foreign bodies or gas
- Failure to appreciate that extensive abscesses cannot be adequately drained in the emergency department

CHAPTER 329

Complications of Parenteral Drug Therapy

Robert P. Fern

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Parenteral drug administration may be accomplished by subcutaneous (SC), intramuscular (IM), intravenous (IV), intradermal (ID), intraosseous (IO), intraarterial (IA), intrathecal (IT), or intracardiac (IC) injection. Parenteral routes are used when greater efficacy, more rapid effect, and the ability to more accurately titrate the dose are desired. For some agents, a parenteral route is essential for drug effect; for others, oral formulations may be unavailable. There are unique risks associated with the inherently invasive nature of parenteral routes, but with proper techniques and precautions, these risks can be minimized.

Adverse effects due to parenteral drug administration can be divided into local and systemic complications ([Table 329.1](#)). Reactions uniquely associated with parenteral drug administration include localized pain, inflammation, and infection; infiltration or extravasation; nerve injury; vascular injury; inadvertent IV or IA administration; fluid and electrolyte overload; and diluent toxicity. The annual cost associated with complications of IV drug therapy alone was estimated at greater than \$112 million.⁶

LOCAL
Pain (all routes)
Infiltration/extravasation (IV)
Phlebitis/thrombosis/thrombophlebitis (IV)
Cellulitis (all routes)
Abscess (all routes)
Granuloma (IM, SQ)
Allergic (all routes)
Nerve injury (all routes)
Vascular injury (all routes)
Ischemia (all routes)
Inadvertent IV injection (IM, SQ)
Inadvertent IA injection (all routes)
Tissue irritation/necrosis (all routes)
SYSTEMIC
Noninfectious febrile reactions (all routes)
Sepsis (all routes)
Anaphylaxis (all routes)
Fluid overload (IV)
Diluent toxicity (IV)

TABLE 329.1. Adverse Effects of Parenteral Drug Administration

CLINICAL PRESENTATION

Unless the agent is given through an indwelling catheter, patients experience some pain regardless of the route of injection. Drugs notorious for causing pain on SC or IM injection include ceftriaxone, local anesthetics, benzodiazepines, glucagon, dimercaprol or British Anti-Lewisite (BAL), and calcium and magnesium salts. Those typically causing pain on IV administration include potassium, calcium, and magnesium salts, phenytoin (because of its high pH), glucagon (because of phenol diluent), chemotherapeutic agents, adenosine, hypertonic solutions, ethanol, and propofol. Local allergic reactions and histamine release may result from the injection of some drugs, particularly morphine and protamine. Manifestations include pruritus, urticarial eruptions, localized swelling (sometimes painful), and erythema over the course of veins or lymphatics.

The earliest sign of infusion phlebitis, tenderness proximal to the infusion cannula, is followed by redness, warmth, pain, edema, and induration along the course of the vein.¹⁸ Similar localized signs accompany tissue inflammation caused by IM or SC injections and infections secondary to any route of administration. Venous thrombosis may complicate inflammation or infection. Manifestations include a tender, palpable thrombosed cord and distal edema.

Signs and symptoms of venous extravasation include immediate or delayed pain, swelling, induration, erythema or pallor, warmth or coolness, and blistering or frank necrosis. Findings are more diffuse than with phlebitis. Underlying mechanisms include hypertonic tissue injury from hyperosmolar solutions (e.g., 50% dextrose, sodium bicarbonate, and hyperalimentation preparations), ischemia from vasoconstrictors (e.g., epinephrine, dopamine, other catecholamines, and vasopressin), and direct cellular toxicity from vesicant drugs (e.g., doxorubicin, dactinomycin, and other antineoplastic agents), highly alkaline or acidic preparations (e.g., phenytoin), or irritant vehicles (e.g., propylene glycol, phenol, and ethanol).⁸ Osteomyelitis may also result from IO infusions when used for protracted periods or for the administration of hypertonic fluids.

Injection injury to a nerve most typically results in sudden, immediate onset of severe pain radiating in the distribution of the affected nerve along with a neuropathy. Motor dysfunction is often more severe than sensory deficits. Less commonly, patients may experience instantaneous or delayed neuropathy without immediate pain. Inadvertent injury to peripheral nerves has been described from several different procedures involving a number of different peripheral nerves,^{4,7,11,18} but most commonly involves sciatic nerve injury from intragluteal IM injections. Inadvertent intraneural (as opposed to perineural) injection with both direct physical and chemical injury is the likely mechanism of nerve damage.

The inadvertent IV administration of drugs intended for IM or SC injection may lead to systemic effects as well as vascular injury. Systemic reactions may include pulmonary, cardiovascular, or central nervous system (CNS) toxicity due to the drug (e.g., seizures or cardiovascular collapse associated with the intravascular injection of local anesthetics) or vehicle (discussion follows).

Accidental IA injection may lead to severe pain, pallor followed by patchy blue discoloration, and infarction or gangrene of tissue supplied by the involved vessel. If retrograde flow occurs, more proximal effects may be noted. Serious injuries have been reported following IA infusion of a wide variety of agents, including antibiotics (e.g., penicillin), antiinflammatory drugs, sedatives and tranquilizers (e.g., barbiturates, phenothiazines, benzodiazepines), anticonvulsants (e.g., phenytoin), and hyperalimentation solution.^{3,12,13} and ^{14,17}

Fluid and electrolyte overload may result from infusions of drugs given in large volumes (e.g., cisplatin, EDTA, vancomycin) or with large salt loads (e.g., sodium and potassium salts of antibiotics).

Systemic toxicity may also be due to the vehicle or solvent in which the drug is delivered. Propylene glycol has been linked to CNS depression, seizures, hypotension, cardiac dysrhythmias, hemolysis, and lactic acidosis. Toxicity has been associated with administration of phenytoin, nitroglycerin, etomidate, and other medications at excessive rates.¹ [Table 329.2](#) lists some drugs containing propylene glycol. Alcohol intoxication has resulted from excessive coadministration of ethanol with nitroglycerin infusions.

may be successful in reversing vasospasm. Sympathetic blockade (e.g., stellate ganglion block) has also been used.

Anticoagulation with heparin, prostacyclin, and low-molecular-weight dextran infusions and oral aspirin may also be helpful. Antiinflammatory agents such as aspirin and dexamethasone have been used. Analgesics may be necessary. Both elevation (to inhibit edema formation) and lowering (to maintain arterial flow) have been recommended in the management of limb injury, so immobilization at heart level is a reasonable compromise.

The initial management of injection injuries to peripheral nerves involves the use of antiinflammatories and analgesics, as well as protection from further injury (e.g., splinting a nonfunctional extremity). Indications for and the timing of neurolysis are controversial.⁵ All injection injuries to nerves should be urgently evaluated by the appropriate surgical specialist, usually an orthopedic, vascular, or neurologic surgeon.

Treatment options for digital ischemia resulting from accidental discharge of epinephrine autoinjectors include local infiltration of phentolamine at the site of injury, perivascular phentolamine infiltration as in a digital nerve block, or both.^{2,9,10} Phentolamine doses of 1.0 to 3.5 mg have been used. Local infiltration of terbutaline (e.g., 0.5 to 2.0 mL of a 0.5-mg/mL dilution) also has been reported to be an effective treatment.¹⁶ Alternative therapies, such as lidocaine digital block and local application of nitroglycerin paste, have been used but are less effective.

Ischemia induced by infiltration of vasopressors may be treated by injecting 5 to 10 mg of phentolamine in 10 mL of saline into the area of infiltration. A lower total dose of the same formulation has been used successfully in a neonate.¹⁵ Terbutaline infiltration (1 mg in 10 mL of normal saline) has been reported to be similarly effective.¹⁶ Success has also been reported with the application of 2% nitroglycerin ointment to treat tissue ischemia from either catheter-induced arterial vasospasm or dopamine extravasation.²⁰ Hypotension may complicate nitroglycerin therapy, especially in neonates and despite careful attention to dose (4 mm/kg).

Fluid and electrolyte overload, anaphylaxis, and sepsis complicating parenteral drug therapy are managed in the usual manner, which may include diuresis, fluid restriction, ion exchange resins, antibiotics, epinephrine, or cardiovascular supportive therapy. The treatment of diluent toxicity includes discontinuing or slowing the rate of infusion, as well as standard supportive care.

DISPOSITION

Reliable patients with minor extravasations of IV fluids or nonirritating medications, localized infections (cellulitis, abscess), and local allergic reactions may be discharged and treated at home, with arrangements made for appropriate follow-up. Decisions regarding continuing care and disposition of patients with more significant local injuries should be made in consultation with the appropriate specialist (see previous discussion).

COMMON PITFALLS

- Lack of knowledge of proper injection techniques
- Failure to monitor for systemic reactions after local injections
- Failure to consult the appropriate specialist in cases of neurovascular injury
- Failure to recognize the potential significance of IV infiltrations, especially those involving vesicants (e.g., antineoplastics) or vasoconstrictors (e.g., dopamine)
- Use of epinephrine-containing anesthetic mixtures where vasoconstrictors are contraindicated
- Failure to consider the use of antidotes for extravasation injuries

CHAPTER 330 Corrosive Ingestions

Robert P. Dowsett and Christopher H. Linden

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Corrosive poisoning can result from exposure to compounds that cause tissue injury as the result of a chemical reaction. This chapter focuses on ingestions. The evaluation and management of exposure by other routes are discussed in [Chapter 309](#) and [Chapter 346](#). Hydrofluoric acid exposures are discussed in [Chapter 339](#).

Most corrosive injuries involve acids and alkalis. Acids are defined as proton donors. They dissociate into conjugate bases and hydrogen ions (H^+) in solution. Alkalis accept protons, resulting in the formation of conjugate acids and hydroxide ions (OH^-). The acidity or alkalinity of a solution is measured by its pH, the negative log of H^+ concentration. The pH of water (7) is neutral. Acidic solutions have a pH of less than 7, and alkaline solutions, greater than 7. Solutions with a pH of less than 2 or greater than 12 are highly corrosive. [Table 330.1](#) lists the pH of some common solutions. The pH is dependent not only on the concentration of acid or alkali in solution, but also on the ease with which the acid donates H^+ or the alkali accepts H^+ .

Solution	pH
1.0 M HCl	0
Battery acid (1% solution)	1.4
Acid toilet cleaner (1%)	2.0
Citrus juices	1.8-4
Wines	2.8-3.8
Black coffee	5.0
Rainwater	6.5
Water (25°C)	7.0
Bleach (1% solution)	9.5-10.2
Automatic dishwasher detergents	10.4-13
Laundry detergents	11.6-12.6
Ammonia cleaners (<10%)	11.9-12.4
Alkaline drain cleaners	13.3-14
1.0 M NaOH	14
Saturated ammonia solution	15

TABLE 330.1. Approximate pH of Some Common Solutions

The pK_a , which is equal to the pH of a solution in which half of the acid has dissociated, is a measure of the ease with which the acid donates a proton. For an alkali, the pK_a of the conjugate acid inversely reflects the strength of the alkali as a proton acceptor. Strong (i.e., easily dissociated) acids and alkalis are those with a pK_a of less than 0 and greater than 14, respectively. [Table 330.2](#) lists the pK_a of common chemicals.

Acids	Formula	pK_a	Alkalis	Formula	pK_b
Perchloric	$HClO_4$	-8	Calcium carbonate	$CaCO_3$	5.7
Hydrochloric	HCl	-3	Hydrazine	N_2H_4	8
Chromic	CrO_3	8.1	Ammonia	NH_3	9.3
Bromic	$HBrO_3$	-1	Ammonium hydroxide	NH_4OH	9.3
Nitric	HNO_3	<1	Ethanolamine	$NH_2C_2H_4OH$	9.5
Oxalic	C_2O_4	1.3	Magnesium hydroxide	$Mg(OH)_2$	10
Sulfuric	H_2SO_4	1.5	Zinc hydroxide	$Zn(OH)_2$	11
Phosphoric	H_3PO_4	2.1	Calcium hydroxide	$Ca(OH)_2$	11.6
Asenic	H_3AsO_4	2.3	Trihexane diamine	$(NH_2)_2C_6H_{14}$	11.8
Nitrous	HNO_2	3.3	Lithium hydroxide	LiOH	>14
Hydrofluoric	HF	3.4	Potassium hydroxide	KOH	>14
Acetic	H_3C_2COOH	4.8	Sodium hydroxide	NaOH	>14
Sulfurous	H_2SO_3	6.9	Calcium oxide	CaO	>14
Hydrogen sulfide	H_2S	7.0	Sodium carbonate	Na_2CO_3	>14
Boric	H_3BO_3	9.2	Potassium carbonate	K_2CO_3	>14
Hydrogen peroxide	H_2O_2	11.6	Sodium hypochlorite	NaClO	>14

TABLE 330.2. pK_a of Acids and Alkalis

Acid-base reactions damage biologic tissue by altering the ionized state of molecules, which, in turn, may disrupt covalent bonds, catalyze further reactions, or alter the structure of macromolecules. Acids denature protein, resulting in the formation of a firm coagulum, or eschar (coagulation necrosis). The resulting eschar may limit tissue penetration, but this does not appear to be a major variable in determining the extent of injury.¹⁷

In contrast, alkalis saponify fats and dissolve proteins, resulting in the softening of tissues (liquefaction necrosis). Cell death results from the emulsification and disruption of cellular membranes. Sloughing of tissue may assist the penetration of alkalis to deeper levels. Tissue injury is exacerbated by thrombosis of small vessels and the production of heat. Heat generated during the neutralization of acids is typically greater than that of alkalis. Tissue injury progresses rapidly over the first few minutes but can continue for several hours. Bacterial invasion, inflammatory response, and development of granulation tissue ensue. Because collagen deposition may not begin until the second week, tensile strength of the healing tissue is low during the first 3 weeks. Scar retraction begins in the third week, commonly continuing for months, and may result in stricture formation and shortening of the involved segment of the gastrointestinal tract. Mucosal repair can take weeks to months.

Corrosives can also cause injury by mechanisms such as reduction, oxidation, denaturation, fixation, dissolution, or thermal injury. Reactions between strong acids and strong bases are usually highly exothermic and can be explosive. Dissolving a strong acid or base in water also generates heat. Explosive reactions can occur when water is added to metallic lithium, sodium, and potassium; to aluminum and lithium salts; and to titanium tetrachloride. Chlorine, bromine, and nitrogen oxides react with water, liberating heat and forming acids, elemental ions, and free oxygen radicals. Dissolving ammonia in water results in the exothermic production of ammonium hydroxide. Ammonia and hypochlorite bleaches generate corrosive chloramine gases when mixed. When bleach is mixed with an acid (e.g., acidic toilet bowl cleaner), another corrosive gas, chlorine, is liberated. Baking soda (sodium bicarbonate) is unique in that, when it is mixed with acid (e.g., after ingestion), large amounts of carbon dioxide gas are liberated in an endothermic reaction.

Chemicals can be classified as weak irritants, strong irritants, or corrosives to indicate the likelihood of potential tissue injury, and commercial products may carry corresponding "signal words" on their labels ([Table 330.3](#)). For acids and alkalis, the likelihood of injury depends on the number of H^+ or OH^- ions available to react with tissues. The availability of H^+ or OH^- ions depends on the concentration, volume, and pH of the solution as well as the pK_a of the acid or alkali and can be measured by the titratable reserve. The titratable reserve is expressed as the amount of sodium hydroxide or hydrochloric acid required to neutralize an acidic or basic solution.¹⁰

Label	Classification	Description
Caution	Weak irritant	Irritating to eyes, nose, throat, and mouth.
Warning	Strong irritant	Irritating to eyes, nose, throat, and mouth. May irritate the skin.
Danger	Corrosive	May be fatal or cause permanent damage. Vapor harmful. Causes severe burns.

TABLE 330.3. U.S. Consumer Safety Committee Recommendations (1982) for the Use of Signal Words on Product Labels

Titrateable acid or alkaline reserve appears to be the best indicator of corrosive potential; however, it is usually impossible to measure in the clinical setting. Hence, product classification, signal words, pH, pK_a , volume, and concentration must be used as surrogate indicators. Concentrated solutions or large volumes of any corrosive, any concentration or amount of strong acids or alkalis, and products labeled as corrosive or dangerous should be considered highly toxic to tissues.

Additionally, the extent and severity of injury depend on the physical state of the corrosive, the duration of tissue contact, the presence of food, and the tonicity of the pyloric sphincter. Solid compounds dissolve on contact with body fluids, producing highly concentrated solutions, which may result in severe but localized damage. Solutions of a high viscosity (e.g., concentrated alkali) tend to cause deeper burns, possibly by a similar mechanism. Solids and solutions of high viscosity tend to adhere to tissues and frequently result in injury to the oropharynx. Pain, too, may limit the amount ingested but, if swallowed, severe upper esophageal burns typically occur. When taken without water or while the patient is recumbent, medications, particularly potassium chloride, iron, quinidine, antiinflammatory agents, and sustained-release formulations, can lodge in the esophagus and cause deep mucosal ulceration.

Sites commonly affected by corrosive ingestion are the oropharynx, esophagus, and stomach, although sites as distal as the proximal jejunum may be injured.^{15,16,17} and ¹⁸ Areas at, or immediately proximal to, points of gastrointestinal tract narrowing are particularly at risk.¹³ Alkali ingestion is associated with a significantly higher incidence of esophageal lesions, whereas acids tend to affect the stomach.^{1,5,6,16} There are, however, many exceptions.^{16,17,19} Esophageal lesions occur predominantly in the lower half, and gastric burns are usually most severe in the antrum.^{17,18} Multiple sites are affected in up to 80% of patients.¹⁸ In the presence of food, gastric injuries tend to be less severe and involve the lesser curve and pylorus.

Systemic toxicity may sometimes accompany severe gastrointestinal injuries and is usually secondary to tissue inflammation, acidosis, infection, and necrosis. Fluid and electrolyte shifts accompanying extensive burns can cause hypovolemic shock. Although corrosives are usually neutralized on contact with tissues, products of this reaction may be absorbed and cause systemic effects.

Deaths due to the ingestion of corrosive agents constituted 2.8% of all reported deaths due to poisoning in the United States in 1997.¹⁴ Household cleaning products represented the largest group involved in all corrosive exposures. Nearly one-third of cases involved children younger than age 6 years who had commonly ingested relatively low-toxicity disinfectants and bleaches; the incidence of significant injury was only one-fourth of that in adults. Adults, either by deliberate intent or because of concomitant intoxication, often ingest a larger amount of corrosive and are more likely to suffer severe injury.^{6,8,19} The elderly are at increased risk of dying from the accidental or intentional ingestion of corrosives and accounted for nearly 25% of all deaths due to corrosives ingestion.¹⁴

Before 1970, domestic alkali drain cleaners containing highly concentrated sodium or potassium hydroxide caused most of the serious injuries due to corrosive ingestion.¹ The less concentrated (less than 20%) alkali drain cleaners are still responsible for the largest number of severe gastrointestinal injuries and deaths. Until very recently, acid toilet bowl cleaners were responsible for as many deaths, but none were reported in 1997.¹⁴ Domestic liquid (but not powder) automatic dishwasher detergents, ammonia (5% to 10%), bleaches (less than 10% sodium hypochlorite), and hydrogen peroxide solutions (less than 3%) rarely cause significant injury.

CLINICAL PRESENTATION

Patients usually present with oral, retrosternal, or abdominal pain. Other symptoms and signs include dysphagia, drooling, and vomiting; less commonly, symptoms and signs include stridor, hoarseness, hematemesis, and melena.⁸ Young children may refuse to drink fluids, cry excessively, or be unable to swallow their secretions. The presence of vomiting is associated with severe esophageal burns; drooling and stridor appear to be predictive of severe injuries but not necessarily of a particular site.^{5,7,8,16} Patients with pill-induced esophageal injury usually present with the sudden onset of retrosternal pain and odynophagia.

Visible superficial burns are often covered with a pale membrane, whereas deeper burns are black, hemorrhagic, or friable. The presence of burns in the oropharynx is not reliably predictive of more distal injuries.^{5,7,8,15,16,17,18} and ¹⁹ Burns of the larynx, however, are associated with a greater incidence and severity of esophageal lesions.¹⁶ Laryngeal burns occur in nearly one-half of patients with serious esophageal injuries and are more commonly the cause of respiratory distress than are tracheitis or pneumonitis secondary to aspiration.¹⁶ Usually, the epiglottis and aryepiglottic folds are involved. Initial stridor and hoarseness do not reliably predict the presence or severity of laryngeal involvement.⁸ Additionally, the absence of respiratory symptoms or signs on presentation does not preclude the existence of airway burns that may require later intervention.¹⁶

Full-thickness injuries to the esophagus or stomach are at risk of perforation and fistula formation into the mediastinum, peritoneum, or trachea.¹⁸ Patients with mediastinitis may have chest pain, respiratory distress, fever, subcutaneous emphysema, pleural rub, and Hamman's sign (crunching sound heard during cardiac systole on auscultation of the mediastinum). Chest radiographic findings may include mediastinal widening, pleural effusion (usually left-sided), pneumomediastinum, and pneumothorax. Peritonitis may result from viscus perforation or the extension of severe gastric burns to surrounding abdominal organs.^{6,19} In addition to usual findings, patients with peritonitis may have marked third-spacing of fluids, resulting in abdominal distention and hypotension. Tracheoesophageal-aortic fistula is a potential complication in patients with extensive esophageal burns and may present with hemoptysis or hematemesis.

Esophageal strictures develop in up to 70% of patients with deep esophageal ulcers and in nearly all patients with areas of necrosis.^{18,19} Ulceration superficial to the muscularis mucosa layer does not lead to stricture formation.^{2,6,9,17} Half of all esophageal strictures develop during initial hospitalization, and 80% are evident within 2 months. Strictures may also develop in the mouth, pharynx, and stomach.^{17,18} and ¹⁹ Esophageal carcinoma, a late sequela of alkali ingestion, has been diagnosed 22 to 81 years after ingestion. This complication has not been associated with acid burns.

Systemic toxicity has been reported following skin or gastrointestinal burns caused by acetic acid, salts of arsenic and other heavy metals, cyanide, formic acid, hydrofluoric acid, hydrazine, hydrochloric acid, nitrates, phenol, sulfuric acid, and phosphoric acid. Severe acid burns may be accompanied by metabolic acidosis.

It is unclear whether metabolic acidosis results from the absorption of an acid or is secondary to hypovolemic shock. The anion gap is usually elevated, although a hyperchloremic acidosis may be seen in hydrochloric acid ingestion. Hyperphosphatemia and hypocalcemia have occurred with phosphoric acid ingestion. Methemoglobinemia (see [Chapter 352](#)) can occur following burns with phenol. Cardiovascular collapse is the most common cause of early death following hydrochloric acid ingestion. Other findings associated with severe acid injuries include hemolysis with hyperkalemia and hemoglobinuria, nephrotoxicity, pulmonary edema, and organ dysfunction resulting from hypovolemic shock.

Coma, bradycardia, hypotension, acidosis, pulmonary edema, liver dysfunction, and coagulopathy have been reported after the ingestion or inhalation of ammonia. After absorption, ammonia is rapidly taken up by the liver, where it enters the urea cycle. Systemic toxicity occurs when the rate of hepatic clearance is exceeded. Hydrazine can be absorbed through the skin and lungs as well as the gastrointestinal tract. Systemic toxicity is due to the inhibition of enzymes involved in intermediary metabolism and may be delayed up to 14 hours after initial exposure. Hypotension, ataxia, coma, hypoglycemia, hyperglycemia, hepatitis, renal tubular

necrosis, hemolysis, and, possibly, methemoglobinemia may occur in severe cases of hydrazine poisoning (see [Chapter 352](#) and [Chapter 353](#)).

DIFFERENTIAL DIAGNOSIS

The most important diagnosis to exclude is the potential coingestion of foreign bodies or systematically absorbed chemicals. If shock or altered mental status is present soon after ingestion, a search for other causes should be undertaken. Hematemesis and esophageal perforation can result from protracted vomiting of any cause. Gastroenteritis due to the corrosive effects of ingested heavy metals and hydrocarbons can cause similar symptoms. Allergic reactions may present with some of the features of corrosive ingestion if the hypopharynx or larynx is involved. Foreign-body ingestion and infections such as epiglottitis, croup, retropharyngeal abscess, and mucosal ulceration due to herpesvirus or coxsackievirus should be considered in infants, toddlers, and elderly patients who are unable to provide an adequate history.

EMERGENCY DEPARTMENT EVALUATION

The identity, concentration, and amount of chemical or product ingested and the time and circumstances of ingestion should be determined. Product labels should be examined for ingredients and signal words. If a sample is available, the pH should be measured. A pH meter is more accurate than pH paper (e.g., pHydriion paper, which is also used for testing amniotic fluid) but is not generally available.

Initial and ongoing attention should be directed to airway patency, because obstruction may develop with progressive mucosal edema. In the absence of clinical indications for immediate endotracheal intubation, patients with respiratory symptoms should have upper airway assessment, preferably by direct fiberoptic laryngoscopy. Patients suspected of having a significant injury should have an electrocardiogram, arterial blood gas analysis, complete blood count, type and cross-match, prothrombin time, and electrolyte, glucose, and liver and renal function tests. Radiologic studies should include an upright chest radiograph and an abdominal film. Methemoglobin levels should be checked in patients who have ingested hydrazine or phenol. The evaluation of cyanide, fluoride, and heavy metal poisoning is discussed in [Chapter 331](#), [Chapter 339](#), and [Chapter 318](#), respectively.

Endoscopy of the upper gastrointestinal tract should be performed in all symptomatic patients. The lack of symptoms or signs usually indicates that significant injuries (i.e., those that require treatment or are likely to lead to complications) are absent and that endoscopy is not necessary. ^{5,8,16} Endoscopy should be considered for apparently asymptomatic young children or patients who have intentionally ingested a strong acid or alkali if the history is unreliable. Because injuries may progress over a period of several hours, endoscopy is optimally performed 6 to 24 hours after exposure. If undertaken earlier, the full extent of injury may not be apparent; if performed later, the risk of perforation may be increased. Iatrogenic esophageal perforation has only been reported with the use of rigid endoscopes. ¹⁸ Fiberoptic endoscopy is safe as long as it is performed gently, with minimal air insufflation and avoidance of retroversion or retroflexion.

Initially, the cricopharynx and larynx should be visualized to assess any laryngeal burns and the need for intubation. If laryngeal burns are noted, prophylactic endotracheal intubation should be performed before distal evaluation is begun. When a flexible, small-diameter endoscope is used, it is not necessary to terminate the procedure at the level of the first circumferential or full-thickness lesion, although the endoscope should not be forced through a narrowed area. ¹⁸

Contrast esophagography is less sensitive than endoscopy in assessing burn injury, although it is useful for the detection of perforation. A water-soluble contrast agent should be used. Cine-esophagography can detect esophageal motility disorders, which are predictive of stricture formation. All patients with an atonic dilated or atonic rigid esophagus and some patients with abnormal uncoordinated contractions later develop esophageal strictures. ¹²

EMERGENCY DEPARTMENT MANAGEMENT

Airway management is the first priority. Any patient with respiratory distress, stridor, or inability to speak should undergo immediate endotracheal intubation. Patients who are hypoxic but not in respiratory distress should be given supplemental oxygen. If laryngoscopy reveals laryngeal mucosal edema, prophylactic intubation is advised. Patients with pneumonitis and hypoxia unresponsive to oxygen should be managed with endotracheal intubation and positive-pressure ventilation. Symptomatic patients should have an intravenous line established.

Although most tissue injury occurs within minutes of ingestion, decontamination should be considered if the patient presents within 2 hours of ingestion. Emesis is contraindicated because it may reexpose the thin-walled esophagus to the corrosive agent and may increase the risk of aspiration. ¹⁶ For this reason, antiemetics should be given to patients with persistent vomiting. Unless it is likely to prevent absorption of coingestants, activated charcoal should not be given, because it does not effectively bind corrosives and obscures endoscopic evaluation. The mouth should be rinsed liberally with water, milk, or other noncarbonated beverage in patients with oral burns or symptoms. Dilution by giving oral fluids may be beneficial. The amount swallowed should be limited to 5 mL/kg to avoid inducing emesis. This may also wash any corrosive adherent in the esophagus to the stomach, which has a thicker wall and may be less susceptible to injury.

The use of a nasogastric tube to evacuate gastric contents may be useful in patients with large intentional ingestions who present within 1 to 2 hours of ingestion. Although controversial, this procedure has not been reported to cause perforation. ¹³ If performed, the tube should be gently inserted, gastric contents aspirated, and the tube firmly taped in place to avoid motion. Dilution or lavage with small aliquots (5 mL/kg) of water can then be undertaken. Patients should otherwise be given nothing by mouth until the need for endoscopy is determined.

Although corticosteroids reduce the incidence and severity of esophageal strictures in animal studies, their value in humans is controversial. In animal studies, steroids were given before, coincident with, or immediately after exposure. In clinical trials in which steroids were not given until up to 24 hours after exposure, there have been conflicting conclusions as well as several points of general agreement. Patients with first-degree esophageal burns do not require steroids, because strictures do not develop in this group. ^{2,6,9} Steroids do not appear to influence the development of esophageal strictures in patients with extensive areas of deep ulceration or necrosis and may increase complications such as hemorrhage or perforation. ^{2,9} For patients between these two extremes, whose injuries consist of circumferential or extensive superficial ulceration or small areas of deep ulceration or necrosis, steroids are of potential benefit. ^{2,9,11} Esophageal strictures are less common after acid ingestion, and the effect of steroids has not been studied; their use deserves consideration in exceptional cases.

Animal studies show that, if steroids are to be effective, they must be given as soon as possible after exposure (i.e., on presentation). Because endoscopy is usually delayed for several hours, the first dose of steroids should be administered before endoscopy is performed. The decision to continue steroids can be based on the findings at endoscopy. Recommended dosages are 1 mg/kg/d of dexamethasone or 2 mg/kg/d of prednisolone or methylprednisolone for 3 weeks, then tapering the medication. Dexamethasone has been suggested to be superior to prednisolone in improving healing and reducing the need for stricture dilatations. ³ Active bleeding or perforation are contraindications to steroid use. Animal studies indicate that antibiotics, when used in conjunction with steroids, have a synergistic effect in the prevention of stricture formation. Therefore, patients who are to continue steroids should also be given antibiotics (e.g., cefazolin). Patients with extensive transmural ulceration or necrosis, who are not candidates for steroid therapy, should also be given antibiotics to reduce the incidence and severity of perforation.

Although they are of no benefit in promoting healing or reducing complications, antacids, sucralfate, H₂-blockers, and analgesics can provide symptomatic relief. Oral medications should generally be withheld until the results of endoscopy are known, and then they should be given only to patients with injuries limited to mucosal inflammation or small areas of superficial ulceration. These patients may be given oral fluids when they are able to swallow their own secretions. Those with more severe injuries should receive intravenous fluids and nothing by mouth. Hyperalimentation, either parenteral or by jejunostomy feeding tube, is recommended for these patients.

Silastic stents, placed in the esophagus at the time of endoscopy, may also prevent stricture formation. ⁴ Alternatively, a nasogastric tube or string may be inserted and left in place to maintain patency of the esophageal lumen and facilitate subsequent dilation by bougienage if strictures develop. The use of lathyrogenic compounds, such as beta-aminopropionitrile and D-penicillamine, have decreased the rate of collagen deposition and stricture formation in animal studies but have not been studied in humans. Their use is not recommended. Therapy for systemic toxicity is primarily supportive. The treatment of methemoglobinemia and systemic heavy-metal, cyanide, and fluoride poisoning is discussed in [Chapter 318](#), [Chapter 331](#), and [Chapter 339](#).

Surgical exploration is indicated if perforation or full-thickness necrosis is suspected. Laparotomy and early excision of necrotic tissue have been recommended for patients with extensive full-thickness esophageal necrosis, but the advantage over more conservative treatment is unproved, and surgical mortality in this group is high. In patients who develop strictures, attempts at dilatation earlier than 3 weeks after ingestion is of unclear benefit and has been associated with an increased risk

of perforation. Indications for delayed esophageal replacement are (1) inability of the patient to swallow; (2) persistent symptomatic strictures despite sequential dilatation; (3) a need for frequent esophageal dilatation, requiring extended hospitalization; and (4) perforation during dilatation. Esophageal substitutes include the colon, most commonly, but also the stomach (reverse gastric tube) and jejunum.

DISPOSITION

Patients who are asymptomatic or become asymptomatic after oral rinsing and dilution may be discharged from the emergency department if they have ingested a compound classified as a mild irritant. Admission is recommended for all symptomatic patients. The choice of bed (e.g., floor, intermediate, or intensive care unit) depends on the patient's clinical status. Patients with the potential for airway compromise should be admitted to an intensive care unit. Patients with suicidal ingestions require psychiatric evaluation and one-to-one monitoring. All symptomatic patients should be evaluated by an endoscopist (gastroenterologist or surgeon). Consultation should also be considered when significant injury is suspected in a patient who is unable or unwilling to describe symptoms and who has ingested a potentially corrosive substance. If endoscopy is unavailable, patients who require hospital admission should be transferred to a facility where it can be performed. Patients with a history, symptoms, or signs suggestive of moderate or severe injury, or endoscopic evidence of such, should also have early consultation with a general, pediatric, or thoracic surgeon, depending on local referral patterns and the location of injury. Signs and symptoms of perforation require early surgical consultation. A toxicologist or regional poison control center should be consulted regarding treatment recommendations.

After endoscopy, patients with no visible injury or with injuries limited to mucosal inflammation or small areas of superficial ulceration may be discharged or referred for psychiatric care, as long as they are able to tolerate oral fluids.^{2,6,9} Patients with persistent symptoms or inconclusive findings at endoscopy should remain for observation.¹ If symptoms persist, endoscopy should be repeated. Patients with deep or extensive superficial ulceration or areas of necrosis should be managed in an intensive care setting.

COMMON PITFALLS

- Failing to positively identify the substance ingested, test its pH, or seek information on its potential for corrosive injury
- Failing to evaluate the airway and intubate patients with respiratory distress or signs of laryngeal edema
- Attempting to neutralize the ingested corrosive with weak acids or alkalis
- Giving syrup of ipecac or unintentionally inducing vomiting by giving excessive amounts of oral fluid for initial decontamination
- Assuming that the absence of oropharyngeal burns precludes the presence of significant distal injuries
- Failing to consult a gastroenterologist and surgeon regarding the evaluation of all symptomatic patients

CHAPTER 331

Cyanide Poisoning

Alan H. Hall

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Acknowledgment](#)
[Common Pitfalls](#)
[Chapter References](#)

Acute cyanide poisoning is a rare, potentially fatal but treatable condition.²⁰ It may be encountered in a variety of settings: smoke inhalation, chemical exposures, thermal degradation or acid contact with chemical compounds (e.g., cyanogen, cyanogen halides, calcium cyanide), and metabolic release after systemic absorption of laetrile, amygdalin, other cyanogenic glycosides of plant origin (e.g., apricot, cherry, and peach pits) and aliphatic nitrile compounds.^{3,4,6,9,18} Sodium nitroprusside therapy at high doses may sometimes cause elevated blood cyanide levels.¹⁵

Of the 347 cases of cyanide exposure reported to poison centers in the United States during 1997, there were seven deaths.¹⁶ While 127 patients developed some signs or symptoms, only six who had severe cyanide poisoning survived. Antidotal treatment with amyl nitrite was administered in 47 cases, sodium nitrite in 43 cases, and sodium thiosulfate in 73.¹⁶

Cyanide produces intracellular hypoxia by complexing with the ferric iron of mitochondrial cytochrome oxidase, inhibiting the electron transport chain and oxidative phosphorylation, and causing anaerobic metabolism with decreased adenosine triphosphate and increased lactic acid production.³ Tissues with the greatest oxygen demand (myocardium and brain) are most profoundly and rapidly affected. Initial central nervous system and cardiovascular stimulation is followed by depression.

Human cyanide toxicokinetics are poorly understood, but the volume of distribution is probably between 0.4 and 0.5 L/kg, and the initial half-life between 30 minutes and 1 hour. Systemic absorption by the ingestion route is nearly complete, but only a small percentage of a dose is excreted unchanged in the urine.^{2,8} Whole blood cyanide levels in acute ingestion poisoning decrease rapidly after specific antidote treatment, but they may remain elevated for prolonged periods when antidotes are not administered.⁸ Except in rare cases, patients with whole blood cyanide levels greater than 3.0 µg/mL have not survived unless specific antidote therapy was administered.^{8,9}

Although a number of specific antidotes are in clinical use worldwide, only the amyl nitrite, sodium nitrite, and sodium thiosulfate combination (the Cyanide Antidote Kit) is available in the United States. Hydroxocobalamin, commercially available in some other countries, is less toxic and generally equally efficacious.^{2,3,5,7} Oxygen has an antidotal effect of its own as well as having synergistic action with certain specific cyanide antidotes, perhaps because oxidized cytochrome oxidase resists inactivation by cyanide to a greater extent than does reduced cytochrome oxidase.¹⁷

CLINICAL PRESENTATION

Inhalation of high concentrations of hydrogen cyanide gas may cause sudden loss of consciousness after only a few breaths.⁸ With ingestion of alkaline cyanide salts (calcium cyanide, potassium cyanide, sodium cyanide), the onset of life-threatening symptomatology may occur in 30 minutes to 1 hour.⁸ In fatal cases, rapid progression to coma, seizures, arrhythmias, intractable hypotension, apnea, and death is common.

Onset of symptoms may be delayed with exposure to cyanogens such as laetrile and cyanogenic glycosides from plant sources (up to 1.5 hours), or aliphatic nitrile compounds, such as acetonitrile in artificial glue-on nail removers (up to 6 to 12 hours).^{4,6,9} Systemic poisoning may occur after dermal cyanide exposure,¹³ although such cases are extremely rare.

Initial signs and symptoms include central nervous system stimulation (giddiness, headache, and anxiety), hyperpnea, mild hypertension, and palpitations.⁸ Later manifestations include nausea, vomiting, hypotension, generalized seizures, coma, apnea, mydriasis, noncardiogenic pulmonary edema, and a variety of cardiac effects (tachycardia or bradycardia, supraventricular and ventricular arrhythmias, atrioventricular blocks, ischemic electrocardiographic changes, and, eventually, asystole).^{3,8} Patients with significant cyanide poisoning have elevated serum lactate levels and an elevated anion gap metabolic acidosis.^{2,8} Cyanosis is a late sign, noted only at the stage of apnea and circulatory collapse. The retinal veins and arteries may appear nearly equally red, due to the inability of tissues to extract oxygen from the blood. Development of a diabetes insipidus–like condition secondary to severe brain damage following acute cyanide poisoning is an ominous prognostic sign.²⁰

During high-dose nitroprusside infusion, whole blood cyanide levels may become elevated. However, even when this occurs, clinical signs of cyanide poisoning (e.g., elevated lactate levels, metabolic acidosis) are not necessarily present.¹⁵ Cyanide poisoning in this setting can be prevented by the concomitant administration of sodium thiosulfate.

DIFFERENTIAL DIAGNOSIS

Early symptoms may be confused with anxiety or hyperventilation, which are common after nontoxic exposures. Development of more serious clinical signs differentiates these benign conditions from true cyanide poisoning. Hydrogen sulfide and sodium azide poisoning may cause similar findings, and diabetic decompensation has been initially suspected in patients who were later found to have ingested cyanide.

Cyanide poisoning should be suspected in patients with rapid development of unexplained coma, seizures, elevated anion gap metabolic acidosis, and intractable hypotension. Severe hypoxic signs in the absence of cyanosis also suggest the diagnosis.⁸

The following laboratory values may suggest the diagnosis when no history is available:^{6,8,12,20} elevated serum lactate level, elevated anion gap metabolic acidosis, relatively normal pO₂ in ventilating patients, and an elevated peripheral venous pO₂ (greater than 40 mm Hg) or decreased arteriovenous O₂ saturation difference (central venous or mixed pulmonary artery O₂ saturation greater than 70% with a relatively normal co-oximeter–measured arterial O₂ saturation), owing to decreased tissue oxygen extraction from the blood. Hydrogen sulfide and sodium azide poisoning can also cause this combination of laboratory findings.^{8,11,12} Patients exposed to hydrogen sulfide may have the odor of sulfur or “rotten eggs” on the body or clothes or in a freshly drawn tube of blood.¹¹

EMERGENCY DEPARTMENT EVALUATION

Whenever possible, the history should include the specific compound involved, route of exposure, any decontamination measures already undertaken, possible dose, time since ingestion or exposure, and any preexisting allergies or chronic medical conditions. Initial physical examination should focus on vital signs (monitored frequently and serially) and the respiratory, cardiovascular, and central nervous systems. The cardiac rhythm should be continuously monitored.

Determination of serum electrolytes (with calculation of the anion gap), blood glucose levels, pulse oximetry, arterial blood gas analysis, chest radiography, and 12-lead electrocardiography should be done initially and monitored frequently if clinical signs or symptoms of cyanide poisoning are present. Whole blood cyanide levels can be measured, but these determinations usually take hours or days to obtain, and thus cannot be used to guide emergent diagnosis or treatment. They are useful only to document exposure.

EMERGENCY DEPARTMENT MANAGEMENT

Rescuers must not enter areas of potential cyanide gas exposure without a self-contained positive-pressure breathing apparatus.⁸ Mouth-to-mouth resuscitation should be avoided, if at all possible. If it is unavoidable, rescuers must be careful not to inhale the victim's expired air. Prehospital care consists of airway management, administration of 100% supplemental oxygen, cardiac monitoring, placement of at least one large-bore intravenous line, administration of sodium bicarbonate if hypotension (and, presumably, metabolic acidosis) is present, decontamination of exposed skin or eyes, and administration of standard anticonvulsant or antiarrhythmic medications, if indicated. If intravenous access cannot be established or in severe poisoning cases, amyl nitrite pearls may be given by inhalation (broken in gauze and held close to the nose and mouth of spontaneously breathing patients or placed into the lips of the face mask or inside the ventilation bag in apneic patients) for 30 seconds out of each minute, using a fresh pearl every 3 to 4 minutes.^{2,15,19}

Exposed skin or eyes should be copiously flushed with water. Contaminated clothing should be removed and isolated. Induced emesis must be avoided, because rapid progression to coma or seizures with potential pulmonary aspiration of gastric contents may occur. Activated charcoal has decreased mortality in experimental cyanide poisoning,¹⁴ and 1 g may bind as much as 35 mg of cyanide.¹ An activated charcoal dose of 1 g/kg should be administered to patients who have ingested cyanide.

Supportive measures alone may be satisfactory treatment for some patients, although supportive therapy and specific antidotes have resulted in survival with higher whole blood cyanide levels.⁸ Standard anticonvulsant and antiarrhythmic medications should be administered when clinically indicated. Pulse oximetry or arterial blood gases should be monitored and metabolic acidosis corrected with sodium bicarbonate. Pulse oximetry may be unreliable following administration of methemoglobin-inducing nitrite antidotes. Usually, less sodium bicarbonate is required when specific antidotes are administered.

Patients with coma, seizures, apnea, acidosis, or hypotension should be administered specific antidotes. Once intravenous access has been established, amyl nitrite inhalation should be discontinued and sodium nitrite administered intravenously. The dose is one 10-mL ampule (300 mg) of a 3% solution for adults and 0.12 to 0.33 mL/kg (3.6 to 9.9 mg/kg) for children. Sodium nitrite is a potent vasodilator; rapid administration may result in severe hypotension, which can be avoided by slow infusion. Sodium nitrite is administered by slow intravenous push over no less than 5 minutes, unless the patient is in cardiac arrest. It can be diluted in 50 to 100 mL of 5% dextrose in water. The infusion is begun slowly, with frequent blood pressure monitoring, and then increased to the most rapid infusion rate not causing hypotension. Rarely, sodium nitrite may induce excessive methemoglobinemia.⁸ Methemoglobin levels should be monitored, especially if multiple doses of sodium nitrite are required, and should be kept less than 30% of total hemoglobin.

Sodium nitrite should be followed by intravenous sodium thiosulfate in a dose of one 50-mL ampule (12.5 g) of a 25% solution for adults or 1.65 mL/kg for children. When used as a cyanide poisoning antidote, no significant adverse effects due to sodium thiosulfate infusion have been reported.

Second doses of sodium nitrite and thiosulfate at one-half the initial amounts may be given 30 minutes later if there is incomplete clinical response. Continued metabolic release of cyanide from cyanogenic glycosides or aliphatic nitrile compounds may cause prolonged poisoning, necessitating multiple antidote doses.^{6,8} Repeated doses or a continuous infusion (1 g/h) of sodium thiosulfate (without further sodium nitrite) should be considered in such cases.^{6,10}

When available, hydroxocobalamin is administered in a dose of 4 to 5 g intravenously over 20 to 30 minutes.^{2,3,5,8} Sodium thiosulfate in the preceding doses may be infused after hydroxocobalamin is given.⁷

Hyperbaric oxygen therapy may be useful in patients unresponsive to supportive and antidotal therapy.^{3,17} Smoke inhalation victims (see [Chapter 396](#)) may have significant cyanide as well as carbon monoxide poisoning.² Inducing methemoglobinemia could be dangerous in this setting. When hyperbaric oxygen therapy is available, it is suggested that sodium thiosulfate be given first, with administration of sodium nitrite only while the smoke inhalation victim is receiving hyperbaric oxygen therapy. Extracorporeal elimination procedures such as hemodialysis and hemoperfusion have no place in the treatment of acute cyanide poisoning.

DISPOSITION

Consultation with a clinical toxicologist or regional poison center can be invaluable in guiding therapy. Physicians admitting cyanide-poisoned patients should be skilled in intensive care medicine.

Asymptomatic cyanide-exposed patients should be observed in a controlled setting for a minimum of 4 to 6 hours. With aliphatic nitrile and cyanogenic glycoside exposure, the observation period should be extended to 12 hours.^{6,8} Mildly symptomatic patients can be observed in the emergency department until symptoms resolve. Those requiring antidote administration should be admitted to an intensive care unit until all symptoms have resolved, or for a minimum of 24 hours.

A few survivors of acute cyanide poisoning have developed parkinsonian-like states or more subtle neuropsychiatric deficits.^{8,13} Outpatient follow-up should be arranged for patients with significant acute toxicity to screen for these rare sequelae.

If transfer is necessary, the most rapid means available should be used. Accompanying personnel should be able to initiate intravenous access, perform endotracheal intubation and mechanical ventilation, and administer specific antidotes as well as sodium bicarbonate and standard anticonvulsant and antiarrhythmic medications.

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of Barry H. Rumack who wrote the previous version of this chapter.

COMMON PITFALLS

- Failure to stock an in-date cyanide antidote kit in the emergency department or other readily available location
- Failure to consider the diagnosis of cyanide poisoning in patients with sudden-onset coma, cardiovascular collapse, or metabolic acidosis of unknown etiology
- Inappropriate antidote administration to a hemodynamically stable, conscious patient
- Failure to administer antidotes to patients with more serious symptomatology
- Rapid administration of sodium nitrite, resulting in hypotension
- Administration of adult doses of cyanide antidotes to children
- Failure to monitor methemoglobin levels in patients receiving sodium nitrite, especially in children or when multiple doses are given

The term *digitalis* originally referred to the dried leaf of the *Digitalis purpurea* plant (foxglove). It is now used as a generic term to designate all cardiac glycoside (CG) drugs. CGs are found in the leaves and seeds of a variety of plants and in the skin, salivary glands, and venom glands of toads of the *Bufo* species ([Table 332.1](#)). Digoxin is the only digitalis preparation in common therapeutic use in the United States. It is used in the treatment of congestive heart failure and for certain dysrhythmias, such as atrial fibrillation or flutter and supraventricular tachycardia. CGs have a narrow therapeutic window, a characteristic that leads to frequent toxicity. Digitalis toxicity is believed to occur in 5% to 20% of all patients being treated with digitalis, and 30% of those taking CGs who are admitted to the hospital exhibit some degree of toxicity.¹¹

Genus and Species	Common Name	Part Used
<i>Digitalis purpurea</i>	Purple foxglove	Leaf
<i>Digitalis lanata</i>	Grecian foxglove	Leaf
<i>Strophanthus kimbé</i>		Seed
<i>Strophanthus gratis</i>		Seed
<i>Urginea maritima</i> (squill)	Sea onion	Bulb
<i>Nerium oleander</i>	Oleander	All parts
<i>Thevetia peruviana</i>	Yellow oleander	All parts
<i>Convallaria majalis</i>	Lily of the valley	All parts
<i>Bufo</i> spp.	Toad	Skin

TABLE 332.1. Sources of Cardiac Glycosides

CGs inhibit the sodium–potassium adenosine triphosphatase (ATPase) membrane pump found in cardiac cells.² This leads to an elevation of intracellular sodium and calcium and the loss of potassium. Magnesium is an essential cofactor for the sodium-potassium ATPase pump and may also have direct effects on membrane calcium and potassium transport.¹³ The electrophysiologic effects of CGs include a decrease in the refractory period of atrial and ventricular myocardial cells, leading to improved conduction. Phase 4 of the action potential in most myocardial tissue is increased, leading to an increase in automaticity. A lowering of resting membrane potential leads to more excitability. There is an augmenting of vagal tone and a prolongation of phase 3 of the action potential in the atrioventricular (AV) node and the His-Purkinje system. The other major effect is an increase in inotropic function in the myocardium due to the amount of calcium available for the myofibrils.

The therapeutic daily dose of digoxin ranges from about 0.005 mg/kg in premature infants to as much as 0.75 mg in adults. The absorption of digoxin tablets is 70% to 80%, with capsules being 95% bioavailable. An initial small volume of distribution leads to high blood levels early after ingestion. Actual volume of distribution is about 10 L/kg in adults and more in children. The elimination half-life is about 1.5 days with renal excretion. Protein binding is only 25%.

Serum digoxin levels are measured by radioimmunoassay. Normal levels are 0.5 to 2.0 ng/mL. Some patients are toxic at levels in this range, and others manifest no toxicity at levels greater than 2.0 ng/mL. Drug levels drawn less than 8 hours after a dose, during the distribution phase, do not reflect tissue levels, and hence do not correlate with effects. Following acute ingestion, the serum digoxin level merely verifies that an ingestion has occurred: A level as high as 10 ng/mL 2 hours after ingestion may be seen without significant clinical toxicity.

Oleander and *Bufo* toxins can result in an apparent or false-positive digoxin level on radioimmunoassay. In both of these instances, there appears to be partial cross-reactivity in the assay, but levels have not been correlated with toxicity. There may or may not be cross reactivity between monoclonal digoxin assays and other nondigoxin cardiac glycosides. Endogenous digoxin-like steroidal substances (EDLS), which also cross-react with digoxin assays and yield false-positive results, may be present in patients with renal insufficiency, hepatic disease, hypertension, agonal states, and pregnancy, and in premature and full-term infants.¹⁴ Levels are usually low, but have been measured above 2.0 ng/mL. Digoxin assays can lead to large errors in excess of 50% above the true level in children with EDLS.

With therapeutic doses, the QT interval may be shortened and the PR interval relatively prolonged on the electrocardiogram (ECG). The “digitalis effect,” with downsloping ST segments giving a scooped appearance, may also be noted. In atrial fibrillation, there is a slowing of the ventricular response.

Toxicity results from an exaggeration of therapeutic effects. Adverse effects may also be due to coronary vasoconstriction.¹⁶ Excessive suppression of pacemaker function may lead to bradyarrhythmia, and increased automaticity may lead to atrial, junctional, and ventricular tachyarrhythmias ([Table 332.2](#)). Adolescents appear to be more sensitive to the toxic effects of digoxin than are younger children. In one study, ventricular ectopy was often the earliest sign of digoxin toxicity in adults, whereas sinus bradycardia and AV block were the initial dysrhythmias in children.¹⁸ In another study, there did not appear to be any age-related differences in patients with life-threatening toxicity.¹⁹

Bradyarrhythmias	Tachyarrhythmias
Sinus exit block or sinus arrest	Atrial tachycardia with block
Sinus bradycardia	Junctional tachycardia
Atrioventricular nodal block:	Ventricular premature beats
first degree; second degree,	Ventricular tachycardia,
type I; third degree	especially bidirectional
	Ventricular fibrillation

TABLE 332.2. Digitalis-Induced Dysrhythmias

Digoxin toxicity may be chronic or acute. In chronic ingestion, there is a narrow therapeutic range, with toxic amounts being only two to three times therapeutic doses. Most instances of chronic toxicity occur in the elderly. It is frequently associated with hypokalemia, which tends to exacerbate tachyarrhythmias. Chronic intoxication is associated with ventricular dysrhythmias, atrial tachycardia, and junctional tachycardia. Exercise-induced ventricular tachycardia was reported in a patient with coexisting valvular heart disease, which itself can result in oversensitivity to digoxin.⁸ Many other factors are known to contribute to or predispose the patient to

toxicity ([Table 332.3](#) and [Table 332.4](#)).

Advanced age
Renal impairment
Hypoxia
Myocardial ischemia
Hypothyroidism
Hypokalemia
Hypomagnesemia
Hypercalcemia

TABLE 332.3. Conditions Contributing to Digoxin Toxicity

Causing hypokalemia	Diuretics Amphotericin B Corticosteroids
Increasing sympathetic tone	Beta agonists Theophylline
Increasing atrioventricular nodal block	Beta blockers Verapamil Diltiazem
Increasing serum digoxin level	Quinidine Verapamil Amiodarone Propafenone Erythromycin Tetracycline Itraconazole

TABLE 332.4. Drugs Enhancing Digoxin Toxicity

Acute toxicity is most often associated with an accidental or intentional massive ingestion. It is more likely to be associated with hyperkalemia, because there is massive poisoning of the sodium–potassium ATPase pump, leading to accumulation of potassium in the extracellular space. In healthy adults, single acute doses of less than 5 mg of digoxin seldom cause severe toxicity, and fatal doses are almost always greater than 10 mg. In this setting, sinus bradycardia and varying degrees of AV block occur, with fewer ventricular dysrhythmias.

CLINICAL PRESENTATION

Nausea and vomiting are often present. In chronic toxicity, confusion, lethargy, depression, fatigue, headache, paresthesias, weakness, scotomata, and disturbances of color vision, especially xanthopsia (yellow vision), are also common.

Many dysrhythmias can occur (see [Table 332.2](#)). The most common is ventricular premature contractions. The combination of any tachyarrhythmia with any type of block (e.g., paroxysmal atrial tachycardia with AV block; regularization of the ventricular response to atrial fibrillation due to AV block with a junctional escape rhythm) is highly suggestive of CG toxicity. In 150 patients with acute ingestions, life-threatening complications were high-grade AV block (53%), refractory ventricular tachycardia (46%), hyperkalemia (37%), and ventricular fibrillation (33%).¹ Hypotension suggests a hemodynamically significant dysrhythmia, loss of vasomotor regulation, or the presence of coingestant.

The overall mortality rate varies with different studies but is probably about 10%. In those with suicidal or accidental ingestions, mortality ranges from 13% to 25%.¹¹ Ventricular tachycardia is associated with a 50% mortality rate. Other risk factors include advanced age, heart disease, male sex, high-degree AV block, or hyperkalemia.¹² In acute ingestions, poor prognostic factors are old age, a digoxin level over 15 ng/mL, and hyperkalemia.³

Complications such as hypoxic seizures, encephalopathy, loss of vasoregulation, and acute tubular necrosis may result from inadequate tissue perfusion secondary to dysrhythmias.²⁰

EMERGENCY DEPARTMENT EVALUATION

The history should include the time, amount, route, duration, and intent of exposure. The presence of conditions and agents that can influence toxicity should be noted. Physical examination should concentrate on the vital signs and assessment of hemodynamic stability. Vital signs should include measurement of the oxygen saturation. The patient should be specifically examined for signs of congestive heart failure and inadequate peripheral perfusion. Cardiac monitoring should be routine. A 12-lead ECG should be performed. Routine laboratory studies include determination of serum electrolytes, calcium, magnesium, blood urea nitrogen, and serum creatinine levels. Serum digoxin level also should be measured. Serial levels should be obtained for at least 12 hours following an acute ingestion. Patients with abnormal cardiac rhythms, hypotension, underlying cardiac disease, or hypoxia should have a chest x-ray and arterial blood gas analysis. Those with chronic intoxication should have liver function tests.

EMERGENCY DEPARTMENT MANAGEMENT

Antidotal therapy with digoxin-specific Fab fragments of sheep IgG antibodies (Digibind) is the treatment of choice for life-threatening bradydysrhythmias. Atropine (initially 0.5 mg intravenously) can be given. Refractory or recurrent bradycardia should be treated with antidotal therapy, which appears to be more effective and safer than electrical cardiac pacing.¹⁵ Although pacing may sometimes be necessary, the pacing wire can irritate the myocardium and precipitate ventricular dysrhythmias, and this therapy should not delay definitive therapy with Fab fragments.

Antidotal therapy is also the definitive treatment for life-threatening ventricular tachyarrhythmias. Intravenous phenytoin (25 mg/min until a desired effect is reached or about 15 mg/kg has been given) and lidocaine (1 mg/kg) can be given initially. Magnesium sulfate (2 to 3 g intravenously over 1 minute) may also be effective.⁷ Refractory digoxin–induced cardiac dysrhythmias have responded to magnesium infusions (2 g/h for 4 to 5 hours).²⁰ Because serum magnesium represents less than 1% of the total body magnesium pool, it should be assumed that hypomagnesemia exists at the cellular level, even if the serum magnesium level is normal.¹⁴ As usual, pulseless rhythms require defibrillation or cardioversion. Cardioversion of ventricular tachycardia is risky in digitalis toxicity because it may result in ventricular fibrillation. If possible, drug therapy should be tried first. When necessary, cardioversion should initially be performed at reduced power settings, for example, at 5 or 10 watt-seconds.

Fab fragments are indicated for life-threatening or hemodynamically compromising dysrhythmias, when standard therapy fails, and when hyperkalemia (serum potassium greater than or equal to 5.5 mEq/L) occurs after acute overdose. An elevated digoxin level is useful only to confirm toxicity and should not be used as the sole criterion for use of the Fab fragments. The prophylactic use of Fab for patients with non–life-threatening dysrhythmias and risk factors for severe toxicity has been advocated but remains to be proven.¹⁵ In one cost analysis, even patients who did not have life-threatening dysrhythmias had lower medical costs when treated with Fab fragments.¹¹ In addition, older patients appear to respond to Fab fragments as well as younger patients do.⁹

The Fab fragments are given intravenously over 30 minutes unless the patient is in cardiac arrest, when it can be given as a bolus. The dosage (in vials) is estimated

by dividing the acutely ingested dose in milligrams (body load) by 0.6 mg per vial. Each vial contains 38 mg of Fab fragments, with each milligram binding 0.015 mg of digoxin. The usual initial dose for acute overdose is 5 to 10 vials. In chronic toxicity, the body load in milligrams can be estimated by multiplying the steady-state serum concentration of digoxin by 5.6 times the patient's weight in kilograms divided by 1,000. The usual initial dose for chronic poisoning is 1 to 2 vials. Because Fab fragments cross-react weakly with other CGs, larger doses may be needed for toxicity involving digitoxin, oleander, or *Bufo* toxins.^{4,5} and ^{6,12} A response is usually noted within 30 minutes of Fab administration, but it may take several hours to see the maximal effect. Doses should be repeated if there is no clinical improvement in 1 hour.

Theoretically, skin testing should be performed before treatment with Fab fragments. The necessity of this practice, however, is questionable. In a study of 717 adults with digitalis intoxication who were treated with Fab, only six had adverse reactions that may have been due to components of the antibody preparation, and all reactions were benign. In addition, nearly all patients with reactions have negative skin tests; antibodies to Fab have not been detected in such patients, and the risk of delaying Fab therapy in order to perform skin testing far outweighs the risks of an adverse reaction to Fab. It may be important to perform skin testing, however, in patients repeatedly treated with Fab fragments.¹⁰ No case of serum sickness has been reported.

After using Fab fragments, the serum digoxin level measured by most radioimmunoassays rises because the drug is pulled out of tissue to bind with the antibodies, and the assays measure both bound and unbound drug. The free digoxin level, which can be measured only by equilibrium dialysis or ultrafiltration to remove protein, is very low if the appropriate amount of antibodies are administered. The elimination half-life of the drug-antibody complex, which is excreted renally, is about 16 hours in patients with normal renal function and 4 days in those with renal failure. A rebound increase in free digoxin, presumably due to metabolic degradation of the drug-antibody complex, may occur within 24 hours of Fab administration in patients with normal renal function and up to 8 days after Fab in those with renal failure, but recurrent clinical toxicity is rare.¹⁷

Activated charcoal is the preferred method of gastrointestinal decontamination for patients with acute ingestions. Vagal effects associated with vomiting and gastric lavage might worsen CG toxicity in patients with bradycardia. Subsequent doses of activated charcoal are effective in shortening the elimination half-life of digoxin, digitoxin, and probably the CGs. Resin binders such as cholestyramine are no more effective than charcoal. Elimination cannot be enhanced by increasing urine flow or by peritoneal dialysis, hemodialysis, or hemoperfusion.

Patients with altered mental status (either secondary to toxicity from digoxin or coingestants) may require endotracheal intubation for airway protection or mechanical ventilation. Hypoxia, acid-base abnormalities, and fluid and electrolyte disturbances should be corrected. Caution is advised when giving potassium to hypokalemic patients with chronic intoxication and renal failure. Hyperkalemia associated with acute overdose is a consequence rather than a cause of poisoning and should be treated with Fab. Temporizing measures include intravenous sodium bicarbonate, glucose and potassium, and inhaled beta agonists. Calcium may enhance CG toxicity and should be avoided. Because hyperkalemia reflects a change in potassium distribution and not total body overload, exchange resins, which can lead to subsequent potassium depletion and consequent problems, should also be used with caution.

DISPOSITION

When the use of Fab fragments is considered, consultation with a poison center, toxicologist, or cardiologist is advised. Patients who are acutely symptomatic or who have elevated digoxin levels and those with significant dysrhythmias should be admitted to an intensive care unit. Those with chronic intoxication who are hemodynamically stable and do not require active treatment can be admitted to a telemetry unit. If Fab fragments and pacemaker therapy are not available, patients should be transferred by advanced life-support personnel (or mobile intensive care unit, if available) to the nearest center that possesses these treatment modalities.

COMMON PITFALLS

- Failure to appreciate that a serum digoxin level drawn less than 8 hours after ingestion does not reflect toxicity or need for treatment
- Failure to recognize that CG toxicity can result from exposure to nonprescription products such as herbals or teas
- Failure to recognize that digoxin immunoassays may or may not yield a measurable digoxin level with plant or *Bufo* toxin exposures
- Failure to appreciate the differences between acute and chronic toxicity
- Failure to use Fab fragments for potentially life-threatening dysrhythmias and for hyperkalemia after an acute ingestion
- Failure to correct electrolyte abnormalities, especially those that involve potassium
- Failure to initially use low-power settings for cardioversion of tachyarrhythmias

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of Frank A. Agnone who wrote the previous version of this chapter.

CHAPTER 333

Disk Battery Exposures

Toby L. Litovitz

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

In 1998, 1,946 button battery ingestions were reported to U.S. poison centers and logged into the American Association of Poison Control Centers Toxic Exposure Surveillance System.⁸ Children less than 5 years old are at greatest risk and accounted for 57% of ingestions reported nationally in 1998, with a peak incidence in 1- to 3-year-olds. Six- to 12-year-olds were implicated in 21% of the ingestions, and adults comprised 12% of cases.

Hearing aid batteries are the most commonly ingested button cells, accounting for 46% of battery ingestions (with known source) reported to the National Button Battery Ingestion Hotline and Study during the year ending in June 1999. Games and toys were the second most common source of ingested batteries (19%). Other battery sources included musical, talking, or lighted books, greeting cards, key chains, jewelry, T-shirts, shoes, doormats, teapots, and picture frames; calculators; cameras; clocks; computers; thermometers; flashlights; laser pens and pointers; pagers; phones; remote control devices; and watches.

Nearly 21% of patients ingested the battery after mistaking it for a pill. Five percent of patients ingested the battery while it was in a hearing aid (the aid was also ingested). Unintentional ingestion also occurred while replacing a battery, using the mouth as a “third” hand, and while testing the battery using the ineffective method of placing it in the mouth to determine if there is a “buzz.” One percent of cases involved intentional ingestion to avoid incarceration. Suicide attempts occurred in less than 3% of cases. Eight percent of patients swallowed more than one battery.

Most button battery ingestions have a benign clinical course.^{8,13} Clinical manifestations of the ingestion occurred in only 9.9% of battery ingestion cases, and most symptoms were gastrointestinal (GI).⁸ Sometimes, ingestions of larger cells (greater than 20 mm in diameter, as opposed to the more common 7- to 12-mm button cells) are followed by esophageal lodgment. Disastrous injuries are possible, ranging from minor esophageal burns to permanent esophageal injury that requires colon interposition or recurrent dilatation. Significant esophageal injury may develop in just 2 to 6 hours. At least two fatalities after battery lodgment in the esophagus have occurred in young children in whom the diagnosis of foreign-body ingestion was delayed 24 hours to 4 days.^{3,11} Fortunately, most ingested disk batteries rapidly pass to the stomach and then traverse the entire GI tract without complications.

The mechanism of disk battery–induced injury is multifactorial. Leakage of the potassium hydroxide electrolyte from the battery was long accepted as the major mechanism. More recent studies have identified an alternative and possibly primary cause of injury: an external current generated between the cathode and the anode across the battery crimp area. This electric current can pass through tissue, causing hydrolysis of tissue fluids and local hydroxide generation. Thus, both the external electric current mechanism and the leakage theory have a final common denominator: alkaline-type injury to the tissue. A third, less important mechanism involves pressure necrosis of an impacted battery on adjacent tissue. More severe corrosion occurs in the acid medium of the stomach than in the more alkaline intestine.

Despite much concern regarding the role of heavy-metal leakage from button cells in subsequent injury, symptomatic cases of heavy-metal poisoning after battery ingestion have not been reported. In four cases, modestly elevated mercury levels were noted after button cells broke apart or nearly split, leaving radiopaque droplets in the GI tract without clinical manifestations of mercury toxicity.^{5,8,9 and 10} The theoretic mercury hazard is minimized by the reduction of toxic mercuric oxide released from a split button cell to nearly nontoxic elemental mercury in the presence of gastric acid and iron dissolved from the corroding steel battery can.² In addition, in 1996, environmental concerns relating to disposal of mercury-containing batteries led to federal legislation banning the sale of mercuric oxide button cells in the United States. Whereas mercuric oxide button cells were implicated in 25% of ingested batteries in the 1980s, this percentage had declined to 2% by 1998.

CLINICAL PRESENTATION

Most battery ingestions cause no symptoms and pass through the GI tract without consequence. Symptoms are present in only 9.9% of ingestion cases and are generally minor. Most batteries pass within 72 hours, but passage requires more than a week in nearly 5% of cases, and more than 2 weeks in 1% of cases. Extremely delayed passage (up to 596 days) may occur without symptoms or adverse effects when battery transit is arrested distal to the stomach. About 1% of battery ingestion cases report a diffuse, nonspecific rash that may be caused by nickel hypersensitivity, as many button cells are nickel plated. Dietary nickel is a known factor in nickel dermatitis flare-up.¹

In contrast, a battery that lodges in the esophagus may cause vomiting, fever, dysphagia, odynophagia, tachypnea, and refusal to eat. Failure to promptly remove a battery located in the esophagus may result in tracheoesophageal fistula, tension pneumothorax or hemothorax, or perforation through the aortic arch or its branches, with massive exsanguination and cardiac arrest.

Esophageal lodgment generally follows ingestion of larger cells (20 to 23 mm in diameter), although cells as small as 11.6 mm have caused severe injury after becoming lodged. Preliminary data suggest that lithium cells may pose a greater hazard, causing earlier and more severe symptoms when lodged, due to the higher voltage of these cells. Esophageal burns, perforation, and subsequent stenosis have occurred after battery lodgment of just 2.5 hours. Unfortunately, symptom occurrence alone cannot be used as a reliable indicator of battery position in the esophagus, as patients with batteries lodged in the esophagus may be asymptomatic initially.

A battery in the ear or nose frequently causes injury to surrounding tissue, such as tympanic membrane perforation or destruction, necrosis of the dermis of the external ear canal, destruction of the ossicles, hearing impairment, nasal septal perforation or destruction, nasal turbinate destruction, and atrophic rhinitis.^{4,12} Immediate removal of a battery in the ear or nose is essential to prevent severe injury.

DIFFERENTIAL DIAGNOSIS

Most battery ingestors are asymptomatic; thus, the history of ingestion provides the best diagnostic clue. Patients who are symptomatic after ingesting a miniature battery are most frequently misdiagnosed as having a nonspecific flulike illness or upper respiratory tract illness that causes pharyngitis and subsequent dysphagia. Delayed diagnosis is likely to occur in a young child, in the case of an unwitnessed ingestion. If the battery is lodged in the esophagus, presenting symptoms are limited to pain on swallowing, fever, vomiting, and tachypnea.

When a battery is lodged in the nares, the patient is likely to present with unilateral nasal discharge or pain. This presentation mandates evaluation for a nasal foreign body. Sinusitis, trauma, chemical irritants, and upper respiratory infections may produce a similar clinical picture.

A battery in the ear is likely to be discovered when otic discharge or pain is experienced. A thorough examination to exclude a foreign body is imperative. Mastoiditis, acute perforation of the tympanic membrane in otitis media, external otitis, and trauma to the ear canal may have similar presentations.

EMERGENCY DEPARTMENT EVALUATION

Prompt evaluation and definitive management are critical to successful outcomes. All patients suspected of disk battery ingestion or placement in a body cavity must be immediately evaluated to locate the battery. When ingestion is suspected, an x-ray should be obtained to exclude esophageal impaction. When a foreign body in the ear or nose is suspected based on history, pain, or discharge, thorough, direct visualization of these orifices is essential. The type of cell involved may be

identified from a replacement battery or product instructions listing the battery's imprint coding. Assistance in identifying a battery, and specific management guidelines, can be obtained by contacting the National Button Battery Ingestion Hotline and Study at 202-625-3333. Please report all cases to enhance identification of emerging product problems and to support changes in clinical management guidelines.

EMERGENCY DEPARTMENT MANAGEMENT

A battery lodged in the esophagus must be removed expeditiously by endoscopy. Any delay could convert a rather benign outcome to a lifelong disability. Emetics are ineffective and should be avoided. Removal with a magnet attached to the end of a nasogastric tube or with a balloon-tipped catheter passed beyond the battery is not recommended. Neither technique allows direct visualization, which is valuable in determining the degree of injury for subsequent management; endoscopic retrieval is less likely to cause esophageal perforation, a complication of blind intubation of the injured esophagus.

If the battery has traveled beyond the esophagus and the patient is asymptomatic, a regular diet and normal activity are advised to promote GI transit. These batteries do *not* need to be retrieved endoscopically or surgically. In routine cases, cathartics, H₂ antagonists, and metoclopramide are withheld; these therapies were investigated in the dog model without significant effect.⁵ Observation of the stool for battery passage is recommended. Slow passage of batteries that are clearly beyond the esophagus, in the absence of other symptoms, should not prompt intervention. Battery passage occurred within 24 hours in 23% of cases, within 48 hours in 61%, within 72 hours in 78%, and within 96 hours in 86%.⁸ Battery passage required more than 1 week in 5% of cases and more than 2 weeks in 1% of cases.

A battery that appears "hung up" in the bowel (beyond the esophagus) does not require removal, despite its persistence in a single location, as long as the patient remains asymptomatic. These batteries eventually pass. Minor GI symptoms, such as transient vomiting or stool discoloration without blood, are *not* indications for battery retrieval.

A notable exception is a battery 15 mm or more in diameter, especially when ingested by a child younger than 6 years. In these cases, if the battery fails to pass beyond the stomach within 48 hours, perhaps with the added benefit of metoclopramide and an H₂ antagonist, endoscopic removal is advised. Although no longer sold, an older 15.6-mm-diameter mercuric oxide cell is occasionally ingested, and because this type of battery is more likely to split in the GI tract, a known ingestion is an indication for more frequent x-ray evaluation (once or twice weekly). In other cases, if battery passage in the stool is not documented, an x-ray may be taken 1 to 2 weeks after the ingestion; this x-ray frequently shows that passage occurred unnoticed.

Batteries lodged in nasal or ear cavities require urgent removal. Nasal and otic medications should be avoided before battery removal because they bathe the battery in an electrolyte-rich medium and enhance corrosion, leakage, generation of an external current, and local injury. A magnetized instrument can be helpful in the removal process. Sedation and direct visualization through an operating microscope may be required. In this situation, a 1-mm 90-degree pick can be inserted, rotated behind the battery, then retracted. Treatment with nasal decongestants, oral antibiotics for sinusitis, and topical antibiotics for otitis external should be considered after removal.

DISPOSITION

Batteries lodged in the esophagus, nose, or ear require emergent removal. Subsequent inpatient or outpatient management is determined by the rapidity of intervention and the resulting local injury.

In contrast, patients with ingested batteries located beyond the esophagus who do not have signs or symptoms indicative of significant injury to the GI tract should be managed at home. A regular diet and normal activity will promote GI transit. Stools should be checked to confirm battery passage. Patients with significant symptoms should be evaluated by an endoscopist.

COMMON PITFALLS

- Failure to obtain an x-ray to identify the location of an ingested battery
- Failure to appreciate the fact that patients with esophageal battery lodgment may initially be relatively asymptomatic and symptoms may mimic upper respiratory infections
- Failure to suspect and look for batteries in the ear or nose
- Failure to appreciate that delayed identification and removal of batteries in the ear, nose, and esophagus may cause severe, permanent injuries
- Failure to appreciate that endoscopic or surgical removal is unnecessary and should be avoided in asymptomatic patients who have ingested batteries, including batteries that have split apart, located beyond the esophagus

CHAPTER 334

Disulfiram Poisoning

Edward P. Krenzelok

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Disulfiram (Antabuse) is used primarily to deter the use of ethanol in highly motivated alcoholics and those with recidivistic tendencies. Although the ethics of prescribing disulfiram and its efficacy have been questioned, it is still used extensively.⁸ Disulfiram is also used in the rubber industry as an antioxidant.

Disulfiram inhibits aldehyde dehydrogenase, thereby inhibiting the metabolism of acetaldehyde, the product of ethanol's metabolism by alcohol dehydrogenase, and causing acetaldehyde to accumulate and produce unpleasant effects. A metabolite of disulfiram, carbon disulfide, may also produce pyridoxine depletion, which may ultimately reduce gamma-aminobutyric acid (GABA) activity and result in the development of seizures (see [Chapter 347](#)). Disulfiram also interferes with the conversion of dopamine to norepinephrine, resulting in catecholamine depletion.

Toxicity associated with the use of disulfiram is common and sometimes serious. A disulfiram–ethanol reaction (DER) can be precipitated by ingesting small amounts of ethanol—much less than one drink (one 12-oz beer, a 5-oz glass of wine, or 1 oz of 80-proof liquor). DERs have developed after the ingestion of ethanol-containing products such as liquid cold medicine and mouthwash; the topical use of ethanol-containing products, such as aftershave lotions and even beer shampoo, may produce dermal reactions.

A blood ethanol concentration as low as 5 to 10 mg/dL may precipitate a DER and a full-blown DER is likely to occur when ethanol concentrations reach approximately 50 mg/dL.⁵ Alcohol-free beers may contain ethanol in concentrations of less than 0.5%.¹³ In a volunteer study, the consumption of six alcohol-free beers in 60 minutes resulted in breathalyzer ethanol concentrations of up to 100 mg/dL.¹³ The breathalyzer values were not correlated with blood ethanol concentrations, and it is possible that the results reflected a “mouthwash” effect. However, alcohol-free beers should be regarded as a possible explanation for a DER in a compliant patient. In addition to ethanol, many substances produce disulfiram-like reactions when used in conjunction with ethanol.

Disulfiram is administered in a dosage of 500 mg daily for 1 to 2 weeks, followed by a maintenance regimen of 125 to 500 mg daily thereafter.⁵ It is absorbed rapidly and acts quickly. Within 3 to 12 hours, the ingestion of ethanol will result in a DER.⁵ Giving test doses of disulfiram and ethanol is not recommended, even under controlled medical supervision, because DERs may be associated with profound morbidity.¹⁷

Disulfiram is eliminated slowly, and effects may persist for 2 weeks.⁵ Thus, a DER may occur well after disulfiram therapy has been discontinued. Up to 20% of the drug is eliminated unchanged in the feces; the rest is eliminated renally as metabolites.⁵ Disulfiram should not be prescribed by emergency physicians; the patient needs placement in an alcohol treatment program with continuous follow-up since the medicolegal considerations are too significant.

Disulfiram also produces various adverse drug reactions, but pure overdose is uncommon. American poison centers reported only 636 exposures to disulfiram in 1997.¹⁰ Only 12.3% were adverse reactions. Adverse effects are most prominent during the first 2 to 4 weeks of therapy and include drowsiness and general lethargy, headache, dermatitis, and a sulfur or garlic breath odor. More severe and less common reactions include sensorimotor peripheral neuropathies, psychosis, and hepatitis.

Disulfiram-induced hepatitis is reported to have a very precipitous onset.⁴ Orthotopic liver transplantation has been necessitated as a consequence of disulfiram-induced hepatic failure.¹⁴ Psychosis secondary to disulfiram therapy may be more common than thought previously.¹² Irreversible neuropsychiatric impairment has been reported.^{16,20} Prenatal exposure to disulfiram has been implicated in the development of fetal malformations.¹⁵ It is difficult to associate a direct teratogenic correlation with disulfiram use, because the concurrent or prior use of ethanol or other substances of abuse is often a complicating variable.

Overdoses of disulfiram represent extensions of the drug's pharmacology and adverse effects. The primary manifestation is central nervous system (CNS) depression, but seizures may occur because of the reduction of endogenous GABA.

CLINICAL PRESENTATION

Most DERs are mild and consist of extensive vasodilation in the head and neck, resulting in notable facial and neck flushing and throbbing, and a throbbing headache. Other common findings include dyspnea, diaphoresis, hyperventilation, nausea, vomiting, diarrhea, tachycardia, hypotension, anxiety, and confusion. Electrocardiogram (ECG) findings include sinus tachycardia with occasional premature atrial contractions, flattening of the T waves, and ST depression.

Symptoms usually begin within 30 minutes of ethanol ingestion and last several hours. Onset has been delayed for up to 12 hours, but rarely. An extended period of lethargy and somnolence may follow the reaction, and recovery without sequelae usually occurs. Intermittent myoclonus was reported as the sole neurologic manifestation of a DER.¹⁶ Severe DERs may result in secondary complications such as dehydration, myocardial infarction, and intracranial hemorrhage, as well as severe respiratory and cardiovascular collapse, profound coma, seizures, and death.

Overdose of only disulfiram results in distinctly different toxidromes in adults and children. Significant overdose in children is associated with a symptom complex similar to that of Reye syndrome, but without elevated ammonia and transaminase levels.¹ Children are extremely susceptible to disulfiram's CNS depressant properties and become ataxic, weak, and lethargic.¹ This state may progress to coma and has a poor prognosis.¹ Serious toxicity in children has been associated with ingestions of as little as 2.5 to 3.25 g.¹ Massive basal ganglia infarction, with persistent neurologic deficits, occurred in a 5-year-old who ingested an estimated 4.75 g of disulfiram.¹¹

Overdose in adults may result in excessive nausea and vomiting, mental confusion, and hemodynamic compromise. Although adults may also develop severe encephalopathy after an acute disulfiram overdose, they usually recover without sequelae.⁹ Toxic manifestations are most severe within the first 24 hours, but recovery may take several days.

DIFFERENTIAL DIAGNOSIS

Manifestations of the DER, adverse reactions, disulfiram overdose, and interactions between disulfiram and other agents can be difficult to distinguish from the manifestations of alcoholism itself. Specific clues to the DER include a history of alcoholism or disulfiram use, the onset of symptoms within 15 to 30 minutes of ethanol exposure, a positive blood ethanol level, flushing, a sulfur or garlic breath odor, and recovery in about 4 hours. Disulfiram overdose and DERs should be differentiated from other substances that produce disulfiram-like reactions, from disulfiram side effects and adverse reactions, and from interactions between disulfiram and other medications.

When a DER-like reaction occurs in a person with no history of alcoholism or disulfiram use, investigation must be directed toward medication use, recent dietary habits, and occupation. Agents that can produce disulfiram-like reactions when used in conjunction with ethanol include antimicrobials (e.g., griseofulvin, metronidazole, cephalosporins), oral hypoglycemic agents, monoamine oxidase inhibitors, mushrooms (inky caps [*Coprinus atramentarius*]), and other drugs and industrial chemicals.

Concurrent use of disulfiram with other medications, such as paraldehyde,⁵ cotrimoxazole,⁷ and tranlycypromine,² can precipitate a DER. Concomitant isoniazid use

can produce behavioral and neurologic aberrations. A contemporary drug interaction reference text should be used to evaluate patients who are taking disulfiram and experiencing unexplained symptoms.

Chronic disulfiram toxicity is supported by the absence of medical problems prior to the initiation of disulfiram therapy. Psychosis usually results only after high-dose, long-term use. Nonpsychotic catatonic behavior has been linked to chronic disulfiram use.⁵ Sensorimotor peripheral neuropathies are more prominent distally and occur after prolonged daily doses of 500 to 3,000 mg. Although not unique to disulfiram, a sulfur or garlic breath odor may establish the suspicion of a disulfiram-related problem in patients with a decreased level of consciousness or in those who are compromised behaviorally. Hepatotoxicity usually occurs 2 weeks to 12 months after therapy begins; it normally resolves promptly after discontinuing therapy. If the medical history fails to reveal the use of disulfiram, many of the symptoms may mistakenly be attributed to chronic alcoholism.

EMERGENCY DEPARTMENT EVALUATION

The history should include alcohol and drug use, the nature of symptoms, and the time between exposure and onset of symptoms. The physician should be persistent in tracing the source of ethanol. The physical examination should focus on vital signs and the skin, chest, abdominal, and neurologic examinations to rule out other pathology or trauma. Cardiac monitoring and an ECG are recommended if the patient is tachycardic or hypotensive or experiencing chest pain, in order to detect ischemia and dysrhythmias.

If a DER is suspected, the presence of ethanol in the blood is strong presumptive evidence. Disulfiram and metabolite concentrations are not readily available on a stat basis, and there is no established correlation between ethanol and disulfiram concentrations and the severity of DERs or patient prognosis in acute and chronic overdosage. Disulfiram interferes with a variety of laboratory tests and can also worsen the electroencephalogram. If disulfiram-induced hepatotoxicity is suspected, alanine aminotransferase is the most sensitive hepatic chemistry screening indicator.¹⁹

EMERGENCY DEPARTMENT MANAGEMENT

Because the DER can be life-threatening, patients should be transported to the emergency department by ambulance. Basic and advanced life-support measures should be instituted as necessary. Supportive care is the cornerstone of DER management. Profuse vomiting may occur, and the Mallory-Weiss syndrome may develop. Seizures may be treated conventionally with lorazepam, diazepam, and phenytoin.

Hypotension should be managed initially by placing the patient in the Trendelenburg position and giving intravenous crystalloid. Direct-acting pressors such as levarterenol (preferred because of catecholamine depletion) may be necessary in refractory cases. Dysrhythmias, ischemic changes, and metabolic derangements are treated conventionally. There are no specific antidotes to reverse the DER, but the use of glucose, thiamine, and naloxone should be considered in alcoholics with an altered mental status.

Fomepizole effectively inhibits alcohol dehydrogenase³ and, therefore, may have hypothetical benefit by preventing the metabolism of ethanol to acetaldehyde. Extracorporeal methods of removal have not been useful, but hemodialysis should be considered if the patient has high ethanol concentrations and the reaction is severe and prolonged. Other drug-ethanol reactions are similarly managed.

An acute overdose of disulfiram is also treated supportively. After the patient is stabilized, gastric decontamination should be considered. Activated charcoal is the preferred method. Ipecac syrup is not recommended, because vomiting may lead to aspiration and because syrup of ipecac contains ethanol (1.0% to 2.5%).

DISPOSITION

Most DERs resolve within about 2 to 4 hours and can be managed in the emergency department. Severe DERs may be life-threatening and mandate critical care management. Indications for admission to the intensive care unit include persistent or abnormal vital signs, metabolic derangements, persistent chest pain, and ECG changes (myocardial infarction must be ruled out). Moderate responses in patients with preexisting pathology also dictate admission. Alcoholics should be referred to alcohol rehabilitation or detoxification units once their DERs have resolved. Explicit instructions should be given to avoid all sources of ethanol.

Because of delayed toxicity, all patients with disulfiram overdoses should be admitted for 12 to 24 hours of observation or treatment. Depending on severity, patients suffering from adverse drug reactions may require inpatient monitoring or outpatient follow-up. Overdose patients should be referred for psychiatric evaluation before discharge.

COMMON PITFALLS

- Attributing symptoms of a DER or a disulfiram adverse effect to ethanol or underlying physical and behavioral pathology
- Failure to appreciate that foods, medicines, and "alcohol-free" beverages can be a source ethanol and provoke the DER
- Failure to appreciate that drugs and chemicals other than disulfiram can interact with ethanol and produce a DER-like reaction
- Failure to admit all patients with disulfiram overdosage
- Discharging a patient with a DER before symptoms have resolved
- Prescribing disulfiram or initiating such therapy in the emergency department
- Failure to warn patients with a DER to avoid further exposure to all sources of ethanol

CHAPTER 335

Dystonic Reactions

Mary A. McCormick and Anthony S. Manoguerra

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Dystonic reactions are seldom life-threatening, but the pain and discomfort of the bodily contortions that develop often prompt the victim to seek help in the emergency department. *Acute dystonias* (acute dyskinesias), along with parkinsonism and akathisia, are considered extrapyramidal manifestations of antipsychotic and other drug administration. These effects appear early and are reversible with reduction or discontinuation of the antipsychotic medication. *Tardive dyskinesia* refers to the sometimes irreversible involuntary movements that develop later. *Primary dystonia*, abnormal movements that occur spontaneously in the absence of drug treatment, is a separate diagnosis with similar manifestations. Dystonias may begin during infancy, childhood, adolescence, or adulthood for both the primary and secondary or environmentally produced types.¹³

Dystonias of all types probably result from an abnormality of neurotransmitter function in the basal ganglia. Several specific mechanisms have been proposed for those that are drug-induced. According to one theory, they are due to direct blockade of central dopaminergic receptors. Another theory proposes that the underlying mechanism involves both dopamine and acetylcholine, with an imbalance of neurotransmitters resulting in excessive cholinergic activity. A third theory holds that acute dystonic reactions may be caused by a combination of dopamine blockade and dopamine activation in the nigrostriatal system. The delay in onset of acute dystonias after the administration of antipsychotic medication may be explained by this mechanism. Dopamine synthesis and release have been shown to increase in response to an initial blockade of dopamine receptors. A single dose of an antipsychotic drug has also produced supersensitivity of dopamine receptors 24 to 48 hours after drug administration. This occurs at a time when plasma and red-cell drug concentrations are actually falling. Therefore, enhanced dopamine release, occurring simultaneously with the unblocking of supersensitive receptors, may result in acute dystonias.¹⁴

The true incidence of dystonia is unknown, but it occurs in about 2% of patients treated with phenothiazines and in about 25% of patients treated with haloperidol and the depot phenothiazines. Half of these dyskinesias develop within 48 hours, and 85% are apparent within 4 days of initiation of therapy. Such reactions are more common in men than in women.¹³

The patient who presents to the emergency department with a drug-induced dystonic reaction will probably be a young male, manifesting a buccolingual or torticollar reaction. The presence of a piperazine side chain attached to the phenothiazine nucleus increases the likelihood that a compound will produce a dystonic reaction. Symptoms seem to develop earlier with haloperidol than with other neuroleptics. The development of a dystonic reaction depends more on individual susceptibility than on the chemical structure, milligram potency, dosage, or duration of treatment. The drugs currently known or suspected to produce acute dystonic reactions are listed in [Table 335.1](#).

TABLE 335.1. Drugs Reported to Have Caused Acute Dystonic Reactions

Patients under age 15 and those with a family history of dystonia are at greatest risk of developing drug-induced dystonias. Another factor that may predispose a patient to dystonic reactions is a history of drug abuse (especially cocaine) or alcohol use.¹⁴

CLINICAL PRESENTATION

Any striated muscle group may be involved in a dystonic movement. Blepharospasm, progressing to oculogyric crisis, is the most common form of dystonia in the upper face. It usually begins with increased blinking of the eyelids. The muscles of the lower jaw most commonly involved are those of the pharynx and tongue. The term *oromandibular dystonia* describes the involvement of any combination of these muscles. Specifically, mandibular dystonia is manifested as a pulling down or up of the jaw. Lingual dystonia may present as either a sustained protrusion of the tongue or an upward deflection so that the tongue curves and touches the hard palate. In the neck region, torticollis is most common, although retrocollis and anterocollis may also occur. In most cases, the shoulder is elevated on the side toward which the chin is pointing. Jerking, rhythmic movements of the head may also occur. When the trunk is involved, twisting movements and postures such as lordosis, scoliosis, kyphosis, tortipelvis, and opisthotonos develop. Dystonic movements may begin as focal but become segmental as they spread in a contiguous manner. *Generalized dystonia* refers to involvement of the leg plus other body parts, with or without the trunk. Dystonic movements are usually continual, repetitive, and twisting, varying in speed from rapid to slow and being sustained from seconds to minutes at the height of the involuntary contraction.

The prognosis is excellent for patients with drug-induced dystonias when correctly treated. Cardiorespiratory arrest and death have been linked to metoclopramide in a case in which diagnosis and treatment were delayed.

DIFFERENTIAL DIAGNOSIS

Dystonic reactions have been misdiagnosed as tetanus, hysterical conversion, and even seizure disorders. Children with such abnormal movements have been thought to have encephalitis or meningitis.

EMERGENCY DEPARTMENT EVALUATION

The patient, family, or friends should be asked about the recent use of medications. Physical examination is remarkable for abnormal posturing or movements. Urinalysis may provide information about recent drug use in a patient who is unable or unwilling to provide a history.

EMERGENCY DEPARTMENT MANAGEMENT

Because dystonic reactions are not usually associated with drug overdosage, gastrointestinal (GI) decontamination is seldom necessary. Induction of emesis, administration of activated charcoal, or gastric lavage could lead to airway compromise in the patient with abnormal head or neck posturing or swallowing difficulty. In

addition, charcoal may prevent the absorption of oral antidotes. If indicated, GI decontamination should be done after the dystonic reaction has been treated.

Administration of an anticholinergic medication rapidly reverses the symptoms, presumably because of restoration of the cholinergic–dopaminergic balance in nigrostriatal neurons. Diphenhydramine (Benadryl) and benztropine mesylate (Cogentin) are used more often than biperiden (Akineton) or trihexyphenidyl (Artane). Intravenous administration is preferable to intramuscular or oral administration. Symptoms abate within 2 minutes and completely resolve within 15 minutes when the intravenous route is used; muscle relaxation begins in 30 minutes but may not be complete for 90 minutes when the antidote is given intramuscularly or orally. Benztropine has been advocated over diphenhydramine because of fewer side effects and more rapid improvement of both objective and subjective findings, regardless of route. One report describes a patient who responded minimally to multiple doses of diphenhydramine but completely to a subsequent dose of benztropine.¹⁴ Diphenhydramine should be used in children under age 3, because benztropine is contraindicated in this age group. Drowsiness should be anticipated as a side effect of anticholinergic administration, especially with diphenhydramine.

After reversal of the reaction, treatment should continue with an oral agent for 72 hours to prevent a relapse.

The usual dose of benztropine is 1 to 2 mg for adults and 0.02 to 0.05 mg/kg for children age 3 years or older, given intravenously over 2 minutes, followed by the same dose given orally twice a day for 3 days. The dose of diphenhydramine is 50 to 100 mg for adults and 1 to 2 mg/kg for children, given intravenously over 2 minutes, followed by 12.5 to 50.0 mg orally three or four times a day for 3 days. Some patients require more than one dose of intravenous medication to control the reaction.

DISPOSITION

The patient may be discharged after the acute dystonia resolves. Consultation with the prescribing psychiatrist is advisable if the patient is to remain on neuroleptic medication. When anticholinergics are prescribed, patients should be advised not to drive or perform potentially dangerous activities for 72 hours. They should be instructed to return if symptoms recur.

COMMON PITFALLS

- Dystonic reactions may be delayed in onset 12 to 24 hours from the time of drug ingestion.
- The timely administration of an anticholinergic medication may prove to be diagnostic as well as therapeutic.
- Dystonic reactions are not usually the result of an overdose; because of their delayed onset, GI decontamination is seldom indicated and may be dangerous in patients with head or neck involvement.
- Prescribing oral anticholinergic medication for 3 days after acute treatment may prevent relapses.

CHAPTER 336

Ergot Alkaloid Poisoning

Leslie S. Carroll and Donald B. Kunkel

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Ergot alkaloids are natural and semisynthetic derivatives of compounds produced by parasitic fungi of the genus *Claviceps* (most classically, *Claviceps purpurea*).¹⁴ Various flowering grasses and grains, particularly rye, are susceptible to fungal infestation during warm, wet weather. Historically, epidemics of ergotism resulted from the ingestion of bread made from contaminated grain. Ergotism was known as holy fire (*ignis sacer*) or St. Anthony's fire in the Middle Ages; victims claimed that a pilgrimage to the Shrine of St. Anthony relieved their symptoms. The mold *Claviceps* did not infect the rye in the area of the shrine, so spontaneous cures probably did result. Today, ergot poisoning is caused almost exclusively by the ingestion or parenteral administration of medicinal preparations.

Ergot alkaloids are derivatives of the tetracyclic compound 6-methylergoline. This compound is structurally similar to the amine neurotransmitters: dopamine, norepinephrine, and serotonin. There are three classes of ergot alkaloids, including the naturally occurring amine and amino acid groups and the synthetic dihydrogenated groups. The naturally occurring ergot alkaloids consist of a lysergic acid base; the amine alkaloids contain amine side chains, and the amino acid alkaloids contain polypeptide side chains.^{1c} The synthetic alkaloid also contains a lysergic acid base that has been dehydrogenated. Individual agents are listed in [Table 336.1](#). The structural similarity between the lysergic acid nucleus of ergot alkaloids and the endogenous amines dopamine, norepinephrine, and serotonin accounts for their pharmacologic activity.² Effects are complex and may include simultaneous stimulation and blockade of peripheral and central neuroreceptors.

TABLE 336.1. Ergot Alkaloids

Physiologic effects are variable and depend on the particular alkaloid's affinity and specificity for receptors, the dose of the drug, individual sensitivity, the route of administration, underlying disease states, and preexisting vascular tone. For instance, ergotamine produces both partial alpha-agonist and partial alpha-antagonist effects; in addition, the drug mediates vasoconstrictor action by way of a direct effect on serotonin receptors¹⁶ and vasodilatation secondary to central vasomotor center depression. The net clinical effect may be either vasoconstriction or vasodilation, depending on the dose taken and preexisting vascular tone. Variable activities of the ergot alkaloid derivatives may produce unexpected complications, such as acute myocardial infarction.⁶

Ergotamine, the classic ergot prototype drug, is the agent most commonly involved in poisoning. It has been used for migraine and other vascular headaches because of its cranial vasoconstrictive effect, and it can be given orally, sublingually, rectally, parenterally, and by inhalation. Rectal bioavailability is 20-fold greater than an equivalent oral dose.¹⁷ Suppository formulations of ergotamine combined with caffeine and other products are popular and are implicated in many cases of iatrogenic ergotism. The usual recommendations for rectal ergotamine use (2 mg rectally at the beginning of a headache, not to exceed 10 mg a week) may be grossly exceeded and may produce true physical dependency with withdrawal headaches, prompting more ergotamine use.¹⁸ Although severe vasospasm has been reported with single-dose use of ergotamine, it is the setting of cyclic and increasing self-dosing with ergotamine by any route that usually precedes vasospastic toxicity.⁵

Bromocriptine is used in the treatment of hyperprolactinemia and Parkinson disease. Because of cardiovascular toxicity, bromocriptine must be used with caution when prescribed for the suppression of postpartum lactation. Usual adult doses range from 1.25 to 7.5 mg two to six times a day and vary with the condition being treated.

CLINICAL PRESENTATION

Toxicity of two major forms—gangrenous and convulsive—has been historically recorded after ingestion of contaminated grain products. The most recent natural outbreak of ergotism was of the gangrenous form and occurred in Ethiopia from 1977 to 1978 as a consequence of the ingestion of ergot-infested wild oats.⁹ In the gangrenous form of natural ergotism, the clinical progression is of early paresthesias of the extremities, vomiting, diarrhea, and, finally, excruciating extremity pain, heralding the onset of gangrene. The convulsive form terminates in painful spasms of limb muscles, culminating in epileptic-like activity.¹¹

Toxicity from an acute overdose of ergot alkaloids is unusual. A 13-month-old child survived a dose of 15 mg of ergotamine (plus 1 g of phenobarbital), whereas a dose of 12 mg of ergotamine (plus 1.2 g of caffeine) was fatal to a 14-month-old child.¹² Seven cases of acute neonatal toxicity resulted from inadvertent intramuscular administration of ergotamine (0.25 to 0.5 mg), which culminated in reversible encephalopathy, seizures, peripheral vasoconstriction, and occasional oliguria.⁴ An obese man who ingested 120 mg of ergotamine (plus 3 g of cyclizine and 6 g of caffeine) developed myocardial ischemia and peripheral arterial spasm.¹² Symptoms of acute toxicity may include nausea, vomiting, diarrhea, severe thirst, formication (skin tingling), chest pain, bradycardia or tachycardia, hypotension, confusion, convulsions, or coma. Overdose in a gravid female may result in fetal death.¹ The use of dihydroergotamine–heparin–lidocaine as prophylaxis against postoperative venous thrombotic disease has caused severe peripheral ischemia.⁷

Chronic toxicity of ergotamine may present with a multitude of neurologic, gastrointestinal (GI), and vascular symptoms.²⁰ Neurologic complications include lassitude, impaired mental function, headaches, vertigo, psychoses, convulsions, and coma. Nausea, vomiting, diarrhea, and abdominal pain may occur. As in the acute overdose, abortions may occur. Vascular effects are usually prominent and may involve both the venous and arterial circulations. Angiography may reveal spasm, formation of collaterals, and intravascular thrombi. Vascular involvement may be unilateral or bilateral, and virtually any vascular distribution may be involved. The legs are most often involved; signs and symptoms include pallor, numbness, progressive pain, progressive loss of pulses, demarcation of ischemic areas, and, finally, frank gangrene. Other complications include angina, myocardial infarction, and stroke. Factors that may accelerate ergot toxicity include tobacco smoking, concomitant use of beta-blocker medications, sepsis, and hepatic or renal disease.

Bromocriptine poisoning may result in nausea, vomiting, dizziness, lethargy, confusion, hallucinations, and either hypertension or hypotension.¹³

Sumatriptan was approved for the acute treatment of migraine headache in December 1992. The compound is structurally similar to the indole serotonin but does not have the tetracyclic structure particular to the ergots. The side-effect profile, however, is similar to the ergots secondary to vasoconstrictive properties. Sumatriptan is a serotonin 1D receptor agonist that results in extracranial vasoconstriction and resultant resolution of migraine headache. Chest tightness has been reported in 3%

to 5% of patients taking sumatriptan.¹⁹ A 47-year-old woman developed an acute myocardial infarction immediately after taking sumatriptan.¹⁵ Two cases of severe ventricular dysrhythmias have been described subsequent to sumatriptan administration.³ Thus, sumatriptan should be given cautiously, especially in patients experiencing chest pain after administration.

DIFFERENTIAL DIAGNOSIS

The diagnosis of ergotism should become readily apparent when the history reveals the use of an ergot derivative. Unfortunately, however, patients may be reluctant to admit to self-use of ergot preparations, and the entire range of causes of vasoocclusive disease may need to be considered. Included in the differential are arteriosclerosis, compartmental and entrapment syndromes, Raynaud disease, thromboangiitis obliterans, thromboembolic disease, vasculitides, and drug-induced vasospasm (e.g., ingestion of amphetamines, cocaine, and other sympathomimetics).

EMERGENCY DEPARTMENT EVALUATION

Details regarding the use, abuse, and accidental or suicidal ingestion of ergot preparations are of paramount importance in the clinical evaluation of vasospastic disease. Physical examination should include a careful evaluation of central nervous system function, cardiovascular and peripheral vascular status, and potential pregnancy, in addition to a meticulous general examination. Doppler-technique pulse measurements, digital pulse monitoring, skin temperature recordings, and other noninvasive techniques should be considered as objective markers of peripheral vasospasm. Laboratory tests that measure plasma drug levels have been developed but are unavailable for routine use and are probably not clinically helpful.^{12,16} Laboratory assessment of renal and hepatic function, baseline coagulation tests, pregnancy testing, drug screens to rule out other agents, and an electrocardiogram are indicated.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures are instituted as necessary. In the acute overdose, GI decontamination is performed. In chronic presentations, all ergot preparations, as well as caffeine and nicotine, must be discontinued. No current evidence supports the efficacy of extracorporeal removal procedures (hemodialysis and hemoperfusion) or repeated oral doses of activated charcoal. Immediate attention is directed toward treating emergent catastrophes such as acute myocardial infarction, seizures, and threatened abortion.

Ischemic extremities must be protected from trauma and should be warmed but not overheated. Numerous drugs have been recommended to reverse vasospasm, including nitroprusside (the current drug of choice for severe spasm),²⁰ prazosin, nitroglycerin, and nifedipine.⁸ Oral cyproheptadine, a serotonin receptor antagonist, has been used adjunctively. Vascular stasis and the formation of thrombi may require the use of heparin and low-molecular-weight dextran; streptokinase has been recommended to dissolve thrombi. Intraarterial balloon dilation and the use of hyperbaric oxygen have been recommended as adjuncts to therapy. The optimal management of ergot-induced vasospasm is unsettled and requires consideration of multiple modalities.

Bromocriptine overdoses require supportive care, with attention to reversal of hypotension with fluids and protection from self-injury if confusion and agitation are present.¹³

DISPOSITION

Asymptomatic patients with acute overdoses are observed for 4 to 6 hours. Those who become symptomatic and those with vasospastic sequelae are admitted to a facility that can perform vascular diagnostic procedures (e.g., arteriography) and continuous vascular monitoring and can administer anticoagulant and vasodilatory drugs. Physicians with expertise in the management of peripheral vascular diseases and in the use of vasoactive agents (e.g., vascular surgeons) should be consulted. After the toxic episode resolves, consideration must be given to continuing care of headache symptomatology.

COMMON PITFALLS

- Failure to inform patients of the toxic effects of ergot preparations, and failure to carefully monitor ergot use
- Failure to consider ergot poisoning in the differential diagnosis of vasoocclusive disease
- Failure to appreciate that almost any vascular bed may be affected by ergot, potentially giving rise to diverse clinical presentations
- Continuing ergot therapy in the presence of early vasospastic signs or symptoms
- Failure to consider the additional toxic effects of concomitantly used drugs, such as caffeine, beta blockers, and nicotine

CHAPTER 337

Ethanol, Isopropanol, and Acetone Poisoning

Susan S. Fish

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Ethanol (ethyl alcohol or “alcohol”) is probably the oldest and most commonly ingested poison. In addition to beverages, sources include aftershaves, antiseptics, colognes, mouthwashes, and perfumes. Beer and ale are 2% to 8% ethanol, wine is 10% to 20% ethanol, and liquor is 20% to 95% ethanol. Other sources vary in alcohol content but may be as high as 90% ethanol.

The acute effects of ethanol are seen primarily on the central nervous system (CNS), where the drug is thought to act directly on neurons, similar to the action of general anesthetics.³ Ethanol appears to interfere with ion transport at neuronal membranes, preventing the generation of electrical impulses. The neurons of the reticular activating system are the first to become affected as blood alcohol concentrations rise.

Ethanol is rapidly absorbed from the gastrointestinal (GI) tract, primarily the small intestine, although, in an overdose, complete absorption may not occur for up to 6 hours. Food slows absorption by delaying gastric emptying time. Alcohol distributes into body tissues and fluids with an apparent volume of distribution of about 0.6 L/kg.

Metabolism is primarily by hepatic enzymatic oxidation. Ethanol exhibits zero-order elimination (constant elimination; the serum concentration decreases by a constant amount per unit of time) at concentrations between 20 and 300 mg/dL and first-order elimination (concentration-dependent; the serum concentration decreases by half during each half-life) at concentrations below 20 mg/dL or above 300 mg/dL.¹⁶ The average nontolerant person metabolizes about 100 mg/kg/h, reducing the blood alcohol concentration by 15 to 20 mg/dL/h. Enzyme induction in tolerant patients can increase metabolism to 175 mg/kg/h, reducing the blood alcohol concentration by 30 to 40 mg/dL/h. At high concentrations, first-order elimination half-lives of 4 to 5 hours have been reported. A lethal dose is said to be 5 to 8 g/kg in adults and 3 g/kg in children, but there is substantial interpatient variability.

Isopropanol (isopropyl alcohol) is used in the home and in industry as a disinfectant and solvent. It is an ingredient in many products, including rubbing alcohol, some radiator and fuel-line antifreezes, window cleaners, animal repellents, and aftershaves.¹¹ Unfortunately, these products also frequently contain ethanol or the more toxic methanol or ethylene glycol. Isopropanol is the most commonly ingested nonbeverage alcohol, despite its slightly bitter taste and distinctive odor.

Isopropanol is rapidly absorbed from the intestine after ingestion. It is also well absorbed rectally. Toxicity has been reported after sponge baths with isopropanol, but the route of absorption is not agreed on; experimental evidence supports both dermal and inhalation absorption.¹² The apparent volume of distribution is about 0.6 L/kg, that of total body water. Isopropanol, like ethanol, is metabolized by alcohol dehydrogenase.^{2,13,14} The metabolite acetone is eliminated by the kidney and lungs, producing a sweet ketotic odor on the breath. Isopropanol is secreted into the saliva and gastric juices, but the amounts found in these fluids are probably clinically insignificant. Isopropanol exhibits first-order elimination, with an elimination half-life of about 6 hours in nonalcoholics and 3 to 4 hours in alcoholics. A fatal dose is said to be about 8 oz in an adult, although, as with ethanol, much variability is seen.¹

Acetone is found in household and industrial cleaners and solvents, and is a major ingredient in most fingernail polish removers. In diabetic ketoacidosis, endogenous production due to fat metabolism can produce acetone concentrations of 10 to 70 mg/dL. Acetone is rapidly absorbed after ingestion or inhalation. The apparent volume of distribution is 0.8 L/kg. Acetone is metabolized to glucose by saturable enzymes. The major route of elimination is by the lungs, producing a fruity breath odor. Acetone is also minimally eliminated unchanged by the kidney. The elimination half-life is 20 to 30 hours in adults and about 11 hours in infants.^{10,17} Toxicity in children is seen after ingestion of 2 to 3 mL/kg. An ingested dose of 200 to 400 mL in an adult produces CNS depression but no serious complications.

CLINICAL PRESENTATION

Ethanol, a CNS depressant, initially produces a paradoxical CNS stimulation due to disinhibition.³ During this phase, an intoxicated patient may appear energized and loquacious. As ethanol levels rise, the patient may become aggressive, abusive, irritable, dysarthric, confused, disoriented, ataxic, and lethargic. Severe intoxication may lead to coma and respiratory depression. Aspiration pneumonia may occur due to suppression of the gag reflex and a tendency to vomit, caused by the irritating effects of ethanol on the GI tract. Physical examination may reveal tachycardia, hypotension, hypothermia, hypoventilation, mydriasis, and nystagmus. Rarely, alcohol induces a histamine-mediated urticaria. Hypoglycemia, common in children but rare in adults,¹⁹ may be present primarily because of an inhibition of gluconeogenesis by ethanol; this may lead to confusion, seizures, or coma. Death may result from respiratory depression.

In nontolerant people, there appears to be a good correlation between the blood alcohol concentration and the degree of neurologic impairment, with signs of intoxication beginning as blood levels reach 50 to 100 mg/dL. When the blood alcohol concentration approaches 200 mg/dL, motor skills and speech are impaired; at 300 mg/dL, equilibrium, perception, and vision are altered; and at levels above 450 to 500 mg/dL, coma, respiratory depression, and peripheral vascular collapse occur. However, people who are tolerant to ethanol have been reported not only to survive incredibly high concentrations, but also to be resistant to many of the toxic effects. A 24-year-old woman presented to an emergency department complaining of abdominal pain and appearing agitated and confused but oriented to person and place; she was discovered to have a blood alcohol level of 1,510 mg/dL.⁶

Isopropanol is considered twice as toxic as ethanol, although some disagree whether this applies to the clinical situation.^{9,11,20} The signs and symptoms of isopropanol toxicity are similar to those of ethanol toxicity with only a few exceptions. The early disinhibition seen with ethanol is absent with isopropanol. CNS depression may persist for more than 24 hours, long after levels of isopropanol are undetectable. This prolonged CNS depression is due to the metabolite acetone, which has a long elimination half-life (20 to 30 hours in adults).¹⁰ Hypoglycemia, a result of altered gluconeogenesis, is rare but may contribute to the CNS depression. Ketonemia and ketonuria commonly occur. Pupil size varies, and both miosis and mydriasis have been reported. GI irritation, a hallmark of isopropanol toxicity, may manifest as abdominal pain, vomiting, gastritis, and hematemesis, which may lead to hypotension.⁷

Hypothermia may also be seen. Tachycardia is the most common finding. Fatalities have occurred in patients who were in deep coma and were hypotensive. Coma in the absence of hypotension did not indicate a poor prognosis.

Blood levels of isopropanol do not correlate well with toxic symptoms, although toxicity is seen with levels of 50 to 100 mg/dL.⁹ Most comatose patients have levels above 125 mg/dL, and death may occur with levels above 200 mg/dL. However, patients with levels above 500 mg/dL have recovered.

The signs and symptoms of acetone intoxication are also similar to those of ethanol intoxication, and the doses required to produce toxicity are also similar. However, acetone has a greater anesthetic potency than ethanol. After an acetone ingestion, nausea, vomiting, and gastric hemorrhage may occur. Inhalation of acetone can produce coughing, bronchial irritation, and eye irritation. Pharyngeal irritation and soft-palate erythema and erosions have been reported. CNS depression causes drowsiness, weakness, dysarthria, and ataxia. Lethargy can progress to coma more rapidly with acetone than with ethanol. Mild hyperglycemia and ketonemia can mimic acute diabetic coma. Acute tubular necrosis has been reported.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis should include the ingestion of other CNS depressants, as well as other causes of coma, such as metabolic derangements, CNS infection, head trauma, and tumors. Other causes of increased serum osmolality include ethylene glycol and methanol ingestion. Ketosis caused by isopropanol and acetone

intoxication should be differentiated from that secondary to alcoholic and diabetic ketoacidosis, starvation ketosis, and salicylate intoxication.

Acetone interferes with the measurement of creatinine by automated chemistry analyzers that utilize a colorimetric change based on the Jaffe method and can result in a falsely elevated creatinine value.⁵ Hence, the finding of an elevated creatinine in an intoxicated patient with a normal blood urea nitrogen (BUN) is suggestive of acetone or isopropanol ingestion.

EMERGENCY DEPARTMENT EVALUATION

The history should document the type, amount, and alcohol or acetone concentration of the substance ingested; the route and time of ingestion; the ingestion of any other agents; chronic use of drugs or alcohol; the nature and time of onset of symptoms; and medical history. A history of trauma or disulfiram use should be specifically elicited.

The physical examination should focus on the mental status, neurologic function, and GI and cardiopulmonary systems, with frequent monitoring of vital signs for tachycardia, hypothermia, hypotension, and hypoventilation. The breath odor may provide a clue to the diagnosis (e.g., the fruity odor of acetone and isopropanol). The patient should be examined for evidence of concomitant trauma.

Laboratory tests should include a quantitative serum level of the ingested agent, routine chemistries, and a blood glucose determination.⁴ Gas chromatography is the preferred testing method. A Breathalyzer may give a quick estimate of the blood alcohol concentration, but reliable readings require patient cooperation.⁸ Isopropanol, methanol, and nonalcoholic beer may also result in a positive breath analysis.¹⁵ Factors that interfere with the Breathalyzer include recent use (within 15 to 30 minutes) of ethanol-containing products (e.g., inhaled bronchodilators), methanol or isopropanol ingestion, recent belching or vomiting, and obstructive pulmonary disease. Serum ethanol concentrations are about 10% to 15% higher than whole-blood concentrations, depending on the patient's hematocrit. Enzymatic methods using alcohol dehydrogenase do not differentiate among the alcohols (ethanol, isopropanol, methanol, and ethylene glycol) and should not be used. Deaths have occurred when blood levels continue to rise while the patient is put in a corner to "sleep it off." If there is doubt, additional levels should be obtained.

Arterial blood gas analysis and serum and urine ketone measurements may be helpful. Ketonemia and ketonuria may suggest isopropanol or acetone intoxication, but their absence does not rule out these ingestions.

Measuring the serum osmolality by freezing-point depression (not the vapor-pressure method) may be helpful if quantitative serum levels are not immediately available. A measured osmolality greater than that calculated from the serum levels of sodium, BUN, and glucose ($2 \times \text{Na} + \text{BUN}/3 + \text{glucose}/18$) of more than 10 mOsmol/kg suggests the presence of a low-molecular-weight compound such as ethanol, ethylene glycol, acetone, isopropanol, and methanol. If the agent ingested is known, its concentration may be estimated from the difference between the measured and calculated osmolalities (the osmolar gap). The gap increases by about 1 mOsmol/kg for each 4.3 mg/dL of ethanol, 5.5 mg/dL of acetone, and 5.9 mg/dL of isopropanol present.¹¹

EMERGENCY DEPARTMENT MANAGEMENT

The treatment of a patient who has ingested a large amount of ethanol, isopropanol, or acetone is primarily supportive. Breathing is evaluated, and the patient is endotracheally intubated, as needed. A comatose patient is given thiamine 100 mg intravenously (i.v.), dextrose 25 g i.v., and naloxone 2 mg i.v., if indicated. Although there are reports that naloxone has reversed ethanol-induced coma, no controlled studies have shown its efficacy in this situation. Studies of flumazenil's ability to reverse ethanol-induced CNS depression have shown equivocal results. Activated charcoal is of questionable benefit, although its administration with a cathartic is probably indicated for adsorption of possible coingestants.¹³ The hypothermic patient should be warmed (see [Chapter 386](#)). Sodium bicarbonate may be given if there is a substantial lactic acidosis. Fluids and electrolytes are replaced as needed. In rare cases of hypotension unresponsive to crystalloid administration, vasopressors may be necessary. Although fructose may accelerate the metabolism of ethanol by as much as 25%, the adverse effects of vomiting, abdominal pain, lactic acidosis, and shock prohibit its use.

Patients with ethanol intoxication usually recover within 12 hours, but recovery from severe isopropanol or acetone poisoning may take 2 to 3 days.^{9,11} Hemodialysis can be used in severe cases unresponsive to supportive therapy to increase the elimination of all of these agents.¹⁸

DISPOSITION

Patients with acute ethanol intoxication seldom require admission unless a complication such as aspiration is present. Even those who are comatose improve within hours with supportive care. Only if they cannot be treated and observed in the emergency department do such patients require admission. In contrast, patients with moderate-to-severe isopropanol or acetone poisoning and high blood levels of these agents usually require a day or two for toxicity to resolve; therefore, they should be admitted. Clinical severity (e.g., need for airway protection and mechanical ventilation, severe acid-base disturbances) should be used to determine the appropriate level of hospital care.

COMMON PITFALLS

- Failure to appreciate that tolerance, trauma, coingestants, hypoglycemia, and underlying disease may alter a patient's response to a particular level of alcohol, and to treat the patient, not the alcohol level
- Failure to rule out coingestions and traumatic injuries, particularly if the clinical severity is inconsistent with the alcohol level
- Failure to appreciate that nutritional deficiencies in chronic alcoholics can also cause confusion and to consider empiric therapy with thiamine for Wernicke's encephalopathy and dextrose (or a bedside glucose level) for hypoglycemia
- Failure to recognize alcohol withdrawal and to appreciate that withdrawal can occur in the presence of a positive blood alcohol concentration
- Assuming that the alcohol level has peaked by the time the patient is examined and failing to monitor and reevaluate the intoxicated patient
- Failure to protect the airway and to evaluate and support respiratory function in patients with CNS depression
- Failure to appreciate that acetone causes falsely elevated serum creatinine levels, and diagnosing renal failure when the BUN is normal
- Failure to appreciate that enzymatic methods may underestimate isopropanol concentrations
- Failure to appreciate that the serum osmolality is useful for estimating acetone and alcohol concentrations only if it is measured by the freezing-point depression method

CHAPTER 338

Ethylene Glycol Poisoning

Michael J. Burns and Francis P. Renzi

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Ethylene glycol (EG; 1,2-ethanediol) is a colorless, odorless, sweet-tasting, water-soluble liquid that has a wide variety of household and commercial uses.¹ Because of its low freezing point (−13°C) and high boiling point (198°C), EG is commonly used as an antifreeze-coolant. Automotive antifreeze contains about 95% EG and is the source of most EG poisonings. EG may also be found in adhesives, brake and hydraulic fluids, cosmetics, de-icers, detergents, fire extinguishers, inks, lacquers, paints, pesticides, polishes, and some windshield-washer fluids. The majority of exposures occur unintentionally through misuse or by accident. Intentional ingestion of EG for purposes of inebriation or suicide accounts for a minority of exposures but the most fatalities. Widespread availability, interesting color, and pleasant, bittersweet taste likely account for its ingestion by alcoholics seeking an ethanol substitute and by children.

Unmetabolized EG produces about the same degree of central nervous system (CNS) depression and has a similar range of toxicity as ethanol. Serious toxicity (anion gap metabolic acidosis, coma, seizures, cardiopulmonary dysfunction, and acute renal failure) results largely from accumulation of the toxic metabolites, glycolic and oxalic acids.^{1,4,6,9,10 and 11}

EG is rapidly absorbed from the gastrointestinal tract and distributed throughout total body water (0.6 L/kg). Peak blood concentration occurs about 2 hours after enteral administration.¹⁰ About 20% to 50% of EG is excreted unchanged in the urine.¹⁰ The remaining EG is metabolized in the liver to a variety of compounds with varying toxicities (Fig. 338.1).

Figure 338.1. Metabolism of ethylene glycol. *Solid lines*, known pathways of metabolism; *dotted lines*, postulated pathways of metabolism.

The first step in the metabolism of EG is its oxidation to glycoaldehyde by alcohol dehydrogenase.^{9,10} Because alcohol dehydrogenase has a much higher affinity for ethanol and fomepizole (synthetic inhibitor) than for EG, these substrates are preferentially bound, when present, with EG. Their presence inhibits the metabolism of EG sixfold and prevents the formation of toxic metabolites.^{1,2 and 3,5,7,9,10,17}

When formed, glycoaldehyde is rapidly metabolized by aldehyde dehydrogenase to glycolic acid, which is further metabolized slowly to glyoxylic acid. Glycolic acid oxidation is rate-limiting; for this reason, it tends to accumulate.^{4,11,14} Glycolic acid accumulation correlates with the increased anion gap, decreased arterial pH, development of renal injury, and mortality associated with advanced EG poisoning.^{3,4,6,10,11,14}

Glycolic acid is directly nephrotoxic and causes renal tubular damage and interstitial edema.¹⁵ Once formed, glyoxylic acid is rapidly oxidized by one of several pathways. Its principal metabolite, oxalic acid, rapidly precipitates as calcium oxalate crystals in various organs and tissues.¹¹ Calcium oxalate precipitation within renal tubules contributes significantly to the development of acute tubular necrosis and renal insufficiency.¹⁰ Crystal deposition is likely responsible for much of the end-organ injury that results from serious EG poisoning (e.g., cerebral and pulmonary edema).

Significant systemic toxicity from EG occurs only after ingestion.^{1,10} Skin exposure may cause minor irritation, and direct eye contact may result in conjunctivitis, chemosis, and iridocyclitis.¹⁸ Inhalation of EG vapors is not normally hazardous. The toxic and lethal doses of EG after acute ingestion vary. Death has been reported in two men who shared 60 mL of 95% EG, but one patient survived after ingesting about 2 L of EG.^{17,19} Because as little as 0.1 mL/kg of pure EG may result in potentially toxic blood concentrations, the ingestion of even a mouthful of EG should be considered hazardous. Conversely, although the oral lethal dose is approximately 1.5 mL/kg, the relationship between the amount consumed and prognosis is usually poor.^{5,9,10}

CLINICAL PRESENTATION

With EG poisoning, three distinct stages of organ system involvement—CNS, cardiopulmonary, and renal—have been classically described, but the onset, progression, and confluence of these stages vary widely.^{1,5,10} Thirty minutes to 12 hours after ingestion, CNS signs and symptoms predominate. Initially, slurred speech, ataxia, nystagmus, and lethargy occur. The patient may appear drunk but lacks the odor of ethanol; instead, a faint, sweet, or aromatic odor may be detected on the breath. Nausea, vomiting, and abdominal pain may also be present.

At this early stage, the presence of an elevated osmolal gap may provide a clue to the diagnosis of EG poisoning.^{5,9,10} The difference between the measured serum osmolality and the calculated osmolality ($[2 \times \text{sodium}] + [\text{glucose}/18] + [\text{blood urea nitrogen}/2.8] + [\text{serum ethanol concentration}/4.6]$) is the corrected osmolal gap. Normally, serum osmolality ranges from 280 to 300 mOsmol/kg H₂O, with an corrected osmolal gap of −2 (±6) mOsmol/kg H₂O.⁸ Low-molecular-weight solutes such as EG, acetone, isopropanol, and methanol increase serum osmolality, and thus increase the osmolal gap. Osmolality measured by the freezing-point depression (not vapor pressure) method will detect these agents. A large osmolal gap (particularly if greater than 25) is suggestive of toxic alcohol poisoning.^{5,10} A small osmolal gap, however, cannot be used to exclude significant EG poisoning.⁸ EG poisoning should be confirmed by the presence of EG in serum or urine.

Following a latent period of 3 to 12 hours, the signs and symptoms caused by accumulated toxic metabolites develop. CNS depression progresses to stupor and coma. Hyporeflexia, tremors, tetany, and seizures (both focal and generalized) may occur. Severe CNS disturbances may reflect the development of cerebral edema and are associated with calcium oxalate deposition within the brain and leptomeninges.¹⁰ A decreased serum bicarbonate may be seen as early as 3 hours following EG ingestion.^{1,2,5,7} Hyperventilation signifies the development of an anion gap metabolic acidosis.

Cardiopulmonary signs and symptoms, such as hypertension, tachycardia, dysrhythmias, and pulmonary edema, develop 12 to 36 hours after the ingestion of EG. During this stage, tachypnea and Kussmaul respirations reflect a progressively worsening anion gap metabolic acidosis. A normal anion gap (serum sodium minus chloride and bicarbonate) is 12 (±2) mEq/L and represents unmeasured anions in the serum. The presence of nonvolatile acids, such as formic acid, keto acid, lactic

acid, or, in the case of EG poisoning, glycolic acid, increases the anion gap.

If the history is not suggestive of lactic acidosis or ketoacidosis, then a high osmolal gap with anion gap metabolic acidosis strongly points toward EG or methanol poisoning.^{5,10} Present in approximately 80% of patients, anion gap metabolic acidosis is the most frequently reported laboratory abnormality associated with EG poisoning.^{3,13} Its absence in a patient with known EG ingestion suggests early presentation, insignificant poisoning, or the coingestion of another toxic alcohol (e.g., ethanol) that has blocked the metabolism of EG.

Urinalysis may provide additional evidence of EG poisoning. Proteinuria and microscopic hematuria may be seen in over 60% of cases.³ Calcium oxalate crystalluria, virtually pathognomonic of EG poisoning, is present on admission in nearly 50% of patients; this percentage increases with serial urinalysis.^{3,10,13} Calcium oxalate is often excreted as needle-shaped monohydrate crystals that may be misidentified as hippuric or uric acid crystals.^{5,10} At higher urinary concentrations, calcium oxalate is also excreted in an envelope-shaped dihydrate form.^{9,10} The formation of calcium oxalate may cause hypoglycemia with myoclonic jerks or tetanic contractions. Because fluorescein is added to many commercial antifreeze preparations, fluorescence of urine or gastric contents with a Wood lamp may support EG poisoning early after ingestion.²⁰ Lack of urine fluorescence, however, cannot be used to exclude EG poisoning.

Death is most common during the cardiopulmonary stage and results from cerebral edema and infarction, multiple organ failure, and irreversible shock.^{10,13,15} Even with conventional treatment, mortality rates of 5% to 17% are still described.^{3,13} The time elapsed between ingestion and treatment and the degree of metabolic acidosis at the initiation of treatment are the factors most closely correlated with survival.^{10,13} Rapid diagnosis and treatment prevents EG bioactivation and lethality, regardless of the initial plasma EG concentration.^{10,13}

Patients who survive may complain of severe flank pain and develop costovertebral angle tenderness and acute renal insufficiency 18 to 48 hours after ingestion. Renal dysfunction is seen in nearly 70% of cases and is characterized by oliguria, proteinuria, and urine with a low specific gravity and sodium content (acute tubular necrosis).¹³ The high frequency of renal injury reflects the delayed presentation and diagnosis of the majority of EG-poisoned patients. The degree of metabolic acidosis or glycolic acid accumulation at the initiation of treatment is closely correlated with the subsequent development of renal injury.^{3,10,13}

Conversely, patients who have normal renal function upon initiation of treatment are unlikely to develop renal insufficiency.^{3,16} Although most patients treated for EG poisoning have a complete recovery, some may have protracted renal insufficiency that requires months of hemodialysis. Uncommonly, cranial neuropathies may develop 1 to 2 weeks after acute poisoning.¹⁰

DIFFERENTIAL DIAGNOSIS

EG intoxication can mimic a large variety of poisonings or disease states, depending on the amount of EG ingested and the degree of EG metabolism at presentation. Diagnostic clues include drunkenness without the odor of ethanol, latency between ingestion and significant illness, hyperventilation on physical examination, increased osmolal or anion gaps, metabolic acidosis, calcium oxalate crystalluria, and hypocalcemia. Similar findings may be present in methanol intoxication, but crystalluria is absent and visual complaints and an abnormal eye examination may be present. Other common diagnostic considerations that must be ruled out include alcoholic, diabetic, and starvation ketoacidosis; lactic acidosis; renal failure; and advanced, untreated acetaminophen or salicylate poisoning.

EMERGENCY DEPARTMENT EVALUATION

The history should include the time of ingestion, the volume and concentration of the ingested product, and the onset, nature, and progression of symptoms. The ingestion of any other substance, particularly ethanol, and the details of such events should be documented. Patients should be specifically asked about symptoms of ethanol-like intoxication, shortness of breath, flank pain, and urinary dysfunction.

Initially, the physical examination should focus on the neurologic status and cardiopulmonary function. A complete physical with documentation of any abdominal and back tenderness should then be performed. In symptomatic patients, routine laboratory evaluation should include a complete blood count; measurement of serum electrolytes, blood urea nitrogen, creatinine, glucose, amylase, calcium, ketones, and lactate; serum osmolality; arterial blood gas analysis; toxicologic screen; and a urinalysis.

A quantitative serum EG concentration should be obtained in all patients, preferably by gas chromatography and mass spectrometry. In all patients with intentional ingestion, a serum ethanol concentration should also be obtained. In addition, because many antifreeze products also contain methanol, a methanol concentration should be ordered if the identity of the ingested substance cannot be confirmed.

If results are not readily available, the serum EG concentration can be estimated by calculating the osmolal gap and assuming that the serum osmolality will increase the normal gap by 1 mOsmol/kg for each 6.2 mg/dL of EG (and each 4.6 mg/dL of ethanol) present.^{9,10} However, the absence of an increased osmolal gap does not rule out the possibility of EG poisoning, particularly in the later stages of poisoning, when significant metabolism has already occurred.⁸ Conversely, the presence of a large osmolal and anion gap is not specific to EG intoxication.⁸

Symptomatic patients should also have an electrocardiogram and a chest radiograph.

EMERGENCY DEPARTMENT MANAGEMENT

Aggressive supportive measures, including airway protection and respiratory and circulatory support with cardiac and hemodynamic monitoring, should be instituted as necessary. Initially, intravenous fluids should be liberally administered to maintain an adequate urine output; a large urine flow increases the urinary excretion of EG in those without renal failure.^{9,10}

If the patient has ingested EG within 4 hours, gastric aspiration, with or without lavage, via a nasogastric tube should be performed immediately. Activated charcoal does adsorb EG but may be clinically ineffective because EG is rapidly absorbed, because of the relatively large amounts often ingested, and because the patient may delay coming to the emergency department. Regardless, the administration of activated charcoal is recommended, particularly if a coingestant is a possibility.

Specific treatment for EG poisoning consists of sodium bicarbonate to correct metabolic acidosis, calcium to correct hypocalcemia, ethanol or fomepizole to inhibit production of toxic metabolites, hemodialysis to remove EG and its toxic metabolites, and pyridoxine to theoretically enhance endogenous clearance of toxic metabolites.¹

Correction of metabolic acidosis may require the use of large amounts of intravenous sodium bicarbonate, given slowly in 1-mEq/kg increments. The acid–base status should be frequently reevaluated to assess the response to therapy. Hypocalcemia may be worsened by sodium bicarbonate administration.¹⁰

Serum calcium levels should be monitored frequently. Hypocalcemia, tetany, and seizures should be treated initially with intravenous calcium chloride or gluconate (7 to 14 mEq for adults and 1 to 7 mEq for children). The 10% chloride solution contains 1.4 mEq of calcium per milliliter, while the 10% gluconate solution contains 0.46 mEq/mL. Seizures should otherwise be treated with standard drugs (diazepam, lorazepam, or a barbiturate).

Traditionally, ethanol has been used to inhibit the alcohol dehydrogenase–mediated metabolism of EG. Fomepizole (4-methylpyrazole, 4-MP; Antizol) is a potent and long-acting, competitive alcohol dehydrogenase inhibitor that appears to be a safe, easy, and effective alternative to ethanol.^{1,2,3 and 4,6,7,10,16} It was approved by the Food and Drug Administration in 1997 for treatment of EG poisoning. Fomepizole has been shown to both attenuate and prevent metabolic acidosis and renal failure in humans and animals poisoned by EG by halting the accumulation of glycolic and oxalic acids, respectively.^{1,2,3 and 4,6,7} Fomepizole offers several advantages over ethanol, which include a higher potency, longer duration of action, and easier dosing regimen.^{1,3,9} Unlike treatment with ethanol, fomepizole treatment does not require frequent monitoring and adjustment of plasma concentrations. Additionally, fomepizole does not produce the CNS depression, hypoglycemia, gastritis, pancreatitis, and habituation that are commonly associated with ethanol therapy.^{1,3,4,6,9}

Potential disadvantages of fomepizole include its high cost (\$1,000 U.S. per 1.5-g vial) and incompletely established safety profile. Although likely safe, fomepizole has been associated infrequently with transient hepatic transaminase elevation, rash, eosinophilia, and seizures in humans. ^{1,3,7,9}

Regardless of which antidote is used, both ethanol and fomepizole preferentially bind alcohol dehydrogenase and prevent further EG metabolism. Once administered, EG can then be eliminated by urinary excretion or hemodialysis. Indications for treatment with ethanol or fomepizole include a documented history of recent EG ingestion when a serum EG concentration is not immediately available, particularly if the osmol gap is elevated; strong suspicion of EG ingestion based on abnormal clinical or laboratory findings (e.g., oxalate crystalluria, unexplained anion gap metabolic acidosis or elevated corrected osmolar gap, or a combination thereof); or a measured serum EG concentration greater than 20 mg/dL. ^{1,3,9,10}

For ethanol therapy, the therapeutic goal is a serum ethanol concentration of at least 100 mg/dL. ^{9,10} Although it can be accomplished with oral administration of ethanol, ¹⁵ intravenous administration provides a more constant serum concentration. An intravenous loading dose of 10 mL/kg of 10% ethanol (with glucose to avoid hypoglycemia), followed by a maintenance infusion of 1.5 mL/kg/h, generally produces a serum ethanol concentration of slightly greater than 100 mg/dL. ^{9,10} Serum ethanol and glucose concentrations should be monitored and the dose of ethanol adjusted, as necessary, to maintain a therapeutic ethanol concentration.

For fomepizole, a loading dose of 15 mg/kg should be administered, followed by doses of 10 mg/kg every 12 hours thereafter. ³ All doses are diluted in 100 cc of 5% dextrose in water or normal saline and are administered by slow intravenous infusion over 30 minutes. ³ Like ethanol, fomepizole is also effective following oral administration. ¹ Antidotal therapy is continued until EG concentrations fall below 20 mg/dL. ³

Hemodialysis rapidly removes both EG and glycolic acid. ^{9,10} and ^{11,14} Elimination half-lives are reduced to approximately 3 hours for each, as compared with 19 and 10 hours, respectively, during alcohol dehydrogenase inhibitor therapy alone. ^{1,2} and ^{3,7,11,14,16} Indications for hemodialysis include significant metabolic acidosis (arterial pH less than or equal to 7.20), renal insufficiency (serum creatinine greater than 1.2 mg/dL), as well as deterioration in these parameters or clinical status despite conventional treatment. ^{1,3,9,10}

Traditionally, hemodialysis has also been recommended for a serum EG concentration greater than or equal to 50 mg/dL. ^{5,9,10} This concentration, however, does not define toxicity, predict prolonged elimination, or correlate with patient outcome. Recent evidence suggests that patients who present before the development of metabolic acidosis and renal impairment can be effectively and safely managed with fomepizole monotherapy (no hemodialysis), regardless of initial EG concentration. ^{1,2} and ^{3,7} For these patients, EG is excreted by the kidneys, with an approximate half-life of 18 hours. ^{1,2} and ^{3,16} For patients who present with elevated serum creatinine, however, EG elimination half-life is prolonged to approximately 49 hours and hemodialysis is recommended. ^{3,16} These patients will also likely require hemodialysis based on the presence of a significant metabolic acidosis. When initiated, hemodialysis should be continued until acid–base and metabolic abnormalities are corrected and serum EG concentrations are below 50 mg/dL. ^{3,9,10}

During hemodialysis, the infusion rate of ethanol should be increased to 3 mL/kg/h to compensate for losses. ^{1,9,10} Because fomepizole is also dialyzable, dosing frequency should be increased to every 4 hours during hemodialysis. ^{3,12} If hemodialysis is unavailable or technically difficult (e.g., in infants), peritoneal dialysis can be used, although this method is considerably less effective than hemodialysis.

Pyridoxine and thiamine are cofactors in the degradation of EG to less toxic products. They theoretically shunt metabolism of glyoxylic acid away from oxalic acid. They should both be given intravenously in doses of 100 mg four times daily. ^{9,10}

DISPOSITION

Patients with EG poisoning almost always require admission to an intensive care unit. Early consultation with a toxicologist or local poison center is encouraged to aid in patient care and to determine the availability of EG concentrations. The need for hemodialysis should always be anticipated, and the patient should be transferred if such treatment is unavailable.

COMMON PITFALLS

- Failure to consider EG as a cause of ethanol-like intoxication and anion gap metabolic acidosis
- Failure to appreciate that a normal osmolal and/or anion gap does not exclude the presence of potentially toxic amounts of EG
- Failure to treat with ethanol or fomepizole before the results of confirmatory testing for EG when there is sufficient clinical suspicion of EG poisoning
- Failure to correct EG-induced metabolic acidosis with bicarbonate
- Failure to employ emergent hemodialysis for the EG-poisoned patient who presents with significant metabolic acidosis or renal insufficiency, regardless of the EG concentration

[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Fluoride is found in various commercial and household products. Inorganic salts of fluoride have been extensively used as insecticides and rodenticides. Sulfuryl fluoride (Vikane) is used as a “tent” fumigant to eradicate pests in buildings. Sodium fluoride is also used in the manufacture of fertilizers and plastics. The inorganic acid of fluoride, hydrofluoric acid (HF) is an extremely corrosive substance used in the etching of glass, metal, and stone and in the electronics and semiconductor industries.

HF is also a common constituent of rust and scale removers designed for commercial and home use, often found in poorly labeled containers with little warning about the potential toxicity of HF. Fluoride is added to the municipal water supply in many communities, and to toothpaste and other dental hygiene preparations because of its role in preventing tooth decay. The recommended dose is 0.7 to 1.2 ppm in drinking water, or 0.25 to 0.5 mg/d as a dietary supplement.

Because of the variety of fluoride compounds and differences in the duration and routes of exposure, there are three primary forms of fluoride poisoning: acute systemic fluoride poisoning; acute topical exposure to HF; and chronic “fluorosis,” a syndrome of osteosclerosis, brittle bones, exostoses, ectopic calcification (e.g., of ligaments and tendons), and renal calculi, which results from long-term exposure to low concentrations of fluoride.

Acute systemic fluoride poisoning may be due to the intentional or accidental ingestion of fluoride salts or to oral or dermal exposures to HF. ^{5,19} More than 600 deaths have been attributed to acute fluoride poisoning since the 1930s. There has been a marked increase in recent years in the number of reports of topical HF exposure, no doubt because of the rapid growth of the semiconductor industry and of other industrial applications for fluoride. ¹⁹

Soluble fluoride salts, such as sodium fluoride and stannous fluoride, are rapidly absorbed through the gastrointestinal (GI) tract. ⁵ Fluoride may also be absorbed through the skin, although dermal absorption is probably limited to HF exposures. Fatal accidental and intentional fluoride poisoning has also been reported after inhalational exposure. ^{5,16}

Once absorbed, fluoride is distributed to virtually every tissue and organ and is slowly eliminated in the urine. Normal fluoride levels are 0.4 to 2.0 µg/dL in blood and 0.2 to 1.1 µg/mL in urine. As little as 2 g of sodium fluoride or 32 mg/kg may be lethal in an adult, and 16 mg/kg in children. A dose of more than 5 to 10 mg/kg should be considered serious and may result in hypocalcemia. GI effects may occur with lesser amounts. Severe chemical burns may result from exposures to very dilute (less than 5%) solutions of HF, and fatal systemic poisoning has resulted from relatively small (less than 5% total body surface area) burns caused by more concentrated solutions. ^{5,6,13,14}

Several pathologic mechanisms are involved in both local and systemic fluoride poisoning. Fluoride binds to divalent cations, especially calcium and magnesium, to form insoluble fluoride salts. The resulting hypocalcemia, hypomagnesemia, and depletion of other trace nutrients have profound effects on a number of cellular and organ functions. Fluoride is also a general protoplasmic poison, inhibiting numerous aerobic and even anaerobic metabolic enzyme systems and interfering with cellular respiration. ⁵ Fluoride also interferes with Na⁺/K⁺-ATPase and activates calcium-dependent potassium channels in cell membranes, resulting in massive leaks of potassium into the extracellular space, with subsequent hyperkalemia. ⁷ Precipitation of calcium also interferes with calcium-dependent clotting factors, resulting in coagulopathy. Finally, exposure to HF may produce direct corrosive injury.

The evaluation and management of HF burns and systemic fluoride toxicity are very different and require separate consideration. Systemic fluoride toxicity may accompany topical HF exposure due to absorption of fluoride, however, and HF injury may accompany systemic fluoride poisoning due to the conversion of fluoride salts to HF in an acidic medium (e.g., gastric juices).

CLINICAL PRESENTATION

Systemic fluoride poisoning is manifest by various toxic effects, including direct tissue injury at the site of absorption. Signs and symptoms usually begin within minutes of exposure. Fluoride ingestion is associated with an acute gastroenteritis, vomiting, diarrhea, and abdominal pain. ⁵ Fluoride inhalation is associated with pulmonary injury, including the development of noncardiogenic pulmonary edema and adult respiratory distress syndrome. ^{5,16} Dermal fluoride exposure produces typical HF burns.

Patients with systemic fluoride poisoning typically present with significant metabolic acidosis; it is usually ascribed to interference with intracellular metabolism. The most lethal complications are due to the severe electrolyte abnormalities produced by direct interaction with fluoride or effects on cell membranes. ^{5,7} Severe hypocalcemia (serum calcium level less than 5 mEq/L), frequently reported as a major finding in systemic fluoride poisoning, is presumably due to the complexing of calcium by fluoride ions. Severe hypomagnesemia and hypomagnesemia have also been reported. Most recent evidence, however, indicates that the primary cause of the lethal dysrhythmias (refractory ventricular tachycardia, ventricular fibrillation, and pulseless idioventricular rhythm) is the development of hyperkalemia. The combination of hypocalcemia and hyperkalemia is extremely harmful, but studies have shown that lethal hyperkalemia may occur despite maintenance of normal serum calcium levels. ⁷

Systemic manifestations of hypocalcemia include carpopedal spasm, positive Chvostek's and Trousseau's signs, hyperreflexia, tetany, and coagulopathy. Headache, paresthesias, and visual complaints may be noted. In severe cases, coma, seizures, shock, and dysrhythmias may precede death.

A patient with an acute exposure to HF may be a difficult diagnostic problem. First, the patient may not even know that the product he or she was using contained HF, as product labels may be incomplete. Second, the patient may have been exposed to HF inadvertently, through unrecognized HF contamination of materials and work sites. Finally, the typical signs and symptoms of an acute HF injury may be delayed for many hours after an exposure, and patients may not recognize that their symptoms are related to the exposure. The onset of symptoms following acute dermal HF exposure depends on the concentration of the acid and the duration of exposure. ⁵ Highly concentrated (70%) HF may contain enough hydrogen ions to produce some burning sensation on the skin and may provide some degree of warning of an acute exposure with symptom onset within 1 to 2 hours. Low concentrations of HF (less than 10%), found in products such as over-the-counter rust removers, however, produce no symptoms at the time of contact, and patients may present as long as 10 to 12 hours following the initial exposure. This delay is due to the fact that the relatively small dissociation constant ($K = 3.53 \times 10^{-4}$) limits the concentration of free hydrogen ions. ¹⁵ In addition, the fact that HF tends to remain in an undissociated, neutral state enhances its ability to penetrate through the skin into deeper tissues, where its gradual dissociation into free fluoride ions leads to the characteristic local tissue injury.

The presenting complaint of acute topical HF injury is pain, often in the absence of any physical signs. HF exposure should always be considered in this situation. It is usually described as a tingling sensation that progresses to a burning pain and, ultimately, to the typical deep, throbbing, unremitting, and excruciating pain. ^{5,12,18,19}

Visible evidence of HF burns also follows a fairly characteristic pattern. The burn site initially becomes erythematous and may be somewhat edematous. As tissue injury progresses, the site assumes a pale, blanched appearance, which may be followed by the development of local vesiculation and frank tissue necrosis (e.g., blackened tissue). Fluoride may penetrate into underlying bone, and demineralization may ensue. This destructive process may progress over several days in

inadequately treated patients, resulting in the development of deep ulceration and extensive tissue loss, including the loss of entire digits.

DIFFERENTIAL DIAGNOSIS

GI manifestations of fluoride ingestion are similar to those of infectious gastroenteritis. Although virtually any poison can cause GI symptoms, alcohols, corrosives, heavy metals, lithium, nonsteroidal antiinflammatory agents, and theophylline typically cause effects of comparable severity. The differential diagnosis of hypocalcemia includes parathyroid hormone deficiency and ethylene glycol poisoning. Hyperkalemia may be caused by alpha agonists, beta blockers, digitalis, and potassium overdose. The combination of hypocalcemia, hypomagnesemia, and hyperkalemia points to fluoride poisoning.

HF burns, when apparent, may resemble those resulting from thermal injury, frostbite, or other corrosives (e.g., acids and alkalis).

EMERGENCY DEPARTMENT EVALUATION

The history should include the dose (the amount of fluoride ingested or the concentration of HF), the time of exposure, first-aid measures taken, symptoms, and current medical problems.

Once vital signs have been obtained, the focus of the physical examination becomes the abdomen, lungs, or skin (and mucous membranes), depending on the route of exposure. Evidence of hypocalcemia (i.e., neuromuscular hyperactivity) is sought. All patients with significant ingestions, inhalations, or topical exposures (greater than 5% body surface area) should have cardiac monitoring, a 12-lead electrocardiogram (ECG), and serum calcium, magnesium, and electrolyte level measurements. A baseline complete blood count, prothrombin time, partial thromboplastin time, and kidney function studies are also recommended. A chest radiograph is ordered for patients with respiratory symptoms or severe clinical toxicity.

Serum and urine fluoride levels are not readily available or clinically useful. They can, however, be used to confirm the diagnosis retrospectively and assess the efficacy of therapy.

EMERGENCY DEPARTMENT MANAGEMENT

The treatment of systemic fluoride poisoning has two primary goals: to remove fluoride from the system and to correct electrolyte abnormalities. Patients with fluoride ingestion should receive rapid, aggressive GI decontamination, including lavage and instillation of calcium-containing substances (e.g., antacids) to complex fluoride in the gut.^{3,4} and ⁵ Urinary fluoride excretion may be enhanced by alkalization, and hemodialysis removes fluoride from the blood directly.

Serum calcium levels should be closely monitored, and intravenous calcium chloride should be given for replacement. Massive amounts of calcium may be required; in one case, the administration of 280 mEq of calcium increased the serum calcium level from 2.2 mEq/L to only 3.1 mEq/L.¹⁴ Either 10% calcium chloride (14 mEq calcium/10 mL) or calcium gluconate (4.65 mEq/10 mL) may be used. The initial dose of 0.2 mL/kg is given intravenously over 5 to 10 minutes and is repeated, as needed, until serum calcium levels are normalized. Similarly, 10% magnesium sulfate, in an initial dose of 0.1 to 0.2 mL/kg, may be given for hypomagnesemia.

Hyperkalemia may first be recognized by the appearance of characteristic tall, peaked T waves on the ECG, but close monitoring of serum potassium levels is warranted, even in the absence of peaked T waves. Hyperkalemia in systemic fluoride poisoning does not respond to some traditional measures, such as insulin, glucose, and bicarbonate. Also, the ventricular dysrhythmias associated with acute fluoride poisoning are refractory to cardioversion and defibrillation, lidocaine has not been shown to be effective, and propranolol may actually exacerbate the hyperkalemia.⁷ Quinidine, on the other hand, has shown promise in preventing or reversing hyperkalemia and ventricular irritability in dogs, although this method of treatment is yet to be tried in humans.⁷ Hemodialysis is indicated for severe or refractory hypocalcemia, hyperkalemia, or clinical toxicity (e.g., dysrhythmias) and may also be useful for removing fluoride ions. Calcium and magnesium monitoring and replacement should continue during this procedure.

The initial step in management of an acute topical HF exposure is thorough skin decontamination with a water flush. It should be accomplished before arrival in the emergency department if prehospital personnel are involved or if the patient contacts the emergency department for advice. Unfortunately, the delayed presentation of most patients with HF burns makes it unlikely that significant amounts of HF still remain on the surface of the skin.

First-aid measures for known or suspected HF burns are the use of topical soaks, creams, and ointments. These usually contain calcium gluconate (2.5% to 10% gel), magnesium oxide (10% paste), or a quaternary ammonium salt (benzalkonium or benzethonium chloride). Topical therapies are intended to form insoluble complexes with any surface fluoride ion to prevent penetration into tissues, thereby minimizing or preventing deep cellular injury.

Animal studies have compared the efficacy of various topical therapies or infiltration techniques, with varied results.^{4,8} Most of these studies involve an immediate therapeutic intervention. Many HF exposures, however, are not promptly recognized, and patients often do not present until symptoms have developed (usually many hours after exposure). Therefore, animal models do not usually reproduce the typical clinical presentation in the emergency department.

Topical treatment is probably of some benefit if applied immediately after initial decontamination of a known, recognized exposure. It may also be of benefit in patients with mild pain and minimal evidence of tissue damage (e.g., erythema only) who present late. It should be considered adjunctive, however, in patients who present with progressive pain and signs of deeper tissue injury. At worst, reliance on topical therapies delays definitive treatment and allows greater tissue injury to develop.¹⁹

Definitive treatment of acute HF burns involves the administration of calcium gluconate into the tissues affected by the exposure.¹⁹ It may be achieved by a number of methods: direct tissue infiltration, regional intravenous infusion using a Bier's block technique, and intraarterial infusion. The choice of method depends on the site and concentration of HF involved.

In soft tissues with sufficient loose tissue space for injection of a volume of fluid, this is most easily accomplished by the direct injection of approximately 0.5 mL per square centimeter of 10% calcium gluconate solution at the burn site. A small needle (25- to 30-gauge) should be used to minimize discomfort and mechanical tissue damage, and care should be taken to infiltrate into, around, and beneath the burn area as completely as possible. By loading the local tissue with calcium, the mechanism of fluoride injury is terminated and even reversed by the precipitation of free fluoride and replenishment of decreased tissue calcium levels. Only calcium gluconate should be used for local infiltration; calcium chloride produces direct injury when injected into tissues.^{3,5}

Digital HF burns are relatively common and deserve special consideration. Fingertip burns are particularly painful because of the rich sensory nerve supply, and are difficult to infiltrate with calcium gluconate for the same reason. In addition, only small amounts of calcium gluconate may be injected directly into the fingertips because of limited space for introduction of additional fluid volume in an end-arterial circulation region. Repeated injections are frequently necessary to neutralize all the fluoride present. HF may penetrate beneath the fingernails, and the nails must be removed before calcium gluconate is injected directly into the nail bed, to avoid the unbearable pain associated with administering even a minimal volume of fluid into the closed space between the nail plate and distal phalanx.^{3,11,18,19}

Currently two techniques are available as an alternative to direct injection of calcium gluconate into digital HF burns. The first is to infuse calcium gluconate into the arterial supply of the involved digit(s). This technique involves inserting an indwelling arterial catheter into the radial or brachial artery of the involved extremity and slowly infusing a dilute solution of calcium gluconate by an infusion pump. It allows the calcium to be delivered to the affected tissues through the vascular supply and avoids the pain and tissue distention associated with direct injection.^{12,19} A typical dose is 10 to 20 mL of 10% calcium gluconate in 50 to 100 mL of dextrose 5% in water given over 4 hours and repeated as necessary. Because extravasated calcium salts are themselves corrosive, the arterial waveform should be monitored during the infusion to confirm proper catheter placement. The end point for therapy should be the absence of pain at rest. In one large case series, the average number of intraarterial infusions was four, with a range of one to ten.¹⁷

The second technique that may be considered in the treatment of digital HF burns is regional intravenous calcium gluconate infusion using a Bier's block technique.^{9,10,15,20} This technique is similar to that originally described by Bier for regional limb anesthesia and has the advantages of relative simplicity and of not requiring arterial cannulation. Success has been reported for digital, hand, and forearm exposures,^{9,10,15} as well as for exposures to the leg.¹⁵ The technique involves placing a canula in the dorsum of the hand (or foot) of the affected limb, raising the arm to exsanguinate the superficial venous system, and then inflating a surgical pneumatic tourniquet applied to the upper arm to a pressure 100 mm Hg above systolic blood pressure. Ten to 15 mL of 10% calcium gluconate is diluted to a total

volume of 50 mL with normal saline and infused via the canula to the ischemic arm. The tourniquet is sequentially released after 20 to 25 minutes.⁹ When successful, relief is apparent within 30 minutes of tourniquet release.

In cases in which exposure has been to high-concentration HF (greater than 20%) or multiple digits are involved, the arterial route appears to be more effective, perhaps because of the more focal provision of calcium to the site of digital exposure than is possible with the regional intravenous route. Additionally, it is possible to administer multiple infusions by intraarterial canula in patients with ongoing pain. If the intravenous route is selected as primary therapy and it is unsuccessful following one treatment, the intraarterial route should be used subsequently.

Finally, ocular HF exposures should also be mentioned; they can result in serious consequences if left untreated. The use of topical calcium gluconate drops is controversial. Animal studies suggest that they are no better than copious irrigation with normal saline and may, in fact, result in delayed corneal healing.² Patients should be treated as for other chemical exposures to the eye, with copious saline irrigation, local anesthetic drops for pain relief, and early ophthalmologic referral.

To date, there have been no controlled, prospective human studies comparing the techniques for the management of HF exposure. Retrospective and even prospective case series are difficult to evaluate, as the concentration, amount, and duration of HF exposure are frequently unknown. Numerous animal studies have been reported with varying results. In an *in vivo* porcine model, using high-concentration HF (49%) and comparing regional intravenous and intraarterial infusions of calcium gluconate, there was a trend toward lesser burn depth following intraarterial therapy.¹ At present, the most logical approach seems to be an initial trial of topical therapy. Invasive techniques should be used in patients who do not respond to topical therapy within 30 to 60 minutes of application of calcium gluconate gel, those who have been exposed to a known high concentration of HF, or those who have had extensive skin exposure.

DISPOSITION

Any patient who presents with persistent symptoms or signs after acute ingestion, inhalation, or topical HF exposure requires admission to a monitored bed for close observation. Many patients with severe poisoning have presented in relatively stable condition and with normal initial laboratory values, only to develop severe complications after several hours of evaluation and treatment.

Patients with HF burns require much closer follow-up than do patients with almost any other kind of corrosive injury. Repeated calcium infiltrations or infusions are frequently required, and patients with lesions that demonstrate vesiculation or necrosis before or despite adequate treatment should be referred to a plastic surgeon for wound care. Extensive HF exposures should be carefully monitored for the possibility of systemic fluoride poisoning. Unless the physician is familiar with treating this type of poisoning, initial consultation with a poison center, toxicologist, or plastic surgeon is advised. Eye exposures should be referred to an ophthalmologist as soon as possible.

COMMON PITFALLS

- Failing to appreciate that patients with fluoride or HF exposure are at risk for progressive poisoning, with life- and limb-threatening complications
- Failing to recognize and treat patients with symptomatic HF exposures despite lack of visible evidence of tissue injury
- Failing to monitor serum calcium, magnesium, and potassium and to admit patients with significant exposures
- Relying on topical therapy for HF burns when calcium gluconate infiltration or infusion is indicated
- Using calcium chloride rather than calcium gluconate for infiltration or parenteral therapy
- Failing to appreciate that large doses of parenteral calcium and magnesium may be necessary in severe cases of systemic poisoning
- Failing to arrange follow-up in 12 to 24 hours for patients who have been symptomatic after a topical exposure

[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Despite improvements in detection and increased regulatory oversight, food-borne illness remains a serious cause of morbidity and mortality throughout the world, including the United States. With the growth in modern mass-production farms and food-handling and -processing plants, the potential for amplification of food-borne pathogens is great. Although common, the exact incidence of food-borne illness is not accurately known.² What is known is that each year, millions of people are affected worldwide,¹ and although the majority of persons suffer only temporary discomfort, for the very young, the old, and the immunocompromised, food-borne illnesses can be fatal.

Improper food handling, leading to fecal contamination of food, is the usual cause of most food-borne illnesses. Causative agents include bacteria, viruses, parasites, and toxins. More recently, prions, a new infectious class of agents have been implicated in causing transmissible spongiform encephalopathies.⁴ This chapter focuses on the bacterial causes of food poisoning.

Alterations in normal gastrointestinal (GI) tract function are the hallmark of bacterial food poisoning. Patients with food poisoning may have some or all of the following: nausea, vomiting, diarrhea, abdominal pain, cramps, and fever.

Bacterial causes of food poisoning can be characterized as toxin induced, invasive, or inflammatory. Breaking them up like this allows easier identification of the causative agent.

Organisms such as *Staphylococcus aureus*, which produce a toxin, cause symptoms such as vomiting quickly, as little as 8 hours after ingestion. Toxins can also lead to diarrhea as the toxin disrupts intestinal sodium absorption. This, in turn, leads to massive amounts of salt and water being presented to the large intestine, with subsequent volume-overload diarrhea. Invasive bacteria, on the other hand, invade or destroy the mucosal layer, leading to bloody diarrhea with fecal leukocytes. Examples of such bacteria include *Escherichia coli*, *Campylobacter*, *Salmonella*, *Shigella*, and *Yersinia*.

CLINICAL PRESENTATION

Almost all types of food poisoning present with similar complaints. After a variable incubation period ([Table 340.1](#)), alterations in GI functions begin. The patient may present with all or only some of the following: fever, abdominal pain, cramps, nausea, vomiting, diarrhea (bloody or watery), myalgias, and arthralgias. The pain of food poisoning is most often characterized as colicky, but can be more severe. Patients with *Salmonella* as a causative agent occasionally present with severe abdominal pain, even peritoneal signs. Bloody diarrhea is seen with the invasive organisms, such as *Campylobacter*. Watery diarrhea can be seen with any food-borne pathogen. Fever and dehydration can be seen, and the dehydration may be profound.

Pathogen	Incubation Period	Clinical Features
<i>Staphylococcus aureus</i>	1-6 hours	Vomiting, diarrhea, abdominal pain
<i>Bacillus cereus</i>	1-6 hours	Vomiting, diarrhea, abdominal pain
<i>Clostridium perfringens</i>	8-16 hours	Diarrhea, abdominal pain
<i>Escherichia coli</i>	1-8 hours	Diarrhea, abdominal pain, fever
<i>Salmonella</i>	6-72 hours	Diarrhea, abdominal pain, fever
<i>Shigella</i>	1-3 days	Bloody diarrhea, abdominal pain, fever
<i>Yersinia</i>	4-6 hours	Diarrhea, abdominal pain, fever

TABLE 340.1. Bacterial Causes of Food-Borne Illness

DIFFERENTIAL DIAGNOSIS

The actual number of cases of food-borne illness is unknown. It is a diagnosis often considered but rarely confirmed. Only in multiperson outbreaks is a diagnosis usually reached. In addition, the long incubation period of some food-borne pathogens and the overlap with multiple other causes of GI disturbances can easily lead to a missed diagnosis.

Viral gastroenteritis is the most common diagnosis for patients with nausea, vomiting, and diarrhea. Common viral causes of gastroenteritis are rotavirus (in the winter), Norwalk virus, enteric adenovirus, and hepatitis A (no seasonal predilection).

Parasites are another source of gastroenteritis and often can be linked with specific habits and activities. *Giardia lamblia* is most commonly seen among hikers, campers, and travelers who are infected through drinking contaminated water. Other parasites, such as *Entamoeba histolytica*, *Cryptosporidium*, and *Isospora belli* are linked to either male homosexuals or the human immunodeficiency virus (HIV) infection.

Clostridium difficile can overgrow the GI tract in persons taking wide-spectrum antibiotics. The resulting pseudomembranous colitis can cause bloody diarrhea and severe abdominal pain.

Other diagnoses to consider in the differential include biliary disease, food intolerance or allergies, inflammatory bowel disease, irritable bowel disease, urinary tract infections, appendicitis, peptic ulcer disease, and gynecologic disorders.

Contamination of food with toxins, pesticides, or chemicals can lead to illness.³

EMERGENCY DEPARTMENT EVALUATION

In the patient with suspected food poisoning, supportive therapy should be instituted even as the diagnostic workup proceeds. Intravenous access for fluid resuscitation and to obtain blood samples for potential laboratory evaluation are usually required. Fluid resuscitation should be ongoing during the evaluation of the patient.

The history should focus on recent meals, what foods were consumed, how they were prepared, the manner in which they were kept after being prepared, and who ate with the patient and their current health. The time of onset, nature, and progression of the illness may provide diagnostic clues to uncover the etiology of the

infecting agent. Any recent travel, especially to regions such as Mexico (well known for having a high incidence of food-borne infections), should be noted. Drinking water sources should be asked about, especially in campers and hikers who might have been drinking from “back country” water sources. Underlying medical conditions, such as HIV, sickle cell disease, malignancies, diabetes, cardiac or renal disorders, immunodeficiencies, and medications should be asked about.

The physical examination should be structured so as to quickly ascertain the hydration status of the patient and perform an abdominal examination. This should include a rectal examination, looking for the presence or absence of fecal blood. As is true with any patient with abdominal pain, serial examinations and vital signs are imperative to ensure that any clinical deterioration in the patient is detected quickly.

The extent of the laboratory evaluation varies from patient to patient. A white blood cell count is not usually useful; a high white blood cell count only confirms that an inflammatory process is going on. It will do little to narrow the diagnostic possibilities. On the other hand, a hematocrit and hemoglobin may be useful, especially if followed serially in patients with invasive organisms and bloody diarrhea. Anemia can occur with *Salmonella*.

Likewise, the amount of chemistries obtained varies from patient to patient. In the well-hydrated patient who appears well, routine chemistries are unlikely to add anything to the diagnosis. Patients who are dehydrated or who have the possibility of other diagnoses may require additional testing. In general, serum electrolytes, blood urea nitrogen (BUN), creatinine, blood sugar, and urinalysis are sufficient. A urine specific gravity greater than 1.025 or a BUN–creatinine ratio greater than 20:1 is consistent with severe dehydration. Likewise, a serum bicarbonate level below 20 mEq/L is consistent with significant dehydration, particularly in children.

Patients with significant abdominal tenderness or a high fever may require a more extensive evaluation. In addition to the aforementioned tests, consideration should be given to obtaining liver function tests, an amylase or lipase, a complete blood count, bilirubin, and blood cultures. Virtually any woman of childbearing age should have a human chorionic gonadotropin test performed. In patients with heme-positive stools or diarrhea, it is common to obtain stool for routine bacterial culture. As this rarely affects the acute management of the illness, it is probably not indicated. In patients who present with weeks or months of diarrhea, three separate specimens for ova and parasites may well be indicated.

In patients with clear indications of food poisoning who are otherwise healthy, do not appear seriously ill, and have little abdominal pain, radiologic evaluation is not indicated. In the elderly, infants, patients who appear very ill, and patients who have significant abdominal pain or a history of intraabdominal pain, upright views of the abdomen and chest are indicated to rule out perforation or obstruction. In the elderly, the possibility of an abdominal aortic aneurysm should be considered. If the diagnosis is uncertain, abdominal computed tomography imaging is indicated in the ill patient.

In patients with significant risk factors for coronary artery disease, or have an actual history of the same, an electrocardiogram is warranted to rule out a cardiac cause for the illness.

EMERGENCY DEPARTMENT MANAGEMENT

The first priority in treating patients with suspected food poisoning is to replace fluid and electrolyte losses. In mild or moderately ill patients who are not vomiting and can take fluids by mouth, oral rehydration is acceptable. Intravenous crystalloid, either lactated Ringer's or normal saline, with or without 5% dextrose, is indicated for moderately to severely ill patients, especially if they continue to vomit and/or are seriously dehydrated. The initial bolus should be from 5 to 20 cc/kg, depending on the patients' age, cardiovascular status, and degree of dehydration. A maintenance infusion should be initiated and further boluses tailored to the patients' clinical response to treatment. The adequacy of the resuscitation can be judged by subjective response, appearance, urinary output, vital signs, and improving laboratory parameters.

Intravenous, intramuscular, or rectal antiemetics (prochlorperazine or metoclopramide) may be helpful in patients with persistent nausea, vomiting, and abdominal cramping. Although antidiarrheal drugs (e.g., diphenoxylate [Lomotil] or loperamide [Imodium]) have traditionally been held to be contraindicated in the treatment of food poisoning, in some situations, such as traveler's diarrhea, their use may speed recovery.⁵ However, they are not appropriate for use in patients with bloody diarrhea. Their use can prolong symptoms (e.g., with *Shigella*), cause perforation (with amebiasis), and increase mortality (e.g., with *Campylobacter*).

Antibiotics are usually not indicated. Patients with viral sources of diarrhea and those with many bacterial illnesses do not improve more rapidly when given antibiotics. Some organisms, such as *Salmonella*, may have prolonged colonic colonization when antibiotics are used. In patients who are septic, immunosuppressed, or HIV-positive; are elderly; or have other coexistent illnesses, antibiotics may be appropriate. Specific treatments for each causative organism are given in [Table 340.1](#).

DISPOSITION

Most patients can be discharged once they are rehydrated and are feeling better. The ability to take fluids orally should be documented before discharge. These patients should be instructed to maintain a generous intake of clear fluids and begin frequent small feedings as soon as they can be tolerated. Patients should be advised to return to the emergency department or to contact their personal physician if symptoms have not abated within 24 hours, or to return sooner if they cannot maintain a sufficient oral intake, if they develop a high fever, or if abdominal pain persists. The parents of small children should also be warned that the hemolytic–uremic syndrome (see [Chapter 211](#)) is a potential complication.

Patients with severe dehydration, especially those with significant underlying illness or at the extremes of age, should be admitted. Those with suspected bacteremia (e.g., fever, elevated white count, or toxic appearance) and those patients who do not improve with therapy should be admitted or observed over a period of several hours. Likewise, any patient in whom the diagnosis is in doubt should be considered for admission. Patients who may not be able to seek further medical care because of social circumstances or those who cannot tolerate oral intake should be admitted. For most patients needing admission, a floor bed or observation unit will suffice. Occasionally, a patient with an underlying illness or who remains hemodynamically unstable may require an intensive care admission.

Local health authorities should be contacted if other persons in the community may be at risk. If the suspected food was bought at a store or restaurant, other members of the public may be exposed. Such actions can limit the numbers of people who become ill.²

COMMON PITFALLS

- Failure to consider the possibility of food poisoning in all patients with nausea, vomiting, diarrhea, and abdominal cramps
- Failure to obtain a history of antecedent antibiotic use, travel, camping, and diet in patients with nausea, vomiting, diarrhea, and abdominal cramps
- Failure to exclude life-threatening etiologies of abdominal complaints, such as appendicitis, aortic aneurysm, pyelonephritis, cholecystitis, pneumonia, and myocardial disease, and pregnancy-induced conditions
- Discharging patients who cannot take oral fluids, especially if they have been inadequately rehydrated
- Failure to consider the effects of underlying diseases in the management of patients with suspected food poisoning
- Failure to consider potential public health hazards and failing to notify public health authorities when appropriate

Hallucinogens, also known as psychedelic or psychotomimetic agents, are chemicals whose predominant effect is the production of sensory misperceptions, disordered thought processes, and mood changes. Included in this category are lysergic acid diethylamide (LSD) and related tryptamine derivatives ([Table 341.1](#)); marijuana; mescaline and related analogues of amphetamine ([Table 341.2](#)); and phencyclidine (see [Chapter 363](#)). Hallucinogens are classified as Food and Drug Administration schedule I agents (i.e., no proven medical value) and are primarily regarded as substances of abuse. They are readily available through illicit street markets, but their use was more common during the 1960s and 1970s than it is today. Use is most prevalent in teenagers and young adults.

2,5-dimethoxy MDA (DMMDA) and other dimethoxy analogues
2,5-dimethoxy-4-bromo-phenylethylamine (2CB)

TABLE 341.2. Hallucinogenic Amphetamine Derivatives (Mescaline Analogues)

Marijuana and its main active ingredient THC (delta-9-tetrahydrocannabinol) are used medically to treat glaucoma, as appetite stimulants to treat cachexia (e.g., in acquired immunodeficiency syndrome patients), and as antiemetics to treat the nausea and vomiting associated with cancer chemotherapy. They are also being studied for the treatment of neuropathic pain, seizures, and spasticity. The therapeutic potential of amphetamine derivatives is being studied in patients with psychiatric disorders.

LSD (“acid”) is a colorless, odorless, tasteless, water-soluble derivative of ergot (see [Chapter 336](#)). It is available as single doses (“hits”) in tablet, capsule, or powder form and also as impregnated sugar cubes, small pieces of blotter paper (“blotter acid”), and gelatin (“windowpane”). Foods (e.g., animal crackers, gum, and fruit punch) and lickable paper materials (e.g., stamps, stickers, and decal tattoos) have also been used as vehicles.

Analogues of LSD (see [Table 341.1](#)) are most commonly synthetic and are supplied as pills or powders. Tryptamine and alphamethyltryptamine are also present in foods such as aged cheese and smoked meat. Psilocin and psilocybin are found in certain mushrooms (see [Chapter 348](#)). Bufotenin, an isomer of psilocin, is a component of the skin secretions and venoms of some frogs and toads (e.g., *Bufo*, *Hyla*, *Leptodactylus*, and *Rana* species).¹³ Toad venom also contains catecholamines (e.g., dopamine, epinephrine, and norepinephrine) and digitalis-like cardiac glycosides (bufadienolides; see [Chapter 337](#)). Bufotenin, dimethyltryptamine (DMT), and 5-methoxy-DMT are found in species of *Mimosaceae*, plants that grow in South America. Analogues of LSD are also found in the seeds of plants from the morning glory (*Convolvulaceae*) family, such as the common morning glory (*Ipomoea violenceae*), Hawaiian baby woodrose (*Argyreia nervosa*), Hawaiian woodrose (*Merremia tuberosa*), and Mexican morning glory (*Rivea corymbosa*).

LSD and its analogues are usually taken orally, by chewing, licking, or swallowing. Hallucinogenic plants may also be smoked or sniffed. Dried toad skin or toxin extracts may be ingested. “Toad licking” (licking the skin of live toads), another means of exposure, is most commonly practiced by teenagers in the southeastern United States.¹³

Marijuana is a mixture of the branches, flowers, leaves, and seeds of the plant *Cannabis sativa*. Although its THC concentration usually ranges from 1% to 3%, high-potency strains such as sinsemilla, with THC concentrations of 7% to 14%, have been cultivated. Common street names include grass, Mary Jane, pot, and weed. Hashish and keefe, dried resin extracts of marijuana, usually contain 5% to 15% THC. Hash oil, the liquid resin, has a THC concentration of 30% to 50%.

Marijuana is most commonly smoked as a cigarette (known as a bone, joint, or reefer) or from a pipe. Hashish is usually smoked from a pipe. Hash oil is usually applied to marijuana or tobacco cigarettes and then smoked. Marijuana and its derivatives may also be brewed as a tea or mixed into baked goods, such as brownies, and then ingested. The intravenous injection of marijuana extracts has also been reported.

Mescaline (3,4,5-trimethoxyamphetamine) is a natural product of the peyote cactus, *Lophophora williamsii*, indigenous to the southwestern United States and northern Mexico. The San Pedro cactus of Peru, *Trichocereus pachanoi*, may also contain mescaline. The dried, brownish gray, fleshy top of the peyote cactus is cut up and sold as “buttons,” reflecting their size. Peyote buttons contain 1% to 6% mescaline. The seeds of nutmeg (*Myristica fragrans*) contain psychoactive volatile oils (terpenes) as well as myristican and elemicin (MMDA and PMA, respectively; see [Table 341.2](#)).

Mescaline and its synthetic derivatives (see [Table 341.2](#)) are also available as pills and powders. These agents are almost always taken by ingestion. The most commonly abused agents of years past were DOM, also known as STP (“serenity, tranquility, and peace”), and the “love drug,” MDA. Currently in vogue are MDMA

("Ecstasy," "XTC," or "Adam") and 2CB and MDEA (both known by the street name of "Eve").⁷

LSD, mescaline, and their analogues are structurally similar to the endogenous neurotransmitters serotonin (5-hydroxytryptamine), dopamine, and norepinephrine, and act by stimulating central nervous system (CNS) receptors.^{10,19} The pyrrole structure of the indole ring of tryptamine derivatives and the methoxylated or methylenedioxyethylated catechol ring of amphetamine derivatives appear to be essential for hallucinogenic activity. Tryptamine derivatives appear to cause stimulation of type 2 serotonin receptors primarily, with lesser effects resulting from dopaminergic stimulation and monoamine oxidase inhibition. Amphetamine derivatives may act directly by stimulating catecholamine receptors or indirectly by causing the presynaptic release of endogenous transmitters, by inhibiting their presynaptic reuptake, or by preventing their synaptic degradation by monoamine oxidase. In addition, hallucinogenic amphetamines may undergo biotransformation to tryptamine analogues. Sympathetic effects also appear to be due primarily to CNS stimulation. Amphetamine derivatives may also activate the sympathetic nervous system by directly stimulating peripheral alpha- and beta-adrenergic receptors. Marijuana was originally thought to interact with membrane lipids, thereby distorting CNS neurotransmitter receptor sites.^{9,15} It is now known that most of its effects result from an interaction with unique "cannabinoid receptors" in the brain.¹⁴

LSD is rapidly absorbed from all mucosal surfaces, with an onset of action of about 30 minutes, peak effects in 3 to 5 hours, and a duration of action of 8 to 12 hours. The hallucinogenic oral dose usually ranges from 50 to 300 µg; peak plasma levels of 1 to 4 ng/mL occur 1 to 2 hours after ingestion. LSD has a small volume of distribution (0.28 L/kg), undergoes hepatic metabolism, with a half-life of 3 to 4 hours, and can be detected in the urine for up to 5 days after an hallucinogenic dose. The potentially lethal dose is estimated to be about 100 times the hallucinogenic dose.^{8,19}

Analogues of LSD are far less potent than the parent compound, with hallucinogenic doses ranging from 3 to 100 mg. A dozen Hawaiian baby woodrose, several hundred common morning glory, and one to three whole nutmeg (5 to 15 g) seeds can cause symptoms. Absorption is rapid after intravenous and inhalational use, with onset and peak effects occurring in minutes and duration of effects ranging from 2 to 24 hours. The onset of effects occurs about 30 minutes after ingestion and peaks in 1 to 6 hours. Hepatic metabolites are excreted in the urine.

Marijuana and THC are also rapidly absorbed. The onset of effects and peak plasma levels occur within 10 minutes of smoking and within 30 minutes to 3 hours of ingestion. Peak effects are noted about 30 minutes after smoking and 2 to 6 hours after ingestion. The hallucinogenic dose is 5 to 10 mg. The average marijuana cigarette contains about 30 mg of THC, but only 20% to 50% is absorbed. The amount of THC per puff increases as the cigarette is smoked, with about 25% remaining in the butt, known as a "roach" (which may also be smoked). Medical THC (dronabinol, Marinol) is given orally in daily doses of 2.5 to 20.0 mg. Peak plasma THC concentrations after smoking average 20 ng/mL after an hallucinogenic dose and are several times higher than those obtained after ingesting an equivalent dose. THC is highly lipid-soluble and has a large volume of distribution (4 to 14 L/kg). It undergoes extensive hepatic metabolism, with a half-life of 15 to 35 hours. THC metabolites can be detected in the urine for up to 1 week after a single dose in occasional users and for a month or more after the cessation of chronic intake. The estimated lethal dose of THC is several hundred times the hallucinogenic dose.^{9,15}

Mescaline is readily absorbed, with the onset of effects occurring about 1 hour after ingestion. Physiologic effects usually peak within 2 hours and then abate, whereas hallucinogenic effects peak at 3 to 6 hours and last 6 to 12 hours. The hallucinogenic dose is 200 to 500 mg. Because a single peyote button contains about 45 mg of mescaline, the usual hallucinogenic dose is six to 12 buttons. Blood levels range from 2 to 4 µg/mL 2 hours after an hallucinogenic dose. Mescaline is eliminated by renal excretion as well as hepatic metabolism, with a half-life of about 6 hours. Mescaline and its metabolites can be detected in the urine for about 24 hours after intake. The potentially lethal dose is between ten and 100 times the hallucinogenic dose.^{8,10,19}

Analogues of mescaline are more potent than the parent compound, with hallucinogenic doses ranging from 1 mg for DOB to 150 mg for MDMA. Effects are similar to those caused by mescaline in time of onset and time of maximal intensity, but they may last two to three times as long. As a result of their sympathetic activity, potentially lethal doses are usually only several times the usual hallucinogenic dose, but even the latter is occasionally fatal.^{16,18}

Tolerance may develop after the chronic use of all hallucinogens. Cross-tolerance occurs between LSD and mescaline and their derivatives and probably between marijuana, ethanol, and barbiturates. A drug-free interval of 3 to 4 days is usually sufficient for the disappearance of pharmacokinetic tolerance, but pharmacodynamic tolerance may persist for many years. A withdrawal syndrome has been reported only with marijuana.^{16,19}

CLINICAL PRESENTATION

Hallucinogen use is usually intentional, results in expected effects, and does not attract particular attention. Patients who present to the emergency department usually do so because of accidental intake; lack of experience with these agents; excessive, persistent, or unpleasant reactions; and psychotic or violent behavior. They are typically brought in by friends, family, paramedics, or police.

The hallucinogenic effects of LSD, marijuana, mescaline, and related synthetic agents are qualitatively similar.¹² Patients usually remain aware that their hallucinations are drug-induced and maintain their ability to distinguish what is real from what is not. Sensory misperceptions may take the form of auditory, gustatory, olfactory, tactile, and visual dysesthesias (i.e., exaggerated or diminished sensations) or synesthesias (i.e., one sensation interpreted as another, such as sound resulting in color perception). LSD, mescaline, and their analogues tend to cause visual hallucinations, whereas marijuana tends to provoke auditory and gustatory hallucinations. Anorexia is typical of the former, whereas an increased, sometimes ravenous appetite is often associated with the latter. Altered sense of time occurs with all agents. Disordered thought processes may result in illusions of movement, misinterpretation of the meaning or significance of an event (e.g., religious or evil connotations), impaired judgment and memory, or frankly psychotic behavior. Although the drug experience is usually considered pleasant and associated with mood elevation, it is occasionally perceived as being noxious or frightening, resulting in a panic reaction.

Catatonic, paranoid, homicidal, and suicidal behavior can also occur. The mood may swing unpredictably from one extreme to the other. Although effects usually last less than 24 hours, a few patients may develop persistent psychosis. Acute adverse reactions appear to be more common in teenagers who take single large doses, whereas persistent reactions are more common in older people who have been chronic users. Flashbacks (spontaneous, short-lived, intrusive images, such as flashes of light; halos; trails; objects appearing to be moving, enlarged, or shrunken; and double exposures; and recollections or re-creations of hallucinogenic experiences) have been described following the use of LSD, morning glory seeds, and psilocybin. Persistent and prolonged afterimages (palinopsia) can also occur after LSD use. Chronic marijuana smoking may result in adverse pulmonary effects similar to, but more pronounced than, those caused by tobacco.¹⁹ Decreased levels of luteinizing hormone-releasing hormone, prolactin, and testosterone have been reported in experimental animals, and gynecomastia and decreased sperm count and motility have been noted in humans. Female marijuana users are more likely than nonusers to have unintended pregnancies, premature labor, abruptio placentae, low-birth-weight children, and children with features of the fetal alcohol syndrome, but these effects are more likely due to concomitant poor nutrition, low socioeconomic status, and use of alcohol, tobacco, and other drugs than to marijuana itself. Although cannabinoids are capable of suppressing immune function, evidence of a clinically significant effect is lacking. Similarly, although high doses of THC have caused fetal malformations in experimental animals, there is no evidence that marijuana is a human teratogen.

Regardless of the agent taken, CNS effects are usually associated with sympathetic hyperactivity, as evidenced by mydriasis, diaphoresis, piloerection, tremors, and mildly elevated blood pressure, pulse, respiratory rate, and temperature. Nausea, vomiting, diarrhea, blurred vision, ataxia, dizziness, and weakness may also be present. LSD, mescaline, and their analogues tend to cause pallor and salivation, whereas a dry mouth, flushing, coughing, conjunctival injection, and orthostatic hypotension are characteristic of marijuana.^{4,6,8,9 and 10,15,19}

In severe intoxications, physiologic effects vary, depending on the identity of the hallucinogen. Massive LSD doses may cause hypotension, hyperthermia, coma, seizures, respiratory depression, coagulation abnormalities, and death.^{4,12,19} Although seizures from usual hallucinogenic doses of LSD are poorly documented, the author has seen them in a patient who was taking a serotonin reuptake inhibitor for depression. The ingestion of marijuana, especially in children, may result in marked CNS depression.²⁰ Its intravenous administration has been reported to cause abdominal pain, vomiting, headache, fever, hypotension, respiratory distress, rhabdomyolysis, renal failure, and death.⁵ Although mescaline itself has relatively mild sympathetic effects, more potent analogues, such as MDMA and MDEA, may cause tachyarrhythmias, marked hypertension, vasospasm with limb or organ ischemia, cardiovascular collapse, acute respiratory distress syndrome, malignant hyperthermia, coma, seizures, rhabdomyolysis, acute renal failure, disseminated intravascular coagulation, and death, probably as a result of their serotonergic effects (see also [Chapter 370](#)).^{7,17} Hepatotoxicity, sometimes fatal, has also been reported as a complication of MDMA ingestion. Overall, fatalities are rare, and far more often result from physical violence caused by dangerous behavior than from direct drug effects.^{16,19}

Laboratory findings include nonspecific leukocytosis and hyperglycemia in mild intoxications. Lactic acidosis, prolonged prothrombin and partial thromboplastin times,

and elevated creatine phosphokinase, blood urea nitrogen, and creatinine levels may be seen with severe cases. Although ventricular ectopy is occasionally noted, the electrocardiogram (ECG) normally reveals only sinus tachycardia. The chest radiograph is usually normal. Pneumothorax, pneumomediastinum, and pneumopericardium have been reported after marijuana smoking.³ Evidence of noncardiogenic pulmonary edema may be present in patients with severe poisoning by LSD or synthetic agents. Marked hyponatremia and consequent mental status changes, including coma and seizures, may be seen in patients who attend “rave” parties and drink large amounts of water in order to prevent dehydration and hyperthermia.

Hallucinogens are not readily detectable in the urine by routine toxicology screening (e.g., thin-layer chromatography). Their detection requires specific analysis, using techniques such as radioisotope or enzyme-linked immunoassay and gas or high-pressure liquid chromatography with fluorometry or mass spectrometry.

Abrupt withdrawal from chronic marijuana use may result in anxiety, insomnia, tremors, nausea, and, possibly, vomiting.¹⁵

DIFFERENTIAL DIAGNOSIS

Medical and psychiatric conditions that cause similar effects include hypoxia, hypoglycemia, hyponatremia, encephalopathy, encephalitis, meningitis, cerebral trauma, drug withdrawal, thyrotoxicosis, and major affective disorders (schizophrenia and manic–depressive illness). In patients with hyperthermia, motor hyperactivity, autonomic instability, rhabdomyolysis, the neuroleptic malignant syndrome, and the serotonin syndrome (see [Chapter 370](#)) must also be considered in the differential. Poisons that cause hallucinations with a relatively high frequency include sympathomimetics (e.g., amphetamines, cocaine, and methylxanthines), anticholinergics, local anesthetics (e.g., lidocaine), phencyclidine (PCP), ergot derivatives, aromatic and halogenated hydrocarbons, and mushrooms. PCP is distinguished by its propensity to cause amnesia, anesthesia, nystagmus, and wide fluctuations in the level of consciousness. The physiologic effects of sympathomimetics are usually much more pronounced relative to their hallucinogenic activity than is the case with LSD, marijuana, mescaline, and related agents.

Uncommon toxic causes of hallucinations include heavy metals, nutmeg (which contains an amphetamine derivative as well as volatile oils), morning glory seeds (which contain tryptamine derivatives), and toad poisons. In addition, hallucinations have been reported as idiosyncratic reactions to almost all medications.

Street-drug adulterants (e.g., cyanide, local anesthetics, quinine, quinidine, caffeine, theophylline, and strychnine) should also be considered in the differential of the cause of toxic effects of alleged hallucinogens.

EMERGENCY DEPARTMENT EVALUATION

The history includes the name or description of the hallucinogen, the time of ingestion, amount(s) taken, and the route of exposure. Slang names may provide a presumptive identity if the chemical name is not known. The time of onset and the nature of symptoms are noted. A history of previous drug use, psychiatric problems, and medical conditions, particularly cardiovascular disease, is documented. The clinician should specifically ask about the possibility of concomitant traumatic injuries.

The physical examination focuses on the mental status, neurologic evaluation, and cardiovascular system. A full set of vital signs is documented and repeated frequently. The patient is examined carefully for evidence of trauma and underlying diseases.

Ancillary testing is neither necessary nor useful in patients with mild hallucinogen intoxication, except to rule out other diagnoses. Patients with moderate or severe symptoms (e.g., excessive agitation and significantly abnormal vital signs) should have a chest radiograph; cardiac monitoring and a 12-lead ECG; complete blood count; determination of electrolyte, glucose, blood urea nitrogen, creatinine, and creatine kinase levels; and urinalysis (including myoglobin). Routine toxicology screening may be useful for detecting or excluding other agents. Specific assays of the urine are usually necessary to confirm the presence of hallucinogens. Quantitative blood (or urine) hallucinogen levels are not clinically useful or routinely available.

EMERGENCY DEPARTMENT MANAGEMENT

Although most patients with hallucinogen intoxication are physiologically stable, cognitive impairment and emotional lability place them at risk for unpredictable, self-destructive, or violent behavior. Those who are merely anxious and have normal or mildly elevated vital signs should be reassured and continuously observed in a quiet environment until symptoms abate. It is often helpful to have a friend or relative stay with the patient. Those with agitated, psychotic, or paranoid behavior require restraints to protect themselves and others from harm. Pharmacologic measures are preferable to physical ones, because the latter may predispose the patient to hyperthermia and rhabdomyolysis. Most such patients respond to treatment with a nonspecific sedative such as diazepam (5 to 10 mg) or lorazepam (2 to 4 mg), orally or intravenously, repeated as necessary. Those who are severely agitated or psychotic may require an antipsychotic agent such as chlorpromazine (0.5 to 2.0 mg/kg)⁶ or haloperidol (0.05 to 0.1 mg/kg), orally, intramuscularly, or intravenously, repeated as necessary. Those with hallucinations lasting more than 12 to 24 hours should also be treated with an antipsychotic medication. Persistent LSD-induced psychosis may also respond to oral L-5-hydroxytryptophan (400 mg/d) and carbidopa (100 mg/d).^{1,2}

Gastrointestinal decontamination is indicated for asymptomatic patients with recent ingestions. Activated charcoal is preferred. Except for large ingestions of marijuana, decontamination is unlikely to be of benefit in patients who present after the onset of hallucinations.

Patients with CNS depression, seizures, or significant vital sign abnormalities should have an intravenous line established and cardiac monitoring. Advanced life-support measures should be initiated as necessary. Seizures should be treated with lorazepam, diazepam, or a barbiturate. Marked tachycardia and hypertension should be treated with an adrenergic blocker such as labetalol (20 mg intravenously, with additional doses as needed) or a vasodilator–beta blocker combination (e.g., nitroprusside and esmolol or propranolol). Hypotension usually responds to fluid administration. Vasopressors (e.g., dopamine and norepinephrine) should be used for refractory hypotension. Hyperthermia should be aggressively treated with cooling measures (see [Chapter 387](#)) and pharmacologic control of behavioral hyperactivity.¹¹ Patients with the serotonin syndrome may respond to serotonin antagonists (see [Chapter 370](#)). Vascular spasm should be treated with nitroprusside or nifedipine and with heparin.² Alkaline diuresis may prevent myoglobinuric renal failure in patients with rhabdomyolysis. Symptoms of marijuana withdrawal do not require specific therapy.

DISPOSITION

Patients with hallucinations and mildly elevated vital signs can usually be observed in the emergency department and discharged (with a responsible friend or relative) once they become asymptomatic. Those with persistent hallucinations and stable vital signs should be referred for psychiatric evaluation and admission for behavioral observation and treatment. Those with coma, seizures, or abnormal vital signs requiring active treatment should be admitted to an intensive care unit. A vascular surgeon should be consulted in patients with arterial spasm. Physicians unfamiliar with the management of hallucinogen intoxication should consult a regional poison control center or a toxicologist for further advice, as needed. All patients with intentional hallucinogen use should be referred for drug-abuse counseling and rehabilitation before discharge.

COMMON PITFALLS

- Failure to closely observe the patient, to prevent physical injury to the patient and others, and to sedate and restrain the patient, if necessary
- Failure to evaluate for and treat coexisting trauma or medical problems
- Failure to obtain a complete set of vital signs, especially an accurate core temperature
- Failure to evaluate for occult rhabdomyolysis in patients with coma, seizures, hyperthermia, or behavioral or physiologic hyperactivity
- Failure to appreciate the potential severity of poisoning after the ingestion of marijuana, particularly in children
- Failure to appreciate that street drugs are frequently not what the user thinks they are and to consider adulterants or other drugs misrepresented as hallucinogens as the cause of toxicity

CHAPTER 342

Halogenated Hydrocarbon Poisoning

Mohamud R. Daya

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Halogenated hydrocarbons are aliphatic and aromatic organic compounds that contain one or more molecules of bromine, chlorine, fluorine, or iodine. The solvent properties of these substances make them useful for extracting, dissolving, and cleaning fats, waxes, grease, adhesives, resins, and oils that are insoluble in water. They are also used as refrigerants, aerosol propellants, fire-extinguishing agents, and fumigants ([Table 342.1](#)). They are constituents of various household cleaners, paint removers, aerosols, and office products. Due to environmental persistence and their ozone-depleting properties, some older halogenated hydrocarbons (e.g., chlorofluorocarbons [Freon], 1,1,1-trichloroethane [TCA]) are being phased out of use.

SOLVENTS
Chloroform
Carbon tetrachloride
Trichloroethylene (TCE)
Tetrachloroethylene (perchloroethylene [PCE])
1,1,1-Trichloroethane (TCA)*
Methylene chloride (dichloromethane [DCM])*
Trichlorofluoroethane (Freon 113)

REFRIGERANTS/AEROSOLS
Ethyl chloride
Trichlorofluoromethane (Freon 11)
Dichlorofluoromethane (Freon 12)
1,2-Dichlorotetrafluoroethane (Freon 114)
Difluoroethane (Freon 152)

FUMIGANTS
Methyl isocyanide
Ethylene dibromide

* Also known as aerosol propellants.

TABLE 342.1. Common Halogenated Hydrocarbons

Toxicity may result from deliberate or accidental overexposure. These hydrocarbons are frequently abused by male adolescents, and as many as 20% of high-school seniors have experimented with volatile substances at least once.^{1,7} These agents are readily available, conveniently packaged, easily concealed, inexpensive, and legal, and they provide a rapid state of intoxication when inhaled.⁸ Abuse can be accomplished by directly inhaling vapors from an open container (sniffing), inhaling from a piece of cloth (rag or towel) soaked with the substance and placed in front of the nose and mouth (huffing), or breathing in and out of a plastic or paper bag filled with the volatile substance (bagging).^{7,11}

In industry, about 10 million workers are exposed to organic solvents, a significant portion of which are chlorinated hydrocarbons. Risk of occupational inhalation exposure is determined by factors such as volatility, method of use, ventilation, and the presence of personal protective equipment. Dermal exposure is also common and may result in skin injury and systemic absorption.¹⁶ Ingestions of halogenated hydrocarbons are infrequent and usually involve accidental pediatric cases or deliberate adult suicide attempts.

These highly lipid-soluble hydrocarbons are rapidly absorbed following inhalation and ingestion. Distribution is rapid, with significant uptake in the brain and other organs of high fat content.¹¹ Absorption depends on the vapor concentration and minute ventilation and is increased with physical activity.¹⁶ There is considerable variation in the extent of hepatic metabolism and route of excretion among different compounds. Freons, TCA, and tetrachloroethylene (perchloroethylene [PCE]) are primarily excreted unchanged by the lungs. Methylene chloride (dichloromethane [DCM]) is excreted after almost complete metabolism in the liver to carbon dioxide (70%) and carbon monoxide (30%).^{15,16} Trichloroethylene (TCE), carbon tetrachloride, and chloroform undergo significant biotransformation in addition to excretion of the parent compound in expired air. TCE and, to a lesser extent, PCE are metabolized to trichloroacetic acid and trichloroethanol. These metabolites are excreted in the urine and may be useful for monitoring industrial exposures and compliance with abstinence from abuse.¹¹ Carbon tetrachloride and chloroform metabolism generates carbon dioxide along with hydrochloric acid.

Cytochrome P-450-mediated biotransformation of chloroform, carbon tetrachloride, and other halogenated hydrocarbons can produce toxic reactive intermediates (e.g., phosgene) that result in subsequent hepatic and renal damage.^{9,10} Ethanol, by inducing these microsomal enzyme systems, increases the toxicity of these compounds.

CLINICAL PRESENTATION

Central nervous system (CNS) depression is the primary effect of the halogenated hydrocarbons. Changes in consciousness are similar to those of ether anesthesia. Initially, there is euphoria, in association with visual or auditory hallucinations and perceptual disturbances. An intoxicated appearance, accompanied by ataxia and disorientation, is characteristic.²⁰ In addition, there is often a feeling of invulnerability, which can result in impulsive and dangerous behavior. Continued exposure results in increasing CNS depression, leading to stupor and coma. Coma may be associated with respiratory depression and seizures.

The irritant effects of halogenated hydrocarbons can result in pulmonary complaints, such as cough and dyspnea, following inhalational exposures. Bronchospasm can also occur in susceptible patients, and massive exposures may result in pneumonitis or pulmonary edema. Respiratory symptoms may also be present in instances of aspiration (see [Chapter 362](#)). Nausea, vomiting, diarrhea, and abdominal pain may be prominent symptoms, especially following ingestion. Delayed or persistent gastrointestinal (GI) symptoms usually reflect direct hepatic or renal injury. Dermal exposure may result in skin rashes due to the defatting and irritating properties of these agents.

Halogenated hydrocarbons can sensitize the myocardium to the dysrhythmogenic effects of circulating catecholamines, with resultant ventricular and supraventricular dysrhythmias.^{2,13,14,20} This sensitization is thought to account for the sudden deaths that occur following exposure in conjunction with agitation or strenuous physical activity.⁴ Death can also result from respiratory depression, anoxia (bag-breathing), and injuries from impulsive and irrational behavior.¹¹ Additional cardiac effects include bradycardia, depressed contractility, decreased cardiac output, and increased autonomic reflex activity.^{2,11}

Exposure to some halogenated hydrocarbons may result in distinct clinical presentations. For example, degreaser's flush is a cutaneous vascular reaction characterized by red blotches on the face, neck, and trunk that sometimes occurs following ethanol ingestion in workers recently exposed to TCE.¹⁸ The red discoloration, due to dilatation of superficial skin vessels, peaks within 30 minutes and fades completely within 1 hour.

Intoxication with TCE has also been associated with palsies of the oculomotor, trigeminal, and abducens cranial nerves.²⁰ Exposure to DCM or its two-halogen analogues (methylene iodide, chlorobromomethane), which are also metabolized to carbon monoxide, may produce carboxyhemoglobin levels of 5% to 50%.¹⁵ Although accompanying symptoms of carbon monoxide poisoning are usually mild (see [Chapter 323](#)), patients with underlying coronary artery disease can experience angina or myocardial infarction.¹⁹ The apparent half-life of carboxyhemoglobin produced from DCM is considerably longer than that produced following carbon monoxide exposure, because of the continued metabolism of DCM that is slowly released from adipose tissue stores.^{12,15}

DIFFERENTIAL DIAGNOSIS

Alternative diagnoses include intoxication from psychoactive agents such as phencyclidine, lysergic acid diethylamide, mescaline, and other hallucinogens. Anticholinergic and stimulant (cocaine, amphetamines) drug abuse should be considered in patients presenting with a toxic delirium. Drugs that produce CNS depression (e.g., opiates, ethanol, sedative-hypnotics, cyclic antidepressants, phenothiazines, gamma hydroxybutyrate) should be considered in the lethargic, obtunded, or comatose patient. Infectious, metabolic, traumatic, and other nondrug causes of altered mental status should also be considered.

EMERGENCY DEPARTMENT EVALUATION

The history should focus on the time of ingestion, the amount and identity of ingested substances, and the duration, nature, and identity of inhalational and dermal exposures. The time of onset and nature of symptoms and any prehospital interventions should be noted.

Inhalational solvent abuse should be suspected in an adolescent if bags or rags have been discovered at the scene, if he or she has a sweet, chemical breath odor, and if residual solvent stains are present around the face, hands, or clothes. The physical examination focuses on the cardiac, pulmonary, and neurologic status and the abdomen in cases of ingestion and inhalation, and on the involved area in topical exposures. An electrocardiogram and chest x-ray are obtained for symptomatic patients. Measurements of baseline liver enzymes, blood urea nitrogen, and creatinine and a urinalysis are helpful in the evaluation of renal or hepatic toxicity. Carboxyhemoglobin levels are valuable in DCM exposures.

Halogenated hydrocarbon ingestions may be confirmed by visualizing radiopaque material on abdominal radiographs.³ A serum ethanol concentration and a urine screen for drugs of abuse may be necessary to rule out other intoxications. Qualitative and quantitative analysis of blood and other tissues, using headspace gas chromatography, may be helpful in confirming volatile substance abuse in fatal cases.

EMERGENCY DEPARTMENT MANAGEMENT

First, direct attention to advanced life-support measures, because treatment is primarily supportive. Monitor cardiac rhythm and establish intravenous access. The regional poison control center may be a useful resource for substance information and patient management issues.

Decontamination measures depend on the route of exposure.¹⁶ The skin should be irrigated immediately with water, followed by soap-and-water washing. The eyes should be irrigated immediately with isotonic saline solution. Eye exposures should be evaluated with a slit lamp after irrigation. Antibiotic ointment may be indicated if corneal erosion is present. With significant ocular injury, consultation and follow-up with an ophthalmologist is recommended.

Patients with fumigant exposures or pulmonary symptoms after inhalation should be managed as described for irritant gas exposures (see [Chapter 346](#)). Mechanical hyperventilation may enhance the elimination of some substances and is recommended in intubated patients.¹¹ Adrenergic agents (beta agonists and theophylline) should be used with caution because of their potential dysrhythmogenic (cardiac sensitization) effects.¹¹ GI decontamination should be considered for all patients with recent ingestions, especially those with evidence of radiopaque material on abdominal radiographs. Gastric aspiration and activated charcoal are the preferred methods.

Seizures are treated with a benzodiazepine (e.g., lorazepam, diazepam), followed by phenytoin or phenobarbital. Life-threatening tachydysrhythmias following inhalational exposure are treated with beta blockers (e.g., propranolol, esmolol, metoprolol) or lidocaine. Beta blockade is also the treatment of choice for dysrhythmias encountered in chloral hydrate ingestions.⁸ Hypotension is treated with volume expansion and, if necessary, pure alpha vasopressors (e.g., norepinephrine). Dopamine should be avoided, because it promotes cardiac dysrhythmias in some cases.¹¹ Hepatotoxicity and nephrotoxicity are managed primarily by intensive supportive care.

Several unproved but potentially beneficial treatments, including *N*-acetylcysteine (NAC), hemoperfusion, and hyperbaric oxygen (HBO), should be considered for hepatotoxic agents such as carbon tetrachloride.^{5,17} These treatments must be started early if they are to be of benefit. The dosing regimen for NAC is similar to that used in acetaminophen overdose.¹¹ In large overdoses, treatment may have to be extended beyond the usual 18 doses, in light of continued release of solvent into the circulation from adipose tissue stores. The mechanism of action may relate to NAC's ability to bind toxic metabolites such as phosgene, or to the maintenance of intracellular glutathione concentrations. NAC and HBO may act primarily as free-radical scavengers, because their hepatoprotective effects have been related to reduced lipid peroxidation in animal models.⁵

Degreaser's flush does not generally require pharmacologic treatment but may respond to propranolol (40 to 80 mg orally).¹⁷ The management of carbon monoxide poisoning is discussed in [Chapter 323](#).

DISPOSITION

Patients with evidence of dysrhythmias require admission for cardiac monitoring. Those with persistent CNS and respiratory depression should also be admitted to a monitored unit. Patients with potential hepatic or renal toxicity or those with persistent GI symptoms may require admission for observation. Similarly, patients with significant DCM exposures and elevated carboxyhemoglobin levels should be admitted for oxygen therapy and serial monitoring of their carboxyhemoglobin levels. Patients who improve rapidly and become asymptomatic after a 4- to 6-hour observation period in the emergency department may be discharged. If indicated, appropriate psychiatric consultation should be obtained before discharge.

Patients must be warned to avoid circumstances that could result in future reexposure. Volatile substance abuse is a risk factor for progressive illicit drug use, and rehabilitation counseling should be offered. Employers and appropriate governmental regulatory agencies (e.g., the Occupational Safety and Health Administration) should be notified in cases of workplace exposures.

COMMON PITFALLS

- Failure to consider inhalant abuse in intoxicated patients, especially male adolescents
- Failure to use adrenergic drugs with caution in the treatment of bronchospasm and hypotension
- Failure to use beta blockers in the treatment of life-threatening tachydysrhythmias
- Failure to anticipate the need for prolonged treatment due to release of solvent from adipose tissue stores
- Failure to warn patients about the dangers of halogenated hydrocarbons and of reexposure
- Failure to notify employers and governmental agencies in cases of occupational exposures

PARAQUAT

Paraquat (1,1'-dimethyl-4,4'-bipyridium) is a relatively nonselective, rain-fast, foliage-applied, contact herbicide. Although it forms an inert complex with most types of soil, becoming rapidly harmless to both plants and animals, paraquat is one of the most toxic herbicides when ingested, producing multisystem failure, pulmonary fibrosis, and death. Mortality has been estimated at 20% to 50% from accidental ingestions and is probably greater after intentional ingestions.

Paraquat is a bipyridium quaternary ammonium compound available as a dichloride or dimethyl salt. Commercial paraquat preparations contain about 20% (wt/wt) cation, and household products, 0.2% (wt/wt). Common brand names include Herbaxone, Gramoxone, Gramonol, Preglone, and Weedol. Its herbicidal activity is due to interference with electron transfer during photosynthesis. The resulting inhibition of the reduction of nicotinamide-adenine dinucleotide phosphate (NADP) to NADPH leads to the production of superoxide and peroxide radicals, reactive forms of oxygen, which destroy lipid cell membrane components.

Only 1% to 5% of paraquat is absorbed from the gastrointestinal (GI) tract. Peak concentrations are achieved within 2 hours. Although dermal absorption is minimal unless the skin is abraded, fatal cutaneous exposures have been reported after a single or chronic application of commercial concentrates.¹⁶ Inhalation of paraquat spray is unlikely to cause systemic toxicity because its low vapor pressure and large spray droplets prevent its absorption. The smoking of paraquat-sprayed marijuana results in minimal absorption, estimated at 0.03% to 0.2%. Nevertheless, an estimated 60% to 70% of the paraquat in marijuana is converted to bipyridene when smoked, and this is a direct respiratory irritant.

Paraquat has a large volume of distribution (2 to 8 L/kg). Although it is distributed to all major organ systems, it selectively accumulates in the lungs. Its pulmonary toxicity may be accounted for by lung tissue concentrations ten to 15 times greater than plasma levels. Peak lung concentrations are achieved 4 to 5 days after ingestion. Paraquat is not metabolized. Most of an oral dose is eliminated by glomerular filtration and active tubular secretion within 48 hours, but 20% to 30% that may remain tissue-bound is excreted over 2 to 3 weeks.³

Although not fully understood, the mechanism of human toxicity is believed to be due to the formation of superoxides that may damage cells directly or through the generation of other active oxygen species. The lung is the site of greatest toxicity, but paraquat poisoning can cause multisystem damage involving the kidneys, liver, heart, orogastric passages, skin, eyes, and adrenal glands.

The severity of paraquat poisoning depends on the amount ingested. The ingestion of less than 20 mg/kg of paraquat results in a mild poisoning consisting of corrosive injury to the GI tract. Moderate-to-severe poisoning follows ingestions of 20 to 40 mg/kg, causing corrosive injury and the gradual (days to weeks) development of renal failure and pulmonary fibrosis. Death occurs in most patients but is usually delayed 2 to 3 weeks. An acute fulminant course with corrosive effects, multiorgan failure, and death occurs within hours to days after the ingestion of more than 40 mg/kg.¹⁶

The more concentrated the solution, the greater the corrosive effect. Depending on the route of exposure, burns may involve the eyes, respiratory tract, and skin, as well as the oropharynx, esophagus, and stomach. The major pathologic changes in the lung consist of alveolar epithelial destruction, with pulmonary hemorrhage and congestion progressing to intraalveolar and obliterative fibrosis. Oxygen potentiates the paraquat-induced pulmonary fibrosis.⁸

CLINICAL PRESENTATION

Exposure to dilute solutions usually results in local signs and symptoms such as dermatitis, conjunctivitis, cough, sore throat, and burning pain in the oropharynx. Exposure to more concentrated solutions can cause dermal burns, corneal abrasions, and esophageal and gastric ulcerations, causing burning of the mouth and throat, dysphagia, substernal chest pain, abdominal cramps, diarrhea, and vomiting.

Additional systemic toxicity may include acute proximal renal tubular necrosis and reversible renal failure, centrilobular hepatic necrosis, myocarditis and necrosis, and adrenal hemorrhage. In fulminant cases, severe local symptoms are accompanied by multiorgan failure, with death occurring within hours to days from pulmonary edema, seizures, and cardiogenic shock.¹⁶ The findings of elevated serum creatinine, low serum potassium, and metabolic acidosis on presentation are associated with the development of renal failure and death within 48 hours. Stomatitis, epistaxis, and bronchial irritation have been reported after inhalation.

Renal, hepatic, and cardiac involvement may be manifested by uremia, proteinuria, and oliguria or anuria; right upper quadrant tenderness with elevated serum bilirubin and transaminase levels; and chest pain with ischemic electrocardiogram (ECG) changes or evidence of myocarditis. With adequate treatment, renal and hepatic changes may be reversible, but pulmonary fibrosis and respiratory failure usually progresses relentlessly.

Pulmonary dysfunction is manifested by dyspnea, chest pain, tachypnea, and slowly progressive cyanosis. The chest radiograph may demonstrate pulmonary infiltrates, atelectasis, and pleural effusions. Pulmonary function testing may reveal low compliance and decreased lung volumes and diffusing capacity. Blood gas analysis reflects a worsening hypoxemia, with respiratory alkalosis and metabolic acidosis. Paraquat plasma concentrations above 2.0, 0.9, 0.3, 0.16, and 0.10 g/mL at 4, 6, 10, 16, and 24 hours after ingestion, respectively, represent potentially lethal concentrations.⁷

DIFFERENTIAL DIAGNOSIS

Paraquat poisoning is either known or suspected by a history of access to paraquat-containing products at the time of presentation or is realized retrospectively based on the characteristic corrosive effects, followed by multisystem involvement, particularly progressive pulmonary failure. The initial presentation may resemble that of other corrosive exposures. Heavy-metal poisoning can cause multisystem organ toxicity as well as corrosive GI effects. Paraquat should not be confused with diquat, which, although structurally related, differs in toxicity. Diquat poisoning is associated with cerebral hemorrhagic lesions, a higher incidence of severe acute renal failure, and paralytic ileus. It has minimal corrosive effects and does not appear to cause pulmonary fibrosis.¹⁷

EMERGENCY DEPARTMENT EVALUATION

The history should include the concentration, amount, and route of paraquat exposure, as well as the time of onset and nature of symptoms. Vitals signs should

include measurement of the oxygen saturation. The physical examination should include inspection of exposed surfaces for evidence of corrosive injury. Patients with eye exposures should have fluorescein and slit-lamp examinations. Esophagogastric endoscopy should be considered for patients with GI symptoms following ingestion.

Patients with significant ingestions should also have an ECG, chest radiograph, arterial blood gas analysis, pulmonary function tests, complete blood count (CBC), electrolytes, blood urea nitrogen (BUN), creatinine, glucose, amylase, liver function tests, cardiac enzymes, and urinalysis. Urine and serum paraquat concentrations as early as 4 hours after ingestion can confirm the exposure and may be prognostic.⁷ A qualitative urine test detects paraquat concentrations greater than 1 g/mL and confirms exposure but is not prognostic. It may be performed by adding 1 mL of a 1% solution of sodium dithionite in 2N sodium hydroxide to 10 mL of urine. A blue color indicates the presence of paraquat.⁷ Arrangements for quantitative paraquat assays can be made by calling ENECA (800-327-8633).

EMERGENCY DEPARTMENT MANAGEMENT

Contaminated skin should be flushed with copious amounts of water. Material splashed in the eyes should be removed by prolonged irrigation with water. Immediate and aggressive GI decontamination is critical, even when small amounts have been ingested. Unless the risk of esophageal perforation is great (i.e., the patient is unable to swallow and many hours have passed since the time of ingestion), GI decontamination should be performed. Activated charcoal is readily available and hence preferred, although Fuller's earth and 7.5% bentonite suspensions are also effective in binding paraquat in animal models.⁸ Preceding activated charcoal by gastric aspiration might be helpful in those with large or intentional ingestions. Repeated doses of activated charcoal should be given until paraquat is no longer detected in the urine or blood. The patient must be monitored for development of diarrhea or an ileus, which would limit the serial use of charcoal.

Early, prolonged hemoperfusion appears to be useful in removing paraquat and limiting systemic toxicity when started within 10 hours of ingestion (15 to 20 hours in the presence of renal failure) and performed 8 hours daily or continuously for 2 to 3 weeks until paraquat can no longer be detected in the urine or blood.^{14,20} Others have questioned the efficacy of hemoperfusion, particularly if initial plasma concentrations exceed 3 mg/L.⁶ Further studies are needed to confirm the effectiveness of this procedure and a new technique, continuous arteriovenous hemofiltration.¹⁴ Cyclophosphamide and methylprednisolone have been used to prevent pulmonary toxicity, but their efficacy remains to be proven.^{11,12} A successful single-lung transplantation has been reported after poisoning by paraquat resulted in end-stage lung disease.¹⁸

Supportive care should include monitoring for and treatment of hepatic, renal, cardiac, and pulmonary dysfunction, and fluid and electrolyte abnormalities. With the exception of supplemental oxygen, standard therapies are employed. Because oxygen increases pulmonary toxicity, concentrations greater than 21% should be used only when the P_O₂ falls below 50 mm Hg. Positive end-expiratory pressure may improve arterial oxygenation while obviating the need for increasing the inspired oxygen concentration.

DISPOSITION

A toxicologist or regional poison center should be consulted in all cases of paraquat poisoning. The National Pesticide Telecommunications Network also provides 24-hour-a-day consultation services (800-858-7378). Consultation with an ophthalmologist or GI endoscopist may also be required. Admission or referral to a tertiary care center capable of providing continuous hemoperfusion and supportive care is required in all but the most minor exposures.

COMMON PITFALLS

- Underestimating the potential toxicity in an asymptomatic patient who has ingested even a small quantity of paraquat
- Failure to obtain blood paraquat levels
- Failure to admit all patients with intentional ingestions or significant skin exposures
- Potentiating pulmonary toxicity with supplemental oxygen therapy when it is not absolutely required

CHLOROPHENOXY ACIDS

The chlorophenoxy acid herbicides include 2,4-dichlorophenoxyacetic acid (2,4-D), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), 4-chloro-2-methyl-phenoxypropionic acid (mecoprop), and related compounds. They act as plant hormones (auxins) to limit the growth of broadleaf and woody vegetation. Agents Orange, Green, Pink, Purple, Blue, and White (the colors of the drums that contained them) were chlorophenoxy acid herbicides used in the Vietnam War. Agent Orange was a 50:50 mixture of the *N*-butyl esters of 2,4-D and 2,4,5-T, whereas agents Green, Pink, and Purple were primarily 2,4,5-T; all contained the contaminant 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD, or dioxin). TCDD is carcinogenic and teratogenic in animals, and an analogous role in humans is suspected. Agents Blue and White were related defoliant.

Only 2,4-D is currently available for general use in the United States, and its TCDD concentrations are quite low. Common brand names include Aqua-Kleen, Emulsamine, Herbidol, Weed-B-Gone, and Weedone. Serious poisoning is rare and almost always results from suicidal ingestion. Pulmonary absorption is possible but unlikely to cause systemic toxicity. Although skin absorption is low, toxicity has resulted from chronic exposure.²

GI absorption is slow; peak blood levels may not occur for 12 hours or longer.¹ 2,4-D has an apparent volume of distribution of 0.1 L/kg, with the highest concentrations found in the blood and heart. Elimination occurs mainly by renal excretion of unchanged 2,4-D, with a half-life of about 12 hours after low doses. With overdose, the volume of distribution and half-life appear to be much greater. Because it is a weak acid (pK_a 3.3), alkaline diuresis shortens the half-life by a factor of 10 or more.^{4,15}

It is unclear how 2,4-D causes toxicity in humans, but uncoupling of oxidative phosphorylation may be involved. Rhabdomyolysis may be due to direct muscle toxicity resulting from increased activity of skeletal muscle mitochondrial enzymes. Neuronal demyelination and rhabdomyolysis are pathologic findings. Doses of roughly 50 mg/kg produce mild toxicity, those of 100 mg/kg cause severe poisoning, and those of 250 mg/kg or more may be fatal.¹⁵ Plasma 2,4-D levels, measured by gas chromatography, are usually in the range of 500 g/mL or more in patients with severe or fatal poisoning.

CLINICAL PRESENTATION

A burning sensation may be noted in the pharynx, chest, and abdomen after ingestion. Vomiting occurs early and may be persistent. Within a few hours, neurologic abnormalities such as agitation, confusion, headache, dizziness, lethargy, coma, and seizures may develop.^{4,5,15,19} Pupils tend to be small but reactive. Deep tendon reflexes and muscle tone may be increased, decreased, or normal. Opisthotonus, myoclonus, fasciculations, and muscle tenderness have been described. Dyspnea and tachypnea are often present. In severe cases, progressive tachycardia, hypotension, and hyperthermia may ensue. Cyanosis, flushed skin, and diaphoresis have been reported. Early death may be due to ventricular fibrillation. Eye, skin, and respiratory tract irritation may follow exposure by these routes.

Laboratory abnormalities include an increased anion gap metabolic acidosis, hypoxia, hyperkalemia, hypocalcemia, leukocytosis, evidence of rhabdomyolysis (increased creatine phosphokinase level and myoglobinuria), mildly elevated hepatic enzyme levels, and renal function disturbances (elevated BUN and creatinine levels, proteinuria, and glycosuria).^{11,19} The ECG may show flat or inverted T waves. Although pulmonary edema and aspiration have been reported, the chest radiograph usually is normal. Nerve conduction and electromyographic studies may show evidence of peripheral neuropathy and myopathy.¹⁵

In mild-to-moderate intoxications, recovery is usually complete within 2 to 3 days; in severe cases, it may take longer than 1 week. Coma and acidemia are poor prognostic signs.⁴ Neuritis and myopathy with limb pain, paresthesias, twitching, tenderness, and weakness may be delayed in onset and persist for several months.¹³

DIFFERENTIAL DIAGNOSIS

The central nervous system depression seen in mild-to-moderate 2,4-D poisoning may be confused with that caused by trauma, infection, hypoglycemia, and sedative-hypnotic poisoning. In contrast to narcotic poisoning, there is no respiratory depression. Severe 2,4-D poisoning, with tachycardia, hypotension, fever, rhabdomyolysis, and metabolic acidosis, may be confused with septic shock, diabetic ketoacidosis, severe stimulant poisoning (e.g., amphetamines, cocaine,

theophylline), and intoxication by methanol, ethylene glycol, and salicylates.

Other uncouplers of oxidative phosphorylation, such as the dinitroresol and dinitrophenol herbicides and the pentachlorophenol fungicides, may produce a similar clinical picture. Cresolic and phenolic herbicides may stain the skin yellow and cause dark-colored urine. Other agents to consider when an unknown herbicide has been ingested include amide, aniline, and arsenic derivatives; carbamates and thiocarbamates; chlorates; glyphosate; paraquat; and triazines. Toxicologic analysis of the blood may be necessary for a definitive diagnosis.

EMERGENCY DEPARTMENT EVALUATION

The history should include the time, amount, and concentration of the agent(s) ingested; the onset, nature, and progression of symptoms; and the patient's health history. A similar description of circumstances should be obtained if other routes of exposure are involved.

The physical examination should focus on the vital signs, neurologic status, cardiovascular system, muscles, and skin. Laboratory evaluation in symptomatic patients should include arterial blood gas analysis; a CBC; measurement of electrolyte, calcium, magnesium, BUN, creatinine, glucose, creatine phosphokinase, and cardiac and liver enzyme levels; and urinalysis for myoglobin and routine analysis. An ECG and chest radiograph should be obtained. Nerve conduction studies and electromyography are sometimes necessary.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures should be instituted as necessary. In severe cases, endotracheal intubation and fluid resuscitation may be required. Active external cooling may be necessary in patients with hyperthermia. Because salicylates can cause uncoupling of oxidative phosphorylation, their use should be avoided. Due to slow absorption, GI decontamination may be effective long after ingestion (possibly as long as 18 hours). Activated charcoal is the preferred method. Gastric aspiration prior to activated charcoal may offer some additional benefit.

Treatment consists primarily of supportive measures. Electrolyte abnormalities should be corrected. The administration of sodium bicarbonate has three beneficial effects: correction of acidemia, enhancement of the urinary excretion of 2,4-D by ion trapping, and prevention of renal failure in patients with rhabdomyolysis. It also appears to improve survival.⁴ Sodium bicarbonate should be given as a constant infusion rather than as a bolus. The urine pH must be increased to 8.0 to enhance excretion significantly.¹⁸ A suggested initial infusion is two ampules (88 mEq) of sodium bicarbonate per liter of dextrose 5% in sodium chloride 0.45% at 150 mL/h. Adjustments in the rate and the amount of bicarbonate should be made on the basis of urine flow and pH.

The use of muscle relaxants should be considered in patients with agitation, fasciculations, myoclonus, or muscle rigidity. A benzodiazepine or nondepolarizing neuromuscular blocker may be preferable to succinylcholine because of the clinical similarity between 2,4-D muscle toxicity and early succinylcholine effects.

Plasma 2,4-D levels have been used to monitor the effect of therapy, but they are not readily available, and treatment must be based on clinical findings. The kinetic profile of 2,4-D suggests that extracorporeal removal (dialysis or hemoperfusion) may be effective, but the use of these techniques has not been reported.

DISPOSITION

Because the onset and peak of toxicity may be delayed many hours after ingestion, all patients except those with trivial ingestions (or exposure by other routes) should be admitted for observation. Symptomatic patients should be admitted to an intensive care unit. If intensive supportive care is unavailable, symptomatic patients should be transferred to a facility with such capability.

COMMON PITFALLS

- Failure to appreciate that GI decontamination may be effective many hours after ingestion
- Failure to appreciate that toxicity may be delayed in onset and to admit all patients with nontrivial ingestions for observation
- Failure to evaluate symptomatic patients for multisystem toxicity, especially rhabdomyolysis
- Failure to use alkaline diuresis to enhance 2,4-D elimination

CHAPTER 344

Hydrogen Sulfide Poisoning

Daniel R. Douglas and Martin J. Smilkstein

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Hydrogen sulfide (H₂S) is a colorless, irritating, heavier-than-air gas recognized at low concentrations by its characteristic rotten-eggs odor. Although less notorious than cyanide, H₂S can be just as deadly and is far more common. Natural sources include sulfur springs, crude petroleum, natural gas, volcanic gas, and bacterial decomposition of sulfur-containing proteinaceous material. Exposure may occur during digging, drilling, mining, and caisson work, or during refining (petroleum and natural gas refineries, coke ovens, and ore smelting).

Chemical reactions that involve sulfur-containing compounds may produce H₂S during rubber vulcanization, viscose rayon manufacturing, Kraft paper milling, leather and fur processing, food processing, dairy and brewery work, and production of pesticides, heavy water, felt, and glue. H₂S exposure may also occur in the setting of hot asphalt use, sewer and septic tank cleaning, and drain cleaning (reaction of acid drain cleaners with sulfur-containing sludge).²

Dermal absorption is negligible, but after inhalation, reversible binding of H₂S to the ferric ion of the cytochrome-aa₃ oxidase complex prevents cellular respiration and leads to cellular asphyxia and lactic acidosis.^{2,13} Although H₂S is a more potent inhibitor of cytochrome oxidase than cyanide, the detoxification of H₂S and the return of cellular respiration is rapid, so that even severe symptomatology is often reversible if the toxic exposure is brief.^{2,5}

Therefore, unlike toxicity from other cellular asphyxiants (cyanide and carbon monoxide), which is more persistent, removal from exposure and administration of oxygen rapidly terminate H₂S inhibition of cellular respiration. In many cases, severely poisoned victims show rapid spontaneous correction of lactic acidosis, often by the time initial resuscitation is complete.⁷

There has been speculation that sulfhemoglobin formation may contribute to cyanosis and to the pathophysiology of poisoning. Although sulfhemoglobin has been present in some cases of sulfide poisoning,¹⁰ it has also been absent in many fatal accidental and experimental cases,¹³ is difficult to assay accurately, and is probably not clinically significant.⁹ Sulfhemoglobin is not readily assayable, but an “oxygen saturation gap” (calculated oxygen saturation minus measured oxygen saturation) that is not explained by the presence of other abnormal hemoglobins (carboxyhemoglobin and methemoglobin) may represent the presence of sulfhemoglobin.

Animal studies have demonstrated that the greatest central nervous system (CNS) uptake of sulfide after sodium hydrosulfide (alkali salt of H₂S) exposure is in the brainstem, which contains the medullary respiratory center.¹⁸ Furthermore, increased levels of monoamines (epinephrine, norepinephrine, serotonin, and dopamine), as well as enhanced monoamine oxidase inhibition, have been found in the brainstem of rats acutely poisoned with sodium hydrosulfide.¹⁵ Although the exact significance of these findings is unclear, they may play a role in the central respiratory paralysis seen after severe H₂S poisoning.¹⁹ The metabolic fate of H₂S has not been studied in humans. Rapid oxidation of sulfide to sulfate is thought to be the primary route of detoxification,² and probably occurs within minutes.³

CLINICAL PRESENTATION

The severity of H₂S poisoning, and thus the clinical presentation, is largely determined by the intensity of the initial exposure. Low concentrations (50 to 100 ppm) may initially cause only mucous membrane irritation, whereas exposure to high concentrations (500 to 1000 ppm) may cause immediate respiratory paralysis and death, even before mucous membrane irritation develops.² The rotten-eggs odor of H₂S is detectable between 0.02 and 0.1 ppm and becomes intense between 20 and 30 ppm. As the sulfide concentration increases to dangerous levels (greater than 100 ppm), olfactory nerve dysfunction occurs and the sense of smell is lost.²

H₂S exposure may cause both local and systemic effects. The direct irritative action of H₂S on the mucous membrane results in both ocular and respiratory inflammation. Eye pain and burning, lacrimation, and blurred vision consistent with keratoconjunctivitis are typically noted first. Patients may complain of colored halos around lights (“gas eyes”) due to inflammation and edema of the cornea. Rarely, corneal ulcerations may develop in more severe exposures. Mucosal irritation of the respiratory tract can result in inflammation from the nasal passages to the pulmonary parenchyma. Thus, patients may complain of nasal congestion, sore throat, hoarseness, cough, bloody sputum, and shortness of breath. Physical examination may reveal nasal and pharyngeal mucosal hyperemia or edema and auscultatory findings of wheezing, rales, and consolidation due to pneumonitis or pulmonary edema. Twenty percent of cases in one study were clinically diagnosed with pulmonary edema.⁹ Both noncardiogenic and cardiogenic pulmonary edema may result from severe exposure.

CNS effects typically predominate after systemic absorption of H₂S. Severe, acute exposures typically cause rapid loss of consciousness and central respiratory paralysis. Corresponding to the possible effects of CNS anoxia, many other neurologic effects have been described, including headache, confusion, vertigo, agitation, somnolence, weakness of extremities, prolonged coma, and seizures.⁵ Horizontal and vertical nystagmus has also been reported.¹⁵ Although less common, reported cardiovascular effects include hypertension,^{1,15} hypotension, tachycardia, bradycardia, conduction defects (left bundle-branch block),¹⁵ and ischemic electrocardiogram (ECG) changes.¹⁷ Nausea, vomiting, and abdominal cramps may occur with more subacute exposures. Vomiting combined with a depressed level of consciousness may result in aspiration.

Because of the potential for sudden loss of consciousness and collapse, the possibility of occult traumatic injuries (e.g., cervical spine injuries) must be entertained. Some form of bodily trauma was noted in 27% of 221 cases in one review.⁵

In contrast to acute H₂S poisoning, chronic toxicity (prolonged low-level exposure or intermittent moderate-level exposures) does not cause dramatic CNS effects but may result in neuropsychiatric sequelae such as fatigue, headache, dizziness, irritability, and cognitive impairment.

Laboratory and ECG findings are nonspecific but reflect the severity of the anoxic injury. In significant poisonings, arterial blood gas measurements may show a combined metabolic and respiratory acidosis. Elevated lactate levels may also be present secondary to inhibited cellular respiration; however, due to rapid correction, significant levels may not be present at the time of the emergency department evaluation if there has been adequate cardiorespiratory support. In addition, the blood gas abnormalities often described after cyanide and carbon monoxide exposure (persistent or worsening acidosis and decreased arterial–venous oxygen saturation difference) are uncommon after H₂S poisoning. There are no readily available tests to confirm the diagnosis.

Methods to assay blood sulfide at low concentrations have been developed and may be useful in determining exposure in less severe poisonings.⁸ Due to the rapid detoxification and metabolism of sulfide, the sample must be taken as soon as possible after exposure, usually no later than 2 hours. Although of interest in some cases, the assay is not readily available, and the meaning of sulfide levels is unknown. Anecdotally, the H₂S odor may be detectable when the stopper is removed from blood specimens drawn from victims, but this finding is not consistently present.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes other toxic gases capable of the same “knock-down” effect, including cyanide and simple asphyxiants (e.g., carbon dioxide and

methane). Cardiovascular, CNS, and thromboembolic causes of syncope and collapse must also be considered.

EMERGENCY DEPARTMENT EVALUATION

The history is directed at documenting H₂S exposure and the severity of symptoms. The physician notes the setting and actions immediately preceding symptom onset, unusual odors, other exposures, associated trauma, the duration of exposure, and the time course (rapidity of onset and duration) of any alterations in level of consciousness.

Physical examination focuses on vital signs, mucous membrane and eye findings, and cardiac, pulmonary, and neurologic findings. An alert mental status is insufficient to rule out CNS dysfunction. A meticulous neurologic examination and mental status testing, including short-term memory, attention, and concentration, may reveal subtle abnormalities indicative of either ongoing toxicity or postasphyxiant dysfunction.

When only eye and respiratory irritation is present, without respiratory distress or alteration in mental status or vital signs, laboratory assessment is unnecessary. Arterial blood gas measurements, a chest radiograph, and an ECG should be done in patients with systemic symptoms or signs. Patients with a prolonged loss of consciousness may also warrant routine hematology, chemistry, and coagulation profiles.

EMERGENCY DEPARTMENT MANAGEMENT

Rescuers and prehospital care providers must wear self-contained breathing equipment if there is a risk of ongoing exposure. Rescue breathing by mouth-to-mouth resuscitation can be attempted if absolutely necessary, because evidence is lacking to suggest that it is potentially harmful to the rescuer. Dermal decontamination is not critical, because no significant skin absorption occurs. Ocular irrigation may provide symptomatic relief but is not an immediate treatment priority, because eye damage is usually limited to superficial irritation.

Supportive care is the mainstay of therapy. Advanced life-support measures should be initiated as needed. To maximize oxygen delivery and reduce ongoing sulfide–cytochrome binding, all patients should receive 100% oxygen. Noncardiogenic pulmonary edema may require positive-pressure ventilation. Pulmonary edema due to cardiac failure may require diuretics and other adjuncts. Routine eye care should be provided.

The use of nitrites and hyperbaric oxygen (HBO) is controversial. Nitrite-induced methemoglobin may act as a competitive inhibitor of sulfide–cytochrome binding by forming a sulfide–methemoglobin complex (sulfmethemoglobin), or it may enhance detoxification by acting as a catalyst for sulfide oxidation.² Despite anecdotal reports^{11,15} and evidence of prophylactic (preexposure) efficacy in animal models,¹⁴ there is no convincing evidence that nitrites are effective when given after the exposure. Laboratory studies³ and the clinical course of patients⁵ indicate that sulfide oxidation is so rapid that the amount of cytochrome-bound sulfide is probably inconsequential by the time most patients reach the emergency department. As a result, nitrite therapy should be reserved for severely poisoned patients who reach the hospital within a few minutes of exposure and fail to improve rapidly.

In such cases, the nitrite portion of the Lilly cyanide antidote kit may be given in the same dosage as for cyanide (adults, 10 mL of 3% sodium nitrite intravenously over 3 to 4 minutes; children, 0.2 to 0.33 mL/kg, up to 10 mL). If intravenous access is established, it is unnecessary to administer amyl nitrite. Nitrite therapy can cause hypotension with rapid administration and can cause significant methemoglobinemia.

HBO has mostly been studied in the treatment of acute carbon monoxide poisoning, but the exact indications for its use remain unclear. Several studies suggest that HBO therapy may decrease the incidence of neuropsychiatric sequelae after acute carbon monoxide exposure,^{6,16} and most authorities recommend its use for the patient with sustained neurologic changes or depressed mental status. The indications for HBO therapy in H₂S poisoning are even less well defined. However, animal studies⁴ and anecdotal reports^{12,20} suggest the possible utility of HBO in treating H₂S toxicity. Although its efficacy and mechanism of action remain unproved, HBO should be considered in patients with a persistently decreased level of consciousness or neurologic changes despite treatment with the previously described measures.

DISPOSITION

Consultation with a toxicologist or poison center is advisable if the physician is unfamiliar with H₂S poisoning. Patients with only mucous membrane irritation may be treated as outpatients. Patients with mild systemic symptoms, including brief syncope (less than 1 minute), may be discharged when asymptomatic if they have no underlying cardiovascular or neurologic disease and the physical examination, arterial blood gas analysis, ECG, and chest radiograph are normal. All other patients should be admitted, and those with persistent vital sign, respiratory, or neurologic abnormalities should be admitted to an intensive care unit. Transfer of severely intoxicated patients should be considered if intensive care admission, antidotal therapy, or HBO is indicated but unavailable.

COMMON PITFALLS

- Failure to consider the possibility of H₂S poisoning in otherwise healthy patients who suddenly collapse at work
- Failure to appreciate that olfactory paralysis prevents odor detection at dangerous H₂S levels and that the absence of an odor does not imply safety
- Failure of prehospital rescuers to wear self-contained breathing gear to avoid becoming additional victims
- Failure to consider the possibility of other victims and perform a scene search when an index case is found
- Failure to evaluate patients for concomitant traumatic injuries
- Failure to appreciate that nitrite therapy has limited usefulness and entails significant risks

[Chapter References](#)

Although iron poisoning occurs in all age groups, it is the leading cause of accidental poisoning death from pharmaceutical agents among young children. The American Association of Poison Control Centers has reported over 29,000 iron ingestions annually, with two fatal outcomes in both 1996 and 1997.^{8,10} Household sources of iron are commonplace, making them readily available for impetuous ingestions. Parental iron supplements of these preparations are often found in homes with young children, and many of these preparations appear nearly identical to candy; some are even sugar-coated. Chewable multivitamins with iron are specifically designed to appeal to young children.

The amount of iron in each preparation varies, and toxicity after acute ingestion depends on the amount of elemental iron ingested ([Table 345.1](#)). Toxic doses are difficult to define, given the frequently unreliable histories surrounding accidental ingestions. In general, the ingestion of more than 20 mg of elemental iron per kilogram of body weight produces significant gastroenteritis; doses above the 40- to 60-mg/kg range are potentially fatal. Though confirmatory epidemiology studies are lacking, many physicians believe that the ingestion of children's chewable multiple vitamins with iron rarely causes severe iron poisoning, and that toxicity from such exposures is less than expected on the basis of elemental iron ingested per body weight.⁸ Some poison centers choose to observe asymptomatic or only mildly symptomatic children at home after ingesting such preparations, even when the estimated ingestion exceeds 20 mg/kg of elemental iron.

Compound	Percent Elemental Iron by Weight
Ferrous carbonate, anhydrous	48
Ferrous fumarate	33
Ferrous gluconate	12
Ferrous phosphate	37
Ferrous pyrophosphate	12
Ferrous sulfate	16
Ferrocobaltate	12
Ferroglycine sulfate	16
Ferric pyrophosphate	12

TABLE 345.1. Iron Compounds and Their Percent Elemental Iron Content

About 10% of ingested iron, mainly the ferrous (Fe^{2+}) state, is absorbed each day from the small intestine. Because free, unbound iron is toxic to tissues, the body has many mechanisms to keep iron bound to proteins or other macromolecules. After absorption, iron changes to the ferric (Fe^{3+}) state and is stored in the intestinal mucosa complexed to ferritin. Transport to other tissues occurs with iron bound to transferrin. The total amount of iron that transferrin can bind is termed the *total iron-binding capacity* (TIBC). Normal serum iron concentrations vary from 50 to 150 $\mu\text{g/dL}$, while normal TIBCs can range from 300 to 450 $\mu\text{g/dL}$. Because the TIBC is far in excess of the iron concentration, there normally is no circulating unbound iron.

Excessive iron is corrosive to the gastrointestinal (GI) tract, resulting in gastroenteritis, with the potential for hemorrhage, hypovolemia, and perforation. If enough iron is absorbed, systemic and metabolic consequences of iron poisoning develop. Iron accumulates mainly in the liver after overdose but can have toxic effects in almost any organ. Iron is concentrated in mitochondria, where it disrupts oxidative phosphorylation and catalyzes the formation of oxygen free radicals, leading to lipid peroxidation and cell death. Toxic amounts of iron also produce venodilation and increase capillary permeability. The metabolic acidosis seen in iron poisoning is due to several factors, including hypovolemia, tissue hypoperfusion, a shift to anaerobic metabolism as mitochondrial function is impaired, and the hydration of the ferric ion with generation of hydrogen ions:

Coagulopathy may occur, even before the onset of hepatic dysfunction, from iron's ability to inhibit serine proteases as thrombin and other coagulation factors. Isolated liver damage may occur, but multiple organ system failure is possible in severe iron poisonings.^{5,12,14}

CLINICAL PRESENTATION

Clinical effects of iron poisoning are usually considered in stages.^{5,12,14} It is important to remember, however, that the time frame for staging is imprecise, patients present at variable times after ingestion, and distinguishing between stages can be difficult due to overlapping signs, symptoms, and laboratory manifestations, and because of rapid progression. Patients can die in any stage of iron poisoning, but for different reasons.

The first stage of iron poisoning develops within the first few hours after ingestion. It is due to the direct corrosive effects of iron on the GI tract, and is characterized by abdominal pain, vomiting, and diarrhea. Hematemesis or melena may occur if significant GI bleeding is present. Serum iron concentrations may be normal or elevated. Diarrhea may be the only manifestation in patients who ingest multiple vitamins with iron, particularly preparations intended for children. Patients with serious stage 1 iron toxicity will develop lethargy, shock, and metabolic acidosis due to hypovolemia, anemia, and tissue hypoperfusion.

Stage 2 is characterized by resolution of the clinical signs and symptoms seen in stage 1, despite continued absorption of toxic amounts of iron and increasing tissue iron burden. Sometimes unseen, this stage may last until about 24 hours after ingestion. Patients frequently lie quietly and clinically appear improved, but the resolution of gastroenteritis can be falsely reassuring. If laboratory studies are obtained, they are likely to show elevated serum iron levels and a progressive metabolic acidosis.

Stage 3 systemic iron poisoning becomes clinically evident. Stage 3 may appear early in patients with severe poisoning (bypassing stage 2) or may appear several hours after the beginning of stage 2. Toxic amounts of iron have moved from blood into tissues, disrupting cellular metabolism, causing third-spacing of fluids and producing venous pooling of blood. Shock and metabolic acidosis in this stage can result from persistent hypovolemia, anemia, hepatic dysfunction, impaired oxidative phosphorylation, heart failure, and renal failure. Fulminant hepatic failure with hypoglycemia, hyperammonemia, and coagulopathy may occur, though significant hepatic injury is unusual when peak serum iron levels remain below 500 $\mu\text{g/dL}$.

Stage 4 is characterized by gastric outlet or small-bowel obstruction. GI obstruction is an unusual occurrence but may develop several weeks after the acute toxicity has resolved, due to scarring produced by iron's corrosive effects.

Elevated serum iron levels obtained within the proper time frame are helpful in confirming the diagnosis of iron poisoning. Serum iron concentrations usually peak 2 to 6 hours after ingestion. Because it is iron in tissue that produces systemic toxicity, a patient may be seriously ill from iron poisoning and have a normal serum iron

level many hours after ingestion. On the other hand, a serum iron level drawn early after ingestion may be misleadingly low if absorption is still occurring. Therefore, a normal serum iron concentration very early or many hours after ingestion does not exclude iron poisoning.

Clinical and laboratory findings can help predict the degree of toxicity. The majority of children who have vomiting or diarrhea, a white blood cell count greater than 15,000/ μ L, and a serum glucose level greater than 150 mg/dL after ingesting iron have a serum iron level greater than 300 μ g/dL.⁷ However, severely poisoned patients can still have normal white count and serum glucose levels.^{6,13} The “deferoxamine challenge” test, in which the presence of *vin rosé*-colored urine after giving a dose of deferoxamine was considered an indication for chelation therapy, is no longer recommended because this color change is unreliable.¹⁸ A kidney–ureter–bladder (KUB) radiograph may demonstrate radiopacities in the GI tract, a finding often present in patients who develop significant poisoning. However, a patient may be seriously ill from iron poisoning and have a normal KUB radiograph. About 50% of children who develop serum iron levels in excess of 300 μ g/dL have a negative KUB.^{7,13} Experience at our center indicates that even when iron tablets are noted initially, they are no longer visible at 24 hours in patients who receive chelation therapy and supportive care.

DIFFERENTIAL DIAGNOSIS

The initial GI signs and symptoms of iron poisoning occur in many disorders, including poisoning by acetaminophen, salicylate, hepatotoxic mushrooms, arsenic, caffeine and theophylline, caustics, copper salts, and mercurial salts. Infectious gastroenteritis, medical and surgical intraabdominal conditions, or sepsis may cause vomiting, diarrhea, acidosis, and shock. Acute iron poisoning, however, is not accompanied by fever unless produced by a sequela of iron poisoning (e.g., aspiration, bowel infarction).

EMERGENCY DEPARTMENT EVALUATION

The history should include the time and amount of ingestion, the identity of the iron preparation ingested, and the nature, severity, time of onset, and progression of symptoms. The physician should specifically ask about abdominal pain, vomiting, and diarrhea, and whether blood was noted. The amount of elemental iron ingested, in milligrams per kilogram, should be calculated. The physical examination should focus on vital signs, overall appearance, and the abdomen.

Patients who have had only one or two episodes of vomiting or diarrhea and are subsequently asymptomatic should have a complete blood count and measurement of serum electrolytes, glucose, blood urea nitrogen, creatinine, and iron levels. Those with more pronounced or persistent GI symptoms, evidence of hypovolemia, or lethargy should also have a prothrombin time, liver function studies, arterial blood gas analysis, and a KUB radiograph. A TIBC is not helpful in the evaluation of iron toxicity and should not be ordered. It does not assist in the treatment decisions, and several laboratory methods to measure the TIBC are inaccurate in the setting of iron overload.

EMERGENCY DEPARTMENT MANAGEMENT

In general, all symptomatic patients and those who ingested more than 20 mg/kg of elemental iron less than 6 hours earlier are referred by poison control centers to emergency departments for evaluation. Prehospital care of symptomatic patients includes adequate oxygenation and intravenous hydration for patients with hypotension or other evidence of hypovolemia.

Gastric decontamination measures are of questionable value in iron ingestion. Activated charcoal does not effectively bind iron, and its use should be limited to cases in which coingestion of other substances that bind to charcoal is known or suspected. If activated charcoal is administered, cathartics should be withheld, especially in patients who already have gastroenteritis, as this may exacerbate hypovolemia. Though gastric lavage is commonly employed in iron ingestions, it has never been shown to be of clinical benefit, possibly because most iron tablets are too large to evacuate by this method. Simulated overdose studies suggest that oral magnesium oxide (Milk of Magnesia)¹⁷ or a slurry of charcoal mixed with deferoxamine³ can reduce iron absorption, but the utility of such treatments in actual overdose patients is unknown. There are no data supporting lavage with sodium bicarbonate solutions or administration of phosphates to prevent iron absorption. Lavage with deferoxamine solutions is not recommended because of the tremendous amounts required and because only a small portion of the ingested iron is absorbed. Whole-bowel irrigation with polyethylene glycol–electrolyte lavage solutions¹⁶ and gastrotomy to remove iron pills² have also been reported, but such recommendations are based on anecdotal data. Whether they are more effective than supportive care alone has not been studied in controlled trials.

Patients who remain completely asymptomatic (including no lethargy) for 6 hours after ingestion and who have a normal physical examination do not require treatment. Those who ingested more than 20 mg/kg of elemental iron but are seen within 6 hours might benefit from gastric lavage. Given the lack of data concerning the efficacy of gastric lavage in this setting, the decision to use it is made on an individual basis. Syrup of ipecac is not recommended, because the vomiting it produces cannot be distinguished from iron-induced gastroenteritis. If vomiting has already occurred, gastric lavage is of questionable benefit. Bicarbonate, phosphate, or deferoxamine solutions should not be used for lavage.⁵ Activated charcoal does not prevent iron absorption and is not indicated for isolated ingestions of iron or vitamins with iron. However, a single dose of Milk of Magnesia (60 mL/g of elemental iron ingested) is recommended, as it may significantly prevent iron absorption.⁵ If the serum iron concentration in an asymptomatic patient is lower than 350 μ g/dL, and a repeat study documents no rise in the serum iron concentration, the patient can be released. On the other hand a KUB radiograph demonstrating numerous tablets suggests that serum iron concentrations will be rising. Patients who have suffered only a single emesis or diarrheal stool but who have remained asymptomatic for several hours and have a normal physical examination, KUB, and laboratory evaluation do not require treatment.

Patients who present with or develop more than two episodes of emesis or diarrhea, have evidence of hypovolemia, or exhibit lethargy require treatment with fluids and deferoxamine mesylate. In patients with significant symptoms of iron poisoning, treatment should not be delayed to wait for results of a serum iron determination, because the therapy is indicated regardless of the serum iron concentration. In contrast, iron ingestions are expected to raise serum iron levels above the normal range, and an “abnormal” iron level does not constitute an indication for deferoxamine or admission in the absence of clinical signs of toxicity.

With rare exceptions, all symptomatic patients are hypovolemic. Fluid challenges of 20 mL/kg of lactated Ringer's or normal saline are given to restore fluid volume and ensure a normal urine output. Patients commonly require maintenance infusions at twice normal rates to keep up with GI losses and third-spacing.

Deferoxamine mesylate is an iron-chelating agent that can remove iron from tissues and non–transferrin-bound iron from plasma. Deferoxamine binds to iron to form ferrioxamine, which is excreted in the urine over days to weeks. Ferrioxamine occasionally imparts a *vin rosé* color to the urine, but this color change is unreliable and inconsistent and should not be used to determine the need for additional treatment.^{12,18} Deferoxamine mesylate can be mixed in any crystalloid and should be continuously infused at 15 mg/kg/h. Higher infusion rates are recommended in severe cases by some authorities. Rapid intravenous administration is sometimes associated with hypotension, presumably from histamine release, but this is not usually a problem with infusion rates below 45 mg/kg/h. Intramuscular deferoxamine is not recommended.

Many statements in the manufacturer's package insert for deferoxamine do not reflect the standard of care. Deferoxamine is not contraindicated for the treatment of acute iron poisoning in pregnancy. Animal data and human experience strongly suggest that toxic amounts of maternally ingested iron, deferoxamine, and ferrioxamine do not cross into the fetal circulation.^{1,11} Fetal death, therefore, results from maternal demise, and a pregnant woman should be treated the same as any other person. At 15 mg/kg/h, many patients receive well over 6 g deferoxamine mesylate each day; this is safe for the short-term treatment of iron poisoning.

Deferoxamine causes falsely low serum iron concentrations.⁴ Because tissue iron, not serum iron, is responsible for toxicity, a normal or low serum iron concentration by itself cannot be used to justify stopping deferoxamine. Intravenous deferoxamine should be continued until clinical toxicity has resolved, serum iron levels are normal or low, and any *vin rosé*-colored urine (if present) disappears.¹² A urinary iron assay, which may objectively define when to stop deferoxamine therapy, has also been described, but its clinical utility has not been proved.¹⁸ Most patients require 12 to 24 hours of deferoxamine infusion, but occasional patients with very large overdoses require therapy for longer periods.

The use of prochlorperazine (Compazine) and deferoxamine together has produced coma in humans that has been reproduced in animals. This drug combination should therefore be avoided.

In renal failure, deferoxamine should be continued but at much lower infusion rates. Assuming that therapeutic deferoxamine levels have been obtained, anuric

patients should continue to receive infusions at about 1.5 mg/kg/h, based on the known prolonged half-life in renal failure. ¹²

General supportive care for attendant complications (e.g., liver failure, GI bleeding) is the same as for any other patient.

DISPOSITION

Patients who remain completely asymptomatic and those with a normal physical examination, KUB, and laboratory evaluation who have had only one or two episodes of emesis or diarrhea and then become asymptomatic 6 hours after ingestion can be discharged.

Patients with mild symptoms should have repeat labs demonstrating no rise in the serum level and no evidence of metabolic acidosis prior to discharge. Symptomatic patients should be admitted. The level of monitoring and treatment required usually necessitates intensive care. If the necessary laboratory and treatment services are not available, the patients should be transferred to a facility where such services are available. A poison center or toxicologist can be consulted for assistance with management.

COMMON PITFALLS

- Failing to administer adequate amounts of intravenous fluids to symptomatic patients
- Waiting for the result of the serum iron level before treating symptomatic patients with deferoxamine mesylate
- Using the TIBC for evaluation and treatment decisions
- Assuming that a “nontoxic” serum iron concentration excludes the diagnosis of iron poisoning or the need for treatment in a symptomatic patient
- Sending a patient home during stage 2 of poisoning because gastroenteritis has resolved
- Relying on normal serum glucose levels, white blood cell counts, and negative x-rays to exclude significant iron poisoning
- Failure to appreciate that deferoxamine may falsely lower serum iron concentration

[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The airway serves as a conduit, allowing the passage of fresh and waste gases. Extrapulmonary forces (muscles) affect inhalation, but the elastic recoil of the lung is primarily responsible for normal exhalation (bellows function). The lungs provide a large surface area for diffusion of gases between the alveolar spaces and the bloodstream. The upper airways are responsible for humidifying inspired air to prevent drying and irritation of lower airway surfaces. Lung compliance is dynamic, and contractile elements (smooth muscles), particularly those of the lower airways, respond to various stimuli by relaxing or contracting. The lung is also a metabolic and immunologically active organ. Mucous secretion (from goblet cells and mucous glands), combined with ciliary motion, is responsible for clearing particles from the airways. Any of the lung's functions may be affected by inhalation of an irritant gas. ¹¹

The response of the nose to inhalation of irritants may vary from rhinitis or hay fever to septal perforation (e.g., with chronic chromate exposure). The trachea and bronchi may respond by bronchoconstriction (immediate or delayed) and the development of asthma or acute tracheobronchitis. The response of lung parenchyma includes allergic alveolitis, pulmonary edema, emphysema, acute alveolitis, bronchiolitis, and interstitial fibrosis. The exact pathology depends on the nature, intensity, and duration of the exposure and the actual properties of the inhaled irritant.

Acute changes in lung function caused by irritant inhalation can be detected by several types of tests. Air flow capacity is best determined by spirometry, especially a flow-volume loop. The peak flowmeter is a simple device useful in determining the presence and severity of bronchoconstriction. In motivated and carefully trained patients, it may be a useful and readily available indicator of the need for, and response to, treatment. However, it has not been demonstrated to be an effective screening tool for patients with subtle changes in small airways resulting from early or mild exposures. The flow-volume loop provides additional information about the status of the smaller airways and probably remains better for this evaluation.

Reversibility of bronchospasm can be determined by the use of a bronchodilator and repeat testing. Changes in the alveolar-capillary permeability can be assessed by the single-breath carbon monoxide diffusing capacity (D_{LCO}). A chest radiograph is also useful, particularly for visualizing inflammatory reactions of the parenchyma. Arterial blood gas analysis can assist in the assessment of blood oxygenation (PO_2) and ventilation (PCO_2). Ventilation-perfusion scanning does not usually provide significant additional information, except to rule out other processes, such as pulmonary emboli. Most important, careful physical examination may demonstrate pathology not detected by these studies, such as fine wheezes in subtle or early asthma and fine crackles in early pulmonary edema.

Toxic gases can also injure internal organs after inhalation. Absorption of gases by routes other than inhalation is usually minimal compared with the dose delivered by inhalation.

The physical characteristics of the inhalant are extremely important in determining the site and depth of lung penetration and systemic absorption, as well as local effects of the exposure. A *gas* is a material without a defined shape when unconstrained at room temperature under ambient conditions. A *fume* is a small, solid particulate dispersion formed by the coalescence of gases volatilized during an oxidative process such as combustion. Fumes are usually submicronic particles that can penetrate deeply into the lung. *Mists* are suspended liquid droplets generated by the condensation of gases or the breaking up of liquids (e.g., by splashing, atomization, or related actions). A *vapor* is the gaseous phase of a material that is normally a liquid at room temperature. Its concentration depends on the liquid's vapor pressure and temperature. Various other definitions apply to fogs, aerosols, smokes, and dusts (see [Chapter 396](#)).

The deposition and absorption of a gas or vapor in the respiratory tract are primarily governed by its water solubility. Highly soluble gases are absorbed in the upper airways, whereas less soluble materials reach the lower airways. The deposition of particulates, such as dusts, is a function of their size. Particles 5 μm or smaller reach the lower airways. Larger particles are deposited more proximally; those of submicron size may pass in and out of the airways without substantial impaction or deposition.

These concepts are important in determining the likely signs and symptoms of a person exposed to irritant gases. Highly water soluble airway irritants usually cause upper airway (eye, nose, and throat) irritation. Materials that are less water soluble may reach the lower airways and alveolar membrane, causing bronchospasm and pulmonary edema. Some common and representative irritants are discussed in this chapter.

CLINICAL PRESENTATION

Primary Pulmonary Irritants

The signs and symptoms of irritant inhalation may be immediate or delayed in onset. Primary irritants include corrosive, acid, or alkaline materials that may become airborne and inhaled. Irritant substances may also adsorb to the surfaces of otherwise inert particles, causing deeper penetration and persistence in the lungs. For example, the products of combustion in a plastics fire may include highly irritant aldehydes and organic acids that may bind to the carbonaceous particulates in smoke (see [Chapter 396](#)).

Signs and symptoms vary with the nature of the exposure. Although low-level and long-term (months to years) exposures may contribute to the development of bronchitis or related lung disease, exposures to high levels for short periods usually cause irritation of the eyes, nose, and throat, leading to lacrimation, rhinorrhea, conjunctivitis, pharyngitis, dyspnea, chest tightness, and, possibly, dysphonia. If the exposure is great enough, tracheobronchitis may occur. Chest tightness, wheezing, decreased inspiration-expiration ratio, and increased sputum production may result. Arterial blood gas analysis frequently demonstrates altered ventilatory mechanics consistent with acute airway obstruction. The chest radiograph is usually normal. Pulmonary function studies, especially a prebronchodilator and postbronchodilator flow-volume loop, usually demonstrate reversible abnormalities.

In severe exposures, pulmonary edema may occur. The diffusing capacity as evaluated by the D_{LCO} is decreased with pulmonary edema. The chest radiograph may be normal, especially at the earlier phases of injury, or it may show signs of interstitial edema. Arterial blood gas analysis may demonstrate hyperventilation with hypoxemia, or it may be normal. Bronchiolitis obliterans has been infrequently reported after these exposures.

Tear gases (see [Chapter 325](#)) can cause severe upper and lower respiratory tract irritation, and asphyxia with prolonged or high-dose exposure (e.g., in a confined space).¹

Chloropicrin is used as an additive to fumigants such as methyl bromide (see later discussion) because it is a strong lacrimatory agent. Mercaptans and thiophene are used to odorize natural gas; they are slightly irritating in high doses, but they are generally known for their particular sulfur odors.

Oxides of sulfur react with water in the air to form sulfuric (or sulfurous) acid vapor or mists. These gases (e.g., SO_2) and vapors are responsible for urban air pollution resulting from fossil fuel combustion, smelting, and paper and rubber manufacturing. They are also used in bleaching, brewing, fumigation, tanning, preserving, and refrigeration.⁴ Oxides of nitrogen and sulfur are the principal causes of acid rain.

Ozone is a by-product of bleaching, water purification, and processes that generate a spark or electric arc in the presence of oxygen (e.g., welding, mercury vapor

lamps, photocopiers, and x-ray generators).¹⁷ It is also found in the atmosphere, and higher levels are found at higher altitudes; flight at altitudes above 35,000 feet may result in transient toxicity.

Isocyanates, classically toluene diisocyanate, can cause chemically induced (occupational) asthma.^{2,19} After long-term, low-level exposures, a worker may develop increasing symptoms of asthma. Alternatively, short-term, high-level exposures may produce the same problem. As there may be a delay of several hours between the exposure and the asthma (delayed hypersensitivity reaction), careful questioning for sources of exposure may be necessary. Isocyanates are used in the production of urethane foams for insulation, packaging, and the sealing and potting of electrical equipment. They are also used in many paints and finishes. Some chemicals in this class have different physiochemical and toxicologic properties—for instance, the more toxic methyl isocyanate was responsible for the deaths at Bhopal.

Oxides of nitrogen (NO, NO₂, N₂O₃, N₂O₄) are generated in many oxidative processes, including welding, fires, and industrial applications such as dye, fertilizer, celluloid, and lacquer manufacturing.¹⁸ The accidental introduction of organic materials into nitric acid may cause combustion and release of nitrogen oxides. They may also evolve during the decomposition of plants with a high nitrate content, as in silo filler's disease. The color of the gas varies according to the exact species, but it may be clear, orange-brown, or red. Symptoms usually occur immediately after inhalation. Any portion of the respiratory tract may be involved, but frequently, only lower airway effects are noted. Pulmonary edema may be delayed for 12 hours. Asthma may develop immediately or over the first few days and may be severe, even in the nonasthmatic patient. After resolution of a moderately severe, acute reaction, relapse may occur 3 weeks later and can be more serious than the original episode.

Phosgene (carbonyl chloride, COCl₂) is a classic inducer of delayed pulmonary edema.⁸ The main chemical warfare agent used in World War I, it is used in various chemical processes (drug, dye, insecticide, and isocyanate manufacturing). It is most frequently encountered in situations of combustion or pyrolysis when carbon, oxygen, and chlorine are available to react (e.g., burning plastics, chlorinated hydrocarbons, or carbons along with hydrochloric acid vapors). A haylike, musty odor may be noted.

Formaldehyde is a reactant or by-product in many chemical processes, such as embalming, cosmetic and resin manufacture, and sterilizing. It may evolve spontaneously from plastics, resins, insulation material, and many other occult sources.^{13,15} Formaldehyde has been noted to be a carcinogen in limited rodent studies and is suspected as a human carcinogen, although no confirmatory human studies have been completed.

Inorganic acids cause immediate irritation or corrosion of tissues, depending on the concentration and the agent. Sulfuric acid is also a desiccating agent, and chromic acid is a strong oxidizer. Although most acids do not cause systemic poisoning, chromates are hepatotoxic and nephrotoxic, and hydrofluoric acid (or hydrogen fluoride) may cause systemic fluoride poisoning. Acid vapor inhalation usually causes upper airway irritation with ocular and nasopharyngeal inflammation. If the acid forms a mist, deeper pulmonary penetration may occur, resulting in pulmonary edema, bronchiolitis obliterans, or asthma.

Chlorine is a heavier-than-air, water-soluble, yellow-green gas that is irritating to the mucous membranes.⁶ The warning properties of chlorine are usually adequate to alert the person to the presence of the material and afford time for escape. However, when a person is caught in a confined space or an overwhelming cloud, inhalation may cause irritation of the lower airways. Chlorine is used in many chemical industries and processes (e.g., sanitation of water) and can be generated by the action of an acid on hypochlorite, as found in bleaches. For example, the inappropriate mixing of bleach with an acid-based cleanser can generate chlorine during the cleaning of toilet bowls.¹⁴ Mixing hypochlorite with ammonia-based cleaners can produce chloramine, another gaseous irritant.¹⁰

Ammonia is highly water soluble and very irritating to the upper airways.⁵ In solution as ammonium hydroxide, its vapors can produce an immediate reaction. Although the odor of ammonia provides excellent warning of its presence, sudden overwhelming exposures, large clouds of the gas, or confined-space exposures can cause severe corrosive burns to the skin or eyes (with potential blindness). The oropharynx is readily burned, and hoarseness is common. Deeper injury to the lung can cause severe pulmonary dysfunction that is usually transient but can be permanent. The effects are rapid; "delayed" effects are usually the result of the progression of burns to the mucous membranes. Ammonia is used in various chemical processes, such as cleaning, fertilization, and refrigeration, and evolves during the combustion of a number of products.

Hydrocarbons comprise a wide variety of compounds. Although the irritancy of these gases or vapors cannot easily be generalized, the ketones, aldehydes, acid anhydrides, and halogenated compounds are most irritating. Aromatic compounds (e.g., benzene, xylene, and toluene) are more irritating than aliphatic ones (pentane, hexane, and butane). In addition, hydrocarbons are often systemic poisons, with central nervous system (CNS) effects predominating.

Epoxy resins, catalysts, and hardeners frequently produce vapors that can cause irritation or allergic sensitization of the airways. Styrene is used in the manufacture of boats, bathtubs, and many other products (polystyrene).

Pulmonary Irritants with Systemic Toxicity

Gases and vapors may gain entry to the body through the lungs and may inflict serious injury on a target organ remote from the portal of entry. The internal dose depends on such factors as the solubility of the gas, blood flow through the lungs (more important with materials with low blood solubility), gas distribution in the lungs, and ventilatory rate (as affected by activity). Delivery to the target organ depends on similar factors, including tissue perfusion, tissue penetration (especially lipid solubility for the liver, brain, and other organs), binding materials in the blood, and pH. Uptake into a temporary depot may occur, allowing the chemical to be redistributed to the target organ over a more protracted period (seen with highly fat soluble materials).

Arsine (AsH₃, arsenic trihydride) may be generated when arsenic-bearing materials come in contact with acids (e.g., during the processing of metals in which arsenic may be a natural contaminant, in sewer gases, and in laboratories).⁹ Arsine gas is also commonly used in the manufacture of computer chips. It has a garlic odor. In addition to its irritant effects, inhalation of arsine in high doses can cause immediate death from CNS toxicity. Classically, however, arsine combines with hemoglobin, causing intravascular hemolysis. Onset is usually rapid but may be delayed. Symptoms include nausea, vomiting, abdominal pain, fatigue, and weakness. The hematocrit may drop by 50% in a matter of minutes. Examination may reveal brownish skin, hepatosplenomegaly, tachycardia, tachypnea, and dark urine. Renal failure may ensue from the effects of the free plasma hemoglobin, the sludging of red cells, and the direct effects of the arsine-hemoglobin complex on the renal cells. Anemia may result in secondary ischemic complications such as congestive heart failure. Systemic toxicity due to inorganic arsenic poisoning may ensue (see [Chapter 318](#)). The urine arsenic level may confirm exposure but is usually unavailable.

Ethylene oxide is a colorless gas with an indistinct odor or taste.⁷ Manufactured by Union Carbide, it is called Oxirane. For gas sterilization, it is frequently supplied with a halogenated hydrocarbon in a nonflammable 12:88 mixture, but, at higher concentrations, it is flammable. In addition to mucosal irritation, ethylene oxide may cause CNS depression, seizures, skin and pulmonary burns, allergic reactions, and mild chemical hepatitis with transient lymphocytosis after acute exposure. It can also cause peripheral neuropathies, is a suspected human carcinogen, and is considered a reproductive hazard. It is used in many chemical industries and in hospitals (e.g., gas sterilization of products that cannot be steam-autoclaved).

Phosphine gas (PH₃, phosphorous trihydride) is used in fumigation (of grains), in silos and ship holds, in the electronics industry, and in the production of acetylene.²⁰ Phosphine can cause severe gastrointestinal (GI) and CNS toxicity, as well as immediate or delayed pulmonary edema. Symptoms are usually mild: headache, nausea, chest tightness, and lethargy. Coma, seizures, and shock may be seen in severe cases. Although there is no specific biologic test for exposure, a fishy or garlic odor may suggest the presence of zinc or aluminum phosphide and phosphine, respectively.

Methyl bromide is used as a fumigant.¹² When pumped into tented structures, the concentrations of gas are usually lethal. Intractable seizures, coma, and severe neurologic sequelae can result from exposure to this material. Severe acidosis may occur, presumably secondary to seizure activity. Mild exposure results in a flulike syndrome that is often delayed in onset. For fumigation, chloropicrin is usually added to methyl bromide to provide olfactory warning of its presence. Serum bromide levels above 5 mg/dL are probably consistent with exposure. If a lumbar puncture is performed to evaluate seizures or coma, determination of the bromide level in the cerebrospinal fluid may also be useful.

Sulfuryl fluoride, marketed as Vikane, is a fumigant that is primarily an irritant, although recent reports have suggested systemic toxicity.³

Ethylene dibromide was commonly used as a fumigant for soil, fruit, and other foods before 1984. Deaths have occurred after high-level exposure to this chemical as the result of combined dermal and inhalation absorption. Although symptoms are mainly limited to the respiratory and GI tracts, severe illness with acidosis and renal

failure has been reported.¹⁶ Because of its potential carcinogenicity, its use is now restricted.

DIFFERENTIAL DIAGNOSIS

Respiratory symptoms after irritant gas exposure are nonspecific. Similar findings may be caused by allergic and infectious etiologies. Although the onset is usually acute with toxic gas exposure, it may be delayed. In addition, a low-grade fever and leukocytosis may be present in patients with pneumonitis. Irritant-induced pulmonary edema is almost always noncardiogenic, as is that caused by severe narcotic and sedative–hypnotic poisoning. Bronchospasm may result from an exacerbation of asthma or chronic obstructive pulmonary disease due to other or unknown factors. Only a careful exposure (environmental or occupational) history will identify the correct cause.

EMERGENCY DEPARTMENT EVALUATION

The history includes medical history, previous exposures, and details of the presenting illness, such as the nature, progression, and severity of symptoms and antecedent activities. The physical examination is directed, but not limited, to the skin, eyes, nose, mouth, and chest. Depending on clinical findings, spirometry, response to bronchodilator inhalation, arterial blood gas analysis, chest radiography, D_LCO , and ventilation–perfusion scanning may be necessary to assess the nature and severity of signs and symptoms. Laboratory evaluation may be necessary with poisoning by systemic toxins (e.g., arsine and methyl bromide), as noted previously. Patients with respiratory distress should have an electrocardiogram.

EMERGENCY DEPARTMENT MANAGEMENT

Removal from the exposure, decontamination, and supportive care are the mainstays of prehospital treatment. A rescuer should never enter an area in which an irritant gas is potentially present without adequate skin, eye, and respiratory protection. Along with provision of supplemental oxygen, thorough flushing of irritated surfaces (skin and eyes) with water (preferably saline) may be required. Eye irrigation is especially important with acid fume, ammonia, chlorine, and tear gas exposure.

Respiratory therapy should include humidified oxygen, bronchodilators, and mechanical measures (intubation, ventilation, continuous positive airway pressure, positive end-expiratory pressure, and suctioning), as clinically indicated for bronchospasm or pulmonary edema. A course of high-dose steroids to reduce inflammation is theoretically beneficial and should be considered in patients with moderate, severe, or progressive symptoms. Data from animal experiments suggest that inhaled steroids decrease pulmonary vascular resistance and improve lung compliance and survival.

With arsine-induced hemolysis, exchange transfusion may be necessary when the resulting anemia is severe and free hemoglobin levels are high (greater than 1.5 g/dL). Chelation therapy may also be indicated if urine arsenic levels are elevated (see [Chapter 318](#)).

Other standard supportive therapies may be indicated for coexisting toxicity, such as anticonvulsant therapy for seizures and dialysis for renal failure.

DISPOSITION

The decision to admit or discharge depends primarily on the severity and progression of clinical and laboratory manifestations. Young, otherwise healthy patients who become asymptomatic or mildly symptomatic after 4 hours of emergency department observation and treatment may be discharged. Those with moderate, severe, or worsening symptoms or abnormal spirometry, arterial blood gas analysis, or chest radiograph should be admitted, especially if they are elderly or have underlying cardiac, respiratory, or other significant medical problems. If delayed toxicity is possible, patients who have persistent symptoms of any degree of severity should be admitted. Asymptomatic patients who are discharged should be instructed to return at the first sign of respiratory symptoms or systemic illness. If the physician is unfamiliar with the toxicity of a certain agent and its treatment, a poison center, toxicologist, or toxicology text should be consulted.

COMMON PITFALLS

- Failure to take an environmental or occupational exposure history
- Failure to recognize that a toxic exposure has occurred
- Failure to evaluate for systemic poisoning after irritant gas exposure
- Failure to use adequate protective equipment (in prehospital treatment) so that additional casualties are avoided
- Failure to obtain additional information and advice when unfamiliar with the toxicity of a particular gas and its management
- Failure to instruct discharged patients to return immediately if delayed symptoms develop or mild symptoms worsen; such instructions should be documented.

CHAPTER 347

Isoniazid Poisoning

Alan D. Woolf

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Isoniazid (isonicotinic acid hydrazide, INH), a derivative of vitamin B₃ (nicotinamide), has been used for the prophylaxis and treatment of tuberculosis since 1952. With the resurgence of tuberculosis in the 1990s has come an increasing incidence also in isoniazid poisoning.¹⁵ There were 480 isoniazid poisonings and one isoniazid-related death reported by the American Association of Poison Control Centers in 1997.¹³ The incidence of self-poisoning is greatest among those adult populations with a high prevalence of both tuberculosis and depression (e.g., Native Americans, immigrant populations).^{2,16}

INH is rapidly absorbed from the small intestine within 30 to 60 minutes after ingestion. Therapeutic doses are 5 to 10 mg/kg (maximum, 300 mg) daily, given orally or by intramuscular injection.¹ Peak INH serum levels (therapeutic range, 5 to 8 µg/mL) are reached within 1 to 2 hours.¹⁵ The drug is minimally bound to plasma proteins and has a small apparent volume of distribution (0.6 L/kg).¹⁹ INH can be detected in such diverse bodily fluids as saliva, cerebrospinal fluid (CSF), and breast milk. Up to 36% of the drug may be excreted unchanged in urine.¹¹ Metabolism by acetylation in the liver yields inactive metabolites that are predominantly excreted in the urine. People with normal renal function excrete 50% to 80% of a therapeutic dose of INH within 24 hours.³

There is great genetic variability in the metabolism of INH. Between 45% and 75% of Caucasians are “slow acetylators” and have a mean serum INH half-life of about 5 hours. By contrast, 95% of Inuit are “fast acetylators” and have an average serum half-life of 80 minutes.¹² These differences are therapeutically important: Slow acetylators can achieve sustained bactericidal drug levels on every-other-day dosage regimens, whereas fast acetylators may have inadequate levels unless they receive the drug daily.¹¹

Various mechanisms are responsible for the toxic effects of INH. In acute overdoses, INH decreases the conversion of glutamic acid to gamma-aminobutyric acid (GABA) by inhibiting the pyridoxal phosphate–dependent enzyme glutamic acid decarboxylase. Because GABA is an inhibitory neurotransmitter, seizures may ensue.²⁰ With chronic therapy, INH hydrazone analogues, which arise spontaneously *in vivo* (especially in slow acetylators), form rapidly excreted complexes with pyridoxine and also inhibit pyridoxine kinase, thereby decreasing the conversion of pyridoxine to its active cofactor form, pyridoxal phosphate.

INH is structurally similar to nicotinic acid and may substitute for it in the synthesis of nicotinamide adenine dinucleotide (NAD), producing an inactive coenzyme. Inhibition of NAD-dependent Krebs cycle enzymes may result in hyperglycemia, and inhibition of NAD-mediated conversion of lactate to pyruvate may contribute to the profound lactic acidosis that typically accompanies seizures.

Patients who are malnourished, pregnant, alcoholic, elderly, diabetic, or uremic may be at particularly high risk for pyridoxine deficiency during chronic INH therapy.¹⁴ In the absence of supplemental doses of pyridoxine (e.g., 10 mg/d), pyridoxine deficiency may develop and lead to peripheral neuropathies, anemia, and a lowered seizure threshold. Pyridoxine depletion can also inhibit the activity of pyridoxine-dependent decarboxylases and transaminases (leading to decreased catecholamine synthesis), cytochrome P-450 enzymes (leading to decreased drug metabolism), histaminase, and monoamine oxidase (see [Chapter 354](#)).

CLINICAL PRESENTATION

Seizures may be seen after acute overdoses of INH as low as 35 mg/kg in adults. Severe toxicity has been noted with ingestions of 5 to 7 g (80 to 150 mg/kg); death has resulted after the ingestion of as little as 3 g.¹⁷ Although ingestions of more than 12 g in an adult have a high fatality rate, survival has been reported after the ingestion of as much as 25 g.¹⁸ Poisoning is associated with an INH serum concentration above 30 µg/mL, although such laboratory assays for INH are not routinely available.

The initial symptoms of acute poisoning, which may occur as soon as 30 to 120 minutes after ingestion, include nausea, vomiting, slurred speech, blurred vision, and disorientation. Anticholinergic signs (e.g., mydriasis, tachycardia, and urinary retention) and hyperreflexia or areflexia may also be prominent. In severe poisonings, seizures appear abruptly and precede the development of a profound metabolic acidosis and coma, the triad of which forms the classic clinical picture. An arterial pH as low as 6.49 was recorded in an adolescent who survived INH poisoning with no sequelae.¹⁰

Multiple seizures over a short time period are the hallmark of INH poisoning. Other symptoms and signs of acute poisoning include confusion or hallucinations, garbled speech, hyperpyrexia, and respiratory depression. Laboratory findings include lactic acidosis, ketosis, hyperglycemia, an increased anion gap, hyperkalemia, peripheral blood leukocytosis, CSF pleocytosis, and renal defects (e.g., glycosuria, albuminuria, and oliguria). An elevated creatine phosphokinase due to rhabdomyolysis may precede myoglobinuria and renal failure. An electroencephalogram (EEG) often demonstrates diffuse slowing or paroxysmal electrical activity compatible with subclinical seizures. A chest radiograph may reveal aspiration pneumonia.

The clinical course of the untreated patient with a massive INH overdose is often unremitting seizures, resulting in death from acidosis and cardiovascular and respiratory collapse. Hepatic damage, manifested by elevated liver enzyme levels, has been documented in as many as 20.7 of 1,000 patients treated chronically with INH.⁴ Although such hepatotoxicity appears transient in most cases, even with continued use of the drug, rarely do patients go on to develop acute liver necrosis, liver failure, and death.^{4,8}

Toxic effects of chronic INH use also include euphoria, tinnitus, ataxia, impaired memory, encephalopathy, and optic neuritis. Allergic manifestations, such as rashes, eosinophilia, vasculitis, arthralgias, and a positive antinuclear antibody test, have also been described.⁹ Progressive lethargy, garbled speech, confusion, and coma were described in a man who mistakenly treated his tuberculosis with 1,200 mg of INH daily for 6 weeks.¹⁴

Patients with underlying impaired renal function or hepatic disease do not metabolize INH well, have a prolonged serum half-life, and are at greater risk for intoxication. Those with a preexisting seizure disorder are at higher risk for neurotoxic effects.

DIFFERENTIAL DIAGNOSIS

Agents that can cause a clinical picture similar to that of INH overdose include salicylates, cyanide, carbon monoxide, other hydrazines, monomethylhydrazine-containing mushrooms, anticholinergics, and sympathomimetics. Neurotoxins such as pesticides, camphor, lead, narcotics, strychnine, and tricyclic antidepressants must also be ruled out.⁵ Other medical conditions, such as meningitis with sepsis, diabetic ketoacidosis, uremia, meningoencephalitis, and head trauma, should also be considered in the differential of patients presenting with seizures, coma, and acidosis.^{5,7}

EMERGENCY DEPARTMENT EVALUATION

INH overdose should be strongly considered in the patient who presents with seizures refractory to conventional anticonvulsants and an evolving metabolic acidosis, especially within the context of a history of a psychiatric condition (i.e., depression) and tuberculosis, with access to INH.

The physical examination focuses on vital signs and the neurologic status, including an accurate scoring of the patient's alertness. The patient is carefully evaluated

for hyperreflexia, focal neurologic deficits, abnormal thought processes, and lethargy.

Laboratory tests include determination of serum electrolytes, glucose, bicarbonate levels and an arterial pH and gases. A toxicology screen of blood and urine should also be obtained. In severe or chronic cases, baseline tests of kidney and liver function are important. A chest radiograph can diagnose aspiration, and electrocardiographic monitoring is routine. An EEG may reveal diffuse slowing or seizure activity.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures should be instituted for victims of severe INH overdose, as necessary. A diagnostic clue to INH poisoning is the prompt termination of seizure activity after the administration of intravenous pyridoxine. Pyridoxine (vitamin B₆) is the specific antidote; it should be given in gram-for-gram equivalency to the estimated total amount of INH ingested.^{15,18} If the total ingested dose of INH is unknown, 5 g of pyridoxine can be given empirically by slow intravenous push and repeated in 20 minutes if there is no clinical response. Typically, the seizures abate and the patient's level of consciousness slowly improves. Diazepam (5 to 10 mg intravenously) may be used as an adjunct to control seizures. Additional pyridoxine is sometimes necessary for the resolution of INH-induced coma.

Although severe metabolic acidosis should be treated with intravenous sodium bicarbonate, large doses are usually unnecessary, because the acidosis is secondary to seizures and resolves shortly after seizures have been controlled.^{6,17} Diuresis is not of proven benefit in INH overdose. The use of adequate doses of diazepam and pyridoxine has essentially eliminated the need for barbiturates, paralyzing agents, anesthesia, dialysis, or exchange transfusion in the management of INH overdose. Chronic pyridoxine overdosing can cause a peripheral sensory neuropathy. Multiple large doses should be avoided because of pyridoxine's neurotoxic potential; only gram-for-gram replacement is recommended in INH poisoning.

After stabilization, instillation of activated charcoal into the gut should be done in all acute overdose patients to prevent further absorption of INH or other coingestants.

DISPOSITION

Asymptomatic or mildly symptomatic patients can be observed in the emergency department for 6 hours. A toxicologist or poison center should be consulted if the physician is unfamiliar with the management of INH poisoning. Such consultants can be helpful in assessing the patient with seizures and acidosis of unknown cause and in locating supplies of pyridoxine.

Moderately or severely symptomatic patients should be admitted to an intensive care unit. Patients with refractory seizures, severe respiratory depression, or renal failure should be transferred to a hospital with intensive care capabilities if they are not locally available.

COMMON PITFALLS

- Failure to appreciate that asymptomatic patients may rapidly deteriorate
- Using syrup of ipecac in patients who may develop seizures and coma while vomiting
- Failure to consider isoniazid poisoning in patients with metabolic acidosis and seizures refractory to conventional anticonvulsants, particularly in patients who are Native Americans or recent immigrants
- Failure to give pyridoxine at the first sign of toxicity
- Giving excessive doses of sodium bicarbonate for the treatment of metabolic acidosis, which spontaneously resolves when convulsions cease

CHAPTER 348

Lead Poisoning

Steven M. Marcus

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Lead is a heavy metal that exists in elemental, inorganic, and organic forms and as a contaminant of other metals. More than 900 hobbies and occupations involve contact with lead, such as metal extracting and refining, plumbing, pottery production, soldering, and painting. Children develop lead poisoning by eating chips of paint from surfaces painted with lead-based pigments or by ingesting dust, which contains lead. Data suggest that lead-contaminated house dust is, currently, the major source of lead exposure for children living in the United States. The potential for developing lead poisoning from the leaching of lead from imported lead-glazed cookware, dinnerware, and glassware and from the use of folk remedies such as azarcon, “pay-loo-ah,” and maha yogran guggula by Mexican, Hmong, and Asian Indian immigrants, respectively, has received much publicity.^{6,13}

Lead is principally absorbed through the gastrointestinal (GI) tract and the lungs. Although there is minimal or no absorption through the skin, absorption of lead from bullets lodged in joints (synovial fluid) or the spinal cord (cerebrospinal fluid) has been reported.⁸ The degree of absorption depends on the particle size and concentration. Lead has a melting point of 327°C and a vapor pressure of 1.77 mmHg at 1,000°C. Thus, lead becomes volatilized and airborne at relatively low temperatures. Gaseous lead and particulate lead with a diameter of less than 5 µm are nearly completely absorbed through pulmonary alveoli. Inhaled lead dust particles of larger size are usually trapped by cilia or in the tracheobronchial mucus and are cleared without being absorbed.

The absorption of ingested lead depends on factors such as the concentration, coincidental or previously ingested food, the status of the metal transfer protein, and age.^{7,11} In laboratory animals and humans, the younger the age, the greater the percentage of absorption of ingested lead. Iron and calcium deficiencies appear to promote absorption of lead, as does the coincidental ingestion of high-fat, low-protein, and low-phosphate meals. Unabsorbed lead is excreted in the stool.

Once absorbed, lead is principally carried on the red blood cell membrane, distributed to all parts of the body, and stored in bones. The calculated volume of distribution is quite high.¹⁷ The average blood lead level in United States residents is currently less than 4 µg/dL.⁵ Lead is not required for normal body function, nor is it metabolized. Lead is primarily eliminated by urinary excretion, with a small proportion excreted in bile and eliminated with stool. The total body elimination half-life of lead is greater than 18 months.

Lead is a protean poison that affects sulfhydryl-containing enzyme systems throughout the body—virtually all enzymes and organ systems are affected. Chief among the enzyme systems affected are those that involve heme synthesis. Inhibition of d-aminolevulinic acid dehydratase levels has been associated with central nervous system symptoms. Interference with ferrochelatase, the enzyme that promotes the incorporation of iron into protoporphyrin to produce heme, results in elevated free protoporphyrin levels.

Acute lead poisoning occasionally occurs from exposure to high concentrations of organic lead (e.g., tetraethyl lead). Although symptoms may suggest acute intoxication, poisoning from metallic and inorganic lead is usually due to chronic or subacute exposure, and the insidious onset of symptoms before presentation can be elicited by taking a careful history.

It is extremely important to have an index of suspicion for the presence of chronic lead poisoning. Chronic lead exposure has been associated with abnormality of semen quality, sperm morphology and physiology, hearing deficits, defects in reaction time (specifically the central component [decision slowing]), decreased numbers of CD16+ cells, chronic nephropathies associated with hypertension,^{10,18} gout, Fanconi syndrome (years after treatment with chelators), and a possible association with various cancers.

CLINICAL PRESENTATION

Patients with lead poisoning frequently present with headache, fatigue, malaise, abdominal pain, constipation, and vomiting. The abdominal pain is usually colicky and not responsive to standard analgesics. There may be complaints of peripheral paresthesias or hypoesthesias and occasional frank neurologic symptoms (e.g., wrist or ankle drop). Muscle weakness may also be noted. Depression and other affective disorders have been reported in lead-poisoned adults.¹ Hyperactivity, delayed development, or loss of recently acquired skills may be seen in children.^{11,14} In severe cases, coma and seizures may be noted.

Physical examination is generally unrevealing, although the blood pressure may be elevated. Occasionally, in adults with poor dental care, a dark bluish-black discoloration of the gingiva at the dental border (lead lines) may be present. This finding is seldom present in children and in those with good dental hygiene. If increased intracranial pressure accompanies lead encephalopathy, examination of the optic fundi may show papilledema. Cardiac dysrhythmias such as premature ventricular contractions have been reported.

An abdominal radiograph may reveal radiopaque foreign bodies in patients with pica or accidental lead ingestion. Long-bone radiographs may show an increased density of metaphyseal lines due to disordered calcium deposition. This finding is seldom present in adults.

The laboratory evaluation usually reveals a hypochromic microcytic anemia. Lead may produce a nonautoimmune hemolytic anemia with increased red cell fragility and an elevated reticulocyte count. Basophilic stippling and eosinophilia are less often noted. Proteinuria, glycosuria, a Fanconi syndrome (with aminoaciduria and renal tubular acidosis), and increased blood urea nitrogen and creatinine levels may be seen in patients with lead nephropathy. Because lead reduces the excretion of uric acid, patients with lead toxicity are prone to develop gout.

The definitive diagnosis of lead poisoning depends on the measurement of whole-blood lead and free erythrocyte protoporphyrin (FEP). The former indicates exposure and the latter is evidence of poisoning, because it is the result of lead's effect on ferrochelatase. Lead levels as low as 5 µg/dL have been reported to produce biochemical abnormalities, and levels between 10 and 20 µg/dL may be associated with clinical pathology (e.g., decreased intelligence and neurobehavioral problems in children).⁵ Lead levels above 10 µg/dL in children are currently considered to be evidence of increased lead absorption, and lead levels above 40 µg/dL in adults are considered evidence of lead poisoning serious enough to warrant intervention. FEP levels above 15 µg/dL are uncommon in healthy people. Although FEP levels over 20 µg/dL may be seen with either iron deficiency or lead poisoning, FEP levels above 35 µg/dL usually indicate lead poisoning.¹⁶

DIFFERENTIAL DIAGNOSIS

Lead poisoning shares symptomatology with other heavy metal poisonings. Unlike poisoning with arsenic, however, the peripheral neuropathy from lead is associated with decreased sensitivity; with arsenic, there are painful paresthesias. Unlike in thallium poisoning, there is no hair loss. Both lead and mercury poisoning are characterized by personality changes. Mercury intoxication is characterized by erythrim and rapid changes in affect, with outbursts of anger alternating with happiness. Lead poisoning is usually accompanied by depressive disorders. Urinary heavy metal analysis may be necessary for differentiation.

EMERGENCY DEPARTMENT EVALUATION

Patients who present to the emergency department with multisystem complaints, particularly chronic abdominal symptoms that have not responded to standard conservative therapy, should be suspected of having lead poisoning. The patient's occupation, hobbies, or living conditions may suggest exposure to lead. The

physician should ask about subtle changes in bowel habits, behavior, mood, and cognitive function, as well as headaches, weakness, and paresthesias.

In addition to vital signs and a general examination, a detailed neurologic examination should be performed. The physician should specifically check for papilledema and gingival pigmentation. If recent lead ingestion is suspected, an abdominal radiograph may be helpful. Long-bone radiographs (knee and wrist) may suggest chronic lead exposure. The laboratory evaluation should include a complete blood count, whole-blood lead and FEP levels, serum blood urea nitrogen and creatinine levels, and a urinalysis.

Elevated blood lead levels should usually be confirmed before initiating treatment. Asymptomatic patients with mildly elevated lead levels (20 to 44 $\mu\text{g}/\text{dL}$ in children, 40 to 80 $\mu\text{g}/\text{dL}$ in adults) may be evaluated with the calcium disodium EDTA lead mobilization test (discussion follows).¹⁵

EMERGENCY DEPARTMENT MANAGEMENT

Cerebral edema should be treated by hyperventilation, elevation of the head, and restriction of fluids. Seizures should be controlled with pharmacologic agents such as diazepam, barbiturates, and phenytoin. In patients with acute encephalopathy (with or without coma or seizures), chelation therapy should be initiated before obtaining confirmatory laboratory data, because the long-term outcome is related to the length of time the vital organs are exposed to elevated lead levels. GI decontamination should be performed if there is radiopaque material in the intestine, but decontamination should *not* delay definitive chelation therapy.

Chelation therapy is usually indicated for children with lead levels above 44 $\mu\text{g}/\text{dL}$, for adults with levels above 80 $\mu\text{g}/\text{dL}$, and for patients with lower levels who have a positive lead mobilization test or evidence of lead-associated symptoms or signs (discussion follows). Dimercaprol (British antilewisite [BAL]) crosses the blood–brain barrier and forms a tight bond with lead; in patients with lead encephalopathy, it is the initial therapy of choice. An oil-based solution of dimercaprol is given intramuscularly in a usual dose of 3 to 5 mg/kg every 4 to 6 hours. Dimercaprol is painful when injected and foul-smelling, and it may produce adverse local and systemic reactions. Sterile abscesses may occur at the site of dimercaprol injection, and febrile responses are not unusual. Many patients complain of a terrible taste in their mouths and of lightheadedness.

EDTA is water soluble and can be given intramuscularly or intravenously. The lead–EDTA bond is very strong and stable at a physiologic pH. However, in acid urine, the bond is less stable, and there is the potential for release of free lead into the renal tubule and subsequent renal tubular damage. The main side effects of EDTA are phlebitis (with concentrations of greater than 0.5 mg/mL) and potential renal toxicity. Because intramuscular injections are extremely irritating and produce elevations of creatine phosphokinase, intravenous administration is preferred.¹⁶ If the intramuscular route is used, procaine or lidocaine is usually added to produce an 0.5% concentration of the local anesthetic.

EDTA is given in a dose of 50 mg/kg/d. Intravenous EDTA is given as a continuous drip. At a concentration of 0.5 mg/mL, an enormous amount of fluid must be infused. However, if the patient can tolerate the fluid load, the incidence of side effects, particularly renal dysfunction, may be decreased. Intramuscular EDTA is given in divided doses every 4 to 24 hours. Because the use of EDTA alone may liberate carcass lead and transiently raise brain lead levels and increase symptoms,^{2,3} it may be advisable to start with a dose of dimercaprol in all symptomatic patients and those with high blood lead levels (greater than 55 $\mu\text{g}/\text{dL}$ in children and 100 mg/dL in adults).

The dose of EDTA for a diagnostic lead mobilization test is 1 g for adults and 25 mg/kg in children, infused over 1 to 2 hours with 250 to 1,000 mL of normal saline solution. The bladder is initially emptied, fluid intake is encouraged, and the urine is collected for 24 hours (3 days in patients with abnormal renal function) and analyzed for its lead content. If the amount of lead excreted (in micrograms) exceeds the amount of EDTA given (in milligrams), therapeutic chelation therapy may be indicated. In children, the challenge dose of EDTA can be given intramuscularly and the urine collected for 8 hours. With this regimen, chelation therapy is indicated if the urinary lead excretion (in micrograms) exceeds 60% of the dose of EDTA (in milligrams).

Two oral chelators are available. Only succimer (Chemet), or dimercaptosuccinic acid (succimer), is currently approved for use by the Food and Drug Administration. It is indicated for children with lead levels above 45 $\mu\text{g}/\text{dL}$ and is as effective in clearing lead as the combination of dimercaprol and EDTA.⁴ The side-effect spectrum is minimal, with a small incidence of skin rash, transaminase elevations, and GI discomfort.¹² Although not officially licensed for use in adults, its effectiveness, combined with its low order of toxicity, argues for its use in this population.⁹ The published dosage in children may be used safely in adults—10 mg/kg/dose every 8 hours for 5 days, followed by 10 mg/kg per dose every 12 hours for an additional 14 days. Patients should be monitored for toxicity with weekly blood counts, chemistry profiles, and urinalysis. The presence of ketones in the urine may be used as a measure of compliance, because it is a very common accompaniment of successful treatment. A mild rash or mild transaminitis is usually not a reason to abandon therapy, but requires closer observation, with more frequent laboratory investigation.

The other oral chelator, D-penicillamine, a derivative of penicillin, is given orally at a dosage of 30 mg/kg/d, with the average adult dose of about 1.0 to 1.5 g/d.^{12,20} It is usually used only for adults with mild or no symptoms but high lead levels. Side effects include diarrhea, renal toxicity, leukopenia, and, occasionally, a rash. Penicillamine is less effective than dimercaprol or EDTA.

If renal toxicity develops as a result of antidotal therapy, fluid input should be increased in an attempt to dilute the lead content of the urine. Alkalinization of the urine may also be helpful.

Therapy should be continued until the lead level drops below 20 $\mu\text{g}/\text{dL}$ in children and 40 $\mu\text{g}/\text{dL}$ in adults. Maximum lead excretion occurs during the first 3 days of chelation therapy and falls off rapidly. After 5 days of therapy, it is unlikely that there will be further significant plumburesis without a rest period to allow lead to redistribute from tissue compartments to the blood. Hence, chelation therapy is usually limited to a 5-day course, followed by a treatment-free interval of 2 to 7 days. Additional courses of therapy are indicated if symptoms persist or blood lead levels remain elevated. Repeat lead levels and perhaps reinstitution of therapy, depending on the rebound in lead level, should be considered. Children with lead levels below 20 $\mu\text{g}/\text{dL}$ and adults with levels below 40 $\mu\text{g}/\text{dL}$ should be managed by preventing further exposure by environmental and educational interventions (see discussion in next section). Follow-up evaluation and periodic monitoring are required.

The vast majority of lead-poisoned patients survive. The final neurologic outcome may not be known for many weeks or months after treatment. Patients with cerebral edema have a poor prognosis.

DISPOSITION

All patients with evidence of encephalopathy should be admitted. Although chelation with EDTA, penicillamine, and succimer can be done on an outpatient basis, it is advisable to admit all patients who are symptomatic or who have markedly elevated lead levels (requiring dimercaprol therapy). However, because blood lead levels are not immediately available at the time of initial evaluation, patients who are not acutely ill can be discharged and admitted later if blood lead analysis or an EDTA mobilization test confirms the suspected diagnosis.

Further exposure to lead must be prevented. Environmental and occupational investigations should be performed to determine the most likely source of lead so that it can be eliminated. Involvement of the public health department, primarily in dealing with a child with lead poisoning, is imperative. The Occupational Safety and Health Administration may be helpful in investigating cases of occupational lead exposure. Many states also have active divisions of occupational and environmental health that may be helpful in the long-term treatment of patients.

Although chelation therapy is not difficult, some of the nuances are appreciated only after treating many patients. Hence, the physician unfamiliar with the evaluation and therapy of lead exposure and poisoning is advised to consult an experienced pharmacologist, toxicologist, or nephrologist.

All patients should be seen within 2 weeks of chelation therapy for repeat lead and FEP levels, because lead will be mobilized from storage sites and blood levels will rebound after treatment. It is not uncommon for the lead level at 2 weeks after therapy to equal or exceed the initial level.

COMMON PITFALLS

- Failure to consider the diagnosis of lead poisoning in patients with cognitive dysfunction, neurologic symptoms, and GI complaints

- Failure to appreciate that elevated lead levels without coincidental elevations in FEP may be seen with recent exposures
- Failure to consult a lead-poisoning expert for management advice
- Failure to treat the patient with an extremely high lead level and a normal FEP level
- Failure to appreciate that, in many states, lead poisoning is a reportable illness, and both state and local health officials must be notified
- Failure to identify the source of lead and to prevent reexposure

CHAPTER 349

Lithium Poisoning

Kenneth W. Kulig

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The primary use of lithium is in the treatment of bipolar disorders. Other uses have included the treatment of drug and alcohol abuse, episodic aggression, anorexia nervosa, Huntington's chorea, tardive dyskinesia, SIADH, neutropenia, and Felty syndrome. ¹

In the United States, lithium is available as lithium carbonate tablets in regular (300 mg; 8.12 mEq) or slow-release (450 mg; 12.18 mEq) form, and as lithium citrate syrup (8 mEq/5 mL). Common adult daily doses are 900 to 2400 mg. Numerous adverse drug reactions and drug–drug interactions have been reported, and serum levels must be monitored carefully to avoid toxicity. Therapeutic lithium levels vary slightly from one laboratory to another but are generally cited as being within the range of 0.5 to 1.5 mEq/L.

The exact mechanism of action of lithium in the treatment of bipolar disorders is unknown. Therapeutic doses have no psychotropic effect in humans who do not have a bipolar disorder. Although lithium can replace sodium in supporting a single action potential in a nerve cell, it cannot maintain membrane potentials. Its ability to substitute for other cations, such as potassium, calcium, and magnesium at the cell membrane, has uncertain physiologic effects. Changes in the release or reuptake of norepinephrine and serotonin or modified hormonal responses mediated by adenylyl cyclase have been postulated.

Understanding the kinetics of lithium, particularly its distribution, is important in the proper management of lithium overdose patients. Lithium ions are completely absorbed from the gastrointestinal (GI) tract. Absorption, which is rapid after therapeutic doses, may be delayed after large overdoses, in the presence of food, or if the patient has decreased intestinal motility from coingestants. Slow-release preparations result in lower peak concentrations, which occur at a later time. ^{3,5}

Lithium is initially distributed into the extracellular space and then more slowly into tissues, including the primary target organ of toxicity, the brain. After an acute overdose, the patient may initially appear well, with a high serum level, but deteriorate as the levels fall. The blood is not a target organ but is only an indirect measure of the total body burden of lithium. Invasive measures to remove lithium, such as hemodialysis or venovenous hemofiltration, may be more effective during the distribution phase in select patients, when the drug is still found in the intravascular compartment. ^{8,10} The volume of distribution is about that of body water—0.8 to 1.2 L/kg.

Lithium is entirely eliminated by renal excretion. The renal handling of lithium is similar to that of sodium; it is filtered and reabsorbed by the proximal tubule. Reabsorption is enhanced and toxicity is more likely in the setting of hyponatremia, volume depletion, renal hypoperfusion, and diuretic use. ¹ Lithium, itself, may be nephrotoxic. ^{6,13} After a single dose, the serum half-life is 9 to 13 hours. At steady state, the half-life may be 30 to 58 hours. After an overdose, the serum half-life depends on how much lithium has been distributed into tissues; the figure is meaningful only after absorption is complete.

CLINICAL PRESENTATION

The toxicity seen depends on the dose, the time since ingestion, underlying medical conditions such as renal disease or dehydration, concomitant ingestions, and the patient's age. It is sometimes useful to classify the overdose as acute (single ingestion), acute on top of chronic therapy, or chronic. Because the latter situation is likely to result in the greatest lithium distribution into tissues, it is the most dangerous. There can be overlap among these categories. The clinical classification given in [Table 349.1](#)⁷ is valuable in the initial assessment.

Grade 1 (mild): Nausea, vomiting, tremor, hyperreflexia, agitation, muscle weakness, ataxia
Grade 2 (moderate): Confusion, dysarthria, rigidity, hypertonia, hypotension, stupor
Grade 3 (severe): Convulsions, myoclonic jerking, coma, cardiovascular collapse

TABLE 349.1. Severity of Lithium Poisoning

Patients may move from one category to another with time, depending primarily on the tissue distribution of lithium, which is not accurately measured by the serum level. ^{3,5,14,16} Electrocardiographic (ECG) changes are nondiagnostic and may occur in patients with therapeutic levels who are not clinically toxic. ¹³ Common changes include nonspecific ST-T wave changes, first-degree atrioventricular block, mild intraventricular conduction delay, and prolonged Q-T interval. These ECG changes may be responsible for the common misconception that lithium is primarily toxic to the heart, when the brain is, in reality, the primary target organ. Cardiovascular collapse generally occurs only as a result of severe central nervous system toxicity.

DIFFERENTIAL DIAGNOSIS

The classic painless rigidity, tremor, and hyperreflexia may not be present early in the clinical course. Other neurologic manifestations might mimic a cerebrovascular accident, a postictal state, metabolic disorders such as hypercalcemia or hyperthyroidism, or meningitis. The common nausea and vomiting seen after an acute overdose may be easily confused with gastroenteritis or another intraabdominal process. Particularly in the elderly, parkinsonism or tardive dyskinesia should be considered. Coingestants should be considered, especially other psychiatric medications such as antipsychotics and antidepressants. Carbamazepine and sodium valproate are also used to treat bipolar illness and may be coingestants.

EMERGENCY DEPARTMENT EVALUATION

Attention should focus on the mental status and a neurologic examination, searching particularly for tremor, myoclonus, hyperreflexia, and stiffness. Hydration status, renal function, and diuretic use should be assessed. When lithium toxicity is suspected, serum electrolytes should be measured, paying particular attention to the sodium, blood urea nitrogen, and creatinine. A lithium level should be taken when the patient has symptoms or signs consistent with lithium toxicity or if an acute overdose is suspected. Lithium levels are not included in broad toxicology screens and must be ordered separately. The screen is indicated if the patient is ill enough to require admission to the hospital. More than one lithium level should be drawn if the patient has taken an acute overdose, ^{15,17,18} particularly if the preparation is of the sustained-release type. ^{3,5}

An ECG should be performed to serve as a baseline and to help rule out coingestants such as the tricyclic antidepressants. ST-T abnormalities are common with therapeutic dosing and do not necessarily mean cardiotoxicity.¹² Obtaining the patient's pill bottles or calling the pharmacy where the patient gets the medications can also help to rule out coingestants. Medications such as acetaminophen, which do not cause early symptoms, should also be considered.

Vital signs, including temperature, should be measured often. Serial neurologic examinations, including a mental status examination, should be performed. A Foley catheter to monitor urine output should be placed if the patient exhibits moderate or severe toxicity.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures are instituted as necessary. An intravenous line of normal saline should be started, and the patient should be rehydrated aggressively. However, once euolemia and normal urine output have been established, there may be little added advantage to aggressive saline diuresis. Fluid overload may occur from overly aggressive saline administration.

The use of ipecac should be avoided, as it is unlikely to remove significant quantities of drug; it also interferes with patient assessment, because vomiting is an early sign of lithium toxicity. Lavage is also unlikely to remove much lithium from the stomach and should probably be considered only if the patient presents very soon after an acute ingestion.

Activated charcoal does not bind lithium, but it should be given if coingestants are suspected. If only lithium was ingested, or if the patient is chronically lithium-intoxicated without other drugs involved, activated charcoal is unnecessary.

Sodium polystyrene sulfonate (Kayexalate) is an ion-exchange resin usually used to treat hyperkalemia. There is experimental evidence that Kayexalate can both prevent absorption of lithium and enhance its removal once absorbed.^{4,11,19} The clinical efficacy of this therapy is unproved, and it is probably best reserved for patients who have taken a massive overdose, have high or rising levels, or are otherwise severely ill. The optimum dose and dosing intervals have not been defined; 15 to 50 g orally or by nasogastric tube every 4 to 6 hours might be a reasonable starting point. Kayexalate can cause nausea, vomiting, and constipation. The serum potassium level should be carefully monitored to prevent hypokalemia.

Whole-bowel irrigation has also been recommended as a GI decontamination measure for lithium overdose.^{9,16} It is uncertain whether this technique is as effective as using Kayexalate, or whether, in fact, either approach is necessary.

Hemodialysis is the most efficient method of removing lithium from the intravascular compartment, allowing lithium to redistribute into it from the brain.^{1,8,10} Because this redistribution is relatively slow, however, clinical improvement lags behind the fall in serum lithium levels. It may take days or weeks for toxicity to resolve, despite hemodialysis. For a critically ill lithium-intoxicated patient or a patient with a very high (greater than 3 mEq/L) or rising lithium level, a nephrologist should be consulted regarding hemodialysis. Permanent neurologic sequelae (e.g., encephalopathy) can result from lithium intoxication.^{2,17,20} Whether late hemodialysis can prevent such complications is unclear. Peritoneal dialysis is much less effective and is not usually considered in this setting.

DISPOSITION

A patient with an acute lithium overdose cannot usually be medically cleared on the basis of a single lithium level, unless it is zero or very near zero and it has been hours since the reported ingestion. In most cases, a second level should be measured to ensure that delayed absorption is not occurring. In all cases of overdose with suicidal intent, psychiatric consultation should be obtained before discharge.

Patients should be admitted if they have any neurologic symptoms from lithium, such as altered mental status, tremor, or stiffness. If patients are dehydrated, are in renal failure, or have a high or rising lithium level, they should be admitted to an intensive care unit.

It is difficult to give a precise lithium level above which all patients need to be admitted or hemodialyzed. Patients on chronic therapy may manifest toxicity even within the therapeutic range. Other patients may be relatively asymptomatic with levels of 5 to 8 mEq/L following acute overdose.^{8,15} Clinical judgment, preferably by a physician experienced in the treatment of lithium-poisoned patients, is necessary in making these important decisions. Consulting a regional poison center or toxicologist can be very helpful.

COMMON PITFALLS

- Failure to appreciate that severe lithium poisoning can lead to permanent neurologic impairment
- Failure to consider the kinetics of lithium and whether toxicity is acute, acute on chronic, or chronic when interpreting serum lithium levels
- Failure to consider the possibility of lithium poisoning and to obtain a serum lithium level in patients taking lithium who present with an illness predisposing them to dehydration
- Failure to obtain serial lithium levels in patients with acute overdose
- Failure to treat dehydration and hyponatremia aggressively
- Failure to consider dialysis in the early stages of care in patients with significant clinical toxicity or very high lithium levels

CHAPTER 350

Local Anesthetic Poisoning

Donna L. Seger and Heeten Desai

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

In 1940, lidocaine was introduced as a local anesthetic agent. Lidocaine causes anesthesia in peripheral nerves by decreasing conduction and membrane stability through reduced permeability to sodium ions, which prevents transmembrane polarization and subsequent propagation of the action potential. Lidocaine is a group II (amide-type) local anesthetic; it does not contain a *p*-aminophenyl group. Other members of group II include dibucaine (Nupercainal), mepivacaine (Carbocaine), prilocaine (Citanest), bupivacaine (Marcaine), and etidocaine (Duranest).

In contrast, group I anesthetics contain esters of benzoic acid, *p*-aminobenzoic acid, and meta-aminobenzoic acid and include cocaine (see [Chapter 326](#)), tetracaine (Pontocaine), procaine (Novocain), proparacaine (Ophthaine), butethamine (Monocane), and ethyl aminobenzoate. Patients who are allergic to an anesthetic in group I are allergic to all group I anesthetics but may safely be given a group II anesthetic, and vice versa.

Lidocaine, also known as lignocaine, became popular as an antidysrhythmic agent in 1960. Lidocaine blocks fast sodium channels during phase zero of the action potential (depolarization). This action, as well as local anesthetic activity, is shared by all class I antidysrhythmics (see [Chapter 311](#)). Lidocaine, along with phenytoin (see [Chapter 364](#)), mexiletine, and moricizine, and tocainide, are grouped as class 1B agents because they shorten the action potential duration. In contrast, class IA agents (quinidine and procainamide) lengthen it, and class IC agents (flecainide, encainide, and propafenone) have little effect on the action potential duration (see [Chapter 311](#)). Lidocaine also diminishes the slope of phase four depolarization (suppressing automaticity and membrane responsiveness) in the His Purkinje system. Lidocaine prevents reentry impulses and increases uniformity of conduction in ischemic tissue where action potential duration is prolonged and propagation of reentry rhythms is enhanced.

Lidocaine is well absorbed through mucous membranes and the gastrointestinal (GI) tract. Peak plasma concentrations are reached within 2 minutes of intravenous administration, within 10 minutes of endotracheal administration, and within 30 to 60 minutes of ingestion. Lidocaine is 50% protein bound. Protein binding is concentration dependent, with a greater amount bound at increased serum concentration. Seventy percent is bound to alpha-1 glycoprotein, and 30% is bound to albumin. Unbound fraction (free) is increased in newborns and in patients with hepatitis or conditions with decreased alpha-1 glycoprotein. The volume of distribution is 1.7 L/kg, meaning the drug is largely tissue bound.

Following intravenous injection, lidocaine is rapidly distributed to well-perfused tissue (brain and heart), with subsequent slower distribution to less well perfused tissues (skeletal muscle and fat). The initial distribution serum half-life is approximately 10 minutes. The peak serum concentration, which depends on the rate of administration, rapidly declines. Because of this biphasic pattern of distribution, an infusion is required to maintain therapeutic serum concentrations following intravenous bolus. A standard intravenous dosing regimen is 1.0 to 1.4 mg/kg, followed in 10 minutes by an additional bolus of 0.7 mg/kg and a maintenance infusion of 1 to 4 mg/min (20 to 50 µg/kg/min for children).

Lidocaine is metabolized to two active metabolites: monoethylglycinexylidide (MEGX) and glycine xylidide (GX). These metabolites achieve peak concentrations in 1 to 2 hours after an oral dose. The plasma elimination half-life of lidocaine ranges from 1.5 to 2.0 hours. The elimination half-lives of MEGX and GX are 3 and 5 hours, respectively. All are excreted in the urine. Only 5% to 10% of the parent drug is excreted unchanged. High concentrations of MEGX may produce toxic effects even though serum lidocaine concentrations are low.¹⁶ The risk of lidocaine toxicity is increased in patients with hepatic dysfunction, congestive heart failure, and shock due to alterations of metabolism, hepatic blood flow, and volume of distribution. The volume of distribution of lidocaine in patients with congestive heart failure can be decreased by 30%. Conversely, in patients with chronic hepatic disease, an increase of parent drug in the circulation and a decrease in alpha-1 glycoprotein may increase the volume of distribution by 30% to 40%. Both of these conditions decrease the hepatic extraction ratio. Cimetidine decreases splanchnic circulation and hepatic blood flow (decreasing metabolism), which may cause toxic concentrations of lidocaine.

Mexiletine (Mexitil) and tocainide (Tonocard) have chemical structures and electrophysiologic properties that are similar to those of lidocaine.^{14,17} Moricizine (Ethmozine), a phenothiazine, depresses sodium current but does not affect phase 4 depolarization.¹⁶ Because of the proarrhythmic activity and increased mortality associated with their use (see [Chapter 311](#)), these agents are generally reserved for patients with dysrhythmias refractory to other drugs who have shown a positive response to them on electrophysiologic testing.⁷ Usual adult doses are 200 to 400 mg every 8 hours for all agents. All are well absorbed from the GI tract and are hepatically metabolized. Unlike lidocaine, they do not undergo significant first-pass metabolism and are 90% to 100% bioavailable after ingestion. Because 40% of the parent drug is excreted unchanged in the urine, tocainide clearance is decreased in patients with renal disease. The half-life is 10 to 12 hours for mexiletine, 1.5 to 3.0 hours for moricizine, and 15 hours for tocainide. Pharmacokinetics do not seem to be altered by concurrent administration of other drugs.^{2,8,16,19}

CLINICAL PRESENTATION

Although intravenous, subcutaneous (infiltration), topical, or oral administration of lidocaine may cause toxicity,^{1,3,15} the emergency department physician most frequently encounters symptoms of toxicity during intravenous infusion.^{4,5,9} Manifestations of toxicity occur in the central nervous system (CNS) and the cardiovascular (CV) system. CNS effects have been reported in up to 47% of patients receiving intravenous lidocaine. Initial symptoms, such as lightheadedness, dizziness, drowsiness, and euphoria, may occur at therapeutic concentrations. At higher concentrations, more serious symptoms include confusion, hearing loss, dysarthria, visual disturbances, ataxia, agitation, and muscle twitching, which may lead to seizures and coma. Seizures may be prolonged.^{4,5}

Cardiovascular toxicity is rare and usually occurs from rapidly administered intravenous infusions. When serum concentrations are above 11 µg/mL, the refractory period is decreased, automaticity and myocardial contractility are depressed, and hypotension and bradycardia ensue.¹⁸ Conduction abnormalities include sinus bradycardia, atrioventricular block, complete heart block, and sinus arrest. Conduction defects may be more common in patients with preexisting bundle-branch abnormalities.¹¹

Although extensive first-pass metabolism occurs following intestinal absorption, mucosal absorption bypasses hepatic metabolism, and significant drug is bioavailable. A number of case reports have documented seizures in children following mucosal application of 10 mL of 2% to 4% viscous lidocaine solution.^{5,15,20} Administration of topical or oral lidocaine for the treatment of painful oral lesions in children should be recommended with caution, if at all.

Seizures have been reported following lidocaine infiltration. During laceration repair, the total dose for infiltration of lidocaine without epinephrine should not exceed 4.5 mg/kg, nor should the dose exceed 7.0 mg/kg of lidocaine with epinephrine.

The toxicity of other local anesthetics is similar to that of lidocaine, and the toxicity of other antidysrhythmics is similar to that of other class I agents (see [Chapter 311](#)). Many local anesthetics have also been reported to cause methemoglobinemia (see [Chapter 352](#)).

DIFFERENTIAL DIAGNOSIS

Physiologic stimulants and metabolic disturbances should be considered in the differential diagnosis of patients with CNS manifestations, and agents with membrane activity should be considered in those with CV system toxicity (see [Table 309.4](#)). Methemoglobinemia (see [Chapter 352](#)) should be considered in a patient who

becomes cyanotic and is responding poorly to oxygen therapy after exposure to local anesthetics.

EMERGENCY DEPARTMENT EVALUATION

The history and physical examination should focus on the concomitant use of prescription and nonprescription drugs, as well as CNS and CV signs and symptoms. Symptomatic patients should have continuous cardiac and oxygen saturation monitoring, as well as a 12-lead electrocardiogram. As always, hypoglycemia should be excluded in those with altered mental status. Those with unexplained toxicity should have serum electrolyte determinations and liver and kidney function tests. Serum levels of lidocaine and tocainide may confirm clinical toxicity but are often unavailable in an emergency situation. Remember that toxicity can occur at therapeutic serum concentrations.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment is primarily supportive. Advanced life-support measures should be instituted as necessary. If the patient becomes symptomatic while receiving intravenous lidocaine, the infusion should either be decreased or discontinued.

Seizures and other manifestations of CNS excitation may be controlled with intravenous lorazepam (adult, 2 to 4 mg intravenously as needed; child, 0.05 to 0.1 mg/kg initially) or diazepam; pay close attention to potential respiratory depression. Severe CV toxicity from lidocaine may require support of blood pressure and pulse by crystalloid, pressor agents, atropine, or a temporary pacemaker.^{4,5 and 6} Sodium bicarbonate should be considered in patients with tachydysrhythmias due to related antidysrhythmic agents (see [Chapter 311](#)). The use of other class IB agents, however, should be avoided.

Although exchange transfusion has been reported for severe lidocaine toxicity, its efficacy has not been substantiated.¹¹ There is no evidence that hemodialysis or forced diuresis effectively increases lidocaine elimination.¹³ Even in severe cases, patients usually recover if vital signs can be supported (e.g., by aortic balloon counterpulsation or extracorporeal bypass pump) while the drug is eliminated.¹¹

DISPOSITION

Patients with mucosal exposure or ingestion should be observed for 4 hours. Patients who remain asymptomatic may be discharged. Those who are or become symptomatic should be observed and have cardiac monitoring until signs and symptoms of toxicity have resolved. The appropriate level of care should be determined by the severity of clinical toxicity. If such care is not available, the patient should be transferred by advanced life-support personnel to a facility capable of providing it. Depending on the nature and severity of toxicity, consultation with a regional poison control center, toxicologist, or cardiologist may be appropriate.

COMMON PITFALLS

- Failure to adhere to recommended dosing guidelines and to check the dose and concentration of parenteral local anesthetic solutions, resulting in iatrogenic poisoning
- Failure to perform cardiac monitoring on patients receiving systemic infusions of lidocaine, intravenous regional blocks with local anesthetics, and large doses of local anesthetics by infiltration
- Failure to appreciate that local anesthetics can cause CNS excitation as well as depression
- Failure to appreciate that class IB antidysrhythmics can cause dysrhythmias and that they can do so at therapeutic as well as toxic doses
- Failure to appreciate that multiple doses of oral viscous lidocaine can be toxic and to warn patients and parents of children that it should not be swallowed

CHAPTER 351

Methanol Poisoning

Dag Jacobsen

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Poisoning may occur after the accidental or intentional ingestion of methanol. Although most cases are isolated, epidemics of methanol poisoning may occur when methanol is mistakenly substituted for ethanol by, for instance, alcoholics, or when methanol contaminants are used to ferment (e.g., wine) or illicitly distill (e.g., moonshine whisky) alcoholic beverages.

Methanol (methyl alcohol, “colonial spirit,” “wood alcohol,” “solvent alcohol”) is a colorless, volatile, highly flammable liquid with a density of 0.81 g/mL and a weak smell that resembles that of ethanol. Methanol is widely used industrially as a solvent and in the production of formaldehyde and methylated compounds. It is found in commercial products such as gasoline, antifreeze, gasohol, windshield washer fluid, copy machine fluid, canned heat (Sterno), paint, shellac, and solvents for removing wood finishes. The lethal dose of methanol is variably given as 30 to 240 mL, with 1 g/kg as the best estimate.^{11,19} The minimum dose that can cause permanent visual defects is unknown. Because a potentially toxic methanol level (20 mg/dL) may result from the ingestion of 0.14 mL/kg of pure methanol, one swallow should be considered potentially toxic.

Methanol is rapidly absorbed after ingestion and distributes in the total body water compartment (about 0.6 L/kg). It is metabolized first to formaldehyde and then to formic acid, which is responsible for the toxic effects in methanol intoxication.¹¹ The metabolism of formate depends on the folate pool.¹¹ Primates have a small folate reserve and are the only species that accumulates formate and, thus, suffers from methanol toxicity.¹⁰ The metabolism of methanol by alcohol dehydrogenase, which accounts for 90% of its elimination, is zero order, with a rate of 8.5 mg/dL/h in one case.⁸ Small amounts are excreted in expired air and urine.

In the early stage, the toxic effects are due to the increasing metabolic acidosis caused by the accumulation of formic acid.⁵ In late stages, when more formate is accumulated, the toxicity is mainly caused by the histotoxic effects of formate as it inhibits the mitochondrial respiration within the cell. This leads to lactate production, which increases the acidosis and the toxicity of formate as more formate is protonated and thereby able to penetrate the blood–brain barrier.⁶ Thus, a vicious *circulus hypoxicus* is initiated (Fig. 351.1).⁹ Why the eye is the primary target organ for methanol's toxic effects is unknown.^{11,15,16}

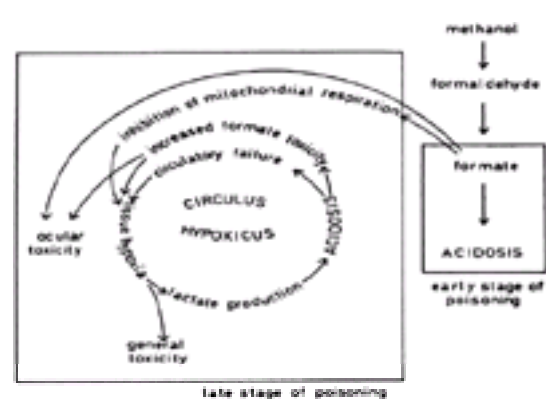

Figure 351.1. The “circulus hypoxicus” resulting from methanol ingestion.

Ethanol and fomepizole bind to alcohol dehydrogenase with a higher affinity than does ethylene glycol, and hence block the production of toxic metabolites. Ethanol is metabolized by alcohol dehydrogenase, but fomepizole is not. When these antidotes are present, the elimination half-life of methanol increases to 30 to 60 hours.

CLINICAL PRESENTATION

Usually 6 to 24 hours elapse from the time of ingestion to the occurrence of symptoms. It takes this much time for sufficient amounts of formic acid to be produced by methanol metabolism. This latent period may be longer, especially if ethanol is coingested, because ethanol competitively inhibits methanol metabolism by alcohol dehydrogenase. A latent period up to 90 hours has been reported when ethanol is coingested.¹⁰

Methanol itself has few direct effects. Mild central nervous system (CNS) depression (ethanol-like intoxication) has been reported.¹¹ With concentrated methanol solutions, nausea, vomiting, and abdominal pain may develop shortly after ingestion. The diagnosis is confirmed by detection of methanol in the serum. Because of its low molecular weight (32), at high concentrations methanol increases the serum osmolality, as do other alcohols and low-molecular-weight solutes (see [Table 309.5](#)). This effect can be detected easily by calculating the difference between the measured osmolality (om) and the calculated osmolality (oc) ($oc = 2 \times \text{sodium} + \text{blood urea nitrogen}/3 + \text{glucose}/18$). The “normal” range for the osmolal gap in unselected patients is 5 ± 7 mOsmol/kg H₂O (mean \pm SD).¹ An osmolal gap above 19, therefore, strongly indicates exogenous osmoles of some kind.^{5,11} If a serum methanol level is not immediately available, it can be estimated by multiplying the excess osmolal gap by 2.6 mg/dL, the amount of methanol that increases to osmolality by 1 milliosmol per kilogram of water. In this early stage, metabolic acidosis is absent as the metabolism of methanol to formate is just beginning.

The first clinical features of systemic toxicity are usually a feeling of weakness, anorexia, headache, nausea, and vomiting, accompanied or followed by increasing hyperventilation as a result of progressive increased anion gap metabolic acidosis.^{11,18,19} The “normal” range for the anion gap ($[\text{Na} + \text{K}] - [\text{Cl} + \text{HCO}_3]$) in unselected, acutely hospitalized patients is 13 ± 4 mmol/L (mean \pm SD).¹ Visual symptoms (blurred vision, decreased acuity, halo vision, tunnel vision, photophobia, and “snowfields”) may appear first or with the aforementioned symptoms. Usually, ocular symptoms precede objective signs such as dilated pupils that are partially reactive or nonreactive to light and funduscopy showing optic disk hyperemia with blurring of the margins. At this stage, the diagnosis is confirmed by detecting methanol or formate in the serum; the osmolal gap may or may not be elevated. A few cases may also present as acute abdomen, probably because of acute pancreatitis.^{11,12}

Without treatment, coma and respiratory and circulatory failure may ensue. A few patients may also develop methemoglobinemia with cyanosis, probably because of an interaction between formate and the ferric part of hemoglobin. In the late stages of methanol poisoning, when most or all of the methanol is metabolized to formate, the anion gap is elevated but the osmolal gap is normal, methanol may be undetectable, and formate detection is the only way to confirm the diagnosis.

The toxic effect on the putamen does not lead to detectable signs and symptoms in the acute stage because it is concealed by pronounced CNS depression. Survivors may later manifest a Parkinson-like syndrome.^{2,13}

DIFFERENTIAL DIAGNOSIS

If quantitative methanol and formate levels are unavailable, all other causes of metabolic acidosis and increased serum osmolality should be considered in the

differential diagnosis ([Fig. 351.2](#); see also [Figure 309.1](#)). Increased anion and osmolal gaps occur in ethylene glycol intoxication as well as in methanol poisoning. Differentiating the two may be difficult, but the treatments are essentially the same. Visual complaints suggest methanol poisoning, whereas hypocalcemia, seizures, and urine oxalate crystals indicate ethylene glycol poisoning. ¹¹

Figure 351.2. Causes of an increased anion and osmolal gap.

EMERGENCY DEPARTMENT EVALUATION

The history should include the amount, concentration, and time of methanol ingestion; the nature and onset of symptoms; and whether ethanol was coingested. Patients should be questioned carefully about the presence or absence of visual complaints, GI symptoms, and a feeling of intoxication.

The physical examination should focus on vital signs (especially respiratory rate) and the neurologic, visual, and cardiopulmonary status. Visual acuity and funduscopic examinations should be documented.

Laboratory evaluation should include arterial blood gas analysis; complete blood count; measurement of electrolytes, blood urea nitrogen, creatinine, glucose, and amylase; urinalysis; and quantitative serum methanol or formic acid level. A chest radiograph and an electrocardiogram are obtained if clinical toxicity is pronounced.

If the diagnosis is based on the osmolal and anion gaps, osmometry must be performed by the freezing-point depression technique and not by the vapor pressure technique, as the latter does not detect the increased osmolality caused by volatile alcohols. A computed tomography scan or MRI of the brain may show necrosis of the putaminal areas, a finding seen late in the course of methanol poisoning. ^{2,13}

EMERGENCY DEPARTMENT MANAGEMENT

General treatment measures include intensive supportive care and GI decontamination. If the patient is seen soon after ingestion (within 2 hours) immediate gastric aspiration, preferably with a nasogastric tube, is recommended. Emesis induction and activated charcoal alone are probably of limited value because of slow onset and limited binding, respectively.

Specific treatment of methanol poisoning includes bicarbonate to combat the metabolic acidosis, antidotal therapy with ethanol or fomepizole to inhibit methanol metabolism to formate, and hemodialysis to remove methanol and formate. Folinic acid (leucovorin), 1 mg/kg up to 50 mg intravenously every 4 hours, may be of value in increasing the metabolism of formate. ¹⁷ If folinic acid is unavailable, folic acid, in the same dose, can be used.

Metabolic acidosis is aggressively treated by infusing sodium bicarbonate. As much as 400 to 600 mEq may be required during the first few hours. The goal should be full correction of the acidosis. Bicarbonate treatment also decreases the amount of undissociated formic acid, resulting in less access of formate to the CNS. ^{6,16} Hence, metabolic acidosis resulting from methanol poisoning, in contrast to other types of metabolic acidosis, should always be treated with bicarbonate.

Alkali treatment must be accompanied by administration of ethanol or fomepizole; otherwise, the acidosis becomes bicarbonate-resistant, as more formic acid will be produced from the metabolism of methanol. If a methanol level cannot readily be obtained, ethanol therapy should be started in any patient with acidosis, symptoms, or a history of a potentially toxic ingestion. Antidotal treatment can be discontinued when the methanol level drops below 20 mg/dL, provided that the acid–base status is normal and there are no complications.

Most authors recommend a therapeutic blood ethanol level of at least 100 mg/dL. However, the amount of ethanol necessary to block methanol metabolism depends on the concomitant methanol level, because there is a dynamic competition for the enzyme alcohol dehydrogenase in the liver. If the blood methanol level is known, the molar–ethanol concentrations should be at least one-fourth of the molar–methanol concentration. ^{11,14}

A blood ethanol level of 100 mg/dL may be achieved by giving a bolus dose of 0.6 mg/kg, followed by 66 to 154 mg/kg/h intravenously or orally, with the higher maintenance dose for heavy drinkers. Mixing 50 mL of absolute ethanol with 500 mL isotonic glucose yields a 10% solution if a 10% ethanol solution for intravenous use is unavailable. With this solution, a bolus of 8 mL/kg (over 0.5 h), followed by 1.5 mL/kg/h, will produce the desired ethanol concentration. The maintenance infusion should be increased or decreased according to measured ethanol levels.

Monitoring the blood ethanol level is important, especially during hemodialysis, as this procedure also removes ethanol. As a rule of thumb, the maintenance dose of ethanol should be doubled during hemodialysis. If not, methanol metabolism can resume when the ethanol level drops, resulting in worsening toxicity despite hemodialysis.

Fomepizole (4-methylpyrazole; Antizol) is commercially available, but it has been approved only for the treatment of ethylene glycol poisoning. ^{3,8} So far, only a few methanol-poisoned patients treated with fomepizole have been reported. ^{4,7} The results from these studies are so favorable, however, that fomepizole should be considered an alternative to ethanol for methanol as well as ethylene glycol poisoning. The dosing of fomepizole and therapeutic considerations are the same as for ethylene glycol (see [Chapter 338](#)).

Hemodialysis effectively removes methanol and formate and also counteracts metabolic acidosis. ¹¹ The only absolute indication for hemodialysis is visual impairment of any degree in a patient with metabolic acidosis or a detectable methanol level. Other indications include severe metabolic acidosis (particularly if unresponsive to bicarbonate and ethanol therapy), a blood methanol level above 50 mg/dL (because of the very slow elimination of methanol during antidotal therapy), and ingestion of more than 1 g/kg of methanol.

Hemodialysis is continued until the blood methanol level is below 20 mg/dL and the acidosis is corrected. If methanol analyses are unavailable, hemodialysis should be continued for at least 8 hours. Peritoneal dialysis may also remove methanol but not as effectively as hemodialysis. Hemoperfusion is ineffective.

DISPOSITION

Consultation with a poison center or toxicologist is strongly recommended if the physician is unfamiliar with the management of methanol poisoning. In addition, information on where to obtain methanol or formate levels may be provided. When the diagnosis of methanol poisoning is made or suspected, a nephrologist should be consulted, as many patients ultimately require hemodialysis, especially when admitted in a late stage.

If a methanol level is unavailable, all patients with suspected methanol poisoning should be admitted to the hospital for continued clinical and laboratory evaluation.

Every patient with a definite diagnosis of methanol intoxication should be admitted and have an initial and follow-up examination by an ophthalmologist.

If hemodialysis is unavailable, the patient who needs it, or will probably need it, should be transferred to a facility with this capability. Alkali administration and antidotal therapy (if available) should be given prior to and during transport.

COMMON PITFALLS

- Failure to appreciate that even small amounts of concentrated methanol may be toxic
- Failure to consider methanol poisoning in the differential diagnosis of metabolic acidosis of unknown origin
- Failure to consider the possibility of multiple victims when the source of methanol is unknown or is known to be contaminated ethanol
- Failure to appreciate that the absence of early symptoms and the presence of normal anion and osmolal gaps do not exclude a potentially toxic methanol ingestion
- Failure to observe all patients with known or suspected methanol ingestion until a methanol level can be obtained
- Failure to appreciate that ethanol and fomepizole are removed by hemodialysis and to adjust their dosing during this procedure accordingly
- Failure to have visual function formally assessed by an ophthalmologist in patients with methanol poisoning

CHAPTER 352

Methemoglobinemia

Steven C. Curry and David A. Tanen

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Reduced hemoglobin (deoxyhemoglobin) normally contains four heme groups, each with a ferrous (Fe^{2+}) ion capable of binding oxygen. Oxidative stress within the red cell produces methemoglobinemia, Heinz body hemolysis, or both. When the iron in reduced hemoglobin is oxidized to the ferric state (Fe^{3+}), methemoglobin is formed. The oxidation of protein in hemoglobin results in denaturation of protein, splenic sequestration of damaged erythrocytes, and hemolysis. Denatured erythrocytic protein can easily be visualized as Heinz bodies by using specialized staining.

Under normal conditions, methemoglobin levels are less than 1% to 2% of total heme pigments.¹² Higher fractions are termed *methemoglobinemia*.

Oxyhemoglobin is red, but methemoglobin is dark brown and cannot transport oxygen, resulting in a functional anemia. Also, the presence of ferric heme groups impairs the unloading of oxygen by oxygenated (ferrous) heme, producing a leftward shift in the oxyhemoglobin dissociation curve.^{3,12} The physiologic consequences of methemoglobinemia are thus due to decreased tissue oxygenation.

The production of cyanosis requires 5 g/dL blood of reduced hemoglobin, but only 1.5 g/dL of methemoglobin produces noticeable discoloration. In the nonanemic patient, 10% to 20% methemoglobinemia produces asymptomatic cyanosis. Headache, dyspnea on exertion, tachypnea, tachycardia, and mild hypertension can be noted with methemoglobin levels of 15% to 35%. Higher fractions can result in confusion, coma, seizures, apnea, ventricular dysrhythmias, bradyarrhythmias, hypotension, and lactic acidosis. Death is frequently seen with methemoglobin fractions above 70%.

What can be confusing is an arterial blood gas report of a normal P O_2 and a normal percentage of oxyhemoglobin (percentage saturation) despite cyanosis. This is because most blood gas instruments do not measure oxyhemoglobin fractions, but only calculate and report what the percentage hemoglobin saturation should be, assuming the absence of methemoglobin, carboxyhemoglobin, and sulfhemoglobin, and assuming no shift in the dissociation curve from changes in erythrocytic 2,3-diphosphoglycerate concentrations.

A co-oximeter is needed to measure true percentage saturation and other hemoglobin pigments. Co-oximeters most commonly used in hospitals can measure and report the total hemoglobin concentration as well as percentages of oxyhemoglobin, methemoglobin, and carboxyhemoglobin in less than 2 minutes. Sulfhemoglobin is usually recognized as methemoglobin by these instruments. The difference between the percentage of hemoglobin saturation calculated by the blood gas analyzer and the saturation measured by the co-oximeter is called the *saturation gap*. A large saturation gap in arterial blood is almost always due to carboxyhemoglobin or methemoglobin. To interpret blood gas reports accurately, the emergency physician must know whether reported percentage saturations on arterial blood gas samples are determined by co-oximetry.

Hyperlipemia, such as that seen after infusions of lipid emulsions (e.g., Intralipid, Liposyn) or in patients with diabetes mellitus, interferes with the measurement of hemoglobin pigments by co-oximeters, resulting in falsely elevated methemoglobin concentrations.¹³ Total blood and plasma free hemoglobin concentrations also can be falsely elevated in patients with lipemic plasma or serum. In these instances, the patient with a normal hemoglobin concentration and without cyanosis does not have serious methemoglobinemia.

Methemoglobinemia does not affect the measurement of hemoglobin concentration, such as in a complete blood count or hemogram. Pulse oximeters (e.g., ear or finger oximeters) usually measure only oxyhemoglobin and deoxyhemoglobin. They do not predictably or accurately recognize the presence of methemoglobin or carboxyhemoglobin. Therefore, a pulse oximeter can report a falsely normal percentage hemoglobin oxygen saturation in the presence of methemoglobinemia or carboxyhemoglobinemia.⁸

If accurate determination of methemoglobin concentration by co-oximetry is unavailable, a drop of the patient's blood can be placed on filter paper and allowed to dry. If the blood appears obviously brown, as compared with a drop of blood from a healthy person, then a level of at least 15% methemoglobin is present, assuming a normal total hemoglobin concentration.³ Furthermore, venous blood from a healthy person becomes bright red when shaken in the air as oxyhemoglobin is formed. Venous blood that contains elevated methemoglobin concentrations remains dark brown after shaking.

Besides determining the methemoglobin fraction, the physician should also seek evidence of hemolysis.^{2,14} Heinz bodies usually are not visible on a normal Wright stain of blood and can be seen only with special staining. Therefore, a hemoglobin-hematocrit, Heinz body stain, and plasma free hemoglobin concentration should be ordered.

Because hemoglobin is slowly oxidized to methemoglobin under normal conditions, the erythrocyte contains enzymes that can catalyze the reduction of methemoglobin back to reduced hemoglobin (Fig. 352.1). More than 95% of methemoglobin reduction is accomplished by the transfer of electrons from NADH (the reduced form of nicotinamide-adenine dinucleotide, which is generated in glycolysis) to cytochrome- b_5 and then to methemoglobin by way of the enzyme variously known as NADH-dependent methemoglobin reductase, diaphorase I, and, most recently, NADH cytochrome- b_5 reductase (EC 1.6.2.2).^{6,12}

Figure 352.1. Pathways of hemoglobin oxidations and methemoglobin reduction.

In normal persons, enzymatic reduction of methemoglobin occurs at a rate 200- to 300-fold greater than its spontaneous formation. However, congenital deficiencies in NADH cytochrome- b_5 reductase¹² or in cytochrome- b_5 itself⁶ can cause methemoglobinemia, or can greatly predispose a person to developing methemoglobinemia after exposure to methemoglobin-producing agents. Neonates, especially those with a metabolic acidosis,¹⁵ are at increased risk for developing methemoglobinemia after oxidant stress (e.g., drugs, toxins, sepsis) because they have lower levels of NADH cytochrome- b_5 reductase and cytochrome- b_5 .^{3,6,12}

A second enzyme, NADPH (the reduced form of nicotinamide-adenine dinucleotide phosphate) methemoglobin reductase, can facilitate the reduction of

methemoglobin by transferring electrons from NADPH (produced in the hexose monophosphate shunt) to an intermediate compound and then to methemoglobin.^{3,12} There is apparently no endogenous cofactor for this enzyme; consequently, it has little or no physiologic role in maintaining methemoglobin levels at low concentrations. However, exogenously administered methylene blue can act as an intermediate for electron transfer and greatly increase the activity of this enzyme. People with depressed levels of erythrocytic NADPH (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency) or a congenital lack of the NADPH-dependent reducing enzyme do not normally suffer from and are not predisposed to developing methemoglobinemia. If they do develop methemoglobinemia, however, treatment with methylene blue is ineffective and can even trigger massive hemolysis in those with G6PD deficiency.¹¹

Exposure to a variety of agents may result in acquired methemoglobinemia (Table 352.1). Not all of the compounds are direct oxidants, implying that their metabolites or oxidizing intermediates (e.g., free radicals) are responsible for producing methemoglobin in some cases. The most commonly reported therapeutic agents that cause methemoglobinemia are local anesthetics, nitroglycerin, phenazopyridine (Pyridium), and diaminodiphenylsulfone (dapsone).^{3,4} Local anesthetics injected or applied topically (e.g., infant teething ointments) are well-documented causes of methemoglobinemia. Aniline and related aromatic amines are potent inducers of methemoglobinemia. The conversion of nitrates to nitrites by bacteria in the gastrointestinal (GI) tract has resulted in fatal methemoglobinemia in infants who ingested well water high in nitrates. Bacteria colonizing burn wounds treated with silver nitrate have been reported to oxidize nitrate to nitrite and produce methemoglobinemia.³ The recreational use of inhalable nitrites such as isobutyl nitrite has resulted in large numbers of casualties.⁷ With toxins such as chlorates and arsine, massive hemolysis can be as detrimental as the methemoglobinemia, or more so.^{2,14}

Acetosalid	Arsinophenols	Arsine nitrite
Aniline dyes	Arsine	Aniline
Chlorates	Chlorobenzene	Benzoic acid
Dapsone	Diaminodiphenylsulfone	Benzoic acid sulfate
Food additives	Hydrazine	Chromates
Inks	Isobutyl nitrite	Commercial marking crayons*
Local anesthetics	Methylene blue	Diaminodiphenylsulfone

* Children's crayons no longer contain methemoglobin-producing dyes. Commercial marking crayons may still contain ingredients that produce methemoglobinemia.

TABLE 352.1. Some Methemoglobin-Producing Agents

CLINICAL PRESENTATION

Nonanemic patients with 10% to 20% methemoglobinemia usually present with unexplained cyanosis and no other symptoms. Headache, dyspnea on exertion, tachypnea, tachycardia, and mild hypertension can be noted with methemoglobin levels of 15% to 35%. Higher fractions can result in confusion, coma, seizures, apnea, ventricular dysrhythmias, bradyarrhythmias, hypotension, and lactic acidosis. Death is frequently seen with methemoglobin fractions above 70%.

Patients with underlying cardiovascular or cerebrovascular disease are more susceptible to the effects of hypoxia. Those with preexisting anemia or with concomitant Heinz body hemolytic anemia suffer greater toxicity at a given methemoglobin level, because the remaining functional hemoglobin concentration is lower. Also, cyanosis is not apparent until a greater percentage of methemoglobin is present, as compared with the nonanemic patient. Hence, anemic patients can suffer from significant methemoglobinemia without exhibiting cyanosis.

The cyanosis of methemoglobinemia is refractory to the administration of oxygen and is present despite a normal or elevated arterial P_{O_2} . A metabolic acidosis develops with severely compromised oxygen delivery to tissues. Pink plasma from hemoglobinemia may be noted in severe cases of hemolysis. The electrocardiogram (ECG) may reveal tachycardia, bradycardia, ventricular dysrhythmias, and changes suggestive of myocardial ischemia.

DIFFERENTIAL DIAGNOSIS

Cyanosis due to methemoglobinemia may be differentiated from that due to hypoxia by the presence of a normal P_{O_2} and by the fact that it is unresponsive to oxygen. A peculiar and poorly characterized cyanosis may also be seen in some cases of hydrogen sulfide or tellurium poisoning. Both carbon monoxide and sulfhemoglobinemia produce a noticeable saturation gap with a normal arterial P_{O_2} . Sulfhemoglobinemia, a rare cause of cyanosis, causes noticeable discoloration at only 0.5 g/dL blood. Most co-oximeters measure sulfhemoglobin as methemoglobin. Fortunately, sulfhemoglobin is rarely (if ever) severe enough to cause life-threatening symptoms. Topical contact with blue dyes (e.g., new towels or clothing) may cause blue skin. Generalized discoloration from excessive administration of methylene blue may also be confused with cyanosis.⁵

EMERGENCY DEPARTMENT EVALUATION

A careful history should be taken from the patient and family regarding medications, occupational exposures to chemicals, family history of methemoglobinemia, recreational drug use, and, in the case of children, any substances in the house that could have been ingested. The physical examination should focus on vital signs, skin color, and any evidence of dysfunction of the central nervous system or cardiovascular system. Laboratory studies should include a complete blood count, arterial blood gas analysis, urinalysis, ECG, a blood methemoglobin concentration or oxygen saturation measured by co-oximetry, Heinz body stain of peripheral blood, plasma free hemoglobin, and serum haptoglobin, electrolytes, blood urea nitrogen, and serum creatinine, and glucose. A bedside screening test for methemoglobin may also be helpful.

EMERGENCY DEPARTMENT MANAGEMENT

Patients with methemoglobinemia should be placed on oxygen to maximize the oxygen-carrying capacity of normal hemoglobin. Intravenous access should be established, and the patient should be placed on a cardiac monitor.

Most patients are blue but asymptomatic and do not require treatment.³ Once exposure to the offending agent is terminated, methemoglobin levels usually return to normal within 12 to 36 hours. Patients with symptoms unrelieved by oxygen, those with methemoglobin fractions above 30%, those with ECG changes, or those with a metabolic acidosis should receive antidotal therapy with methylene blue, provided there is no history of G6PD deficiency. Methylene blue is usually available as a 1% solution (10 mg/mL) and should be given intravenously over 3 to 5 minutes at an initial dose of 2 mg/kg (0.2 mL/kg of a 1% solution).³ A dramatic response with resolution of cyanosis is usually noted within 15 minutes, although more time is sometimes required. If the patient is seriously symptomatic and no response is noted within 15 minutes, or if the patient remains moderately symptomatic after 15 to 30 minutes, repeat doses of 1 mg/kg (0.1 mL/kg of 1% solution) can be given. If methemoglobin levels are readily available, repeat determinations of methemoglobin concentration should be performed before repeat doses of methylene blue are given, because large doses of methylene blue themselves can cause discoloration of skin.^{3,5} The total dose of methylene blue during the first 2 to 3 hours should not exceed 5 to 7 mg/kg.³

Adverse effects of methylene blue include dysuria, substernal chest pain, and anxiety.¹⁰ Urine frequently turns blue and then green as the drug is excreted. Single doses of methylene blue as low as 5 mg/kg can cause methemoglobinemia in animals.⁹

Methylene blue should never be given to patients with G6PD deficiency. Such patients have low erythrocytic NADPH concentrations, making augmentation of the NADPH-dependent, methemoglobin-reducing enzyme by methylene blue impossible. More important, methylene blue can trigger massive hemolysis in such patients, further compromising oxygen delivery to tissues.¹¹ About 15% of African American males are thought to be deficient in G6PD; men and women of Mediterranean ancestry also have an increased incidence of this enzyme deficiency.

As soon as time allows, GI and skin decontamination should be performed to limit continued absorption of the offending agent. Decontamination is particularly important after acute dermal exposures to chemicals or after intentional ingestions of toxic agents. Dermal decontamination can be performed with a triple wash (water rinse, soap scrub, water rinse). GI decontamination is discussed in [Chapter 309](#).

If the drug or chemical causing methemoglobinemia cannot be readily eliminated from the body (e.g., dapsone), methemoglobinemia may continually recur for hours or days after successful treatment with methylene blue. In this instance, serial measurements of methemoglobin levels are required, and a constant intravenous infusion of methylene blue at a rate of 0.1 mg/kg/h has been used successfully to maintain methemoglobin concentrations at a safe level.¹ Repeated oral doses of activated charcoal also enhance the elimination of dapsone. High-dose intravenous cimetidine has been shown to lessen dapsone-induced methemoglobin production. Renal failure is a relative contraindication to using a constant infusion or frequently repeated doses of methylene blue, because the drug is mainly excreted by the kidneys.

Treatment with hyperbaric oxygen or exchange transfusions should be considered for patients with G6PD deficiency or for those who do not respond satisfactorily to methylene blue. Hyperbaric oxygenation can provide enough dissolved oxygen to support life in the presence of 100% methemoglobinemia.

Symptomatic hemolytic anemia may require treatment with blood transfusions. Because massive hemolysis may cause hyperkalemia and acute renal failure, efforts should be made to maintain a good rate of urine flow.

Ascorbic acid also reduces methemoglobin to hemoglobin (nonenzymatically). A dose of 0.5 to 1.0 g ascorbic acid every 6 hours may be given intravenously or orally in conjunction with methylene blue. However, ascorbic acid works too slowly to be useful in the treatment of acute, acquired methemoglobinemia.³

DISPOSITION

Patients with methemoglobinemia should be admitted after emergency department evaluation and management. Patients are best managed at a facility where methemoglobin concentrations can be measured easily and quickly. Physicians unfamiliar with the management of methemoglobinemia should consult a toxicologist or hematologist or the regional poison center. If transfer is necessary, advanced life-support services should be provided and should include a supply of methylene blue, if available. In the case of an accidental or intentional poisoning, the physician must evaluate and treat other toxic effects of methemoglobin-producing agents. All patients who receive methylene blue should be observed for recurrence of symptomatic methemoglobinemia and for adverse effects such as hemolysis.

An asymptomatic and otherwise healthy patient who has been cyanotic for several days while taking therapeutic doses of an offending drug does not necessarily require admission if the total hemoglobin concentration is normal (e.g., no significant hemolysis), the methemoglobin level is below 20%, exposure to the offending agent is terminated, and reliable follow-up is available. Methemoglobin concentrations will return to normal in these patients as the offending drug is cleared from the body. A wise and conservative approach would be to admit all young children and elderly patients for observation, serial methemoglobin concentrations, and, when indicated, serial ECGs.

Any patient who unexpectedly develops methemoglobinemia after ingestion of therapeutic doses of drugs should be referred to a hematologist for evaluation of possible heterozygous NADH cytochrome-*b₅* reductase deficiency. Any patient with methemoglobinemia that is unresponsive to treatment with methylene blue should be evaluated, after full recovery, for G6PD deficiency or, much less commonly, NADPH methemoglobin reductase deficiency.

COMMON PITFALLS

- Failing to consider the diagnosis of methemoglobinemia in patients with cyanosis unresponsive to oxygen
- Failing to appreciate that a normal arterial P_{O_2} and normal oxygen saturation (as measured by pulse oximetry or calculated from arterial blood gases) do not rule out methemoglobinemia
- Failing to appreciate that symptomatic methemoglobinemia may be present in the anemic patient despite lack of cyanosis
- Failing to evaluate for Heinz body hemolytic anemia in patients with methemoglobinemia
- Giving methylene blue to asymptomatic patients who are suffering from mild methemoglobinemia or to patients with G6PD deficiency
- Failing to evaluate and treat other toxic effects produced by agents that cause methemoglobinemia
- Failing to recognize that resolution of cyanosis in a patient with methemoglobinemia may be due to accompanying hemolysis, with actual worsening of oxygen delivery to tissues

CHAPTER 353

Methylxanthine Poisoning

Pierre Gaudreault

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Methylxanthines, methylated derivatives of xanthine, include theophylline, caffeine, dipylline, pentoxifylline, and theobromine. Theophylline (1,3-dimethylxanthine) is used to treat asthma, apnea of premature infants, and chronic obstructive pulmonary disease (COPD), and as an analgesic adjunct. It is available as anhydrous theophylline or as a variety of salts ([Table 353.1](#)). Aminophylline is theophylline ethylenediamine, and oxtriphylline is 7-choline theophyllinate. Available formulations include intravenous solutions of aminophylline and suspensions, capsules, tablets, and sustained-release formulations for oral use. Therapeutic oral doses range from 13 to 24 mg/kg/d, usually administered in divided doses.

Drug	Anhydrous Theophylline (%)
Aminophylline, anhydrous	84-86
Aminophylline, dihydrate	79-82
Oxtriphylline	62-66
Theophylline calcium salicylate	48-50
Theophylline monohydrate	91
Theophylline olamine	73-75
Theophylline sodium acetate	55-65
Theophylline sodium glycinate	49

TABLE 353.1. Theophylline Salts

Caffeine (1,3,7-trimethylxanthine) is a naturally occurring alkaloid contained in beverages such as coffee (60 to 180 mg/5 oz), tea (20 to 60 mg/5 oz), chocolate milk (2 to 7 mg/8 oz), and cola soft drinks (45 mg/12 oz) and in chocolate candy bars (7 mg per bar). It is also contained in analgesic preparations and over-the-counter diet and stimulant (“wake-up” or “stay awake” pills) formulations in doses of 15 to 100 mg. Street-drug capsules that contain caffeine, phenylpropranolamine, and ephedrine are sold as stimulants. These products are called “look-alikes” because they are usually prepared to resemble prescription amphetamines.⁹ Since 1983, it has been illegal in the United States to market products that contain combinations of caffeine and ephedrine, pseudoephedrine, or phenylpropranolamine.

Methylxanthines are rapidly absorbed after ingestion, with peak blood levels occurring in 1 to 2 hours. With sustained-release preparations, peak levels are maintained for 6 to 24 hours. Absorption is prolonged, and peak blood levels are delayed after overdosage, particularly with sustained-release preparations. Theophylline is 60% protein-bound, and caffeine is 35% protein-bound, mainly to albumin. Protein binding decreases with acidemia (resulting in increased free drug) and increases with alkalemia. The volume of distribution averages 0.5 L/kg (range, 0.3 to 0.7 L/kg) for theophylline and 0.4 L/kg for caffeine. Therapeutic serum levels are 10 to 20 µg/mL. Caffeine levels ranging from 12 to 36 µg/mL are effective in preventing neonatal apnea, but levels are only 3 to 10 µg/mL following usual adult doses.

Theophylline is eliminated by hepatic metabolism (90%) and urinary excretion of unchanged drug (10%). The half-life is age-dependent and influenced by concomitant drug therapy and illnesses. It averages 20 hours in newborns, 6 to 7 hours in infants, 3 to 5 hours in ages 6 months to 18 years, and 4 to 6 hours for adults. Hepatic elimination is increased by beta agonists, smoking, rifampin, and antiepileptic drugs (carbamazepine, phenobarbital, and phenytoin) and is decreased by allopurinol, beta blockers (nonselective), calcium channel blockers, cimetidine, congestive heart failure, fever, influenza virus vaccine, interferon, liver disease, macrolide antibiotics, mexiletine, oral contraceptives, and quinolones. Active metabolites include 3-methylxanthine, caffeine, and theobromine. Metabolism is saturable at serum theophylline levels near or above 20 µg/mL, resulting in a prolonged half-life after overdose. Metabolites may also contribute to overdose toxicity. The kinetics of caffeine are similar, with half-lives ranging from 2 to 12 hours in infants, children, and adults. In newborns, the half-life of caffeine is about 4 days, because up to 85% is excreted unchanged in the urine.

Therapeutic, adverse, and toxic effects of methylxanthines are due to the inhibition of adenosine synthesis, resulting in central nervous system (CNS) stimulation, reduction of the ventricular fibrillation threshold, smooth muscle relaxation, and gastric acid and pepsin secretion. Cardiovascular effects also result from epinephrine and norepinephrine release (low theophylline concentrations) and inhibition of phosphodiesterase, leading to increased cyclic adenosine and guanosine monophosphate (high theophylline concentrations).¹⁰ Tachydysrhythmias may result from a decrease of the ventricular fibrillation threshold, a nonuniform increase in the cardiac conduction velocity that favors reentry phenomena, and the liberation of catecholamine. Hypokalemia and a reduced oxygen delivery in the face of increased demand by the myocardium seen with theophylline overdoses might also be contributory. Caffeine, the most potent CNS stimulant of the methylxanthines, stimulates the cortex (increases alertness and enhances performance), increases the spontaneous activity of the reticular formation and directly stimulates the respiratory center located in the medulla, and increases its sensitivity to the stimulatory effects of carbon dioxide. Theophylline and caffeine cause peripheral vasodilation, yet cerebral vasoconstriction. The latter effect may be involved in the pathogenesis of CNS toxicity.

Poisoning may result from chronic (therapeutic) oral overdose, acute ingestion of more than 10 mg/kg, or excessive intravenous dosing. The chronic use of caffeine can lead to a dependence syndrome. Abrupt withdrawal in dependent persons is characterized by headache, lethargy, and depression.

CLINICAL PRESENTATION

Initial symptoms of poisoning include nausea, vomiting, and abdominal pain. Diarrhea and gastrointestinal (GI) bleeding may develop later. Spontaneous vomiting may limit drug absorption, especially with caffeine ingestions. However, serum drug levels may continue to rise despite vomiting, particularly when sustained-release preparations have been ingested. Additional signs and symptoms may include headache, insomnia, agitation, delirium, tinnitus, tremors, motor hyperactivity and hypertonicity, jitteriness, hyperventilation, polyuria, seizures, coma, GI bleeding, hyperthermia, and ventricular and supraventricular tachyarrhythmias.^{1,10,16,19} At low doses, theophylline induces a mild and transitory hypertension. At high doses, the direct effect of theophylline on the beta-2 adrenoreceptors reduces the total peripheral resistance, inducing hypotension. This may partly explain why hypotension is seen with acute, but not chronic, overdose. Laboratory evaluation may reveal leukocytosis, hyperglycemia, hypokalemia, hypophosphatemia, ketosis, metabolic acidosis, and respiratory alkalosis.^{10,16,17} Decreased serum calcium and magnesium levels, elevated serum amylase and uric acid levels, and evidence of dehydration (elevated blood urea nitrogen and creatinine levels) or rhabdomyolysis (elevated creatine phosphokinase level and myoglobinuria) may be noted.²⁰

The risk of tachydysrhythmias depends on the duration of exposure, drug concentration, and age. After an acute overdose (single ingestion), patients aged 6 months to 60 years may develop life-threatening dysrhythmias or seizures when serum concentrations exceed 80 µg/mL.¹⁰ For the same age group, serious toxic manifestations can occur with serum concentrations above 60 µg/mL with chronic intoxication. Patients younger than age 6 months or older than age 60 years may experience serious toxic manifestations with serum concentrations above 30 µg/mL, regardless of the type of intoxication. Patients over age 40 are at risk of developing serious cardiac dysrhythmias when serum concentrations are above 35 µg/mL. In contrast, serum concentrations higher than 50 µg/mL are necessary to

induce serious arrhythmias in younger patients (age 40 or less).¹²

Seizures are usually generalized but can be focal. The neurotoxicity of theophylline seems to be dose-dependent, but other factors also influence the development of neurotoxicity. Indeed, patients younger than age 6 months or older than age 60 years who are chronically intoxicated or have a history of neurologic problems (e.g., seizures, cerebrovascular insufficiency) are at greater risk of seizing.^{8,16} Permanent neurologic damage (e.g., encephalopathy) is not uncommon in patients with prolonged coma or intractable seizures and appears to correlate with their duration.

DIFFERENTIAL DIAGNOSIS

Because the clinical effects of methylxanthine poisoning can be characterized as a "beta-adrenergic storm," poisoning by direct-acting beta agonists (e.g., albuterol and related bronchodilators, terbutaline) can cause an indistinguishable clinical picture. Poisoning by amphetamines, sympathomimetics, anticholinergics, hallucinogens, monoamine oxidase inhibitors, and epinephrine should also be considered in the differential diagnosis. Agitated psychiatric states, drug withdrawal, and medical conditions such as CNS infection, electrolyte disturbance, hypoglycemia, hypocalcemia, pheochromocytoma, and thyroid storm may cause similar signs and symptoms.

EMERGENCY DEPARTMENT EVALUATION

The history should include the time, amount, and formulation of theophylline or caffeine ingested; past or recent therapeutic use of these agents; and routine medical history. Symptoms before arrival should be noted. The maximum possible serum drug level (micrograms per milliliter) can be estimated by doubling the acutely ingested dose (milligrams per kilogram).

The physical examination should focus on vital signs, mental status and neurologic evaluation, cardiorespiratory status, and GI function. Vomitus and stool should be checked for overt or occult blood. Laboratory evaluation should include a quantitative theophylline or caffeine level; complete blood count; determination of electrolyte, glucose, blood urea nitrogen, and creatinine levels; and urinalysis. Drug levels should be repeated every 2 to 4 hours following acute ingestions, until the level is no longer rising. Patients with elevated theophylline levels and moderate or severe clinical toxicity should also have measurements of serum amylase, calcium, creatine phosphokinase, ketones, magnesium, and phosphorus levels, urine myoglobin, and arterial blood gas analysis.

Cardiac monitoring and an electrocardiogram (ECG) should be obtained on all patients. Patients with respiratory symptoms, an abnormal pulmonary examination or ECG, or coma or seizures should have a chest radiograph.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures are instituted, as necessary. Activated charcoal significantly reduces the absorption of theophylline and is the preferred method of GI decontamination. The repetitive administration of activated charcoal also enhances the total body clearance of theophylline.³ The effects of charcoal on the absorption and elimination of other methylxanthines are predicted to be similar. Because serum concentrations may not peak for many hours after ingestion (up to 24 hours with slow-release preparations), every patient with an oral theophylline overdose should receive activated charcoal, regardless of the alleged time of ingestion. A dose of 0.5 to 1.0 g/kg of body weight should be given every 2 to 4 hours until drug levels are in the therapeutic range. If the patient cannot tolerate charcoal because of persistent vomiting, the administration of smaller but more frequent doses (by continuous infusion by way of nasogastric tube, if necessary), metoclopramide (up to 10 mg), ranitidine (50 mg intravenously), droperidol (2.5 mg intravenously), or odansatron (8 to 32 mg intravenously) may be used.^{2,11}

Gastric drug bezoar has been reported after sustained-release theophylline overdose.⁴ Endoscopic evaluation and drug mass removal, if necessary, should be considered in patients with rising drug levels and severe poisoning. Although often recommended, whole-bowel irrigation did not add to the benefit of multiple-dose activated charcoal in an experimental sustained-release theophylline overdose.⁷

Seizures should be treated aggressively. A benzodiazepine (e.g., diazepam, lorazepam, midazolam) should be given first. If the seizures do not stop rapidly or if they recur, phenobarbital (15 to 20 mg/kg) should be administered intravenously. If seizures do not stop within 20 to 30 minutes, thiopental should be given; a loading dose of 3 to 5 mg/kg, followed by an infusion of 2 to 4 mg/kg/h is usually efficacious, but these doses can be increased, if necessary. Phenytoin unlikely to be effective.⁶ Neuromuscular paralysis (e.g., pancuronium) may be necessary to stop muscle contractions, facilitate ventilation, and prevent hyperthermia and rhabdomyolysis. Electroencephalographic monitoring and continued treatment of seizures are necessary during paralysis. Treatment should also include correction of accompanying acidemia, as this may promote dysrhythmias.

Propranolol is the drug of choice to treat supraventricular and ventricular arrhythmias after acute overdose. Intravenous doses of 1 mg in adults or 0.02 mg/kg in children should be given slowly and repeated every 5 to 10 minutes until dysrhythmias stop, or to a maximal dose of 0.1 mg/kg.⁵ Lidocaine may also be used for ventricular dysrhythmias. Although propranolol is normally contraindicated in patients with asthma or COPD, it has been used without adverse effects in asthmatics with acute theophylline poisoning. In such patients, the short-acting beta antagonist esmolol has been used.¹⁵ However, because esmolol is selective for beta-1 receptors, it could theoretically worsen hypotension resulting from beta-2 stimulation. Propranolol may also be effective in treating theophylline-induced seizures.¹⁴ Clinical evidence of bronchospasm is an absolute contraindication to the use of beta blockers. In patients with atrial tachyarrhythmias exacerbated by theophylline intoxication, verapamil has been effective.¹¹ Correction of hypoxemia, acidemia, hypokalemia, and other metabolic abnormalities is also important. Because hypokalemia is due to an intracellular shift of potassium rather than a total body deficit, overly aggressive therapy for this condition may result in hyperkalemia as toxicity resolves and should be avoided. Hyperglycemia is transitory and well tolerated and usually does not necessitate insulin therapy.

Hypotension is initially treated with fluid administration. Persistent hypotension may be treated with pressors (e.g., dopamine and norepinephrine) or propranolol (because of its beta-2 blocking effect).⁵ Hyperthermia and rhabdomyolysis should be treated with standard measures.

Charcoal hemoperfusion can enhance the elimination of theophylline and should be considered for patients with the following criteria: persistently unstable hemodynamic parameters; seizures; or theophylline serum concentrations above 80 to 100 µg/mL after an acute ingestion, above 60 µg/mL after chronic ingestion, and above 40 µg/mL after an acute or chronic intoxication if age is less than 6 months or above 60 years or there is severe underlying cardiovascular disease.^{10,11} and ^{12,16} Similar parameters should be used in patients with caffeine poisoning.

Hemodialysis also enhances the elimination of theophylline and should be used if hemoperfusion is not immediately available. A tandem set-up (in-line hemodialysis and hemoperfusion) can be used for patients with severe metabolic abnormalities as well as high drug levels. Exchange transfusion has also been used in neonates with caffeine intoxication when hemoperfusion is technically difficult.¹³

DISPOSITION

Patients with a serum theophylline concentration above 35 µg/mL should be admitted to a monitored bed. Those with severe neurologic or cardiotoxic manifestations or serum concentrations above 50 µg/mL should be admitted to an intensive care unit. Those with levels under 35 µg/mL and mild symptoms can usually be treated in the emergency department and discharged when they become asymptomatic. A nephrologist should be consulted for patients who meet or are approaching criteria for extracorporeal elimination therapy. If intensive care unit and extracorporeal treatment are not available, the patient should be transferred to a facility with these capabilities.

COMMON PITFALLS

- Failure to consider the effects of age, underlying disease, and potential drug interactions on drug kinetics and dosing when prescribing theophylline
- Failure to appreciate that patients with chronic exposures develop toxicity at lower drug levels than those with acute or acute-on-chronic overdose
- Failure to consider the patient's age, the type of intoxication (acute vs. chronic), and underlying diseases (previous neurologic or cardiac problems) when interpreting theophylline serum concentrations
- Failure to appreciate that hypotension (not hypertension) is characteristic of severe, acute (but not chronic) caffeine or theophylline poisoning
- Failure to obtain serial theophylline levels to assess for delayed and prolonged absorption and to assess the results of treatment

- Failure to administer activated charcoal in single and multiple doses and to give antiemetics, if necessary
- Failure to treat seizures aggressively to prevent acidemia, hyperthermia, rhabdomyolysis, and permanent neurologic damage
- Failure to appreciate that beta blockers can reverse much of the toxicity caused by theophylline overdose but that the risks must be weighed against the benefits in patients with asthma or COPD
- Failure to consider enhanced elimination therapy with hemoperfusion or hemodialysis and to consult a nephrologist in patients with severe poisoning

CHAPTER 354

Monoamine Oxidase Inhibitor Poisoning

Michael J. Burns

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The monoamine oxidase (MAO) inhibitors have been available for the treatment of major depression since the 1950s.¹⁵ They were largely replaced by the less toxic tricyclic antidepressants in the 1970s.

Although effective, MAO inhibitors are infrequently prescribed because of their risk for producing dangerous food and drug interactions and serious toxicity following overdose. These agents are generally reserved for the management of atypical, drug-resistant, neurotic, and reactive depression. MAO inhibitors are also occasionally used to treat anxiety states, bulimia, hypertension, migraine headaches, narcolepsy, obsessive-compulsive disorder, Parkinson disease, and phobias. Newer selective, reversible inhibitors of MAO have a lower propensity for adverse effects and may lead to a resurgence of MAO inhibitor use.^{1,4,5,6 and 7}

These agents block the oxidative deamination of endogenous and exogenous monoamines by means of MAO, a flavin-containing enzyme located in the outer mitochondrial membranes of most tissues.¹⁵ Two subtypes of MAO exist (MAO-A and MAO-B), which differ in their substrate and inhibitor specificities and tissue distribution.^{4,6,8,9,12,15,18} MAO-A is found in the brain (monoaminergic neurons), peripheral sympathetic postganglionic neurons, intestinal mucosa, and liver. MAO-B is located in the brain (glial cells and some serotonergic neurons), platelets, and liver, with smaller amounts in the intestinal mucosa.

Noradrenergic neurons contain predominantly MAO-A; serotonergic neurons contain both. Substrates primarily deaminated by MAO-A include epinephrine, metanephrine, norepinephrine (NE), and 5-hydroxytryptamine (5-HT, or serotonin). Substrates metabolized primarily by MAO-B include beta-phenylethylamine, methylhistamine, phenylethanolamine, and benzylamine. Many substrates are metabolized by both enzymes, including tyramine, dopamine (DA), octopamine, and tryptamine. Substrate specificity is not absolute and is primarily dependent on the relative concentrations of substrate and MAO subtype in a particular anatomic location. Inhibition of MAO-A is necessary for therapeutic efficacy in the treatment of depression.¹⁵

MAO enzymes function to maintain low body concentrations of monoamines.^{4,6,15,18} Hepatic and intestinal MAOs prevent the absorption of and systemic effects from dietary monoamines (e.g., tyramine). Intra-neuronal MAO maintains a low cytoplasmic concentration of monoamine neurotransmitters that allows for net reuptake and termination of effect of extracellular monoamines.^{4,6,15} Glial cell MAO scavenges monoamines and prevents their accumulation within the central nervous system (CNS).^{4,6} All MAO inhibitors are false substrates for the MAO enzyme; they bind to the active site of MAO and prevent it from further activity.^{1,15} MAO inhibitors may be classified by their differential selectivity for MAO subtypes, reversibility of MAO binding (inhibition), or by chemical structure ([Table 354.1](#)). The oldest MAO inhibitors in use are nonselective irreversible (“suicide”) inactivators of MAO. Initially, they bind reversibly to the flavin active site of MAO but are subsequently oxidized to a reactive intermediate, which forms an irreversible covalent bond with the enzyme. New enzyme must be synthesized before the function of MAO returns to normal.

Agent (Trade Name)	Inhibition	Selectivity	Structure
Brofaromine	Reversible	MAO-A	Piperidine
Clorgyline	Irreversible	MAO-A	Amine
Iproniazid (Marsilid)	Irreversible	Nonselective	Hydrazine (Hydrazide)
Isocarboxazid (Morglan)	Irreversible	Nonselective	Hydrazine (Hydrazide)
Moclobemide (Aurorix)	Reversible	MAO-A	Benzamide
Nalamide	Irreversible	Nonselective	Hydrazine
Pargyline (Eutonyl)	Irreversible	MAO-B	Amine
Phenelzine (Nardil)	Irreversible	Nonselective	Hydrazine
Procarbazine (Matulane)	Irreversible	Nonselective	Hydrazine
Selegiline, deprevil (Eldepyl)	Irreversible	MAO-B	Amine
Toloxatone (Humonil)	Reversible	MAO-A	Benzamide
Tranylcypromine (Parnate)	Irreversible	Nonselective	Amine

TABLE 354.1. Classification of Monoamine Oxidase Inhibitors

Currently, only irreversible inhibitors of MAO are available for clinical use in the United States. The nonselective inhibitors include isocarboxazid, phenelzine sulfate, and tranylcypromine sulfate. Procarbazine, an antitumor agent used primarily for patients with Hodgkin disease, also has weak MAO inhibitor activity. Selegiline, an inhibitor of MAO-B used to treat Parkinson disease, is the only selective inhibitor currently available in the United States.⁸ It is not associated with dangerous food and drug interactions at doses used clinically. Its specificity for MAO-B, however, is dose-dependent and lost at supratherapeutic doses.⁸

More recently, reversible selective inhibitors of MAO-A (brofaromine, cimoxatone, moclobemide, and tolaxatone), often termed *RIMAs*, have been developed and are used clinically outside the United States.^{1,4,5,6 and 7} These agents bind competitively (with respect to natural amine substrate) and reversibly at the active site of MAO-A. MAO inhibition is short-lived (enzyme activity commonly restored within 24 hours) and may be overcome by increasing levels of amine substrate. Initial experience with these agents has demonstrated greater safety following overdose and a significant reduction of adverse effects when combined with other pharmaceutical agents or dietary amines.

MAO inhibitors have traditionally been classified by chemical structure into hydrazines (iproniazid, isocarboxazid, and phenelzine) and nonhydrazines (clorgyline, pargyline, selegiline, and tranylcypromine).^{9,10,15} The hydrazine moiety imparts distinct pharmacologic and toxic effects to these agents (discussion follows). Structurally, most MAO inhibitors are similar to amphetamines and other sympathomimetic agents.¹⁵ In fact, both selegiline and tranylcypromine are partly metabolized to amphetamine and methamphetamine.^{8,10,13,15} This characteristic also accounts for additional pharmacologic activity.

MAO inhibitors exert their pharmacologic and toxic effects by increasing neuronal and synaptic concentrations of biogenic amines (see [Figure 354.1](#)).^{6,14,15} By decreasing the degradation of MAO substrates, MAO inhibitors result in expansion of cytosolic and vesicular storage pools of NE, DA, and 5-HT in presynaptic nerve terminals. Increased presynaptic neurotransmitter concentrations increase their quantal release from vesicles during normal neurotransmission, cause spontaneous spill-over into the synaptic cleft independent of nerve activity, and decrease concentration-dependent reuptake by nerve-ending amine transporters.^{4,6,15,18} Spontaneous hypertensive episodes that occur in patients taking therapeutic doses of MAO inhibitors (in the absence of dietary indiscretions or drug interactions) likely result from the spontaneous release of NE from nerve terminals.^{10,12,15,18}

Figure 354.1. Diagram of a noradrenergic synapse illustrating the mechanisms underlying monoamine oxidase inhibitor (MAOI) toxicity: (1) Inhibit MAO to prevent norepinephrine (NE) degradation; (2) inhibit NE reuptake by monoamine transporter; (3) inhibit NE reuptake by vesicles; (4) promote reverse transport of NE from nerve ending; (5) promote reverse transport of NE from vesicles; (6) block dopamine (DA) beta-hydroxylase; (7) indirectly inhibit enzymes necessary for production of NE. Similar mechanisms operate at dopaminergic and serotonergic nerve endings. a and b refer to adrenergic receptors; COMT= catechol-O-methyltransferase, another enzyme that degrades catecholamines.

As amphetamine congeners and indirect-acting sympathomimetics themselves, MAO inhibitors further enhance the release of cytoplasmic amines from the nerve ending in the absence of vesicle exocytosis.^{6,10,15} They bind competitively to the amine uptake transporter and prevent reuptake of natural amine neurotransmitters. When the MAO inhibitor is transported into the neuron, reverse transport of cytosolic biogenic amines occurs that further increases their synaptic concentrations. MAO inhibitors similarly prevent uptake from glial cell transporters that scavenge extracellular (synaptic) monoamines.^{4,6}

Overdose of MAO inhibitors produces an exaggeration of these neuronal effects and may result in profound hyperadrenergic, hyperdopaminergic, and hyperserotonergic states. The delayed appearance of signs and symptoms following overdose is attributed to initial reversible binding with MAO and the time required for significant enzyme inhibition and cumulative effects to occur (e.g., neuronal accumulation of NE, DA, 5-HT).^{10,12} Although effects from NE and DA contribute significantly, the neuromuscular abnormalities (e.g., rigidity, myoclonus), hyperthermia, and unusual ocular movements associated with MAO overdose appear to be mediated primarily by enhanced serotonergic neurotransmission in the brainstem and spinal cord.^{9,14}

Stimulation of 5-HT_{1A} receptors from raphe bulbospinal neurons results in myoclonus and rigidity. These neuromuscular effects combined with stimulation of 5-HT₂ receptors in the diencephalon result in hyperthermia. Enhanced raphe serotonergic neurotransmission, which controls saccadic eye movements, may produce an unusual “ping-pong” gaze in patients with severe MAO inhibitor toxicity.^{3,9} These effects are also seen in the serotonin syndrome ([Chapter 370](#)).

The most serious adverse reactions associated with MAO inhibitor therapy result from drug and food interactions and are also the result of exaggerated neuronal effects. The administration or ingestion of any agent that increases CNS serotonin levels may result in potentially life-threatening toxicity known as the serotonin syndrome (see [Chapter 370](#)).^{9,14,18} The use of indirectly acting sympathomimetic agents (e.g., amphetamine, cocaine, ephedrine, phenylpropanolamine, methylphenidate), which act primarily by causing the release of NE from the presynaptic nerve terminal, may result in the release of the expanded pool of NE and signs and symptoms of catecholamine poisoning (e.g., hypertensive crisis).^{10,11 and 12,18}

A similar adverse sympathomimetic effect, called the “cheese reaction,” may occur when foods containing large amounts of tyramine (e.g., aged cheeses; aged, pickled, or smoked meats; yeast extracts; certain beers; and red wines) and other indirectly acting monoamines (e.g., phenylethylamine, phenylethanolamine, tryptamine, octopamine) are ingested.¹¹ Inhibition of MAO in the liver and intestinal mucosa allows for systemic absorption of these amines. Like other indirect-acting amines, they may precipitate a rapid, massive release of NE when taken up into noradrenergic nerve endings.

Chronic MAO inhibition increases intraneuronal concentrations of false monoamine neurotransmitters (e.g., tyramine, phenylethylamine, octopamine), which are normally present in very small amounts. With the scavenging function of hepatic and intestinal MAO blocked, dietary monoamines gradually accumulate within noradrenergic nerve endings and displace NE from synaptic vesicles (see [Fig. 354.1](#)).^{11,15,18} Stimulation of sympathetic neurons results in release of these false neurotransmitters, which have minimal postsynaptic effect. Functional blockade of sympathetic neurotransmission is manifested clinically by hypotension. This hypotensive effect is potentiated by other adaptive responses that result from chronic MAO inhibition and include upregulation of inhibitory presynaptic receptors and downregulation of postsynaptic receptors.^{11,15,17}

In addition, MAO inhibitors, through feedback inhibition and via direct effects, inhibit tyrosine hydroxylase, L-amino acid decarboxylase, and DA decarboxylase, enzymes necessary for the production of catecholamine neurotransmitters.^{11,15,18} These pharmacologic effects likely contribute to the profound sympatholytic phase that follows an initial sympathomimetic phase in severe MAO inhibitor poisoning.¹⁰ After the initial massive catecholamine release, neuronal stores of these neurotransmitters are depleted, and there is the inability to rapidly regenerate new neurotransmitter. Hypotension and cardiovascular collapse result.

The acute and chronic toxic effects of MAO inhibitors are mediated by several additional mechanisms. MAO inhibitors interfere with the production, activation, supply, and function of pyridoxine and gamma-amino butyric acid (GABA) by binding to and inhibiting pyridoxine, pyridoxine phosphokinase, L-amino acid decarboxylase, and the GABA-A receptor.^{15,16} These effects may mediate seizures that are occasionally associated with acute overdose and chronic use of MAO inhibitors. Hydrazine MAO inhibitors inhibit diamine oxidase, an enzyme that, in addition to MAO, metabolizes histamine.^{10,16} Flushing and hypotension may result from these effects.

Hydrazine MAO inhibitors also inhibit hepatic cytochrome P-450 enzymes, and thus may potentiate the effects of alcohol, antihistamines, barbiturates, opioids, neuroleptics, anticonvulsants, benzodiazepines, and warfarin.^{12,15,16} Additionally, the hypoglycemic effects of insulin and oral antidiabetic drugs may be potentiated by MAO inhibitors.¹² Hydrazine MAO inhibitors are also occasionally associated with the development of severe hepatotoxicity. Hepatic injury is likely mediated by a toxic metabolite that binds irreversibly to hepatocellular macromolecules. The hydrazine MAO inhibitor, iproniazid, was withdrawn from the market because of severe hepatotoxicity associated with its use.^{15,16}

MAO inhibitors are rapidly and completely absorbed from the GI tract, with peak plasma concentrations ranging from 1 to 4 hours after ingestion.^{1,5,8,10,13} Plasma elimination for these agents is also rapid, with half-lives ranging from 1 to 3 hours. For the irreversible MAO inhibitors, plasma drug concentrations do not correlate with level of MAO inhibition, and toxic plasma concentrations have not been defined.^{10,12,18} Maximal inhibition of MAO occurs after 5 to 10 days of therapy with these agents.¹⁶

For reversible inhibitors, however, maximal MAO inhibition is achieved within a few hours after the first dose.^{1,4,5 and 6} MAO inhibitors are extensively metabolized in the liver, often by many different enzymes.^{1,5,8,13} With irreversible MAO inhibitors, the potential for drug or dietary interactions may last for 2 to 3 weeks after discontinuation of treatment.^{11,12,15,16} For reversible agents, MAO activity is restored within 24 hours after the last dose, and the potential for drug and dietary interactions is much less.^{1,5}

The ingestion of 2 to 3 mg/kg or more of an irreversible MAO inhibitor should be considered potentially life-threatening.^{10,12} Fatal amounts have been reported to be 4 to 6 mg/kg.^{10,19} Death has been reported after the ingestion of 170 to 650 mg of tranylcypromine and 375 to 1,500 mg of phenelzine.^{10,19} Survival after larger ingestions has also been reported.^{10,16,19}

CLINICAL PRESENTATION

Drug or food interactions with MAO inhibitors are a common problem. The incidence of hypertensive crisis for MAO inhibitor-treated patients is 1% to 8%.¹² The clinical presentation may include headache, hypertension, tachycardia (or reflex bradycardia), diaphoresis, agitation, hypertonicity, hyperreflexia with myoclonus,

rigidity, seizures, and coma.^{11,12} Hyperpyrexia, intracranial hemorrhage, and death may occur.¹¹ Toxicity begins within 30 to 90 minutes of the ingestion or administration of sympathomimetic amines. The duration of effect is variable but often resolves within a few hours.

Nonselective irreversible MAO inhibitor overdose follows a distinctly different time course.^{2,3,10,19,20} The absence of early symptomatology is typical. The onset of toxicity is usually delayed from 6 to 12 hours after the overdose, peaks from 24 to 48 hours for severe cases, and may last for 72 to 96 hours.^{10,17,19} A latent period as long as 29 hours has been described following tranylcypromine overdose.²⁰

During the latent phase, the patient usually appears well or mildly sedated.^{10,19,20} Poisoning is characterized by alterations in behavior, cognition, autonomic nervous system function, and neuromuscular activity and may be classified as mild, moderate, or severe (Table 354.2).¹⁰ Signs and symptoms vary greatly in their onset, severity, and duration. Patients with early or mild toxicity may demonstrate mild lethargy or restlessness, dysarthria, nausea, headache, ataxia, palpitations, flushing, shivering, sweating, tremor, nystagmus, incoordination, or hyperreflexia. Signs and symptoms of moderate toxicity may include confusion, hallucinations, disorientation, agitated delirium, mutism, salivation, diarrhea, marked diaphoresis, myoclonus, fasciculations, trismus, writhing movements, and mild-to-moderate elevations of temperature, pulse, respiratory rate, and blood pressure. Severe toxicity may be characterized by unresponsive coma; fixed, dilated pupils; “ping-pong” gaze; pathologic reflexes; generalized rigidity; seizures; hyperpyrexia (temperature greater than 104°F); marked tachypnea or respiratory depression; extreme sinus tachycardia or bradycardia; malignant cardiac arrhythmias; hypotension; and death.^{2,3,10,19} Death from cardiovascular collapse is most likely to occur in patients with severe hyperpyrexia.¹⁹

MAO Inhibitor	Typical Dose	Clinical Presentation	Signs and Symptoms	Management
Selegiline	10-20 mg	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Supportive care, benzodiazepines, barbiturates, cooling, anticholinergics, antihypertensives, antiepileptics
Tranylcypromine	30-60 mg	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Supportive care, benzodiazepines, barbiturates, cooling, anticholinergics, antihypertensives, antiepileptics
Phenelzine	30-60 mg	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Supportive care, benzodiazepines, barbiturates, cooling, anticholinergics, antihypertensives, antiepileptics
Isocarboxazide	15-30 mg	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Supportive care, benzodiazepines, barbiturates, cooling, anticholinergics, antihypertensives, antiepileptics
Hydroxyzine	25-50 mg	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Supportive care, benzodiazepines, barbiturates, cooling, anticholinergics, antihypertensives, antiepileptics
Propylthiouracil	100-150 mg	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Agitation, tachycardia, hypertension, hyperreflexia, myoclonus, tremor, nystagmus, incoordination, hyperpyrexia, seizures, coma	Supportive care, benzodiazepines, barbiturates, cooling, anticholinergics, antihypertensives, antiepileptics
Others				

TABLE 354.2. Clinical Course of Monoamine Oxidase Inhibitor Poisoning

Although seizures may occur following MAO overdose, they are uncommon and can be confused with neuromuscular hyperactivity produced by these agents.^{9,19} Secondary complications may occur in patients with moderate-to-severe toxicity and include aspiration pneumonia, adult respiratory distress syndrome, rhabdomyolysis, acute renal failure, metabolic acidosis, and disseminated intravascular coagulation (DIC).¹⁰ The likelihood of secondary complications (e.g., rhabdomyolysis, DIC) and death is related to the degree and duration of hyperthermia. Patients with severe toxicity can manifest fixed, dilated pupils; posturing; and extensor plantar response yet make a complete neurologic recovery.^{2,3,17,19}

When taken alone, reversible inhibitors of MAO-A appear to have a benign course following acute overdose. At doses as high as 20.5 g, no fatalities have been reported following overdose with moclobemide alone.⁵ Large overdoses are characterized by mild CNS depression, agitation, tachycardia, hypertension, and mydriasis.⁵ Mixed-drug overdoses are more serious. Patient deaths have been reported from serotonin syndrome when moclobemide has been combined with other serotonin-potentiating drugs (e.g., citalopram, clomipramine).⁵

Patients with chronic toxicity from irreversible nonselective inhibitors may manifest tremors, insomnia, hyperhidrosis, agitation, hypomanic behavior, hallucinations, confusion, and seizures.

DIFFERENTIAL DIAGNOSIS

Toxicity from amphetamines, cocaine, and other sympathomimetic agents (including over-the-counter appetite suppressants) may produce a clinical picture similar to the hypertensive reactions associated with MAO inhibitors and dietary and drug monoamines. The clinical presentation of MAO inhibitor overdose may be similar to anticholinergic, hallucinogen (e.g., lysergic acid diethylamide, phencyclidine), lithium, salicylate, sympathomimetic (e.g., amphetamines, cocaine), and strychnine poisoning. MAO inhibitor toxicity may be confused with the neuroleptic malignant syndrome and withdrawal from alcohol or sedative-hypnotic agents. The serotonin syndrome has clinical features nearly identical to those following overdoses with MAO inhibitors. Medical emergencies such as hypoglycemia, malignant hyperthermia, intracranial hemorrhage, meningitis, encephalitis, pheochromocytoma, septicemia, tetanus, and thyrotoxicosis may present in a similar manner.

EMERGENCY DEPARTMENT EVALUATION

There are no pathognomonic physical findings or laboratory abnormalities. Accurate and complete historical data are essential in differentiating the toxic syndromes related to MAO inhibitors. Initial testing for patients with suspected intentional overdose should include an electrocardiogram and measurements of serum electrolytes, glucose, renal function, and acetaminophen and salicylate levels. Patients who present with signs and symptoms of toxicity should also have a complete blood count; prothrombin and partial thromboplastin times; creatine phosphokinase, calcium, magnesium, and liver function tests; and a urinalysis. Patients with altered mental status should have a bedside fingerstick glucose determination and appropriate intervention, as necessary. A lumbar puncture and computed tomography scanning may be necessary to differentiate drug intoxication from intracranial hemorrhage, meningitis, and encephalitis.

Toxicology screening may be useful to exclude other intoxications, but it rarely detects MAO inhibitors because of their low concentrations in blood and urine samples.¹⁰ Overdose of selegiline or tranylcypromine, however, may produce a positive qualitative screen for amphetamines.^{8,10,13,15} Quantitative MAO inhibitor levels are not generally available and have not been shown to correlate with the severity of poisoning.^{10,12,19} Similarly, the degree of MAO enzyme activity inhibition does not correlate with clinical toxicity.

EMERGENCY DEPARTMENT MANAGEMENT

Supportive care is the primary treatment for MAO inhibitor overdose. Advanced life-support measures should be instituted, as necessary. The administration of glucose, oxygen, naloxone, and thiamine should be considered for patients with altered mental status. Activated charcoal is the preferred method of GI decontamination for recent acute MAO inhibitor overdose. Before any drug or food is given, the potential for an adverse interaction with MAO inhibitors must be considered.

Agitation, neuromuscular hyperactivity, and seizures should be treated promptly with liberal doses of benzodiazepines (e.g., diazepam, lorazepam) or barbiturates (e.g., phenobarbital).¹⁰ Phenytoin is unlikely to be as effective for seizures associated with MAO inhibitors. Pyridoxine administration is recommended for seizures that occur following overdose with a hydrazine MAO inhibitor.

Rapid cooling is essential to minimize patient morbidity and mortality from hyperthermia. Because it is almost invariably associated with CNS agitation and neuromuscular hyperactivity, initial treatment with benzodiazepines or barbiturates is recommended. In conjunction with these initial pharmacologic measures, evaporative and convective cooling methods, using wet sheets or cool mist sprays and fans, are recommended.^{10,19} Antipyretics and cooling blankets are generally ineffective. If these initial maneuvers do not provide rapid patient cooling, neuromuscular blockade with nondepolarizing paralyzing agents is strongly recommended.

Evidence from animal studies and human case reports suggests that neuromuscular paralysis is effective for the treatment of severe hyperthermia.² Cooling times of

less than 1 hour have been achieved with this method of treatment. Although dantrolene (2.5 mg/kg orally or intravenously every 6 hours) has also been reported to be effective,¹⁷ it is itself toxic and does not terminate muscular rigidity and hyperthermia as rapidly as paralyzing agents. Because the pathophysiology of serotonin syndrome overlaps considerably with MAO inhibitor overdose, nonspecific serotonin receptor antagonists (e.g., cyproheptadine, methysergide; see [Chapter 370](#)) could be of benefit. Because of the lack of any clinical data, however, their use cannot yet be recommended for MAO inhibitor overdose.

Severe hypertension may be treated with the intravenous administration of rapid-onset, short-acting agents such as sodium nitroprusside or phentolamine.^{10,12,16,19} Phentolamine (5 to 10 mg intravenously) is pharmacologically attractive because it can block alpha-adrenergic receptors and antagonize the effects of NE. It has proven effective for the treatment of hypertension associated with the "cheese reaction."¹¹ Long-acting agents (tolazoline, clonidine) also have been used but are not recommended, as hypertension is often followed by severe hypotension.¹⁰

Hypotension should initially be treated with fluid resuscitation. When pressors are required, direct-acting agents (e.g., epinephrine, NE) are recommended.^{10,12} The use of indirect-acting agents (e.g., DA), which require the release of intracellular amines for their pressor effect, may either precipitate a hypertensive crisis or be ineffective on account of depleted stores of catecholamines. Additionally, MAO inhibition is less likely to potentiate the effects of exogenously administered, direct-acting pressors, which circulate extracellularly and are primarily metabolized by catechol- *c*-methyltransferase. Regardless, low doses of direct-acting pressors should be used initially to minimize the risk of an exaggerated pressor response. Phenylephrine, a direct-acting agent, has been associated with an exaggerated pressor response and is not recommended for the treatment of hypotension in MAO inhibitor poisoning.¹¹

Ventricular dysrhythmias and severe bradycardias, usually premonitory signs, should be treated according to current advanced cardiac life-support protocols. Bretylium, however, is not recommended for the treatment of refractory ventricular dysrhythmias; it has initial catecholamine-releasing effects that may potentiate the cardiotoxic effects of MAO inhibitors.^{10,12}

Diuresis, urinary acidification, hemodialysis, and hemoperfusion play no role in the management of MAO inhibitor poisoning.^{10,12,19}

DISPOSITION

Because of the delayed onset of toxicity, all patients with suspected MAO inhibitor overdose should be admitted for extended observation (24 hours) in a monitored setting. Symptomatic patients and those with abnormal vital signs should be admitted to an intensive care unit. If intensive care is unavailable, patients should be transferred to an institution with this capacity.

Patients who present with drug or dietary interactions may not require hospital admission if the clinical response has been mild. Patients with severe reactions, those with persistent symptoms after a 4- to 6-hour observation period, and those with symptoms that necessitate active intervention should be admitted. The level of in-hospital care required (intensive care or floor) depends on the severity of symptoms. For patients well enough to eat, an MAO inhibitor diet (e.g., low tyramine) should be ordered.

COMMON PITFALLS

- Failure to check for MAO inhibitor use before prescribing sympathomimetics or giving pain medications, particularly meperidine
- Failure to appreciate that the onset of toxicity may be delayed and gradual in onset after MAO inhibitor overdose and to admit all patients with MAO inhibitor overdose for observation
- Failure to appreciate that the history is key to differentiating acute overdose from drug and food interactions, including the serotonin syndrome
- Failure to rapidly and aggressively cool the patient with hyperthermia
- Failure to appreciate that early sympathetic stimulation may be followed by catecholamine depletion and cardiovascular collapse in patients with acute MAO inhibitor overdose
- Failure to exclude other CNS pathology in patients who present with fever, altered mental status, hypertension, or neuromuscular hyperactivity

CHAPTER 355

Mushroom Poisoning

Christopher H. Linden and Robert P. Dowsett

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Mushrooms (or toadstools) is a common name for the fruit of certain kinds of fungi. Although foraging for wild mushrooms has long been commonplace in other parts of the world, it has only recently become popular in the United States. Even though the incidence of mushroom poisoning, also known as mycetism, appears to be rising, it remains uncommon. Of the thousands of ingestions reported each year, only a few hundred result in serious toxicity; however, mycetism is sometimes fatal.

Mushroom poisoning is most common during the late summer and early fall, when wild mushrooms are most abundant. Victims include young children who accidentally ingest mushrooms, recreational drug users who intentionally ingest hallucinogenic species, and foragers (and their families and friends) who confuse poisonous mushrooms with edible ones.^{6,8,10,20} Serious poisoning in children is rare and is usually due to the ingestion of mushrooms served to them by adults. Poisoning may also occur after the inhalation of toxic vapors during the cooking (i.e., the attempted detoxification by boiling) of gyromitrin-containing mushrooms.¹⁰ Sometimes, hallucinogenic mushrooms are prepared to be brewed in tea, snorted, smoked, or injected intravenously.^{11,12 and 13}

Edible mushrooms may also cause poisoning. Allergic reactions such as mushroom worker's alveolitis, food allergy, and hemolytic anemia can occur, and they are subject to bacterial, insecticidal, and chemical contamination. Adulteration with phencyclidine has been reported. Idiosyncratic reactions, most likely of genetic origin, such as gastrointestinal (GI) intolerance to *Agaricus bisporus*, the most prevalent grocery store species, are relatively common. Mushrooms containing coprine are edible, but toxic reactions can occur if they are coingested with alcohol.

Only about 100 of the many thousands of species of mushrooms are considered poisonous. They can be divided into eight groups, based on their toxins ([Table 355.1](#)).^{2,7,8,9 and 10,12,17} Amatoxins are found in species of the *Amanita*, *Conocybe*, *Galerina*, and *Lepiota* genera, such as *Amanita phalloides* (death cap) and *Amanita virosa* (destroying angel). These cyclic octapeptides can cause delayed and potentially fatal liver and kidney necrosis. Additional cyclic heptapeptides (phallotoxins) may contribute to GI cytotoxicity. Orellanine and cortinarins are present in some species of the *Cortinarius* genus. These toxins can cause a renal tubulointerstitial nephritis, which does not become apparent until many days after ingestion. Although toxic *Cortinarius* species are found primarily in Europe, *Amanita smithiana*, which is indigenous to North America and sometimes mistaken for the edible pine mushroom or matsutake (*Tricholoma magnivelare*), contains toxins (allenic norleucine and pentynoic acid) that cause similar toxicity.¹⁸ Gyromitrins are contained in mushrooms of the *Gyromitra*, *Paxina*, and *Sarcosphaera* genera. An example is the "false morel," or *Gyromitra esculenta*. The active metabolites of gyromitrins are hydrazines that can oxidize hemoglobin and cause delayed hepatic, neurologic, and renal cytotoxicity. Muscarine is found in species of the *Boletus*, *Clitocybe*, and *Inocybe* genera, such as *Clitocybe dealbata* (the sweater). An aminofuran alkaloid, muscarine, stimulates peripheral parasympathetic nerves soon after ingestion. Ibotenic acid and its active metabolite muscimol are present in some species of *Amanita*, such as *Amanita muscaria* (fly agaric) and *Amanita pantherina* (panther cap). These isoxazole derivatives have a structural skeleton similar to that of γ -aminobutyric acid, but they have complex interactions with multiple types of central and peripheral neurotransmitters and their receptors. Small amounts of muscarine may also be present. The net effect is the early onset of hallucinations and either cholinergic or anticholinergic symptoms. Psilocin is the active metabolite of psilocybin. These dimethyltryptamines are serotonin analogues that cause the rapid onset of hallucinations and sympathetic stimulation. They are present in species of *Conocybe*, *Gymnopilus*, *Panaeolus*, and *Psilocybe*. Coprine is found in *Clitocybe calvipes* and species of *Coprinus*, such as *Coprinus atramentarius* (inky cap). This compound inhibits aldehyde dehydrogenase and results in a disulfiram-ethanol-like reaction if consumed with ethanol. A wide variety of mostly identified (miscellaneous) toxins are present in mushrooms from many genera (e.g., *Boletus*, *Chlorophyllum*, *Entoloma*, *Gomphus*, *Hebeloma*, *Lactarius*, *Omphalotus*, *Paxillus*, *Pholiota*, *Ramaria*, *Russula*, *Tricholoma*, and *Verpa*); toxicity is limited to the GI tract and occurs within a short time of ingestion.

Class of Toxin	Mechanism of Action	Principal Effect ^a
AMATOXIN		
Amatoxins	Inhibition of RNA polymerase II	Hepatic and renal necrosis
Orellanine	Inhibition of alkaline phosphatase	Renal cytotoxicity
Cortinarins	Inhibition of peroxisomal phospholipase and cytochrome P-450 enzymes	Renal, hepatic, and renal cytotoxicity
IBOTENIC ACID		
Muscarine	Stimulation of postsynaptic parasympathetic receptors	Cholinergic syndrome
Ibotenic acid/muscimol	Interaction with CNS serotonin receptors	Hallucinations, anticholinergic or cholinergic syndrome
Psilocybin/psilocin	Stimulation of serotonin receptors	Hallucinations, sympathetic syndrome
Muscimol	Inhibition and stimulation of muscarine	Coma/coma
HYDRAZINE		
Gyromitrin	Inhibition of acetylcholinesterase	Disulfiram-ethanol-like reaction

^aOnset time after ingestion.
^bOnset time after ingestion.
^cUsually includes GI symptoms, regardless of route ingested.
 CNS, central nervous system; GI, gastrointestinal.

TABLE 355.1. Mushroom Toxins

The nature and severity of poisoning depends on the dose, maturity, growing conditions (e.g., geographic location, food source, amount of rainfall, and temperature), method of storage and preparation, route of administration, and species of mushroom, and age and underlying health status of the victim. Mushrooms that contain amatoxins are responsible for most fatalities in the United States. The ingestion of one to three phalloides or 15 to 20 of the smaller *Galerina* species is potentially lethal. The overall mortality rate from amatoxin poisoning is estimated to be less than 5%, but it has been as high as 50% in some series. Children appear to be more susceptible than do adults, probably because of the ingestion of a proportionately greater dose when they partake of a mushroom meal. In some areas of Europe, mushrooms that contain gyromitrin (and sometimes orellanine) account for a significant number of deaths. Serious or fatal poisoning from other mushroom toxins is rare.

CLINICAL PRESENTATION

Except with mushrooms containing hallucinogens, symptoms typically begin with some combination of nausea, vomiting, abdominal cramps, and diarrhea. Associated or subsequent systemic toxicity depends on the type of toxin in the mushroom ingested. For a particular toxin, the higher the dose, the earlier the onset and the greater the severity of poisoning.

GI symptoms after amatoxin mushroom ingestion are characteristically delayed 6 to 24 hours after ingestion but are abrupt in onset, severe, and prolonged.^{4,7,8,9,10 and 11,14,17,20} Diarrhea may be profuse, occasionally bloody, and may result in severe dehydration and metabolic acidosis. Leukocytosis and hyperamylasemia may be present. There may be a period of apparent improvement occurring 24 to 48 hours after ingestion in less severe cases. Biochemical evidence of hepatotoxicity may occur as early as 24 hours after ingestion, but it typically begins at 48 hours and becomes maximal in 4 to 5 days. Hypoglycemia, elevated serum bilirubin, transaminase, and ammonia levels (ten to 30 times normal), and increased prothrombin and partial thromboplastin times are common. Physical findings include mild but tender hepatomegaly, jaundice, lethargy, and confusion. There may be concomitant or subsequent acute renal failure with elevated blood urea nitrogen and creatinine levels, and oliguria, hematuria, and proteinuria. With good supportive care, most patients slowly recover, but, in severe cases, progressive hepatic failure may end in death within 1 week. Delayed polyneuropathy and chronic active hepatitis have also been reported.

GI symptoms caused by *Cortinarius* species are typically mild, transient, and delayed (2 to 3 days after ingestion).^{2,15,16 and 17} They can occur within 20 minutes after ingesting *A. smithiana*. Constipation, rather than diarrhea, may occur. Associated symptoms include headache, chills, polyuria, thirst (intense, burning), and

nightsweats. Renal failure may become apparent between 3 days and 3 weeks after ingestion and is associated with flank pain and tenderness. Hematuria, marked albuminuria, and red cell casts may be seen on urinalysis. In 50% to 70% of cases, renal function gradually returns to baseline over a period of several weeks to several months.

The gastroenteritis that follows the ingestion of mushrooms that contain gyromitrins is usually delayed 6 to 24 hours and is moderate in severity and duration. ^{8,9 and 10,17} The onset may be earlier after inhalation exposure to vapors during cooking. Agitation, ataxia, headache (often severe), hyperreflexia, muscle cramps, vertigo, and weakness may ensue. Methemoglobinemia with cyanosis and associated Heinz body hemolytic anemia, hepatitis with encephalopathy, hyperthermia, and renal failure may develop in severe cases. Hepatic failure may be fatal.

In muscarine poisoning, GI symptoms occur within 15 minutes to 2 hours of mushroom ingestion and are relatively mild and of short duration (2 to 10 hours). ^{8,9,10 and 11,17} Associated findings include diaphoresis, headache, lacrimation, miosis, blurred vision, urinary frequency, and salivation. In severe cases, bronchorrhea, bronchospasm, bradycardia, hypotension, and, rarely, seizures and liver function abnormalities may occur.

GI symptoms after the ingestion of mushrooms that contain ibotenic acid and muscimol are typically absent, although short-lived vomiting may be noted. ^{1,8,9,10 and 11,17} Drowsiness, dizziness, and lethargy may occur within 20 minutes to 2 hours of ingestion and be followed by agitation, euphoria, confusion, delirium, hallucinations (visual misperceptions of color and shape, often with religious associations), and psychosis. Cholinergic (e.g., bradycardia, miosis, salivation) or anticholinergic (e.g., dry skin, fever, hypertension, mydriasis) may be noted. Symptoms in children include crying, screaming, and incoherent babbling. Muscle fasciculation, twitching, hyperreflexia, and myoclonus may also be seen. A fluctuating level of consciousness is common with severe poisoning. Coma and seizures may occur, but symptoms seldom last for more than 6 to 8 hours.

Nausea and vomiting occur in a minority of patients with psilocin and psilocybin intoxication and, if present, they are mild and transient. ^{8,9,10,11,12 and 13,17} Symptoms begin within 30 to 60 minutes of mushroom ingestion and typically include dysphoria followed by disorientation, incoordination, and hallucinations (usually visual but sometimes auditory and tactile as well). Associated signs and symptoms include mydriasis, blurred vision, mild tachycardia, hypertension, hyperreflexia, and irrational, antisocial, and sometimes suicidal behavior. Symptoms typically last for 4 to 6 hours, but flashbacks may occur for several months. Cyanosis with both hypoxia and methemoglobinemia, arthralgias, myalgias, fever, chills, and mild kidney and liver function abnormalities have been noted after intravenous injection. ³ Seizures, coma, hyperthermia, and death have occurred in children.

Mushrooms that contain coprine, although they are edible, may result in a disulfiram-ethanol–like reaction within 15 to 30 minutes of ethanol ingestion. ^{8,9,10 and 11,17} The reaction may occur 2 hours to 5 days after mushroom ingestion and typically lasts for 3 to 6 hours. In addition to GI symptoms, which may be severe, manifestations include diaphoresis, flushing, headache, dyspnea, chest tightness, palpitations, tachycardia, paresthesias, vertigo, and weakness. Hypotension (orthostatic or supine), confusion, coma, arrhythmias (atrial fibrillation and premature beats), and ischemic electrocardiographic changes may occur in severe cases.

Gastroenteritis is usually the only manifestation of poisoning by the miscellaneous mushrooms. ^{8,9 and 10,17} Symptoms begin within 30 minutes to 6 hours, are of variable severity, and last for 4 to 48 hours. In severe cases, diarrhea may become bloody, and dehydration may ensue. Other symptoms include chills, headache, diaphoresis, light-headedness, myalgias, paresthesias, carpopedal spasm, and weakness.

DIFFERENTIAL DIAGNOSIS

Without a history of mushroom ingestion, GI symptoms may be mistaken for food poisoning or viral gastroenteritis. Acetaminophen, chlorinated hydrocarbon, and heavy-metal poisoning may cause toxicity similar to that of amatoxin mycetism. Poisoning by isoniazid and other hydrazines or hydrazones is similar to that caused by the ingestion of mushrooms that contain gyromitrins. Carbamate and organophosphate insecticide poisoning may mimic that caused by ingestion of muscarine-containing mushrooms. Intoxication caused by ibotenic acid and muscimol is similar to the anticholinergic syndrome caused by a number of drugs. Lysergic acid diethylamide and amphetamine and tryptamine analogues cause effects that are similar to those that result from psilocin and psilocybin poisoning.

EMERGENCY DEPARTMENT EVALUATION

All patients with gastroenteritis, hallucinations, or an unexpected reaction to ethanol should be asked if they have ingested wild mushrooms. If such a history is elicited, the number, types, description, and method of preparation of the mushrooms should be noted, and an attempt should be made to obtain a fresh sample of the mushroom. Ideally, the mushroom or its parts should be identified by an experienced mycologist. Experts may be located at botany departments of colleges and universities, botanical gardens, poison centers, and local, state, or regional mycologic societies. If necessary, the suspect mushroom can be dried by hot air, light, or oven (not a microwave) and sent in a paper container to a mycologist. Alternatively, a field guide for mushroom identification can be consulted. Attempting to identify a mushroom from spores obtained from leftovers, vomitus, or stool is seldom fruitful. When mushroom samples are not available, those described as puffballs or as having a white cap, a ring on the stalk, or a sack at the base should be suspected to be one of the deadly *Amanita*, and those described as brainlike should be assumed to be a lethal *Gyromitra*. Any wild mushroom that is not available for positive identification should be assumed to be one that can cause serious or lethal poisoning.

The interval between the time of ingestion and the onset of symptoms, and the nature of symptoms should be determined. The onset of GI symptoms 6 hours or more after ingestion suggests potentially fatal poisoning by a mushroom containing an amatoxin, orellanine, or gyromitrin cytotoxin. ^{8,9 and 10,17} In these patients, laboratory evaluation should include a complete blood count; determination of electrolyte, blood urea nitrogen, creatinine, glucose, and methemoglobin levels; prothrombin time; partial thromboplastin time; liver function tests; and urinalysis. Severe GI symptoms suggest amatoxin poisoning. Thirst, polyuria, and renal abnormalities 3 or more days after ingestion are consistent with orellanine poisoning, and severe headaches, neurologic dysfunction (in the absence of severe dehydration), methemoglobinemia, and hemolysis suggest mycetism caused by gyromitrins. The subsequent development of hepatic and renal failure is consistent with either amatoxin or gyromitrin mushroom intoxication, whereas renal failure alone suggests orellanine poisoning.

The onset of symptoms within 3 hours of mushroom ingestion indicates poisoning by a noncytotoxic mushroom containing muscarine, ibotenic acid–muscimol, psilocin–psilocybin, coprine, or a GI irritant. ^{8,9 and 10,19} It does not, however, rule out poisoning by a cytotoxic species if more than one kind of mushroom has been ingested, nor does it exclude poisoning by *A. smithiana*. Hallucinations with mild or absent GI symptoms indicate ibotenic acid–muscimol or psilocin–psilocybin mushroom poisoning. A fluctuating level of consciousness, central nervous system depression, and either cholinergic or anticholinergic findings suggest the former, whereas signs of sympathetic stimulation occur with the latter. Manifestations of cholinergic hyperactivity imply intoxication by a muscarine-containing mushroom. Flushing, headache, and “beta sympathomimetic” findings after ethanol ingestion suggest an interaction with a mushroom that contains coprine, and symptoms limited to the GI tract suggest ingestion of a mushroom that contains one of the miscellaneous GI irritants.

All patients with prolonged GI symptoms or abnormal supine or orthostatic vital signs should have baseline determinations of electrolyte, blood urea nitrogen, creatinine, and glucose levels and urinalysis. Stool and vomitus should be tested for occult blood. Patients with hypotension, dyspnea, or chest pain should have cardiac rhythm monitoring and an electrocardiogram. Except for muscarine, which can be identified by thin-layer chromatography, mushroom toxins are not detected by routine toxicology screening.

EMERGENCY DEPARTMENT MANAGEMENT

Activated charcoal should be given to all patients, even if spontaneous vomiting and diarrhea are present. Ipecac is not recommended, because it may add to the emetic effects of mushrooms themselves and delay or prevent the administration of charcoal. If a cytotoxic species has been ingested within 6 hours, gastric lavage, preceded and followed by administration of charcoal, may be optimal. Whole-bowel irrigation should also be considered. Repeated dosing of charcoal should be continued for 2 to 4 days or until symptoms resolve. Metoclopramide may facilitate the administration of charcoal in patients with protracted vomiting.

Many patients also need large amounts of intravenous crystalloids to compensate for significant GI fluid losses. Glucose and electrolytes should be included in the replacement solution. A bolus of glucose should be given immediately to patients with altered mental status, particularly those with evidence of liver dysfunction.

Specific therapy primarily depends on the clinical (presumptive) diagnosis of the type of mushroom poisoning, based on the time of onset and nature of symptoms. Positive identification of the species of mushroom ingested is secondary. Patients with delayed symptoms or early symptoms after the ingestion of multiple

unidentified species should be assumed to have ingested a cytotoxic mushroom.

If amatoxin ingestion is possible or confirmed, charcoal hemoperfusion may enhance toxin elimination if performed in the first 24 hours.^{4,17,18} Repeated administration of activated charcoal is recommended, even for late presentation, to interrupt enterohepatic circulation of amatoxins.^{17,20} Forced diuresis is no longer recommended, but maintenance of a normal urine output is essential. Possible antidotal treatments include the use of silibinin or penicillin to reduce the hepatocyte uptake of amatoxins.^{4,6,17,18,20} When high-dose intravenous penicillin is used, the total dose and rate of administration should take into account the potassium content (up to 1.5 mEq per million units) and the risk of penicillin toxicity (e.g., resulting in encephalopathy and seizures), especially if renal impairment is present. A suggested dosing regimen is 1 million units per kilogram per day for the first day, followed by 0.5 million units per kilogram per day for 2 more days. Penicillin should be given in multiple, small, divided doses. Silibinin, an extract of milk thistle, has been used successfully when given within 48 hours of amatoxin ingestion, but it is not available in the United States.⁶ The recommended dosage is 5 mg/kg intravenously over 1 hour, followed by a constant infusion of 20 to 50 mg/kg/d until hepatic recovery. Silimarn, a dietary supplement available in capsules from health food stores, contains silibinin. Oral doses of 1.4 to 4.2 g/d have been suggested as an alternative to intravenous silibinin, but the efficacy of this formulation is unknown.⁶ *Amanita*-induced hepatotoxicity is similar to that caused by toxins that undergo mixed-function oxidase P-450 activation, and cimetidine, an inhibitor of these enzymes, has shown efficacy in experimental animals. Doses of cimetidine of up to 2 g every 4 hours have been used in humans.

Hyperbaric oxygen has been used and should be considered if readily available, but its efficacy is unproved. The use of *N*-acetylcysteine and the iridoid glycosides aucubin and kutkin is also being investigated. Corticosteroids and thioctic acid are no longer recommended.^{17,20} Hepatic and renal failure should be treated by standard measures. Patients with severe liver dysfunction should be tissue-typed and have arrangements made for transfer to a liver transplantation center.²⁰ Liver transplantation should not be performed prematurely (sooner than 1 week), because some patients with significant hepatic failure recover with medical therapy. Patients who develop chronic active hepatitis, a common sequela, may also be candidates for liver transplantation.

Patients with orellanine and orelline exposure may benefit from hemoperfusion if it is performed within 1 week of mushroom ingestion.^{15,16} Hemodialysis should be used supportively. Patients with permanent renal failure may be candidates for kidney transplantation.

Neurologic dysfunction or severe systemic toxicity owing to gyromitrin poisoning should be treated with pyridoxine (vitamin B₆).⁵ A dose of 25 mg/kg should be given intravenously every 15 to 30 minutes (up to four doses) for coma or seizures. A similar dose every 6 hours may be used for recurrent or less severe symptoms. Larger doses have been used, but they are unlikely to be of additional benefit and increase the risk of pyridoxine toxicity. Theoretically, methemoglobinemia could require treatment with methylene blue (see [Chapter 352](#)). Hemolysis usually requires only fluid therapy to prevent renal complications.

Poisoning by other mushroom toxins is treated symptomatically. Agitated behavior and hallucinations may be treated with a benzodiazepine or haloperidol, but phenothiazines should be avoided.¹³ Seizures may be treated with diazepam, a barbiturate, or phenytoin. Coprine-ethanol reactions are treated the same as those caused by disulfiram and ethanol (see [Chapter 334](#)).^{11,17} Severe anticholinergic symptoms may require the use of physostigmine (see [Chapter 312](#)).^{11,17} Patients with excessive secretions, bronchospasm, or bradycardia with hypotension should be given small doses (less than or equal to 0.01 mg/kg) of intravenous atropine.^{5,11,17} Because atropine may increase toxin absorption by slowing its rectal evacuation, however, it should not be given solely for GI symptoms unless they are markedly prolonged or severe.

DISPOSITION

Patients with confirmed or possible cytotoxic mushroom ingestion or those with severe or persistent symptoms from other mushrooms should be admitted to the hospital. Patients with noncytotoxic mushroom ingestions who become asymptomatic after emergency department treatment and observation may be discharged. Those with intentional hallucinogenic mushroom ingestion should be referred for drug abuse counseling.

It is advisable to consult a poison center or toxicologist in all cases of mushroom ingestion. Depending on clinical evaluation and the type of mushroom involved, consultation with or referral to a gastroenterologist, nephrologist, psychiatrist, or transplant surgeon may be necessary. Patients may need to be transferred if intensive or specialized care is necessary but not available.

COMMON PITFALLS

- Failure to appreciate that, contrary to common folklore, there is no easy way to differentiate poisonous mushrooms from edible mushrooms
- Failure to include wild mushroom ingestion in the differential diagnosis of gastroenteritis, altered mental status, and liver or kidney dysfunction of unknown cause
- Assuming that a potentially lethal mushroom has not been ingested along with noncytotoxic species simply because symptoms began soon after ingestion
- Failure to admit patients with possible cytotoxic mushroom ingestion
- Failure to appreciate that therapy is based primarily on clinical symptoms and should not be delayed or withheld because the mushroom itself has not been identified

Neuroleptics, also known as antipsychotic agents and major tranquilizers, are used to treat schizophrenia, the manic phase of bipolar disorders, and agitated behavior. They are also used for nausea, vomiting, sedation, hiccoughs, and tics. The older or classic agents are mainly effective for treating the positive symptoms of schizophrenia (e.g., agitation, hallucinations), whereas the newer or atypical antipsychotic agents are also effective for treating negative and cognitive symptoms (e.g., alogia, avolition, flattened affect, social withdrawal).^{3,12,16} These agents are a structurally diverse group of compounds containing two to five aliphatic, aromatic, or heterocyclic rings (Table 356.1). Formulations include tablets, capsules, liquids, sustained-release preparations, suppositories, and injectable solutions.

Structural Class	Common Name	Trade Name	Child Dose (mg/kg/d)
TRADITIONAL AGENTS			
Butyrophenone	Haloperidol	Haldol	2.5–10.0*
	Pimozide	Orapron	0.5–2.0*
Dibenzazepine	Chlorpromazine	Thorazine	0.5–2.0
	Fluphenazine	Prolixin	0.5–2.0
Phenothiazine	Chlorpromazine	Thorazine	0.5–2.0
	Fluphenazine	Prolixin	0.5–2.0
	Perphenazine	Prolixin-V	4–16
	Propriperazine	Propazine	4–16
	Thioridazine	Mellaril	20–100†
	Trifluoperazine	Stelazine	20–60
	Trifluoromethazine	Trifluoromazine	10–40
	Trifluoroperazine	Trifluoromazine	2–5
	Thioridazine	Mellaril	2–5
	Thioridazine	Mellaril	2–5
ATYPICAL ANTIPSYCHOTICS*	Risperidone	Risperdal	0.5
	Clozapine	Levazine	200–400
	Olanzapine	Lanzapine	10–20
	Ziprasidone	Geodon	16–32

TABLE 356.1. Neuroleptic Agents

Poisoning may be due to adverse reactions following therapeutic doses or may result from accidental or intentional overdose. Poisoning in two infants has been reported after treatment with topical promethazine cream.¹⁸ Side effects include the anticholinergic syndrome (see Chapter 312), dystonic reactions (see Chapter 335) and other extrapyramidal syndromes (e.g., akathisia, parkinsonism, perioral tremor, tardive dyskinesia), the neuroleptic malignant syndrome (NMS; see Chapter 209), hypotension, and sedation.^{3,4} Phenothiazines have also been associated with sleep apnea, sudden infant death syndrome, and sudden death in adults.⁸ Most deaths result from either suicidal overdose by psychotic or depressed adults or the NMS. Clozapine can cause agranulocytosis during therapeutic use.

The mechanism of action of neuroleptic agents is complex and incompletely understood. These drugs block alpha-adrenergic (α_1 and α_2), dopamine (primarily D_2 , but also D_1 and D_4), histamine (H_1), muscarinic (primarily M_1), and serotonergic (primarily 5-HT_{1A}, 5-HT_{2A}, and 5-HT_{1C}) receptors.^{3,12,16} Antipsychotic activity, extrapyramidal effects, and the NMS appear to be due to interference with central nervous system (CNS) (cortical, limbic, basal ganglia) D_2 neurotransmission. Antiemetic activity and the ability to increase prolactin secretion also appear to result from inhibition of dopaminergic receptors (in the chemoreceptor trigger zone of the medulla and in the hypothalamus, respectively). Hypothalamic dysfunction may also be responsible for disordered temperature regulation. The atypical antipsychotic agents have lower and more selective (mesolimbic) D_2 potency and higher M_1 and/or 5-HT_{2A} antagonist activity than the traditional agents. Although higher doses are required for antipsychotic effect, they are less likely to cause acute dystonia and tardive dyskinesia. They also have minimal or no effect on prolactin secretion. Anticholinergic (M_1) potency correlates directly with sedative activity and inversely with the incidence of extrapyramidal reactions. Chlorpromazine, chlorprothixene, and thioridazine have potent sedative effects, whereas fluphenazine, haloperidol, trifluoperazine, and trifluoroperazine are commonly associated with extrapyramidal side effects. Of the atypical agents, only clozapine, olanzapine, and quetiapine have significant M_1 activity. Risperidone can cause extrapyramidal effects. Most antipsychotic agents are much more potent H_1 blockers than diphenhydramine.

Extrapyramidal side effects may occur early (within days) or late (after 3 months) in the course of therapy, particularly in patients treated with high-potency agents. Early effects include dyskinesia, akathisia, and parkinsonism; late effects include tardive dyskinesia, tardive dystonia, and the “rabbit syndrome” (focal perioral tremor).

Hypotension and miosis (common with chlorpromazine) appear to be due to peripheral alpha-adrenergic blockade as well as central effects. Hypotensive effects are primarily orthostatic and systolic in nature and tend to correlate in incidence and severity with sedative potency. Concomitant therapy with beta agonists (e.g., epinephrine) or beta blockers (e.g., propranolol) may result in severe hypotension.

Phenothiazines also have local anesthetic and quinidine-like (class 1a) antidysrhythmic and myocardial depressant effects. They frequently produce electrocardiogram (ECG) changes with therapeutic doses (most commonly with thioridazine and its metabolite mesoridazine).⁵ Sertindole blocks cardiac potassium channels and can delay repolarization.¹⁵ Many antipsychotic agents lower the seizure threshold and can induce epileptiform encephalogram (EEG) discharge patterns.¹⁹ Ventricular dysrhythmias or asphyxia due to seizures, aspiration, or respiratory depression have been postulated as etiologies of sudden death in patients taking therapeutic doses of phenothiazines.

Because neuroleptic agents have a relatively flat dose–response curve, therapeutic doses vary widely (see Table 356.1) and are adjusted on the basis of clinical response and side effects, not by monitoring drug levels. Pharmacologic effects generally last 24 hours or more, allowing once-a-day dosing.

Most antipsychotic agents have an unpredictable pattern of gastrointestinal (GI) absorption, with peak levels 2 to 4 hours after ingestion. Their bioavailability with parenteral administration is two to ten times greater than with oral dosing, due to presystemic (GI and hepatic) metabolism following ingestion. Hence, therapeutic intravenous or intramuscular doses are substantially less than oral ones. After absorption, neuroleptic agents are highly bound to plasma proteins (90% to 99%). Because they are highly lipophilic, volumes of distribution are large (10 to 40 L/kg) and therapeutic drug levels are low (1 to several hundred ng/mL). Neuroleptics tend to accumulate in the brain and easily cross the placenta.

Elimination of these drugs occurs slowly by hepatic metabolism, with serum concentration half-lives averaging 20 to 40 hours. Small amounts (1% to 3%) are excreted unchanged by the kidney. As a rule, hepatic metabolism yields multiple metabolites, some of which are pharmacologically active (e.g., mesoridazine is an active metabolite of thioridazine). Metabolites are eliminated by urinary and, to some extent, by biliary excretion and can be detected in the urine for a month or more after cessation of chronic therapy.³ Concomitant use of agents that inhibit or stimulate hepatic cytochrome oxidases can increase or decrease, respectively, the blood level and effect of these agents.^{3,4}

Toxic effects following overdose result from exaggerated pharmacologic activity. Central effects include CNS and respiratory depression and occasional delirium.²⁰

Central and peripheral anticholinergic effects can occur (see [Chapter 312](#)). Hypothermia may be due both to hypothalamic depression and peripheral vasodilatation. Seizures are rare and occur mainly in patients with underlying epilepsy and in those with loxapine overdoses.¹⁴ Rhabdomyolysis may occur with prolonged convulsions. Cardiovascular effects include hypotension (often with reflex tachycardia), cardiac conduction disturbances, dysrhythmias, and, rarely, pulmonary edema.^{6,11} Conduction delays (prolonged QRS and Q-T intervals) and associated ventricular tachyarrhythmias are most common with thioridazine overdoses.⁵ They can also occur during high-dose intravenous haloperidol therapy.¹⁹

Antipsychotic agents have a high therapeutic index. Of the thousands of overdoses reported each year, only 1% to 2% of patients develop serious toxicity; only about one in 50 overdoses proves fatal. Thioridazine (because of its tricyclic antidepressant-like cardiotoxicity) or mixed overdoses are involved in most successful suicides.

Toxic doses are not well established. In general, acute ingestion of the maximal therapeutic dose results in significant side effects, and ingestion of five to ten times this amount can result in serious toxicity. Death of an infant has been reported after the ingestion of only 350 mg of chlorpromazine. Adult fatalities have been reported with ingestions of 600 mg of olanzapine, 2 g of chlorpromazine and clozapine, 2.5 g of loxapine and mesoridazine, and 1.5 g of thioridazine. Many patients, however, have survived much higher ingestions.

CLINICAL PRESENTATION

Although nausea and vomiting may develop soon after overdose, CNS and cardiovascular effects dominate the clinical picture of acute poisoning.^{1,5,6 and 7,10,13} Findings in mild cases include ataxia, confusion, lethargy, slurred speech, tachycardia, and diastolic or orthostatic hypotension. Anticholinergic signs ([Chapter 312](#)) and hyperreflexia may also be present. ECG changes such as prolonged P-R and Q-T intervals, ST-segment depression, T-wave abnormalities (biphasic, blunting, inversion, notching, widening), and increased U waves may be seen with both therapeutic and excessive doses, particularly with thioridazine and mesoridazine.⁵ A prolonged Q-T interval is also common with sertindole use and overdose.⁴

Signs and symptoms of moderate poisoning include mild coma with respiratory depression and systolic hypotension. Miosis is common, but mydriasis may also be seen. Hypothermia (occasional) and hyperthermia (rare) may be present. Paradoxical agitation, delirium, and tachypnea have been reported. Sialorrhea may be seen following clozapine overdose.

In severe cases, coma, with loss of brainstem and deep tendon reflexes, apnea, hypotension, and cardiac dysrhythmias (especially with thioridazine and mesoridazine), may develop. Bradyarrhythmias include all degrees of atrioventricular block, bundle-branch block, QRS widening, and asystole.^{5,6} Tachyarrhythmias include ventricular premature beats, ventricular tachycardia and fibrillation, and polymorphic ventricular tachycardia in the setting of Q-T interval prolongation (torsades de pointes). Pulmonary edema has been reported.¹¹ Loxapine poisoning is unique in that quinidine-like effects are not seen, but it causes severe, prolonged convulsions, leading to rhabdomyolysis and subsequent renal failure.¹⁴

The onset of poisoning occurs within 1 to 2 hours, with maximal severity usually apparent within 2 to 6 hours of ingestion. The presentation is the same regardless of age and whether the overdose is acute or chronic. Children appear more sensitive than adults to the effects of neuroleptic agents.

Extrapyramidal symptoms are usually related to a change in medication or dosing rather than to acute overdose ([Chapter 335](#)). Akathisia, a subjective sensation of motor restlessness, occurs in about 20% of patients treated with traditional neuroleptics and is sometimes associated with severe parkinsonism (see [Chapter 208](#)). It occurs in up to 50% of those treated with intravenous prochlorperazine for headache, nausea, and vomiting. Women are affected more often than men. Patients complain of feeling restless, jittery, and tense; they cannot sit or stand still, and when standing may shift their weight from foot to foot as if walking in place. Vital signs remain normal. Semipurposeful or purposeless limb movements (especially of the lower extremities), frequent shifting of body position, and tremors and myoclonic jerking may be noted.

The NMS ([Chapter 209](#)) usually occurs on initiation or increased intensity of neuroleptic therapy. A similar presentation has been reported following acute overdose.²

DIFFERENTIAL DIAGNOSIS

Poisoning by antidysrhythmic, anticholinergic, antiepileptic, narcotic, and sedative-hypnotic agents and the veterinary tranquilizer xylazine may cause similar CNS or cardiovascular effects. It may be impossible to distinguish tricyclic antidepressant from thioridazine or mesoridazine poisoning without laboratory assistance. CNS infection, infarction, and trauma should also be considered in the differential diagnosis. Akathisia is commonly misdiagnosed as anxiety or agitation related to an underlying psychiatric disorder.

EMERGENCY DEPARTMENT EVALUATION

A complete history should be obtained from the patient and, to corroborate the patient's history, from the person who either found or brought the patient to the emergency department. The name, quantity, and time of ingestion should be determined. In patients taking chronic neuroleptic medication, the physician should determine whether there was a recent medication or dosage change or a recent illness.

The physical examination should focus on the vital signs, cardiovascular system, neurologic function, and evidence of coexisting trauma. An initial rhythm strip and subsequent 12-lead ECG should be evaluated. Arterial blood gas analysis and a chest x-ray should be ordered in patients with severe poisoning. Because phenothiazines can be radiopaque, abdominal radiographs may be useful if the identity of the overdose agent is unknown. However, the lack of x-ray visualization does not rule out an ingestion and does not necessarily imply successful gastric decontamination. Routine laboratory evaluation should include a complete blood count and measurements of electrolytes, blood urea nitrogen, creatinine, and glucose to rule out concomitant abnormalities. In patients with seizures or hyperthermia, the laboratory evaluation should also include urinalysis (routine and for myoglobin); measurement of serum muscle enzymes (creatine phosphokinase, aldolase, alkaline phosphatase), calcium, magnesium, and phosphate; and a coagulation profile. Toxicologic analysis of the urine and serum by chromatography or immunoassay may be useful to confirm the identity of the agent and rule out other ingestants. Quantitative drug levels are not helpful in predicting clinical toxicity or in guiding treatment. Although neither sensitive nor specific, the Forest, Mason, and Phenistix colorimetric tests are rapid urine screens that may be positive with phenothiazine ingestions.

EMERGENCY DEPARTMENT MANAGEMENT

Supportive care is the priority for patients with neuroleptic overdose. The tempo and sequence of interventions depend on clinical severity. Advanced life-support measures should be instituted as necessary. All patients require cardiac and respiratory monitoring and intravenous access. Those with hyper- or hypothermia should have continuous (rectal or axillary probe) temperature monitoring. Patients with altered mental status or seizures should receive supplemental oxygen and empiric therapy with naloxone, dextrose, and thiamine.

Hypotension is initially treated with intravenous crystalloids. Norepinephrine and high-dose dopamine are the drugs of choice for refractory hypotension. Seizures are treated with incremental doses of lorazepam (initial dose 0.05 mg/kg intravenously) or diazepam (initial dose 0.1 mg/kg intravenously), followed by a loading dose of phenytoin (18 mg/kg intravenously; maximal rate, 50 mg/min) and then a barbiturate (e.g., amobarbital 10 to 15 mg/kg intravenously, maximal rate 100 mg/min; or phenobarbital 20 mg/kg intravenously, maximal rate 30 mg/min), if necessary. Refractory convulsions may require a paralyzing agent to prevent complications such as hyperthermia and rhabdomyolysis. Because succinylcholine itself may cause malignant hyperthermia, a nondepolarizing neuromuscular blocker such as pancuronium (0.06 to 0.1 mg/kg intravenously) or vecuronium (0.08 to 0.1 mg/kg intravenously) should be used. Treatment of seizures, as indicated by continuous or serial EEG monitoring, should be continued during the period of paralysis. Diuresis and alkalization of the urine may prevent myoglobinuric renal failure in patients with rhabdomyolysis. Physostigmine can be given to control delirium in those with other anticholinergic findings who have normal cardiac conduction intervals (see [Chapter 312](#)).¹⁷

Stable ventricular tachyarrhythmias should be treated with lidocaine. Underlying metabolic abnormalities should be corrected. Sodium bicarbonate (1 mEq/kg intravenously) may be given if the QRS complex is wide (see [Chapter 311](#) and [Chapter 313](#)). Type Ia (disopyramide, quinidine, procainamide) and II (beta blockers) antidysrhythmic drugs should be avoided. Unstable rhythms should be treated with electrical cardioversion. Torsades de pointes ventricular tachycardia may respond

to magnesium (50 to 100 mg/kg intravenously over 1 hour) or overdrive pacing using isoproterenol or electricity.⁹ Increasing the heart rate may shorten a prolonged Q-T interval, and thus facilitate conversion of this dysrhythmia. Hypotension may complicate isoproterenol therapy. Bradyarrhythmias are treated according to current Advanced Cardiac Life Support (ACLS) protocols. Complete heart block may require temporary cardiac pacing.

After stabilization, treatment should focus on GI decontamination in cases of acute oral overdose. Activated charcoal and gastric lavage are preferred. Because of the risk of aspiration in patients who may develop CNS depression, seizures, and dystonic reactions, syrup of ipecac should be reserved for asymptomatic patients who can be treated within 30 minutes of ingestion. Drug-induced decreased GI motility may allow for effective decontamination many hours after the overdose. Measures to enhance the elimination of neuroleptic agents, such as diuresis, dialysis, and hemoperfusion, have not been shown to be effective. Repeated oral doses of activated charcoal are of potential but unproven benefit.

Recovery from acute poisoning can be expected within several hours to several days, depending on the severity. Mortality, due to early dysrhythmias or to late cerebral edema, pulmonary edema, disseminated intravascular coagulation, renal failure, or infectious complications, is estimated at 5% to 10%.

Patients who develop akathisia after a single therapeutic dose of a neuroleptic (e.g., prochlorperazine for migraine or vomiting) should be reassured that symptoms will resolve within 24 hours. Diphenhydramine or lorazepam can be given if necessary. Pretreatment with diphenhydramine may prevent this complication. Those with akathisia who require continued neuroleptic therapy can be managed by reducing the dose, switching to an agent of lower potency, or giving additional agents. Benzodiazepines, benzotropine, clonidine, propranolol, and short-acting barbiturates have been used with moderate success.

DISPOSITION

Role of the Consultant

Physicians unfamiliar with the details of the evaluation and management of neuroleptic poisoning should consult a poison center or toxicologist for advice.

Indications for Admission

Asymptomatic patients with an acute overdose should be observed for 6 hours. Symptomatic patients should be observed until alert. Those with hypotension, significant CNS depression, seizures, or dysrhythmias should be admitted to an intensive care unit or a similarly equipped observation area. Alert patients with a history of overdose and quinidine-like ECG findings present a difficult disposition problem, because such ECG changes can be seen with therapeutic doses, yet they have been implicated in sudden death. It seems safest to admit these patients for 24 hours of cardiac monitoring.

Extrapyramidal symptoms, although worrisome to the patient, are not life-threatening. The patient's medications may need to be adjusted; this should be done in consultation with the patient's psychiatrist.

Transfer Considerations

Patients requiring transfer to a facility capable of providing intensive care should be accompanied by advanced life-support personnel and should have cardiac monitoring en route. Because treatment may require the use of agents not included in standard ACLS protocols, if possible, a physician should accompany the patient. Air as well as ground transportation is appropriate for this type of transfer.

COMMON PITFALLS

- Failing to obtain an accurate temperature
- Failing to institute cardiac monitoring and obtain an ECG, especially in patients with thioridazine, mesoridazine, and sertindole overdose
- Failing to appreciate that loxapine can cause intractable seizures, leading to rhabdomyolysis in the absence of cardiotoxicity
- Indiscriminate use of syrup of ipecac in patients with acute neuroleptic overdose
- Failing to institute aggressive treatment of hyperthermia, seizures, and muscle hyperactivity
- Failing to consider magnesium, isoproterenol, and overdrive pacing in the treatment of the torsades de pointes variety of ventricular tachycardia

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of Ross S. Carol who wrote the previous version of this chapter.

NICOTINE

Nicotine, the primary alkaloid of tobacco, is a naturally occurring pesticide obtained from *Nicotiana tabacum*, *Nicotiana rustica*, and other plants. It is also used in gum, nasal inhalers, and transdermal patches to aid in the cessation of smoking. Nicotine binds to nicotinic cholinergic (acetylcholine) receptors in the sympathetic and parasympathetic ganglion cells, neuromuscular junction, adrenal medulla, and the central nervous system (CNS).¹⁷ An initial transitory stimulation of nicotinic receptors is followed by a more persistent depression and paralysis as a result of desensitization. Clinical symptoms may reflect receptor stimulation, depression, or both.

Absorption occurs through intact skin, the gastrointestinal tract, and the respiratory tree. Nicotine has a pK_a of 8.5 and is not well absorbed in the acid milieu of the stomach; alkalinization markedly increases absorption.⁷ The apparent volume of distribution is approximately 1 L/kg. Protein binding is 20%. Once absorbed, 80% to 90% of the chemical is detoxified into cotinine in the liver and 20% is excreted unchanged by the kidneys. The elimination half-life in smokers is 0.8 hours and in nonsmokers, 1.3 hours. Elimination is complete in about 16 hours.

Tobacco leaves contain 1% to 6% nicotine; a cigarette contains 15 to 20 mg of nicotine, with one-fourth remaining in the butt; snuff contains 4.6 to 15.0 mg of nicotine per gram of moist material; chewing tobacco contains 2.5 mg of nicotine per gram of dry material; a cigar contains 15 to 20 mg of nicotine. Nicotine gum (e.g., Nicorette) contains 2 mg of nicotine buffered to a pH of 8.5 to enhance absorption. Transdermal nicotine patches (Habitrol, Nicoderm, Nicotrol, Prostep) release 7 to 21 mg of nicotine per day. However, the total nicotine content may range from 8.3 mg to 114.0 mg per patch.

Poisoning from nicotine can occur from any of the following: exposure to nicotine sulfate insecticides ([Table 357.1](#)); percutaneous absorption of nicotine in tobacco harvesters who pick and brush up against wet tobacco leaves⁵; ingestion of tobacco products, such as cigarettes, snuff, chewing tobacco, and cigars; chewing or ingestion of nicotine chewing gum; and improper use or ingestion of nicotine patches.²⁰ Infants and young children are most susceptible to nicotine poisoning because of their small body size and the lack of tolerance to nicotine. Nicotine-related fatalities are rare because of its decreasing usage as a pesticide.

TABLE 357.1. Common Nicotine Insecticide Preparations

The toxic dose of nicotine varies. As little as 4 mg can cause symptoms; 40 to 60 mg is potentially fatal in an adult. In a small child, 1 mg of nicotine may cause symptoms.⁹ Ingestion of one cigarette, three cigarette butts, one cigar butt, or any amount of nicotine chewing gum or patch should be considered potentially toxic in a child.

CLINICAL PRESENTATION

Onset of toxicity is rapid and can be seen within 15 minutes of exposure. Initial signs and symptoms include nausea, vomiting, salivation, bronchorrhea, abdominal pain, and diarrhea from parasympathetic stimulation and tachycardia; hypertension; and diaphoresis as result of sympathetic and adrenal stimulation. Early CNS effects include dizziness, headache, confusion, agitation, incoordination, and seizures. Muscular fasciculations may result from neuromuscular junction stimulation.

As the symptoms progress, hypotonia, muscle paralysis, respiratory failure, coma, bradycardia, and hypotension may ensue.¹⁻¹² Because of both stimulatory and inhibitory effects on multiple systems, the signs and symptoms vary by the time, dose, and route of exposure. In severe cases, such as nicotine pesticide poisoning, the progression from stimulation to inhibition of the various systems may be rapid.⁹

In mild exposures, the symptoms can last for several hours. In severe cases, clinical toxicity can endure for 18 to 24 hours or more. Severe cases involve seizures and coma within 30 minutes, with respiratory arrest and death within 1 hour or less, especially with concentrated nicotine products. Patients who survive the first 4 hours usually recover fully.

Radiographic and electrocardiographic (ECG) findings are nonspecific. Nicotine can be detected in the urine by chromatographic drug assays. Leukocytosis and

glycosuria may be noted.

DIFFERENTIAL DIAGNOSIS

Without a history of exposure, there are no pathognomonic signs of nicotine poisoning. It could be confused with acetylcholinesterase inhibitor poisoning, such as organophosphate or carbamate insecticides, and carbamate drugs (edrophonium, physostigmine, and pilocarpine). In nicotine poisoning, however, there is no depression of the red blood cell cholinesterase.

Direct-acting cholinomimetic agents such as bethanechol, carbachol, and methacholine can also produce cholinergic effects similar to those of nicotine. However, because these agents have minimal effects on nicotinic receptors (except for carbachol), they produce minimal or no sympathetic or muscular symptoms.¹⁷ Central and peripheral sympatholytics (alpha-adrenergic and beta-adrenergic receptor blockers, clonidine, guanabenz, topical decongestant imidazoline derivatives, and calcium blockers) can mimic the later stages of nicotine poisoning. These agents will not produce any muscarinic symptoms or neuromuscular weakness. Tree tobacco (*Nicotiana glauca*) contains the alkaloid anabasine, an isomer of nicotine that can cause similar symptoms.¹¹ Other substances to consider are the insect repellent diethyltoluamide; *Veratrum* and sabadilla plants; *Clitocybe* and *Inocybe* mushroom species; and poison hemlock (*Conium maculatum*).

EMERGENCY DEPARTMENT EVALUATION

The history should document the time, agent, dose, route, intent, and duration of exposure and the nature and course of symptoms. A complete physical examination should be performed, with particular attention to assessing cardiovascular, respiratory, and neurologic function. Patients with vital sign abnormalities should have an ECG. Symptomatic patients should have cardiac and oxygen saturation monitoring. No specific laboratory tests are diagnostic. The presence of nicotine in the urine of a nonsmoker is supportive. Plasma nicotine levels are not useful. Arterial blood gas analysis, blood chemistries, and hematologic analysis should be obtained based on clinical severity.

EMERGENCY DEPARTMENT MANAGEMENT

Activated charcoal is the preferred method of gastrointestinal decontamination. Except for recent ingestion (less than an hour) of large quantities of a nicotine pesticide, gastric aspiration or lavage would not likely provide additional benefit. Because emesis is usually rapid and spontaneous, ipecac is not advised. In addition, seizures and coma can occur rapidly, and emesis increases the risk of aspiration. If present, the transdermal patch should be removed. Exposed skin areas should be washed with soap and water. Exposed eyes should be irrigated with copious amounts of water for 15 minutes.

The patient should be closely monitored for the first few hours after exposure. Supportive care should be instituted as necessary. Seizures should be treated with intravenous benzodiazepines such as diazepam (for adults, 5 to 10 mg initially, repeated every 5 to 10 minutes as necessary, up to 30 mg; for children, 0.25 to 0.4 mg/kg per dose) or lorazepam (0.05 to 0.1 mg/kg; may be repeated twice every 15 minutes as necessary). If seizures cannot be controlled with diazepam or lorazepam, a barbiturate such as phenobarbital may be given.

Excess parasympathetic stimulation (e.g., marked bronchial secretions) can be controlled by atropine (for adults, 0.5 mg intravenously, repeated every 5 minutes as necessary, to a maximum of 2 mg). For children, the dose is 0.01 to 0.02 mg/kg intravenously, not to exceed 0.4 mg. Hypotension should be treated initially with administration of intravenous fluids; if it fails, dopamine or norepinephrine may be added. Artificial ventilation and oxygen therapy may be necessary. Mecamylamine (Inversine) is a specific nicotine antagonist; it is available only in tablets, however, and is not a practical form of therapy in a patient who is vomiting, convulsing, or hypotensive. Multiple-dose charcoal has not been evaluated, nor have hemodialysis and hemoperfusion.

DISPOSITION

Patients with mild symptoms can be observed for several hours and discharged once they become asymptomatic. All others should be admitted to the hospital, observed, and treated supportively. Because the cardiorespiratory system requires monitoring, intensive care unit (ICU) admission is advised. If such facilities are unavailable, the patient should be transferred. Advanced life-support measures and anticonvulsants should be available during transport. If necessary, consultation can be obtained by calling a regional poison control center or the National Pesticide Telecommunications Network (800-858-7378).

COMMON PITFALLS

- Failure to discover a nicotine patch unintentionally stuck to the skin of an infant or toddler with altered mental status because they were not completely undressed
- Inducing emesis with syrup of ipecac
- Being unprepared to manage seizure activity
- Failure to diagnose and treat respiratory failure, the primary cause of death in nicotine poisoning
- Failure to appreciate that administering antacids for gastrointestinal symptoms may increase the absorption of ingested nicotine

PYRETHRINS

Pyrethrins and pyrethroids are widely used as bug sprays because of their rapid incapacitating (“knock-down”) effects on insects. Most are formulated in petroleum distillates for spray applications; many are marketed in pressurized cases. Synergists such as piperonyl butoxide, *N*-octyl-bicycloheptene dicarbonimide, and sesame oil derivatives are commonly added to inhibit the metabolism of pyrethrins and thus increase their efficiency. Pyrethrins and pyrethroids are also used for the treatment of head lice and scabies and as insect repellents ([Table 357.2](#)).

TABLE 357.2. Common Pyrethrin/Pyrethroid Preparations

Pyrethrins are naturally occurring insecticides extracted from chrysanthemum flowers; they are esters of pyrethric and chrysanthemic acid.¹⁵ Pyrethroids (e.g., permethrin, deltamethrin) are synthetic pyrethrins that are more stable (resist photolysis) in the natural environment and have greater insecticide potency than do pyrethrins. They can be separated into two classes based on their chemical structures: Type II agents contain a cyano group at the alpha carbon, and type I agents do not.⁴

In insects, pyrethrins and pyrethroids rapidly cause death by paralyzing the nervous system. They inactivate sodium channels in nerve axons by binding and prolonging the opened state. Other potential mechanisms of toxicity include the inhibition of adenosine triphosphatases and direct effects on membrane integrity.

Type II pyrethroids also antagonize inhibitory chloride channels at the GABA binding site.⁴ In general, type I agents are less toxic than the type II agents.

These compounds are rapidly degraded and leave almost no residuum in the environment. They are considered less toxic to mammals than any other major class of insecticides. Human toxicity is limited by factors such as a large first-pass effect by the liver, poor bioavailability, and rapid metabolic breakdown by ester hydrolysis, followed by hepatic oxidation.¹³ Ingestion of amounts up to 5 mg/kg is unlikely to cause significant toxicity. The toxic oral dose is estimated to be more than 100 to 1,000 mg/kg, with a lethal dose estimated to be 10 to 100 g.² Synergists also have low human toxicity.⁶

CLINICAL PRESENTATION

Direct toxicity is uncommon. Adverse effects are usually due to hypersensitivity and include bronchospasm, vasomotor rhinitis, contact dermatitis, and, rarely, anaphylaxis.¹⁹ Following inhalation, the most common presentation is a stuffy nose with clear discharge and a “scratchy” throat. In rare cases, sudden bronchospasm, swelling of the laryngeal mucosa, and shock (anaphylaxis) can occur. Patients allergic to ragweed have a higher risk of developing allergic reactions to pyrethrins. Synthetic pyrethroid is less likely to cause these reactions than natural pyrethrins.

Direct dermal exposure to pyrethrins can produce a contact dermatitis consisting of redness, blisters, burning, stinging, and numbness. Ocular exposure to hydrocarbon propellants can cause eye irritation and corneal abrasions. Massive exposure to type II pyrethroids can cause tremors, salivation, paresthesia, ataxia, choreoathetosis, and seizures. Similar exposure to type I agents can result in tremors, agitation, and hyperthermia.⁴

DIFFERENTIAL DIAGNOSIS

Pyrethrins and pyrethroids should be included in the differential diagnosis of patients who present with an apparent hypersensitivity reaction of the skin or respiratory system when exposed to flora, insecticides, or insect bites. Because almost all of the insecticides containing these compounds are in a hydrocarbon base, the risk of hydrocarbon pneumonitis must be considered in humans ingesting these products.

EMERGENCY DEPARTMENT EVALUATION

The history should include details of exposure as described for nicotine, and the physical examination should focus on the respiratory tract, neurologic status, and skin. Chest radiographs, oxygen saturation measurement or arterial blood gas analysis, and pulmonary function tests can help to assess respiratory function and possible aspiration in patients with wheezing, dyspnea, cough, and fever.

EMERGENCY DEPARTMENT MANAGEMENT

Gastrointestinal, skin, and eye decontamination should be performed. Pyrethrins and pyrethroids are lipophilic, so milk, cream, or substances that contain animal or vegetable fats should not be administered. Supportive care should be instituted as necessary. Anaphylaxis should be treated as described in [Chapter 217](#). Hydrocarbon aspiration should be treated supportively (see [Chapter 316](#)). If seizures occur, diazepam or lorazepam should be administered. Refractory seizures may be treated with phenobarbital or other barbiturates. Atropine may be required for the control of secretions from type II agents. Contact dermatitis should be treated with topical corticosteroids.

DISPOSITION

Assistance in management can be provided by the sources described in the Nicotine section. Asymptomatic patients with oral ingestions should be observed for 6 hours; if they become symptomatic, admission to an ICU is advised. Patients with allergic reactions can usually be discharged after treatment. Depending on severity, those with persistent symptoms may require admission to a floor or ICU.

COMMON PITFALLS

- Failure to appreciate that most cases of pyrethrin poisoning are allergic reactions and not direct toxicity
- Failure to recognize and treat anaphylactic reactions
- Failure to consider the possibility of aspiration (hydrocarbon) pneumonitis in patients with respiratory symptoms

CHLORINATED HYDROCARBONS

Chlorinated hydrocarbon (organochlorine) insecticides are low-molecular-weight, fat-soluble aliphatic, aromatic, and complex hydrocarbons that contain chlorine ([Table 357.3](#)).^{6,14,16} The Environmental Protection Agency has banned the use of many of these pesticides in the United States because they are stored indefinitely in human tissue.¹⁶ Chlordane and toxaphene are still available, but their use is restricted. Other available agents include methoxychlor, dicofol, and the miticide and scabicide lindane (gamma benzene hexachloride).

Insecticide	Brand/Trade Name
Aldrin	Aldrex, Aldrite, Drinox
Chlorobenzilate	Acaraben, Folbex, Kop-Mite
Chlordane	1066, Belt, Chlor Kill, Niran
Chlordecone	Depone, Tai Ant Trap
DDT	Ancofex, Dinocide, Penned
Dieldrin	Albit, Dorytox, Octalox
Endrin	Agrine, Endrex, Hexadrin
Heptachlor	Velaicol, 53-CS-17
Lindane	Agrocide, Isotox, Kwell
Methoxychlor	DMDT, Marlite, Moxie
Mirex	Dechlorane, Ferriamide
Toxaphene	Alltox, Camphochlor, Motox

TABLE 357.3. Chlorinated Hydrocarbon Insecticides

Organochlorines can be absorbed from the skin, lungs, and gastrointestinal tract. Enteral absorption is efficient and increased in the presence of animal or vegetable fat. To a lesser extent, they are absorbed across pulmonary membranes, but only 10% or less of a dermally applied dose (e.g., lindane) is absorbed. Different compounds exhibit different tissue-storage and hepatic elimination rates. Many (e.g., chlordane, dieldrin, and heptachlor) can induce hepatic enzymes.

As the body stores decrease, their half-lives markedly increase, due to either altered lipoprotein binding or lessened chemical concentration gradient across body compartments. It may require months to years to eliminate mirex, kepone, DDT, and the beta isomer of benzene hydrochloride; weeks to months for aldrin, dieldrin, heptachlor, and hexachlorobenzene; and hours to several days for endrin, chlordane, toxaphene, endosulfan, methoxychlor, and chlorobenzilate. Most residents of the United States have detectable organochlorine residues in their bodies, especially in fat. These compounds are excreted in the feces and can be found in breast milk.

Toxicity is due primarily to interference with the axonal transmission of nerve impulses. Organochlorines interfere with the normal flow of sodium and potassium ions across the axon membrane as nerve impulses pass.¹⁶ Unlike organophosphate insecticides, they do not depress cholinesterase enzymes.

The acute toxic potential of organochlorines varies with the different compounds and their rates and routes of absorption. The highest risk occurs from endrin, dieldrin,

aldrin, chlordane, and toxaphene.¹⁴ Intermediate-risk products include kepone, endosulfan, heptachlor, mirex, and DDT. The lowest risk products are methoxychlor, perthan, kelthane, chlorobenzilate, and hexachlorobenzene. Lindane is potentially toxic if applications to the skin are multiple.¹⁰ Dermal and inhalational exposures most commonly occur in workers who spray organochlorine insecticides. Oral exposure may result from the ingestion of contaminated food or drinking water.³ The estimated oral lethal dose in adults is 3 to 7 g for aldrin, 6 g for chlordane (less than 2 g can cause stupor and seizures), 1 to 5 g for dieldrin, and 10 to 30 g for lindane (as little as 1.6 g can cause seizures in children).¹⁴

CLINICAL PRESENTATION

The onset of symptoms following exposure may vary from minutes to hours, depending on the route and method of exposure and the physicochemical properties of the agent.³ Nausea, vomiting, and diarrhea can occur as soon as 45 minutes after acute ingestion. Initial CNS effects include apprehension, headache, dizziness, tremors, ataxia, and disorientation. Stupor, coma, and seizures with respiratory depression may be seen in severe cases. Arrhythmias may result from increased myocardial sensitivity to catecholamines. Aspiration of formulations containing a petroleum distillate can result in a chemical pneumonitis. CNS toxicity, including seizures, can also occur in children following prolonged or excessive topical lindane exposures during the treatment of lice or scabies.¹⁰ In severe cases, potential complications include lactic acidosis, rhabdomyolysis, and disseminated intravascular coagulation.

Chronic exposure to organochlorines can cause hepatomegaly. Extensive or prolonged dermal contact can result in skin irritation. Chronic ingestion of hexachlorobenzene has been associated with cutaneous porphyria. Cases of leukemia have been associated with the use of chlordane or heptachlor to control termites in homes.

DIFFERENTIAL DIAGNOSIS

Acute organochlorine insecticide poisoning must be distinguished from any condition that produces "gastroenteritis" with an altered mental status, especially ataxia, tremors, and seizures. CNS disease, drug withdrawal, stimulant intoxication (e.g., from sympathomimetics, xanthines, anticholinergics, hallucinogens, and isoniazid), and infectious etiologies should be considered.

EMERGENCY DEPARTMENT EVALUATION

Details of exposure should be elicited as described for nicotine. The physical examination should focus on the neurologic and cardiovascular systems. Symptomatic patients should have chest radiography, ECG, arterial blood gas analysis, and routine blood tests. Chlorinated hydrocarbons can be measured in the serum by using gas chromatography, but levels are not useful for clinical management.⁸

EMERGENCY DEPARTMENT MANAGEMENT

Activated charcoal is the preferred method of gastrointestinal decontamination. Because organochlorine compounds have an extensive enterohepatic recirculation, repeat doses of activated charcoal are recommended to enhance their elimination. Multiple doses of cholestyramine resin are also effective, but cholestyramine is less well tolerated than charcoal. Powder contaminating the skin should first be vacuumed off. Contaminated clothing should be removed, and the skin, hair, and nails scrubbed. Extracorporeal procedures are not effective in enhancing organochlorine elimination.

Supportive care, including oxygen, endotracheal intubation, and assisted ventilation, should be instituted as necessary. Benzodiazepines and barbiturates should be given for seizure control (see [Nicotine](#) section). Phenytoin may be less effective than barbiturates and may actually increase the incidence of seizures.¹⁸ Intravenous fluids and cardiac monitoring are indicated for all but mild intoxications. Respiratory distress due to bronchospasm is managed with inhaled bronchodilators and humidified oxygen. Parenteral administration of adrenergic amines (e.g., epinephrine) is not recommended, because myocardial irritability may be enhanced.

DISPOSITION

Assistance may be obtained by consulting the sources noted in the Nicotine section. All patients who are symptomatic after an acute exposure should be admitted for observation and treatment. Patients with significant CNS depression or seizures should be admitted to an ICU. If such facilities are not available, the patient should be transferred. Advanced life-support measures should be available during transport. Patients remaining asymptomatic after a 6-hour period of observation following an acute exposure may be discharged with appropriate follow-up. Those with chronic exposures can generally be treated as outpatients.

COMMON PITFALLS

- Mistaking organochlorine insecticides for organophosphate insecticides (and vice versa), resulting in incorrect treatment
- Failure to consider the possibility of pulmonary aspiration after ingestion
- Failure to administer multiple doses of activated charcoal for oral exposures
- Failure to properly decontaminate patients with dermal exposures
- Inducing emesis with syrup of ipecac
- Being unprepared to manage seizure activity

CHAPTER 358

Nonsteroidal Antiinflammatory Agent Poisoning

Marco L. A. Sivilotti

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Nonsteroidal antiinflammatory drugs (NSAIDs) are a heterogeneous group of agents that have antiinflammatory, analgesic, and antipyretic activity. Excluding salicylates (discussed in [Chap. 367](#)), there are a variety of NSAIDs, which can be classified by target specificity and structure ([Table 358.1](#)). With widespread use and over-the-counter availability of some NSAIDs, it is not surprising that NSAIDs constitute one of the most common medications encountered in intentional overdose.

Drug	Brand Name	Dose (mg/kg)	Half-life (hr)	Renal Clearance (mL/min)	Protein Binding (%)
Nonselective COX Inhibitors					
Ibuprofen	Ibuprofen	4-6	1.8-2.6	~0	~99
Naproxen	Naproxen	2.5-5	13-17	~0	~99
Indomethacin	Indomethacin	0.25-0.5	1.5-2	~0	~99
Etodolac	Eto-Dolac	0.5-1	6-8	~0	~99
Phenylbutazone	Phenylbutazone	0.5-1	1.5-2	~0	~99
Miloxicam	Miloxicam	0.5-1	1.5-2	~0	~99
Piroxicam	Piroxicam	0.5-1	1.5-2	~0	~99
Sulindac	Sulindac	0.5-1	1.5-2	~0	~99
Flurbiprofen	Flurbiprofen	0.5-1	1.5-2	~0	~99
Acetylsalicylic acid	Aspirin	5-10	~0.1	~100	~90
Selective COX-2 Inhibitors					
Celecoxib	Celecoxib	0.5-1	~11	~0	~99

TABLE 358.1. Pharmacokinetics of NSAIDs after Therapeutic Doses

Three-fourths of these ingestions involve ibuprofen, the first nonsalicylate NSAID to be approved for over-the-counter use in the United States. Despite this frequency, most NSAID overdose patients develop minimal symptoms, and death is rare. In contrast, major sequelae due to side effects of therapeutic use of (e.g., gastrointestinal [GI] bleeding) are a much greater health concern.

The primary pharmacologic effects of NSAIDs result from the inhibition of cyclooxygenase (COX), the enzyme involved in the initial step of prostaglandin (PG) synthesis. Two isoforms of COX have been identified: COX-1, constitutionally present in platelets, endothelium, gastric mucosa, and the kidney; and COX-2, induced by inflammatory mediators and suppressed by glucocorticoids. Because the antiinflammatory properties of NSAIDs appear to result from COX-2 inhibition, NSAIDs with selective COX-2 inhibition have recently been developed, with the promise of reduced side effects (see [Table 358.1](#)).⁸ The significance and conservation of COX-2 selectivity in overdose are unknown.

Inhibition of COX may result in increased shunting of arachidonic acid to leukotrienes, at times precipitating severe allergic reactions. Inhibition of PGD₂, PGE₂ and PGF_{2α}, which maintain the gastric mucosal barrier, local irritant effects, and inhibition of platelet thromboxane A₂ production, and hence platelet aggregation, are responsible for adverse GI effects such as gastritis and ulceration. Similarly, inhibition of PGI₂ and PGE₂, which have vasodilatory and natriuretic activity in the kidney, has been linked to the salt and water retention and acute renal failure that can occur with NSAID ingestion.⁵

NSAIDs are rapidly and almost completely absorbed.^{3,17} They are weak acids with pK_as ranging from 3.5 to 5.6, have small volumes of distribution (0.08 to 0.4 L/kg; celecoxib, at 6 L/kg, is an exception), and are highly protein bound (more than 90%).^{3,17} Metabolic acidosis after ibuprofen overdose is probably related to high levels of acidic drug and metabolites.^{9,10} Elimination depends on hepatic metabolism primarily via the CYP2C subfamily of cytochrome P-450 enzymes, with subsequent renal excretion of metabolites conjugated with glucuronide. As much as 50% of ketorolac and 30% of indomethacin are excreted in the urine unchanged.³ Only small quantities (less than 10%) of other NSAIDs are excreted unchanged in the urine, limiting the utility of urinary alkalinization in promoting elimination. Indomethacin, sulindac, etodolac, phenylbutazone, miloxicam, and piroxicam undergo enterohepatic recirculation.¹⁷ The renal clearance of naproxen and oxaprozin is increased at high plasma concentrations as a result of saturable protein binding.¹⁷ Only phenylbutazone exhibits dose-dependent (Michaelis-Menten) elimination.¹⁷ Pharmacokinetic data are summarized in [Table 358.1](#).

Except for pyrazolones and fenamic acids, NSAIDs seldom cause serious toxicity, even in large doses.^{4,16} There is inadequate information to determine the minimum toxic or lethal dose for most NSAIDs. In a series of ibuprofen overdoses, all children who ingested less than 100 mg/kg remained asymptomatic, whereas those who ingested more than 400 mg/kg were at risk of developing significant toxicity.⁷ In adults, the correlation between the amount ingested and subsequent development of symptoms was poor, with those ingesting between 6 and 54 g of ibuprofen at risk for potentially serious toxicity. In contrast, seizures have been reported with mefenamic acid ingestions of as little as 2.5 g in a 12-year-old child.⁴ Phenylbutazone has caused death with as little as 2 g in a 1-year-old child and 2.5 g in an alcoholic adult.^{4,15}

CLINICAL PRESENTATION

Most patients remain asymptomatic or develop only mild GI or neurologic symptoms following acute overdose. Specific signs and symptoms are summarized in [Table 358.2](#). Death is rare and usually results from secondary complications such as aspiration or sepsis. In the absence of acute renal failure or secondary complications, full recovery can be expected within 6 to 24 hours. The elderly have an increased propensity to develop adverse effects with therapeutic doses and may be at increased risk of toxicity with overdoses because of preexisting disease. There is very little known about the new selective COX-2 inhibitors in overdose.

Gastrointestinal: nausea, vomiting, anorexia, abdominal pain, diarrhea, gastritis, gastrointestinal bleeding, occasional hepatocellular injury, rare cholestasis
Neurologic: dizziness, nystagmus, diplopia, blurred vision, headache, tinnitus, restlessness, lethargy, ataxia, confusion, coma, muscle fasciculations, seizures
Respiratory: hyperventilation, respiratory depression with cyanosis, apnea, diaphoresis
Cardiovascular: hypotension, bradycardia, occasional tachycardia, rare cardiac arrest
Renal: sodium retention and edema, proteinuria, hematuria, acute oliguric or nonoliguric renal failure
Hematologic: decreased platelet aggregation, prolongation of prothrombin time and partial thromboplastin time
Other: occasional metabolic acidosis, rare electrolyte imbalance

TABLE 358.2. Signs and Symptoms of NSAID Overdose

In contrast, the pyrazolones and fenamates can cause severe toxicity. Phenylbutazone and its active metabolite oxyphenbutazone can cause coma, seizures, arrhythmias, cardiogenic shock, respiratory alkalosis, and metabolic acidosis.^{4,16} Tinnitus, deafness, and a rash may be present. Hepatic necrosis, without other symptoms, may develop 24 hours after overdosage. A red discoloration of the urine caused by the metabolite rubazonic acid may be observed. Mefenamic acid has a propensity to cause muscle twitching and tonic-clonic seizures. In one series, 15 of 54 patients had muscle twitching, and 11 of these progressed to grand mal seizures.¹ One 12-year-old patient seized after taking 2.5 g of mefenamic acid, and four adult patients seized after ingesting less than 5 g.⁴ The time between ingestion and onset of seizures varies between 0.5 and 12.0 hours. Both cardiac and respiratory arrest may follow seizures.

Propionic and acetic acid derivatives are associated with relatively low toxicity. Of these agents, fenoprofen appears to be the most toxic.⁴ Indomethacin, an indole structurally similar to serotonin, frequently causes headaches, even in therapeutic doses. It is also more often associated with tinnitus than are other NSAIDs. Zomepirac was withdrawn from markets because of a high incidence of severe allergic reactions, benoxaprofen because of fatal liver toxicity, and suprofen because of acute renal failure.

After piroxicam overdose, two patients who ingested 300 to 400 mg developed dizziness with blurred vision, and one who ingested 600 mg presented with coma but responded to pain and regained consciousness within 1 hour.⁴ Because of the long elimination half-life of piroxicam, overdose symptoms can be prolonged.^{11,13} Multisystem toxicity was noted in a 2-year-old who ingested 100 mg of piroxicam.¹² Initial effects included severe GI symptoms with fluid and electrolyte imbalance, mental confusion, and a generalized seizure. Liver and kidney dysfunction was evident by day 3, and pancytopenia with bone marrow aplasia and coagulopathy developed later. The white blood cell count nadir and liver enzyme peak were seen on day 9. Although the hospital course was complicated by sepsis, the child recovered by day 46. Experience in the overdose of other NSAIDs with long half-lives (oxaprozin and nabumetone) is limited, but prolonged toxicity should be anticipated. NSAID plasma levels are not routinely available and are not necessary for the treatment of acute ingestion. A rough correlation between ibuprofen plasma levels and clinical toxicity has been noted.⁷

DIFFERENTIAL DIAGNOSIS

Because GI symptoms, neurologic symptoms, and respiratory depression are common to many drug ingestions and medical illnesses, NSAID overdose cannot be diagnosed by clinical findings alone. The diagnosis is made primarily on the basis of history and the exclusion of other etiologies.

The central nervous system (CNS) depression that occurs with NSAID overdose is usually mild; coma unresponsive to stimulation is uncommon. Benzodiazepines, which may cause a similar degree of CNS and respiratory depression, should be considered in the differential diagnosis. Deep coma, marked hypotension, and severe respiratory depression suggest the presence of other drugs. The metabolic acidosis caused by ibuprofen is relatively mild and short-lived compared with that caused by the ingestion of salicylates, isoniazid, ethylene glycol, and methanol.¹⁰

EMERGENCY DEPARTMENT EVALUATION

A detailed history, including all medications available in the household, should be obtained; it may provide the only clue to NSAID overdose. The amount and time of ingestion and the onset, nature, and progression of symptoms should be noted. The physical examination should include complete vital signs and assessment of mental status and cardiorespiratory function, including oxygen saturation measurement. Evaluation for occult GI bleeding should be considered for patients with abdominal pain.

A complete blood count, electrolytes, blood urea nitrogen, creatinine, glucose, and urinalysis should be obtained in all symptomatic patients, those with underlying kidney dysfunction, and the elderly. Etodolac may cause a false-positive urine bilirubin and a false-positive urine ketone test when dipstick methods are used. Because the time of onset of renal failure varies and is poorly defined, it has been recommended that these tests be performed in all adults with ibuprofen overdoses of more than 6 g.⁶ Arterial blood gases should be monitored in patients with significant mental status changes or respiratory depression. In patients with pyrazolone overdose, liver function tests should also be obtained.

Urine and blood samples should be sent for a toxicology screen in cases of altered sensorium of unknown cause. NSAIDs are difficult to detect and correctly identify using common screening procedures. Hence, a negative screen does not necessarily rule out overdose of these agents. Toxicology analysis may also help to rule out other drugs that cause similar symptoms.

EMERGENCY DEPARTMENT MANAGEMENT

Initial management consists of standard supportive care and GI decontamination. Mechanical ventilation may be necessary in severe poisonings. Hypotension can be managed with intravascular volume expansion using crystalloids. Vasopressors are seldom necessary. Atropine may be used for symptomatic bradycardia, and benzodiazepines are indicated for seizures. Sodium bicarbonate should be given to patients with significant metabolic acidosis. GI bleeding should be treated by standard measures. Coagulopathy can be corrected by administering fresh-frozen plasma and vitamin K1.

Activated charcoal is the preferred method of GI decontamination. It should be considered in all patients with intentional overdoses, adults with accidental ingestions of more than ten therapeutic doses, and children with accidental ingestions of more than five adult doses who present within 4 hours of ingestion.¹⁶ Fenamic acids or pyrazolones may cause serious toxicity with even a couple of doses, and decontamination may be appropriate for all patients with these ingestions. Multiple-dose activated charcoal therapy has not been studied with most NSAIDs. Although the elimination half-life of phenylbutazone was decreased by 30% after therapeutic doses,¹⁴ the clinical efficacy of this treatment is likely to be minimal, even for NSAIDs that undergo enterohepatic recirculation. Because most NSAIDs are highly protein bound and rapidly metabolized, diuresis or dialysis is not expected to remove a significant amount of active drug. Charcoal hemoperfusion may benefit patients with severe phenylbutazone poisoning.²

DISPOSITION

Patients should be observed for 4 to 6 hours after ingestion.^{6,16} Those with minor symptoms should be observed until they become asymptomatic. Those with minor symptoms following the ingestion of fenamic acids or pyrazolones should be monitored for at least 12 hours. Patients with significant toxicity (coma, respiratory depression, seizures, or renal failure) should be admitted to a medical intensive care unit.

Patients with an abnormal urinalysis or underlying renal dysfunction should have follow-up kidney function tests. A complete blood count and kidney and liver function tests should be repeated 24 to 48 hours after pyrazolone overdose. Follow-up liver function tests should be obtained in symptomatic piroxicam overdose patients.

Transfer should not ordinarily be necessary. If acute renal failure develops, a nephrologist should be consulted. Psychiatric evaluation is necessary for all intentional ingestions.

COMMON PITFALLS

- Failure to appreciate that, in contrast to other NSAIDs, pyrazolones and fenamates can cause severe toxicity following overdose
- Failure to consider the possibility of other ingestions in patients with significant CNS depression, metabolic acidosis, or vital sign abnormalities
- Inducing emesis in a patient likely to develop seizures or coma
- Failure to observe the patient for 4 to 6 hours after overdose
- Failure to recognize that a negative toxicology screen does not necessarily exclude NSAID poisoning

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of Paula L. Townsend who wrote the previous edition of this chapter.

Vitamins are organic substances that are provided in small amounts in the normal diet to sustain the normal metabolic functions of life. These substances differ in chemical structure, biologic action, and, in most cases, dietary sources. The physiologic functions of each vitamin are complex and may depend on several related compounds. The use of vitamins includes treatment of vitamin deficiencies, treatment of inborn errors of metabolism, and self-prescribed dietary supplements to treat or prevent various medical conditions. Clinical disease may result from vitamin deficiency or vitamin excess.

Vitamin preparations may be solid or liquid oral dosage forms, parenteral solutions, and, in some cases, topical preparations. Most vitamins are available as a single entity or combined with other vitamins in multivitamin preparations.

In the United States, an estimated 23% of adults regularly use vitamin supplements, with higher proportions among females, Caucasians, and people living on the West Coast.³ Several million of these take vitamins in excess of the recommended daily allowance (RDA; [Table 359.1](#)).^{10,15} While such self-therapy may be costly (some have stated that Americans have the most expensive urine in the world), there is little doubt that some of the substances have potent antioxidant-free radical quenching activity, with potential to possibly prevent genetic mutation and carcinogenic activity and other forms of disease secondary to free radical mechanisms.⁴

Age Group	Fat-Soluble Vitamins			Water-Soluble Vitamins			
	Vitamin A μg RE*	Vitamin D μg†	Vitamin E mg TE‡	Vitamin C mg	Thiamine mg	Niacin mg NE§	Pyridoxine mg

TABLE 359.1. Recommended Dietary Allowances for Vitamins

The ubiquitous distribution of vitamins results in a relatively large number of acute poisonings, either accidental or intentional, many of which are treated in emergency departments. In 1997, there were 48,633 vitamin exposures reported.⁹ About 78% involved children under age 6, 91% were accidental, and 11% were treated in a health-care facility. Less than 1% had moderate adverse effects, only 0.04% had major adverse effects, and there were no deaths. The majority of adverse reactions were seen in multivitamins that contained significant amounts of iron (see [Chapter 345](#)).

Data regarding chronic vitamin toxicity consists primarily of isolated case reports of severe toxicity, some resulting from self-prescribed “megadosing.” Megadosing has been defined as the daily intake of more than five to ten times the RDA for longer than 4 weeks. However, even at large doses, chronic vitamin toxicity rarely occurs and, when present, is typically secondary to fat-soluble vitamins and to a few water-soluble vitamins.

Fat-soluble vitamins typically regulate specific metabolic activities, and water-soluble vitamins function as coenzymes. Fat-soluble vitamins include vitamins A, D, E, and K. Water-soluble vitamins include thiamine (B₁), riboflavin (B₂), nicotinic acid (B₃), pantothenic acid (B₅), pyridoxine (B₆), cyanocobalamin (B₁₂), biotin, folic acid, and ascorbic acid. While there are many nutritional substances that are taken for a variety of reasons, other commonly used substances include androstenedione and dihydroepiandrosterone (DHEA), tryptophan, and melatonin. Herbal agents are discussed in [Chapter 365](#).

FAT-SOLUBLE VITAMINS

Vitamin A is comprised of several closely related compounds (e.g., retinol, retinal, retinyl esters, and retinoic acid), all of which are biologically active but have different functions. Retinol functions in reproductive processes, retinal in vision, and retinoic acid in epithelial cell growth and differentiation. Interconversion between these isomers occurs readily in the body. Retinol is preferentially stored in the liver and transported to tissue sites by retinol-binding protein (RBP). Aqueous emulsions of synthetic retinol result in higher blood levels and lower fecal elimination than the older, oily preparation, thus producing toxicity at lower dosage levels.¹² Carotenoids (i.e., beta carotene) are precursors of retinol, but they are rarely associated with toxicity because biotransformation is relatively inefficient.

Vitamin A toxicity appears to result from exaggeration of retinol's normal physiologic action.^{7,12} Retinol acts similarly to a hormone, stimulating mitosis and epithelial cell turnover rates. Thus, excess retinol results in eczema, excessive desquamation, alopecia, bony exostoses, metaphyseal flare, decreased bone remodeling, rarefaction of long bones, and congenital defects. It also appears that unbound retinol and retinyl esters may have membranolytic properties; this may occur when RBP becomes saturated. Diseases that alter RBP levels may increase the risk of toxicity. Preexisting liver disease, protein-calorie malnutrition, cystic fibrosis, febrile infection, proteinuria, and pregnancy have been associated with low RBP levels. When RBP levels are low, less retinol is required to saturate binding sites and increase circulating unbound retinol.¹² Patients with preexisting renal disease have impaired renal catabolism of RBP and elevated RBP levels and are also at increased risk of toxicity. Elevated plasma retinol and plasma retinyl ester levels have also been noted in patients with type V hyperlipoproteinemia.⁶ Vitamin A has teratogenic activity, and doses significantly greater than the RDA should be avoided by women of childbearing age unless there is evidence of a deficit.

Pseudotumor cerebri occasionally occurs and may be related to altered cellular membrane function in the choroid plexus. Hepatic Ito cells also accumulate excess retinol and lipids, leading to fatty hepatic changes, enhanced hepatic collagen production, and, eventually, obstruction of sinusoidal blood flow and cirrhosis.

Vitamin D, a steroid-like substance, is formed by ultraviolet light acting to convert 7-dehydrocholesterol to cholecalciferol. Cholecalciferol is then hydroxylated by the liver to 25-hydroxycholecalciferol (25-OHD), which is then metabolized by the kidneys to a more potent metabolite, 1,25-hydroxycholecalciferol (1,25-OHD). The latter metabolite regulates calcium and phosphorus absorption from the gut and resorption from bone. The mechanisms of vitamin D toxicity are related to exaggerated physiologic effects (i.e., increased calcium absorption and increased levels of the metabolite 25-OHD). 25-OHD may saturate normal protein-binding sites and become bound to albumin, allowing increased cellular membrane damage. 1,25-OHD, the metabolite with more potent physiologic activity, does not appear

to be responsible for toxicity, and serum levels may be normal or even depressed.

Vitamin E comprises at least eight naturally occurring tocopherols. Alpha-tocopherol is the most important because it is the most abundant in animal tissue sources and has the greatest biologic activity. The d optical isomer is more active than the l isomer; most synthetic alpha-tocopherol preparations are mixed dl isomers. Tocopherols function as antioxidants by protecting lipids from oxidation by cellular components. Vitamin E toxicity is minimal, and its mechanism has not been elucidated.

Two naturally occurring substances have vitamin K activity: phytonadione (K₁) and a series of closely related compounds called menaquinones (K₂). The former is found in plants; the latter are synthesized by gram-positive bacteria in the intestinal tract. Menadione (K₃) is a synthetic derivative with vitamin K activity that is available as a water-soluble salt. Vitamin K promotes biosynthesis of clotting factors II, VII, IX, and X.

Vitamin K₃ toxicity is caused by the action of menadione as an oxidizing hemolysin.¹²

WATER-SOLUBLE VITAMINS

Most water-soluble vitamins are relatively nontoxic and their mechanisms of toxicity are unknown.^{12,16} Severe toxicity and death from water-soluble vitamins is exceedingly rare, except for hypersensitivity reactions.

Thiamine (B₁) is converted by adenosine triphosphate to its active form, thiamine pyrophosphate, which functions as a coenzyme in the decarboxylation of alpha-keto acids and in the use of pentose in the hexose monophosphate shunt.

Nicotinic acid (niacin, B₃) is the functional component of nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). These coenzymes activate several dehydrogenases important to cellular respiration. Nutritional requirements can also be satisfied by nicotinamide (niacinamide) and tryptophan. The vasodilatory effects of nicotinic acid are thought to result from direct action on small blood vessels and histamine release.

Several naturally occurring substances have pyridoxine-related biologic activity, including pyridoxine, pyridoxal, and pyridoxamine. All three forms are converted to pyridoxal phosphate, which acts as a coenzyme for biotransformations of amino acids. The specific biochemical cause of their neurotoxicity has not been identified.

Several substances also have activities similar to ascorbic acid, but ascorbic acid itself is the most potent and the most commonly available. Ascorbic acid is reversibly oxidized to dehydroascorbic acid. Both function in oxidative biochemical reactions.

NUTRITIONAL SUPPLEMENTS

Androstenedione and DHEA are precursors for steroid synthesis and may have some steroidal activity of their own. DHEA levels, in particular, have been shown to be elevated in younger animals and tend to fall off with age, poor health, obesity, certain infections, and other disorders. In some animal models, DHEA appears to be partially protective against infection with certain viruses and may inhibit certain types of cancer.^{13,19} Individuals often take this substance as an “antiaging” supplement, to promote health, in an attempt to build muscle mass, and for its purported aphrodisiac effect (a commonly held belief, given that it is a precursor to testosterone synthesis).

Melatonin is a substance released by the pineal gland during times of decreased light. It serves to promote a resting state, alters other neuroendocrine function, and, in animals, appears to affect the ovulatory cycle, gonadal maturity, thyroid function, and the release of other pituitary hormones. It is often taken as a soporific in supraphysiologic amounts of 1 to 3 mg or more. It has also been prescribed in very large amounts, for its immunomodulatory effects, during certain kinds of chemotherapy.

Tryptophan, an essential amino acid, was taken by many individuals in the 1980s in large amounts (up to 8 g or more for extended lengths of time) as a soporific and antidepressant (thought to increase serotonin levels). At that time, approximately 1,500 individuals taking an L-tryptophan agent developed eosinophilia–myalgia syndrome.¹⁷ Its sale was then restricted, but it was later found that a contaminant was likely the responsible etiology, as virtually all of the cases were from tryptophan that was produced by manufacturers using a new production process.

5-Hydroxytryptophan, a direct precursor of serotonin, is currently sold as an antidepressant. The eosinophilia–myalgia syndrome has not been reported with its use, and the valvulopathy seen with high serotonin states and the appetite suppressants fenfluramine and dexfenfluramine has also not been seen.

CLINICAL PRESENTATION

Patients with a single acute exposure to vitamins often present to the emergency department with either no symptoms or mild gastrointestinal (GI) distress, unless other, toxic agents were coingested. Vitamin formulations that contain significant iron are most likely to cause GI symptoms and other adverse sequelae (see [Chapter 345](#)). Notable exceptions include hypersensitivity reactions and nicotinic acid–induced flushing. Patients with toxicity from chronic megavitamin therapy may present to the emergency department with vague, nonspecific clinical findings (see specific vitamins). The key to diagnosis is to ask about vitamins and other supplements. Some patients may deny exposure to vitamins, either because they do not recognize them as drugs or because they perceive megavitamin therapy as unacceptable to physicians.

Fat-Soluble Vitamins

Acute vitamin A toxicity has been reported in Arctic explorers who have eaten polar bear or husky liver, which contains large amounts of vitamin A secondary to a marine diet. Acute toxicity from a single large overdose of vitamin A generally requires more than 25,000 IU/kg (4 million U in an adult and 300,000 U in children have caused toxicity). In adults, manifestations include severe headaches, dizziness, vomiting, diarrhea, and erythematous skin, which can develop within 8 hours. Later, skin typically cracks and peels.¹² In infants and children, anorexia, hyperirritability, vomiting, and bulging fontanelles (secondary to increased intracranial pressure) have been occasionally noted. Within a few days, these infants' skin also cracked and peeled. Symptoms resolved in all age categories, with no apparent long-term sequelae.

Other effects include increased intracranial pressure (pseudotumor cerebri). This condition is most common in women in their 30s to 40s, who often present with headaches, blurred vision, and diplopia. Elevated intake of vitamin A can also lead to hepatic disease.

Chronic vitamin A toxicity is usually associated with 4,000 IU/kg for months, although, occasionally, toxicity can develop with lower dosages (30 to 50,000 IU in adults and dosages of ten times the RDA in children).¹² The minimum toxic dose varies between patients, depending on age, health status, and dosage preparation. Skin and mucous membrane effects (e.g., erythema; eczema; pruritus; dry, cracked skin; epistaxis; conjunctivitis; palmar and plantar peeling; and alopecia) are the most common and first signs of toxicity. Musculoskeletal pain and tenderness over the long bones of the upper and lower extremities is common. Epiphyseal cupping and premature epiphyseal fusion may occur in children. Hypercalcemia has been reported but is not consistently present. Retinal crystals have been noted in patients ingesting carotene for tanning purposes.¹⁸

Neurologic symptoms include frontal headaches, blurred vision and diplopia. Hepatotoxicity, usually a later stage of toxicity, is manifested by hepatomegaly, splenomegaly, abnormal liver function tests (primarily aminotransferases, bilirubin, and alkaline phosphatase), and, eventually, portal hypertension, cirrhosis, and ascites. Liver biopsies reveal perisinusoidal, central vein sclerosis and hypertrophy of Ito cells. Normal retinol levels are 30 to 70 µg/dL, and a level greater than 80 µg/dL would be suggestive of toxicity; however, normal levels do not rule out toxicity, as the majority of vitamin A is hepatically stored.

Acute vitamin D toxicity is exceedingly rare, even with the consumption of rodenticides containing cholecalciferol. In a huge overdose, hypercalcemia would be expected. Chronic vitamin D toxicity, although more common, is also rare. This may occur in ingestion of the parent compound or the cholecalciferol metabolite. Chronic daily doses above 1250 µg of cholecalciferol in adults may cause toxicity. Patients with diseases such as hypoparathyroidism, vitamin D–resistant rickets, and osteomalacia who are taking physician-prescribed calciferol are at risk. Those with sarcoidosis, mycobacterial infections, and idiopathic hypercalcemia and

hypercalciuria may develop toxicity with doses of 25 µg of cholecalciferol daily.

Chronic vitamin D toxicity has been associated with nausea, vomiting, constipation, anorexia, polydipsia, polyuria, hyperlipemia, hypercalcemia, and hyperphosphatemia. Hypercalcemia may be present without any symptoms, or it may cause pruritus, calcium deposits in soft tissue, and renal calculi.¹² Children and infants appear to be more susceptible to toxic effects and can develop cardiovascular, renal, and central nervous system injury.

Acute toxicity from vitamin E is virtually nonexistent, with only mild GI complaints expected. Chronic vitamin E toxicity is quite rare, even at dosages of ten times the RDA,² and many individuals have taken 800 IU or more daily for several years without apparent toxicity. Minor symptoms, such as nausea, fatigue, headaches, diplopia, muscle weakness, creatinuria, and elevated serum creatine kinase levels, can occur with extremely high doses. It appears that large amounts of vitamin E can hinder the absorption of other fat-soluble vitamins and can cause the inactivation of vitamin K, possibly explaining the minor elevation in prothrombin time in individuals on coumadin.²

E-Ferol, a discontinued parenteral dosage of vitamin E used in neonates, was associated with ascites, hepatomegaly, hyperbilirubinemia, azotemia, and thrombocytopenia, possibly caused by the emulsificants (polysorbate 20 and 80), which were used in the formulation.¹¹

No adverse effects have been seen after the ingestion of oral vitamin K. Premature infants given menadione (the synthetic analogue) in parenteral doses of 5 to 25 µg daily have developed hemolytic anemia, hyperbilirubinemia, or kernicterus, and fatalities have rarely been reported. Patients with glucose-6-phosphate dehydrogenase deficiency and premature infants with hypoglycemia are at increased risk for these hemolytic effects. Intravenous phytonadione injections have occasionally resulted in chest pain, hypotension and dyspnea, asystole, and seizures. Chronic toxicity is not usually a concern, as phytonadione is rarely used long term and is not readily stored

Water-Soluble Vitamins

Single, acute thiamine ingestions have not resulted in toxicity. With older preparations and multiple dosing, parenteral administration was associated with tachycardia, hypotension, cardiac dysrhythmias, anaphylaxis, vasodilatation, headache, weakness, paralysis, and convulsions. Toxicity would not be expected in doses of 100 mg (or even much larger dosages) given intramuscularly or intravenously over 1 to 2 minutes as part of the “coma cocktail.” It is unlikely that any chronic toxicity exists.

Most patients who use niacin experience flushing. These effects have been noted with oral doses of 100 mg and intravenous doses of 20 mg and are sometimes accompanied by pruritus, headache, and increased intracranial blood flow. These effects are more common in individuals just starting nicotinic acid therapy. High doses may be associated with nausea, diarrhea, and heartburn. Rarely, near syncopal spells are seen. These symptoms subside rapidly and do not usually require treatment. Nicotinamide has not been associated with these effects.

Chronic nicotinic acid therapy has been implicated as the cause of hepatotoxicity with centrilobular cholestasis and necrosis. This typically occurs at large dosages (3 g) used to treat hyperlipidemia (up to 100 times the RDA).^{5,14} The hepatotoxicity, although rare, also appears to be correlated with using a sustained-release product and, possibly, the dose and frequency. Nicotinamide appears to be more hepatotoxic than nicotinic acid. Acute gouty arthritis has been precipitated secondary to elevated serum uric acid levels. Coagulopathies and hyperglycemia have rarely been reported.

Acute toxicity from pyridoxine is extremely rare but has occurred at extremely large doses (greater than 100 g in adults), resulting in dorsal root and sensory ganglia deficits.^{1,16} Chronic toxicity often results in a nonspecific (primarily sensory) polyneuropathy, which is often, at least partially, reversible with discontinuance. Some studies have suggested that dosages greater than 200 mg/d could be neurotoxic, but toxicity is probably more common at dosages of a gram per day or more in adults.¹⁶

Ascorbic acid may cause diarrhea, nausea, and abdominal cramps with single doses as low as 1 to 2 g in adults. Ascorbic acid may cause a false-negative test for occult blood in the stool, spurious blood and urine glucose determinations, and inaccurate liver function (enzyme) tests. Massive intravenous dosages (greater than 40 g) of vitamin C can result in oxalate crystal precipitation and subsequent renal failure.⁸

With chronic ascorbic acid megavitamin therapy, excessive excretion of oxalate (an ascorbic acid metabolite) may increase the risk for kidney stones. The risk of nephrolithiasis formation (secondary to oxalate) is rare but occurs. This is exacerbated with increased fractional urinary excretion of uric acid and urine acidification, both resulting from chronic high-dose ascorbic acid therapy.

Nutritional Supplements

Acute androstenedione and DHEA overdose would not be expected to cause toxicity. In chronic use, there is a slight potential for all of the effects that are seen with anabolic steroids (which generally are reversible on discontinuation). It is possible that masculinization may occur, as well as possible hepatotoxicity, acne, gonadal suppression, and alterations of lipoproteins. It is also possible that individuals with hormone-sensitive cancers (i.e., prostate) could possibly have acceleration of their carcinoma. Although charcoal would likely bind these substances, it is unclear whether such therapy would be needed. Chronic overdose could be expected to cause these effects.

In acute melatonin overdose, symptoms include mild sedation, headache, and lethargy. Chronically, it has the potential to effect the neuroendocrine axis and possibly ovulation, and may worsen seasonal affective disorder in predisposed individuals (who probably have high endogenous levels of melatonin).

The eosinophilia–myalgia syndrome associated with L-tryptophan consists of the sudden onset of severe myalgias, pulmonary complaints, scleroderma-like cutaneous involvement, eosinophilia and, rarely, a polyneuropathy.¹⁷ It is possible that tryptophan and 5-hydroxytryptophan could cause serotonin syndrome when taken in large amounts or, more likely, when taken with antidepressants or certain other drugs. In acute overdose, sedation, fatigue, and, occasionally, emesis are the most common symptoms.

DIFFERENTIAL DIAGNOSIS

Given that the symptoms of vitamin toxicity, both acute and chronic, can be quite vague and nonspecific, it is important to consider this etiology in any patient with unexplained complaints. Vitamin A toxicity should be included in the differential diagnosis of dry eczematous skin, hepatic disease, or symptoms consistent with increased intracranial pressure. Pseudotumor cerebri can be caused by or associated with a variety of medications (e.g., corticosteroids, oral contraceptives, tetracyclines, thyroxin) and medical conditions (e.g., hypertension, hyperthyroidism, lupus, obesity, pheochromocytoma, pregnancy, sarcoidosis, ulcerative colitis), and it is also frequently idiopathic. Some cases have been misdiagnosed as acute encephalitis and subsequently treated with surgery. Signs and symptoms have also been attributed to optic neuritis and psychiatric illness. The differential of hypercalcemia should include vitamin A and D toxicity, malignancy (osteolytic metastases and malignancies associated with excess production of parathyroid hormone), sarcoidosis, multiple myeloma, milk–alkali syndrome, thyrotoxicosis, adrenal insufficiency, idiopathic hypercalcemia of infancy, and secondary complications in patients undergoing chronic hemodialysis. For neuropathy, causes in addition to pyridoxine include alcohol, heavy metals, solvents, other toxins, various drugs (e.g., isoniazid, nitrofurantoin, phenytoin), diabetes, collagen vascular diseases, and malignancy.

EMERGENCY DEPARTMENT EVALUATION

The history should routinely include asking about over-the-counter medications, vitamins, and herbals. A careful history directed toward medications and all over-the-counter products is necessary to ensure that important details are not missed. It is important to exclude the possibility that the supplements contain large amounts of iron.

Physical examination is frequently nonspecific. Papilledema and a desquamating rash suggest vitamin A toxicity. Serum calcium and, possibly, liver enzyme studies may be important tests for vitamin A and D toxicity. Radiographic changes may be present in vitamin D toxicity. The diagnosis is dependent on the history and the demonstration of persistently elevated blood levels of the vitamin in question.

EMERGENCY DEPARTMENT MANAGEMENT

Therapy is primarily supportive. Most of the signs and symptoms of vitamin intoxication are usually reversible. GI symptoms and niacin-induced flushing usually resolve in a few hours, but resolution of hepatic, metabolic, and neurologic toxicity may take days to weeks. For acute exposures, GI decontamination may be indicated. Charcoal can be administered, depending on clinical likelihood of toxicity and the presence of coingestants. Patients with symptoms secondary to chronic exposure require discontinuation of vitamin therapy. Occasionally, it may be appropriate to begin intravenous fluids to maintain good urine output and promote excretion of calcium or water-soluble vitamins. Hypercalcemia can be treated with intravenous fluids and diuretics. Prednisone, calcitonin, chelators, and dialysis can be used if necessary. Low-grade pseudotumor cerebri typically resolves spontaneously. Diuretics, mannitol, steroids, and daily lumbar punctures may be required for more severe cases. Red cell transfusion and exchange transfusion or dialysis may be needed for neonates with significant hemolysis secondary to parenteral menadione.

DISPOSITION

Most patients can be referred for appropriate outpatient follow-up. Patients with hypercalcemia and evidence of increased intracranial pressure should be admitted. Women exposed to vitamin A during the first trimester of pregnancy should be referred to an obstetrician. Those with sensory neuropathies should be referred to a neurologist. Patients taking megadose vitamins should be warned about the dangers of chronic toxicity. Those with intentional overdose should be referred for psychiatric evaluation.

COMMON PITFALLS

- Failure to appreciate that vitamins, particularly fat-soluble vitamins, can cause poisoning
- Failure to ask about vitamin use and to include vitamin intoxication in the differential diagnosis of unexplained constitutional symptoms, hypercalcemia, and increased intracranial pressure
- Failure to determine whether iron was present in the vitamin preparation in cases of acute overdose
- Failure to warn patients about the dangers of megadose vitamin self-treatment

CHAPTER 360 *Opioid Poisoning*

William H. Dribben and Brent Furbee

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Opioid poisoning is relatively common. The 1997 annual report of the American Association of Poison Control Centers noted 37,300 opioid exposures from pharmaceuticals, with 750 resulting in major toxicity and 113 in death. Heroin has recently made a resurgence in the United States, particularly among adolescents. There are an estimated 325,000 current past-month users (compared with 41,000 in 1990) and 810,000 chronic heroin users. The 1997 National Household Survey on Drug Abuse found that the mean age of initiation declined from 27.3 years in 1988 to 18.1 in 1996, the lowest since 1972. Increased availability of high-purity heroin has made snorting and smoking more common and has profoundly altered the pattern of heroin use. The Drug Abuse Warning Network (DAWN) estimated 72,010 heroin-related emergency department visits in 1997. DAWN received 9,484 reports of drug-abuse deaths in 1996, and 68.5% of those deaths had narcotic analgesics reported by the medical examiners' office as a contributory cause.

Regional fentanyl epidemics have been associated with hundreds of fatal overdoses, particularly among heroin users who have purchased it as “synthetic heroin” or “China White.”²⁰ In 1982, cases of severe, acute parkinsonism occurred after illicit use of a meperidine analogue synthesized in a clandestine laboratory.⁸ Affected individuals were known as “frozen addicts.” A metabolite of the contaminant MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), which selectively destroys dopamine-containing substantia nigra cells through inhibition of oxidative phosphorylation, was found to be responsible.

The term *opioid* applies to all agonists and antagonists with morphine-like activity, including both naturally occurring and synthetic compounds ([Table 360.1](#)). Additional agonists include levomethadyl, levorphanol, and sufentanil. Buprenorphine is another agonist–antagonist. Dextromethorphan is an agonist used only as an antitussive. It is low in potency, but doses of 100 times the therapeutic one can cause moderate toxicity. The distinction between different opioids is important from the standpoint of therapeutic effectiveness (potency), side effects, duration of action, and detectability by drug screens.

Drug	Dose and Route	t _{1/2}	Duration of Action	Approx. Dose (70 kg of Adult)
NATURAL				
Codeine	30 mg PO	2.5 h	4–6 h	120 mg
Morphine sulfate	2–10 mg IV/PO	1.3–2.0 h	4–5 h	30 mg
SEMI-SYNTHETIC				
Heroin	1 mg IV/IV	as MPE	3–6 h	1 mg
Hydrocodone	5–10 mg PO/IV	3.5 h	4–6 h	—
Hydroxycodone	5–10 mg PO	—	—	—
Hydroxycodone	1–2 mg IV/IV	2.6 h	4–5 h	1.5 mg
Chlorobutol	1 mg PO	—	—	—
Chlorobutol	1 mg per rectum	—	—	—
Chlorobutol HCl	0.5–1.0 (IM/IV)	—	—	—
SYNTHETIC				
Diphenoxylate	1 mg PO	12–14 h	4–6 h	—
Fentanyl	0.05–0.1 mg IV/IV	2–4 h	30–60 min IV	0.125 mg
Meperidine	50–100 mg IV/IV	1.5 h	2–3 h	50–100 mg
Nalbuphine	1–4 mg IV/IV	1.5 h	30–60 min	—
Propoxyphene	65–100 mg PO	1.5 h	2–3 h	100 mg
Tramadol	50–100 mg PO	6–11 h	4–6 h	—
AGONIST-ANTAGONIST				
Buprenorphine	1 mg IV	2–4 h	3–6 h	—
Buprenorphine	1 mg sublingually	—	—	—
Naltrexone	50 mg IV/IV	1 h	1–6 h	—
Naltrexone	50 mg PO	1 h	2–3 h	—

TABLE 360.1. Comparison of Common Opioids

Opioids are rapidly absorbed by all routes. Those with high lipid solubility can even be absorbed transdermally. Most opioids are metabolized by hepatic conjugation, with 90% excreted in the urine as inactive compounds. Significant first-pass metabolism results in lesser effects after oral administration than after parenteral administration of the same dose. Opioids have a large volume of distribution (1 to 4 L/kg) and variable penetration of the blood–brain barrier. The rate of metabolism of opiates does not accelerate with ongoing usage.³

Opioids act by binding to and activating specific receptors in the central and peripheral nervous system. At least three opioid receptor classes, some of which have been divided into subtypes, have been identified: the mu, kappa, and delta sites ([Table 360.2](#)). The sigma receptor, originally described as an opioid receptor, has since been reclassified because of its affinity for dextrorotatory isomers (opioid receptors prefer levorotatory isomers).

Receptor	Effects
Mu ₁ (μ ₁)	Supraspinal analgesia Peripheral analgesia Euphoria Prolactin release
Mu ₂ (μ ₂)	Spinal analgesia Respiratory depression Physical dependence Gastrointestinal dysmotility Miosis Pupillary
Kappa (κ)	Bradycardia Spinal analgesia Miosis
Kappa ₂ (κ ₂)	Psychotomimesis Dysphoria
Kappa ₁ (κ ₁)	Supraspinal analgesia
Delta (δ)	Spinal analgesia Modulation of mu ₁ -receptor function Modulation of dopaminergic neurons

TABLE 360.2. CNS Opioid Receptors

Central nervous system (CNS) opioid receptors modulate the transmission or perception of painful stimuli.³ They are coupled to G-proteins and, when stimulated, inhibit adenylate cyclase. This results in blockage of voltage-gated calcium channels, activation of potassium efflux channels, hyperpolarization of the nerve terminal, and suppression of neurotransmitter release.¹⁵ Opioid receptors also have inhibitory effects at postsynaptic sites, interrupting pain sensations at afferent nerves ([Fig. 360.1](#)).⁹ Endogenous CNS peptide neurotransmitters (met- and leu-enkephalins, beta endorphins, and dynorphins) are opioid receptor agonists.¹² These substances may play an important role in drug tolerance and withdrawal.³

Figure 360.1. Mechanism of action: Opioids work at the presynaptic nerve ending by inhibiting calcium influx and promoting potassium efflux, preventing release of neurotransmitter (NT); at the postsynaptic nerve terminal, opioids have similar effects, hyperpolarizing the cellular membrane, preventing effective propagation of nerve impulses.

Therapeutic effects of pure opioid agonists are predominately mu-receptor-mediated, whereas the newer agonist-antagonist agents have antagonist activity at mu receptors and agonist activity at kappa receptors. Although tramadol has only weak affinity for mu receptors, it enhances serotonin release and inhibits serotonin and norepinephrine uptake, effects that may contribute to its analgesic activity.

Mechanisms implicated in opioid-induced seizures include hypoxia, decreased release of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA), inhibition of inhibitory interneuron transmission, and membrane destabilization. Miosis stems from increased activity of the parasympathetic input to the pupil (Edinger-Westphal nucleus). The cause of pulmonary edema remains obscure, but several theories exist. Currently, the most accepted theory is that it involves a neurogenic process initiated by CNS hypoxia. Many opioids have a nonspecific ability to activate mast cell G-proteins, inducing degranulation of histamine-releasing vesicles. Opioids cause an initial stimulation and subsequent depression of the chemoreceptor zone of the medulla. Decreased gastrointestinal motility and increased sphincter tone (e.g., anal, ampulla of Vater) are secondary to mu-receptor stimulation. Cardiotoxicity (and seizures) due to propoxyphene and its metabolite norpropoxyphene is thought to be secondary to sodium channel blockade (also known as quinidine-like or membrane effect).¹⁷ On a molar basis, propoxyphene and its metabolite have greater sodium channel blocking properties than quinidine or procainamide.

Opioid antagonists competitively bind to opioid receptors, reversing the effects of agonists and permitting increased transmission of painful stimuli. Additionally, antagonists are thought to alter the configuration of the receptor, thereby decreasing the availability of agonist-binding sites. Pure antagonists (naloxone, nalmefene, and naltrexone) avidly bind to all opioid receptor subtypes, but their activity at sigma receptors is variable.⁷

Tolerance, a well-known phenomenon whereby steadily increasing dosages are required to produce the same physiologic response, is most pronounced in the euphoric, analgesic, and sedative effects of opioids, whereas constipating and miotic effects show little or no tolerance.³ Some tolerance to the respiratory depressant effects occurs, but the therapeutic index rapidly diminishes as the dose is increased to maintain the same euphoric or analgesic effects. The recurrent administration of exogenous opioids decreases endogenous production and secretion. If exogenous opioid administration is suddenly stopped, inadequate amounts of endogenous opioids are present to preclude neuronal firing; this hyperexcitability state may add to withdrawal symptoms.³ Unlike benzodiazepine, barbiturate, or alcohol withdrawal, opioid withdrawal is generally not life-threatening. It can, however, cause seizures in neonates.^{1,4}

CLINICAL PRESENTATION

Poisoning may occur after intravenous, intramuscular, intranasal, inhalational, oral, subcutaneous, intradermal, or transdermal exposure. Unintentional poisoning in addicts or persons seeking to get “high” and intentional use in suicide attempts are relatively common. In injection, inhalational, and intranasal drug users, poisoning typically occurs in novice users, during binging, or when an experienced user obtains a new supply of heroin (from a different source or dealer) and accidentally miscalculates the dose due to differences in purity. The possibility of an intentional self-overdose or attempted homicide must also be considered. Unintentional exposure is most common in children, although iatrogenic poisonings (therapeutic misadventures) do occur. Children may ingest pills or apply or ingest transdermal patches (that sometimes become stuck on the roof of the mouth). Elderly patients, particularly those on chronic opioid therapy for pain control of systemic illness, also constitute a high-risk group for unintentional poisoning.

The onset of symptoms is nearly immediate after injection, inhalation, and nasal insufflation. Although effects are usually noted within 30 minutes of ingestion, absorption can be erratic and delayed, particularly in children and with sustained-release formulations. Lomotil (diphenoxylate and atropine) is particularly notorious for causing delayed toxicity, perhaps because both constituents can inhibit gastrointestinal motility.¹⁴ The effects of transdermal medications also begin about 30 minutes after application. They can, however, develop or progress after the patch is removed.

CNS depression, miosis, and respiratory depression are the three hallmark signs of opioid poisoning. CNS effects range from drowsiness to deep coma. In some cases, however, paradoxical excitation may be seen. Mixed agonist-antagonists such as pentazocine and butorphanol can cause dysphoric reactions or even psychosis because of their sigma-agonist activity. Seizures can occur in a pure opioid overdose, particularly in children, but are most common in propoxyphene, tramadol, and meperidine poisoning.¹⁷ They have also been reported with therapeutic doses of tramadol.¹¹ Increased muscle tone, tremors, or twitches may be seen with meperidine, and muscle rigidity has been associated with fentanyl.

Miosis is present in most cases.⁶ Mydriasis or midrange pupils do not rule out opioid poisoning; in these instances, diphenoxylate, meperidine, hypoxic injury, hypoglycemia, a postictal state, or a cointoxicant should be considered. Atypical presentations are listed in [Table 360.3](#).

Agent	Prominent/Atypical Features
Propoxyphene (Darvon)	Rapid, sudden onset of opioid effects Seizures, periton (unresponsive to naloxone) Inoperable Prolongation of PR, QRS, and ventricular tachycardia Delayed onset of membrane depressant effects Low dose is life-threatening (11 mg/kg) Higher doses of naloxone needed to antagonize narcotic effects
Diphenoxylate (Lomotil)	Initial anticholinergic features Delayed onset of opioid effects Children at high risk for toxicity
Meperidine (Demerol)	Mydriasis Prolonged half-life of metabolite Seizures
Pentazocine (Talwin) Tramadol (Ultram)	Increased muscle tone, serotonin syndrome Higher doses of naloxone needed to antagonize effects Seizures unresponsive to naloxone Serotonin syndrome

TABLE 360.3. Atypical Presentations of Opioid Poisoning

Initially, the rate (but not the depth) of respirations is decreased. With increasing severity, cyanosis and extreme bradypnea are noted. Rapid, shallow respirations may be noted in patients with noncardiogenic pulmonary edema (NCPE). In such patients, an arterial blood gas analysis reveals hypoxemia, hypercarbia, and a respiratory acidosis.² NCPE can occur with any route of exposure. It is observed in a large percentage of heroin overdose fatalities⁵ and often occurs after opioid antagonist administration. Respiratory decompensation develops within minutes to several hours, but radiographic evidence may be delayed up to 24 hours.¹⁶ Patients who have not been comatose and apneic do not appear to be at risk for this complication. Manifestations include copious pink, frothy sputum and rhonchi, rales, or wheezes. Central venous pressure is normal or low. Hence, jugular venous distention and an S₃ gallop are absent. Chest radiograph findings include a normal-size heart and a variable pattern of pulmonary edema ranging from unilateral localized infiltrates to classic hilar-based bilateral infiltrates. Due to the CNS

depressant effects of opioids, aspiration pneumonitis must also be considered as the cause of abnormal pulmonary findings on examination and radiograph. ² These entities may be difficult to differentiate in the emergency department. Aspiration is more likely the cause when the chest radiograph abnormalities do not resolve within 48 hours.

Opioids have limited effects on the cardiovascular system. They increase venous capacitance (a therapeutic benefit when using morphine to treat cardiogenic pulmonary edema), which may cause a slight decrease in both systolic and diastolic pressures. In the supine patient, this effect often goes unnoticed. Except for propoxyphene, meperidine, or pentazocine, opioids have no direct inotropic or chronotropic effects. ¹⁷ Although significant hypotension can occur in propoxyphene poisoning and as a consequence of nonspecific histamine release, it is usually secondary to hypoxia, a cointoxicant, or shock from other etiologies. Likewise, although rhythm disturbances can occur in propoxyphene poisoning, ¹⁷ they otherwise suggest hypoxia or a coingestant. Propoxyphene can cause QRS widening, ventricular ectopy, decreased contractility, and hypotension. ¹⁷ Other electrocardiographic (ECG) abnormalities include right bundle-branch block, left bundle-branch block, first-degree atrioventricular block, ventricular bigeminy, and ventricular fibrillation. A murmur in an intravenous abuser should raise the possibility of endocarditis. Pulmonary hypertension with cor pulmonale may result from the injection of adulterants or contaminants.

Gastrointestinal effects include nausea and vomiting, decreased bowel sounds, and abdominal distention. Other complications of opioid overdose include urinary retention due to the increased sphincter tone, rhabdomyolysis, hypoglycemia, and hypothermia. Acute parkinsonism in a young person suggests the use of illicitly synthesized meperidine.

DIFFERENTIAL DIAGNOSIS

Opioid poisoning should be considered in any patient with altered mental status (including seizures), miosis, and respiratory depression. Anticonvulsant, antidepressant, antihistamine, ethanol, muscle relaxant, neuroleptic, and sedative-hypnotic intoxication should be included in the differential diagnosis. Pontine hemorrhage, cholinergic agents, clonidine and other imidazolines, phencyclidine, and phenothiazines may also cause miosis. In pontine hemorrhage, the patient exhibits tachypnea (central neurogenic hyperventilation) and hypertension. Cholinergic agents (e.g., organophosphate insecticides) may cause a diagnostic dilemma initially, because the patient may appear to have pulmonary edema (profuse oral secretions, wheezing, and rales). The gastrointestinal tract is stimulated rather than depressed, however, resulting in hyperactive bowel sounds, recurrent vomiting, and diarrhea. Similarly, clonidine and other imidazolines (e.g., tetrahydrozoline, guanabenz) overdosage may result in bradycardia, hypotonia, and bradypnea. Phencyclidine intoxication is usually accompanied by tachycardia, hypertension, and muscle rigidity or tremor. In phenothiazine poisoning, hypotension and tachycardia occur in conjunction with coma. Hypothermia, encephalopathy, postictal state, CNS trauma or infection, cerebral vascular accident, and metabolic or electrolyte abnormalities, including hypoglycemia, hypercalcemia, hyponatremia, and hypernatremia, should also be considered in the differential diagnosis.

EMERGENCY DEPARTMENT EVALUATION

The history should include the identity of the opioid and any cointoxicants and the amount, time, intent, and route of exposure. The physical examination should initially focus on assessing the patency of the airway and the adequacy of ventilation. Patients should be placed on a cardiac monitor and have an oxygen saturation measured or an arterial blood gas analysis. Intravenous access should be established and blood obtained for determination of glucose (at the bedside for patients with altered mental status), electrolytes, blood urea nitrogen, and creatinine. Extra blood should be obtained for potential additional studies. A chest x-ray and ECG should be obtained in patients with unstable vital signs, hypoxia, or abnormal findings on cardiopulmonary examination (after antagonist therapy). An ECG should also be performed in patients with propoxyphene ingestions or abnormal rhythm or conduction intervals on cardiac monitoring. Creatine kinase and urine for myoglobin should be checked in patients with coma. Toxicology testing is appropriate to exclude cointoxicants such as acetaminophen (found in combination with opioids in many prescription medications) in cases of oral overdose. It is unnecessary in nonsuicidal patients with a history of injection drug use or recreational misadventures. Urine screening and comprehensive toxicology testing for drugs of abuse can detect some, but not all, opioids. Hence, a negative toxicology screen does not rule out opioid poisoning. In contrast, a lack of response to opioid antagonists virtually excludes this diagnosis. A positive response to opioid antagonists, although usually diagnostic, must be interpreted with caution, as poisoning with clonidine and valproate (and rarely benzodiazepines, ethanol, and chlorpromazine) sometimes responds to naloxone.

EMERGENCY DEPARTMENT MANAGEMENT

Supplemental oxygen and assisted ventilation should be provided, as necessary. With the expeditious use of opioid antagonists and ventilation temporarily provided by bag-valve-mask, endotracheal intubation can often be avoided. The application of four-point restraints should be considered before antagonist administration, because the patient may become uncooperative and combative. Suction equipment should be set up in advance, because vomiting may occur after naloxone administration. ¹⁹

Opioid antagonists are indicated primarily for the treatment of respiratory depression. They may also be effective for opioid-induced seizures and can be used for diagnostic purposes in patients with altered mental status of unknown etiology. ⁶ In suspected addicts, a low initial dose of naloxone (0.1 to 0.4 mg intravenously) should be administered to avoid precipitating a severe withdrawal reaction. This dose may be repeated every minute until a total of 2 mg has been given or respiratory depression is reversed and the patient awakens. If the patient is not a suspected addict, 0.4 to 2.0 mg of naloxone can be given as the initial bolus. Because some opioid overdoses (e.g., propoxyphene and methadone) are relatively resistant to naloxone, increments of 2 mg every 2 to 5 minutes, up to a total of 10 mg, should be given if there is little or no response to the initial 2-mg bolus. ⁶ The dose of nalmefene is essentially the same as for naloxone. ⁷ Although longer acting than naloxone (4 to 8 hours vs. 30 to 100 minutes), this antagonist is more expensive. Naltrexone, an oral opioid antagonist, is only used for abstinence maintenance.

If intravenous access cannot be obtained, naloxone may be administered intramuscularly, subcutaneously, or endotracheally. The time to response after intramuscular administration is about the same as that required to start an intravenous line and give the drug intravenously. Indeed, because intramuscular administration has less risk of needlestick injury (and attendant potential for infections such as hepatitis and the human immunodeficiency virus) to health-care workers than attempting to start an intravenous line in an uncooperative patient or in one with sclerosed veins from injection drug use, this route is preferred by many, particularly prehospital care providers.

Because naloxone has a shorter duration of action—shorter than almost all of the opioid agents it antagonizes—opioid toxicity can recur (primarily after oral overdose and particularly with diphenoxylate and methadone), and repeat doses of naloxone may be necessary. A continuous naloxone drip may be appropriate in such situations. An infusion of two-thirds of the initial dose of naloxone required to reverse respiratory depression, given every hour, should maintain arousal. It may be necessary to give one-half of the original dose as an additional bolus 15 to 20 minutes after initiation of the drip. ¹⁰ Health-care providers must be diligent in monitoring patients placed on a naloxone drip.

A partial response to naloxone requires a careful search for other accompanying illness, injury, or intoxicants. Endotracheal intubation is necessary in patients with hypercarbia, hypoxia, or an inability to protect their airway. A neuromuscular blocking agent (e.g., succinylcholine) may be needed to perform an atraumatic intubation in some patients. Fluid restriction and positive end-expiratory pressure are also useful in the treatment of noncardiac pulmonary edema, but morphine and diuresis are inappropriate. Seizures unresponsive to naloxone should be treated with intravenous benzodiazepines (diazepam or lorazepam) or phenobarbital. Ongoing seizures suggest a cause other than pure opiate poisoning.

Hypotension is usually not a prominent feature of pure opioid overdose, and its presence should be managed initially with a crystalloid fluid bolus and an aggressive search for another cause. ³ Propoxyphene, however, can cause hypotension, necessitating aggressive use of vasopressors such as dopamine. ¹⁷ Likewise, cardiac rhythm disturbances or cardiogenic shock should suggest that pure opioid poisoning (except with propoxyphene) is unlikely. ^{6,17} Arrhythmias due to propoxyphene are similar to those of the tricyclic antidepressants and may respond to sodium bicarbonate therapy in a similar fashion (see [Chapter 313](#)). Naloxone will not reverse propoxyphene cardiotoxicity. Although naloxone only partially inhibits tramadol-mediated analgesia, it reverses respiratory depression and coma due to this agent. Patients with oral overdoses should receive activated charcoal. Delayed gastric emptying may slow drug absorption and make gastric decontamination efforts effective many hours after ingestion.

DISPOSITION

Careful observation is required for any patient who has demonstrated clinical evidence of opioid poisoning requiring naloxone administration. Although it is often recommended that patients with intravenous overdose be observed for a minimum of 6 hours for evidence of relapse or the development of noncardiac pulmonary

edema, this may not be necessary. Such patients usually have taken only slightly more heroin than necessary to achieve the desired effect. In addition, complications, if they develop, are usually evident soon after presentation. In contrast, all patients who require naloxone after an oral overdose should be admitted to an intensive care unit with cardiac and respiratory monitoring (and suicide precautions, as needed). They should not be discharged until they are symptom-free for 12 hours. Adults who are or become asymptomatic during a 6-hour observation period after oral overdose may be discharged, whereas all children with an oral overdose should be admitted to the hospital for observation and monitoring for 12 to 24 hours. Psychiatric or social work follow-up must be arranged for all intentional or pediatric poisonings. Asymptomatic patients who have been treated with narcotic antagonists should be monitored.

COMMON PITFALLS

- Failure to consider opioid overdose in patients who present with altered mental status, including seizures or combativeness, as well as CNS depression
- Failure to apply restraints, thereby risking injury to staff, before giving naloxone to suspected addicts
- Failure to admit all patients who require naloxone after oral overdose and all symptomatic children
- Failure to evaluate for pulmonary complications, aspiration, and concomitant traumatic and medical illness
- Failure to examine thoroughly for medication patches (i.e., Fentanyl)

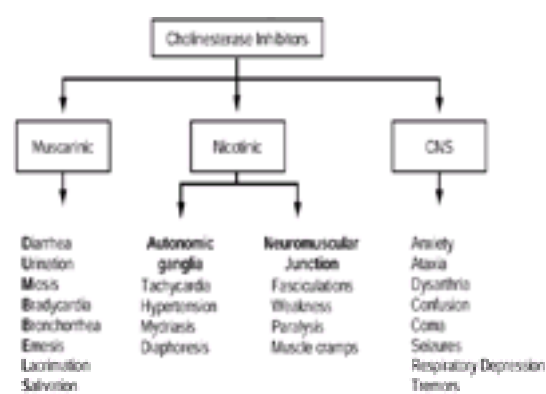

Figure 361.2. Cholinergic toxidrome.

CLINICAL PRESENTATION

Acute Toxicity

Patients with organophosphate poisoning are often critically ill. ^{2,11,14,17} Cholinergic findings (see Fig. 361.2) may be subtle or obvious, depending on the exposure. Vital signs may be unstable, including depressed respirations and heart rate. Respiratory failure may result from excess pulmonary and oropharyngeal secretions, central nervous system (CNS) depression and neuromuscular weakness. CNS toxicity may include altered mental status, confusion, lethargy, seizures, and coma. Overstimulation of postsynaptic receptors at the neuromuscular junction results initially in fasciculations and then muscle fatigue and weakness. In the autonomic nervous system, parasympathetic effects predominate as muscarinic cholinergic nerve fibers are stimulated. The mnemonic DUMBBELS (see Fig. 361.2) is helpful in describing the cholinergic muscarinic findings due to parasympathetic stimulation of hollow viscous organs and glands. Sympathetic ganglia effects may result in hypertension and tachycardia. Diaphoresis occurs commonly due to direct cholinergic stimulation of sympathetic sweat glands. Pancreatitis and rhabdomyolysis are relatively common complications.

The severity and extent of cholinergic toxicity is dependent on dose, route, and agent of exposure. The onset of symptoms is generally most rapid after inhalation and most prolonged after skin exposure. Symptoms have been reported as early as 5 minutes after ingestion but usually occur by 12 to 24 hours. Highly fat soluble agents such as fenthion may cause delayed or prolonged toxicity. ^{4,13} Generally, toxicity is less with carbamate exposures. The organophosphates are a widely variable class, and some may produce protean cholinergic effects, while others may produce selected toxicity. The nerve gas agents (Sarin, Soman) characteristically produce more CNS effects and fewer peripheral signs of cholinergic toxicity. Therefore, characteristic muscarinic findings (DUMBBELS) may be absent despite significant exposures. The elderly are at especially high risk for complications, including aspiration and pneumonia, severe neurologic toxicity, and prolonged weakness. Patients with myasthenia gravis who intentionally or inadvertently develop toxicity from their own medications, such as pyridostigmine, may develop more severe cholinergic findings due to their compromised acetylcholine neurotransmission at baseline.

Intermediate Syndrome

In 1987, a syndrome of recrudescence of organophosphate neurotoxicity was described in a series of patients 1 to 4 days following acute organophosphate poisoning. ¹⁹ Although all had initially improved following therapy with atropine and pralidoxime, cranial nerve palsies and a progressive truncal and proximal limb weakness became evident; 40% of the affected patients required intubation. Symptoms lasted 5 to 15 days, and one patient died. Subsequent prospective studies have demonstrated that this syndrome occurs frequently following exposure to highly fat soluble organophosphates and is related to prolonged cholinesterase inhibition. ⁵ It is proposed that redistribution of organophosphates from tissue reservoirs causes recrudescence of toxicity at a time when atropine and oxime therapy have been completed. ³

Delayed Peripheral Neuropathy

A distinct polyneuropathy may occur 1 to 3 weeks following organophosphate exposure. This syndrome was first described in 1930, when an estimated 40,000 persons became symptomatic due to contamination of an alcoholic beverage by tri-ortho-cresyl phosphate (TOCP), an organophosphate. ¹⁶ The debilitating distal flaccid paresis resulting from the neuropathy was termed the *Jamaican ginger paralysis* after the contaminated beverage, a ginger extract imported from Jamaica. The neuropathy resulting from organophosphate-induced inhibition of the enzyme, *neuropathy target esterase*, is characterized by axonal degeneration followed by myelin degeneration, with the large distal neurons affected first. ¹ Patients with underlying medical problems such as alcoholism or nutritional deprivation may be at higher risk for developing delayed peripheral neuropathy. Recovery is incomplete in many cases, and motor symptoms are often persistent.

DIFFERENTIAL DIAGNOSIS

Identical manifestations can be seen in patients poisoned with direct-acting cholinergic agonists such as bethanechol, pilocarpine, and Urecholine. Digitalis, clonidine, calcium- or beta-receptor antagonist poisoning, myocardial ischemia, or conduction disease should be considered in patients who present with altered mental status and bradycardia, without other obvious signs of cholinergic toxicity. Miosis, bradycardia, lethargy, and respiratory depression would lead to a consideration of opioid toxicity. Lethargy and prominent sialorrhea or salivation may be seen with certain neuroleptic agents, such as clozapine and risperidone. Organophosphate-induced bronchorrhea and pulmonary edema may be difficult to distinguish from any other etiology of pulmonary edema. Patients with nicotine poisoning due to ingestion of tobacco products or harvesting wet tobacco may have similar findings, including vomiting, diarrhea, fasciculations, weakness, altered mental status, and autonomic instability.

EMERGENCY DEPARTMENT EVALUATION

The history should document the amount, time, and route of exposure and the identity of the agent involved. Cardiac monitoring and pulse oximetry are crucial, because bradycardia may be marked and bronchial secretions and pulmonary edema may limit oxygenation. The physical examination should focus on the vital signs and assessment of cardiopulmonary and neuromuscular function, especially motor strength and respiratory effort. Cholinergic signs, particularly respiratory tract secretions, should be noted. Arterial blood gas analysis, forced vital capacity, and bedside spirometry should be performed to quantify respiratory dysfunction. An electrocardiogram, chest radiograph, and routine blood work, including complete blood count, electrolytes, blood urea nitrogen, creatinine, glucose, creatine phosphokinase, amylase, and liver function tests, should be obtained on symptomatic patients.

The diagnosis is confirmed by documenting decreased red blood cell (RBC) cholinesterase and plasma pseudocholinesterase activity. RBC cholinesterase activity is more specific, but plasma pseudocholinesterase activity tests are less expensive and more widely available. Although results are usually unavailable in a clinically relevant time frame, they can be helpful in cases in which the diagnosis is uncertain and in the evaluation of occupationally exposed patients. Specimens should be obtained prior to the administration of pralidoxime, because this antidote can increase measured enzyme activity.

Enzyme depression usually occurs rapidly. Following acute exposure, a 50% decrease in enzyme activity is associated with mild symptoms, and a 90% decrease with severe poisoning. Pseudocholinesterase activity may remain depressed for days to weeks, and RBC cholinesterase activity for 1 to 3 months following organophosphate exposure. In carbamate poisoning, activity may return to normal within minutes to hours. Interpretation of results may be difficult due to the variability in baseline values, which are subject to variety of factors. Pseudocholinesterase activity can be reduced in advanced liver disease, chronic alcoholism, dermatomyositis, malnutrition, and pregnancy, and following exposure to birth control pills, carbon disulfide, ciguatoxin, organic mercury compounds, benzalkonium salts, and solanins. Activity is genetically low than the norm in about 3% of the population. RBC cholinesterase activity is reduced in those with decreased red cell lifespan, such as in patients with hemolytic anemia and sickle cell disease. In some cases (e.g., chronic or occupational exposures), serial activity levels, showing a

return to baseline with time, may be necessary. Specific pesticides can also be identified by detecting alkyl phosphates, phenols, and other metabolites in the urine.

EMERGENCY DEPARTMENT MANAGEMENT

Health-care providers should gown and glove appropriately in advance of treating the patient with potential organophosphate poisoning. Many of these patients carry significant dermal contamination, which can be dispersed unknowingly onto health-care providers. Organophosphates are absorbed via any body surface, and, therefore, nitrile or neoprene gloves, impervious gowns, masks, and head and shoe covers are recommended for the treatment team.

Advanced life-support measures should be instituted, as necessary. This may require endotracheal intubation by emergency medical services in the field. Atropine may be initiated prehospital in patients with bronchorrhea and/or bradycardia, because this may be effective in decreasing respiratory compromise. GI and skin decontamination should be undertaken as soon as the patient is stabilized. Activated charcoal is the preferred method for GI decontamination. Gastric aspiration or lavage should precede administration of activated charcoal in any patient requiring endotracheal intubation.

Patients with muscarinic findings, particularly excessive pulmonary secretions, should be given a trial of atropine immediately: 2 to 4 mg intravenously (0.02 to 0.05 mg/kg intravenously in children). Atropine acts by competitively blocking acetylcholine at muscarinic receptors, thereby reversing the excessive parasympathetic stimulation. It is only partially effective in treating CNS symptoms and has a variable effect on seizures and altered mental status. It has no effect on nicotinic receptors and, therefore, will not reverse muscle weakness or sympathetic ganglionic effects.

Patients who require intubation in the emergency department should undergo a rapid-sequence protocol. Because the duration of effect of succinylcholine may be much longer than usual due to the concomitant inhibition of cholinesterases that degrade succinylcholine,¹⁸ an alternative, short-acting, nondepolarizing neuromuscular blocking agent such as mivacurium may be preferable.

Repeated doses of atropine may be needed to decrease bronchorrhea and oropharyngeal secretions. Atropine should be titrated to the clearing of these secretions, and not to irrelevant end points such as mydriasis or tachycardia. Very often, tachycardia is a result of dyspnea and inadequate atropine dosing. Atropine may be repeated every 5 to 15 minutes, with consideration of an atropine infusion (0.02 to 0.08 mg/kg/h) if frequent doses are needed. Atropine requirements are highly variable; patients with significant poisoning may require as much as 40 mg/d; one reported case describes a patient requiring 1,000 mg of atropine in a 24-hour period.¹⁷

Any patient who requires treatment with atropine should also receive pralidoxime (2-PAM). This should be initiated in the emergency department or as soon as the drug becomes available. Pralidoxime may be infused as a bolus therapy: 1 to 2 g in saline and administered over 30 minutes (20 to 40 mg/kg; maximum, 1 g per dose in children). The dose may be repeated in 1 to 2 hours if fasciculations are still present, and then at 6- to 12-hour intervals for 24 to 48 hours. Alternatively, it may be administered as a continuous infusion of 500 mg/h. Pralidoxime initially binds to cholinesterase enzymes and then to the inhibitor. The inhibitor-pralidoxime complex detaches from the acetylcholinesterase enzyme, returning it to a functional state. Pralidoxime is most effective in reversing the nicotinic effects, and it is synergistic with atropine at muscarinic receptors. Pralidoxime effects are rapid; improvement in muscle strength is noted within 10 to 40 minutes. Although it is not thought to cross the blood-brain barrier, pralidoxime may reverse some CNS effects.^{9,17} Benzodiazepines may be needed for neurotoxic effects such as agitation and seizures.

Certain organophosphates have “aging” properties, which refer to their ability to bind permanently to acetylcholinesterase and not respond to pralidoxime. While many organophosphates share this capability, aging occurs at different rates. The hallmark of the “nerve gas” agents is their ability to age quickly, thereby becoming resistant to any antidotal intervention (see [Chapter 325](#)). Because carbamates undergo spontaneous hydrolysis from the acetylcholinesterase enzyme, early studies raised concerns about the need and safety of treating patients with carbaryl (a carbamate) poisoning with 2-PAM. Recent data support treating any poisoned patient requiring atropine with 2-PAM, regardless of the anticholinesterase agent.¹²

Therapy for the intermediate syndrome includes additional pralidoxime and, possibly, atropine, as well as supportive care. No specific therapy exists for peripheral neuropathy.

DISPOSITION

Patients with an unintentional exposure who remain asymptomatic following at least 6 hours of observation may be discharged home with a family member. Those requiring treatment with atropine or pralidoxime and those with evolving toxicity should be admitted to an intensive care unit (ICU) for close observation and monitoring. If the patient needs to be transferred to an ICU for admission, advance cardiac life-support (ACLS) personnel should accompany the patient. Prophylactic intubation prior to initiating transport may be advisable in patients with respiratory compromise. Consultation with a regional poison control center or medical toxicologist is advised for all exposures. Even asymptomatic patients need follow-up with their family doctor, because peripheral neuropathy can occur even in the absence of initial cholinergic manifestations.¹⁵

COMMON PITFALLS

- Failure to decontaminate the skin of patients with dermal exposures and to take appropriate precautions to prevent secondary exposure to health-care workers
- Failure to appreciate that death is usually due to respiratory failure and to administer oxygen, perform timely endotracheal intubation, and assist ventilation
- Failure to treat based on the presence of characteristic signs and symptoms rather than on the results of laboratory testing for cholinesterase inhibition
- Failure to appreciate that atropine therapy should be titrated to drying of secretions rather than to heart rate or pupil size and that doses far exceeding standard ACLS recommendations may be necessary
- Failure to treat all patients requiring atropine with pralidoxime
- Failure to appreciate that pralidoxime therapy must be initiated early in order to prevent “aging” of the cholinesterase inhibitor to the acetylcholinesterase enzyme and to decrease atropine requirements
- Failure to appreciate that highly fat soluble organophosphates may cause delayed, prolonged, or recurrent toxicity

CHAPTER 362

Petroleum Distillate Poisoning

Sophia Dyer and Michael W. Shannon

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Products of the fractional distillation of natural petroleum include kerosene, mineral seal oil, gasoline, mineral spirits, naphtha, diesel fuel, motor oil, xylene, toluene, and benzene. Petroleum distillates begin as crude oil, which is heated in columns and separated on the basis of volatility. Petroleum distillates are typically classified as either aliphatic (straight-chain) or aromatic (benzene derivatives). Many are mixtures of both. Aromatic compounds are discussed in [Chapter 316](#). Petroleum distillates are found in many household products, and improper storage of these products can result in inadvertent exposure.

Petroleum distillates are also referred to as hydrocarbons. The term *hydrocarbon*, however, describes structure rather than origin and includes compounds derived from plants (e.g., turpentine, pine oil, vegetable oil), animal fats, and coal. Therefore, whereas all petroleum distillates are hydrocarbons, not all hydrocarbons are petroleum distillates.

For clinical purposes, petroleum distillates are either toxic or nontoxic. Nontoxic petroleum distillates are those that have minimal gastrointestinal absorption and systemic toxicity, such as mineral oil. In contrast, halogenated and aromatic hydrocarbons and halogenated derivatives ([Chapter 342](#)) can be absorbed and produce substantial systemic effects. Petroleum distillates are also utilized as components of products such as pesticides.

Until recently, petroleum distillates were a leading cause of poisoning and death in children.¹⁹ There are over 50,000 hydrocarbon exposures reported to U.S. poison centers each year. Over 20,000 occur in children under 6 years of age, with gasoline, kerosene, and lighter fluid most often involved. The majority of these exposures have minor effects. In adults, petroleum distillate poisoning is less common, usually occurring after occupational exposure, intentional ingestion, or accidental ingestion during the siphoning of fuels.¹⁹ Data suggest a marked decrease in the overall frequency of petroleum distillate exposure in the United States. In developing countries, however, exposure remains common and results in significant morbidity and mortality.^{10,14}

The greatest toxicity of petroleum distillates is to the respiratory tract. If they are aspirated, they lead to severe, diffuse chemical pneumonitis. The ratio of the LD₅₀ of petroleum distillates when instilled intratracheally versus intragastrically is 1:140 in animals. Petroleum distillate pneumonitis is characterized by the development of hemorrhagic bronchitis or alveolitis, loss of surfactant, alveolar collapse, respiratory failure, and death.^{6,19} These complications are not seen after ingestion without aspiration, supporting the belief that petroleum distillates are poorly absorbed from the gastrointestinal tract and that pulmonary toxicity occurs only after direct contact with the respiratory epithelium.^{4,8,20} Destruction of surfactant is a major contributor to pulmonary injury from petroleum distillates.

Many petroleum distillates have a central nervous system (CNS) narcotic effect that is the basis of sniffing or huffing, an increasingly common method of substance abuse in adolescents. Whether inhaled, injected, or ingested, such petroleum distillates can cause light-headedness, euphoria, incoordination, and impaired judgment. Inhalational injury and burns secondary to ignition of gasoline, while abusing it for CNS intoxication effects, have been reported. CNS effects may impair judgment and place the user at risk for thermal burns.¹⁷

Two independent physical characteristics govern the pulmonary and CNS effects of the petroleum distillates: viscosity and volatility ([Table 362.1](#)).¹⁹ Viscosity (fluidity) is measured in units of Saybolt seconds universal (SSU) and correlates with aspiration risk. The lower the viscosity, the more likely a petroleum distillate will be aspirated. Substances of less than 60 SSU, such as kerosene and mineral seal oil, pose a significant aspiration risk, whereas those greater than 60 SSU do not. Volatility, measured by vapor pressure, determines the potential for CNS effects. The more volatile a substance, the greater the likelihood of pulmonary absorption and subsequent narcosis.

Volatility	Viscosity	Examples	Clinical Effect
High	Low	Kerosene, gasoline	CNS, respiratory
High	High	Toluene, xylene, benzene	CNS
	Low	Mineral seal oil	Respiratory
	High	Mineral oil, motor oil	No toxicity

TABLE 362.1. Influence of Volatility and Viscosity on the Clinical Effects of Petroleum Distillate Exposure

CLINICAL PRESENTATION

Following inhalation, pulmonary toxicity is usually negligible, but systemic effects are common. As many as 28% of intentional abusers have lethargy and coma.¹⁹ Seizures, cardiac arrhythmias, including ventricular fibrillation, and permanent encephalopathy can occur. Lipoid pneumonia has been reported from chronic inhalation of aerosolized aliphatic petroleum distillates as well as the chronic ingestion or acute aspiration of mineral oil.⁵ Inhalation of leaded gasoline has also been associated with the development of organic lead poisoning.¹⁹

Although the intravenous injection of petroleum distillates is a relatively uncommon event, several reports describe altered mental status, pneumonitis, thrombophlebitis, local cellulitis, venous thrombosis, abscess formation, and necrotizing myositis with an associated compartment syndrome.^{11,15}

The ingestion of petroleum distillates is almost always followed by nausea and abdominal cramping. Spontaneous vomiting is also common, occurring in up to 40% of cases, and is associated with an increase in the likelihood of aspiration.¹⁴ Oral pain, dysphagia, drooling, or hematemesis may also result from mucosal irritation. Additional signs of petroleum distillate ingestion include altered mental status or loss of consciousness (in up to 60% of children), fever (17%), and leukocytosis.^{18,19} In children, intravascular hemolysis, hemoglobinuria, and disruptions of the omentum have also been reported.^{1,19}

Aspiration of petroleum distillates leads to immediate coughing and gagging. Depending on the distillate and the amount aspirated, these symptoms may rapidly progress to tachypnea, nasal flaring, and respiratory distress.¹² Physical examination may reveal use of accessory respiratory muscles and cyanosis, and chest auscultation may reveal diffuse wheezes and rales. In severe cases, arterial blood gas analysis shows marked hypoxia, hypercapnia, and acidosis. Radiographic findings include atelectasis, patchy perihilar and midlung densities, pneumothorax, and pneumomediastinum.¹⁶ Abnormalities on chest radiograph may lag behind clinical manifestations by several hours, but most will be evident within 12 hours.

Symptoms of pneumonitis usually worsen over 1 to 5 days and then resolve. Even after clinical illness has resolved, radiographic abnormalities may persist for days to

weeks. Pneumatocoles have been reported presenting up to 15 days after exposure.³ Although there are usually no overt long-term sequelae, some children have shown evidence of subclinical disturbances in pulmonary function 8 to 14 years after pneumonitis.⁶

DIFFERENTIAL DIAGNOSIS

Gastrointestinal symptoms resulting from petroleum distillate ingestion are similar to those of corrosive ingestion, infectious gastroenteritis, and food poisoning. A hydrocarbon odor on the breath or vomitus may suggest the correct diagnosis. Similarly, although symptoms of aspiration may resemble those caused by asthma, allergic reactions, pulmonary infections, and the inhalation of irritant gases (see [Chapter 346](#)), the history and physical examination usually disclose the correct cause.

EMERGENCY DEPARTMENT EVALUATION

The history should include the identity, amount, and concentration of the petroleum distillate ingested, the time of ingestion, and any symptoms present before arrival at the emergency department, particularly respiratory symptoms and vomiting at the time of ingestion. Because a number of different petroleum distillates may be found in a given product, all ingredients should be determined.

The physical examination should focus on the vital signs, respiratory system, mental status, and gastrointestinal system. Oxygen saturation should be obtained on all patients. Serial or continuous oximetry should be performed to identify the appearance of pulmonary decompensation. A chest radiograph should be obtained on any patient with respiratory symptoms. Arterial blood gases should be obtained in those who have an oxygen saturation of less than 90%. They should also be considered in patients with oxygen saturations less than 95% if significant tachypnea is present.

Routine laboratory studies (e.g., complete blood count, determination of electrolyte levels, blood urea nitrogen, creatinine, and glucose, and urinalysis) should also be obtained in patients with toxic petroleum distillate ingestion or evidence of aspiration. Depending on the specific agent ingested and the suspicion of coingestants, a toxic screen or other laboratory studies may also be indicated.

EMERGENCY DEPARTMENT MANAGEMENT

Management of ingestions depends on whether the compound has the potential to cause systemic toxicity. If a potentially toxic aromatic or halogenated agent has been ingested, gastrointestinal decontamination may be indicated. The risk of aspiration is equally increased by both gastric lavage and ipecac-induced emesis.^{12,13} Because petroleum distillates are liquids, gastric aspiration (without lavage) may be effective and less risky and is the preferred method of gastric emptying. A small-bore nasogastric tube should be sufficient. In the patient with altered mental status, gastric evacuation should be preceded by endotracheal intubation.

Vomiting should be prevented and activated charcoal, which may produce emesis, should not be administered.⁷ The efficacy of activated charcoal for petroleum distillate adsorption is unknown but is thought to be minimal. Similarly, sorbitol, a commonly used cathartic, has significant emetic potential and should not be administered. Because the greatest toxicity of the petroleum distillates results from aspiration and not gastrointestinal absorption, nontoxic petroleum distillates that are ingested do not require removal, regardless of the amount ingested.

All patients with respiratory symptoms should be given supplemental oxygen. The management of severe petroleum distillate aspiration includes early intubation and positive end-expiratory pressure to prevent alveolar collapse. Recent attention has been focused on the respiratory support of the patient with hydrocarbon- or petroleum distillate-induced lung injury. Alternative methods of ventilation are extracorporeal membrane oxygenation, high-frequency jet ventilation, and partial liquid fluorocarbon ventilation.

The clinician caring for a patient with a severe petroleum-induced lung injury should discuss the role of alternative methods of ventilation with a toxicologist or critical care specialist. Bronchodilators should be administered for bronchospasm. Artificial surfactant has been found to improve lung compliance and capillary stability and to increase pO₂. Cardiac monitoring is essential, because these agents may aggravate myocardial irritability due to hypoxia and precipitate dysrhythmias.

Data have consistently shown that corticosteroids are ineffective in the treatment of aspiration pneumonitis and may promote bacterial overgrowth.^{18,19} Similarly, the prophylactic use of broad-spectrum antibiotics may lead to the overgrowth of resistant pathogens and should be avoided.^{18,19} Antibiotics should be given on the basis of a positive sputum culture or Gram stain. However, because petroleum distillate aspiration may cause fever and leukocytosis, antibiotics (e.g., penicillin and clindamycin) are often given empirically.^{9,18}

DISPOSITION

The disposition of patients with suspected aspiration depends on clinical, laboratory, and chest radiograph findings.³ If patients are symptomatic and their chest radiographs and oxygen saturation or arterial blood gas analyses are abnormal, they should be admitted to the hospital for further observation. If their chest radiographs are normal, patients should be reevaluated in 2 to 6 hours. If they remain symptomatic or hypoxemic, or their chest radiographs become abnormal, they should be admitted.

If patients become asymptomatic and have normal oxygenation and normal repeat chest radiographs, they may be discharged. Patients who initially have symptoms suggesting aspiration, but who are asymptomatic on presentation, should also be observed and have a delayed chest radiograph after 2 to 6 hours. If their radiographs are normal and they remain asymptomatic, with normal oxygenation, they may be discharged.

COMMON PITFALLS

- Failure to appreciate that only those petroleum distillates with low viscosity and high volatility represent aspiration hazards
- Failure to differentiate between petroleum distillates that cause systemic toxicity and those that do not when assessing the need for gastrointestinal decontamination
- Failure to appreciate that gastric evacuation procedures may increase the risk of aspiration and are not routinely indicated
- Failure to appreciate that radiographic evidence of aspiration may lag behind clinical findings
- Failure to admit symptomatic patients to the hospital, even if the chest radiograph and pulmonary examination are normal

CHAPTER 363

Phencyclidine Poisoning

Andis Graudins

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Phencyclidine (PCP) is an arylcyclohexylamine related to the “dissociative” anesthetic ketamine. PCP was used briefly in the 1950s as an intravenous anesthetic agent and was used as a veterinary anesthetic agent until 1979, when legal production was stopped. Illicit use of PCP began in the late 1960s, peaked in the early 1980s, and has seen a steady decline since then. PCP use is currently sporadic and relatively infrequent. Ketamine (“K,” “Special K”), a dissociative anesthetic agent with a similar pharmacodynamic action, is also sporadically abused for its hallucinogenic properties. Use of both agents seems to be more common in inner-city areas. PCP, also commonly known on the street as “angel dust,” is sometimes misrepresented as tetrahydrocannabinol (THC) or crystal. It is frequently taken by mouth, by inhalation from tobacco or marijuana cigarettes, and occasionally by intravenous injection.

The powdered form, angel dust, is usually relatively pure, consisting of 50% to 100% PCP; other forms usually contain 10% to 30% PCP. PCP is easy to synthesize, although the process often yields other 1-phenylcycloalkylamines, such as phenylcyclohexamine (PCE), phenylcyclohexylpiperidine (PCPP), phenylcyclohexylpyrrolidine (PHP), and thienylcyclohexylpiperidine (TCP), which have similar pharmacologic activity. In addition, the street drug may be contaminated with piperidinocyclohexane carbonitrile (PCC), which can cause cyanide poisoning (see [Chapter 331](#)).

PCP shows saturable, high-affinity binding to specific receptor sites in brain tissue, such as opioid sigma receptors.¹¹ PCP is an *N*-methyl-D-aspartate (NMDA) receptor antagonist similar to ketamine. These receptors, usually stimulated by glutamate, are the main excitatory neurotransmitters in the central nervous system (CNS). PCP antagonism at the NMDA receptor may be responsible for the cataleptic state seen with use of this drug. Adrenergic, cholinergic, and serotonergic agonist or antagonist effects occur at concentrations 100- to 1,000-fold higher than are necessary to produce maximal neurologic or behavioral toxicity. Phencyclidine-induced psychosis is thought to resemble schizophrenia: Decreased glutaminergic neurotransmission by PCP results in a decrease of gamma-aminobutyric acid release from the nucleus accumbens, striatum, and hippocampus, which, in turn, may result in inhibition of tonic release of dopamine from the nucleus accumbens and striatum.¹⁹

PCP is well absorbed after oral or mucosal administration and inhalation. The onset of effects is rapid (minutes). Termination initially results from redistribution (half-life, about 10 to 15 minutes) and later from elimination (half-life, 8 to 12 hours). The main route of drug elimination is hepatic metabolism, with almost no active drug being excreted in the urine. With chronic use, PCP probably equilibrates with a “deep” compartment, which includes the fatty tissue of the CNS, leading to detectable levels in many tissues days after the last dose.³ PCP has also been experimentally detected in hair root clippings as early as 6 hours following its administration.⁷

The most profound changes observed with PCP are psychological. Doses of about 0.1 mg/kg (5 to 10 mg total dose) consistently cause disorganized thinking, drowsiness, apathy, psychomotor retardation, perceptual distortions, disorientation, and dreamlike experiences.¹ Hostility, paranoia, and stereotyped behavior are common. True hallucinations have not been reported. Other effects include diplopia, nystagmus, nausea, vomiting, increased muscle tone, hyperreflexia, and ataxia. Larger doses cause progressively more obtundation until seizures begin in the 50-mg range. An intravenous dose of 0.25 mg/kg produces optimal surgical anesthesia. Although delirium usually resolves over hours to days, psychotic behavior may occur over the next few weeks, most commonly manifested by intermittent paranoid delusions and anxiety.^{2,9,16} Chronic PCP use may lead to long-term behavioral changes.^{1,18}

Death from PCP alone is unusual, with fewer than 30 deaths reported. With vigorous supportive care, patients have survived ingestions of gram quantities, but tissue levels from coroners' cases suggest that such massive ingestions are usually rapidly fatal. Most PCP deaths are due to behavioral effects leading to automobile accidents, lethal self-injury, and drowning. Death may also be due to complications of the intoxication. Status epilepticus, aspiration pneumonia, rhabdomyolysis and renal failure, hyperthermia with massive hepatic necrosis, primary respiratory arrest, or hypertensive intracerebral hemorrhage have all resulted in the demise of patients following poisoning.

Naloxone does not bind to either the PCP receptor site or the sigma receptor site, and no specific receptor antagonists for PCP have been identified.^{8,11} Experimental monoclonal Fab antibodies have been developed against PCP. These have been used *in vivo* in animal models with good success but have not been used in humans to date.⁷ Although no withdrawal syndrome is apparent, PCP is avidly self-administered by rhesus monkeys, and a two- to fourfold tolerance appears to develop in both monkeys and rats.¹

CLINICAL PRESENTATION

The most striking manifestations of PCP intoxication are behavioral, ranging from agitation and belligerence to coma and seizures. Intoxication may occur in three stages. Mild intoxication, the first and most common stage of presentation, is manifested primarily by lethargy, bizarre or violent behavior, agitation, and euphoria. The second stage is characterized by stupor and coma with intact deep pain responses. Finally, patients do not respond to deep pain stimuli.¹² Other major symptom patterns may include a catatonic syndrome, toxic psychosis, or an acute brain syndrome.⁹ Nystagmus (including rotatory and vertical forms), ataxia, hypertension, increased muscle tone (including twitching, tremors, facial grimacing, localized dystonias, and hyperreflexia), diaphoresis, sialorrhea, and hyperthermia may be noted on physical examination.

Variability is the most striking characteristic of PCP intoxication. The inhaled dose is usually small and limits the drug's effects. Signs and symptoms resolve over 4 to 6 hours. Ingestion often results in a larger exposure and produces more severe and prolonged symptoms. A patient may present with a minor syndrome, such as bizarre behavior, fairly early after an ingestion, and progress to coma rapidly in the emergency department.

Medical complications and traumatic injuries are responsible for most of the morbidity and mortality in hospitalized patients. Rhabdomyolysis is common, particularly in restrained patients.¹⁰ In most cases of myoglobinuric renal failure, if urine flow is maintained, complete recovery can be expected.^{4,14} Aspiration pneumonia is the next most common complication. Lactic acidosis and profound hyperthermia may result from muscular hyperactivity. Fatal intracerebral hemorrhage has been reported.⁵ Prolonged psychosis for 3 weeks, with persistently elevated serum PCP levels, has been observed in a patient who swallowed a plastic bag containing PCP. Symptoms resolved when the bag was passed.²⁰ PCP-intoxicated patients may sustain severe injuries without awareness of pain.^{2,10}

The diagnosis of PCP intoxication is supported by the detection of PCP in the urine. Toxicologic screening for drugs of abuse will not detect PCP unless it is specifically included in the drug panel. Thin-layer and gas chromatography or mass spectroscopy do not reliably detect PCP. A specific assay, such as gas-liquid chromatography, high-performance liquid chromatography, EMIT (enzyme-multiplied immunoassay technique), or radioimmunoassay, must be requested.

DIFFERENTIAL DIAGNOSIS

PCP intoxication should be considered in any patient who presents with an altered mental state, particularly the young patient with acute onset of bizarre behavior or psychosis, or apparent intoxication without evidence of alcohol. Diagnostic clues include irritability and hostility, nystagmus, hypertension, sweating, hypersalivation, fever, stiffness, and dystonias. The constellation of fluctuating mental status, dystonias, nystagmus, and diaphoresis is quite suspicious, as is the combination of coma and rigidity without profound respiratory depression. PCP intoxication should also be considered in trauma patients with prolonged coma, unusual rigidity, hypertension, hyperthermia, or seizures. In patients with coma or seizures, structural neurologic causes must be considered, particularly because hypertension from

PCP can lead to intracranial hemorrhage. Localized dystonias may be seen with PCP intoxication.

Patients with the neuroleptic malignant syndrome have autonomic instability rather than sustained hypertension, and the limbs show “lead pipe” rigidity rather than diffuse hypertonia. Poisoning by sedative–hypnotics (which cause nystagmus but also hypotonia and hypotension), tricyclics (which can cause anticholinergic effects and electrocardiographic abnormalities), and narcotics (characterized by pinpoint pupils and respiratory depression) should be considered in the differential diagnosis. The agitated, paranoid state of amphetamine intoxication can mimic PCP intoxication, but muscle rigidity, nystagmus, and sialorrhea are seen only with PCP. Encephalitis, meningitis, and cranial trauma should also be considered. Occasionally, alcohol or sedative–hypnotic withdrawal may be mistaken for PCP intoxication. A history of recent abstinence, continuous resting tremors, visual hallucinations, and lack of dystonias points to a withdrawal syndrome.

EMERGENCY DEPARTMENT EVALUATION

The history should be obtained from sources other than the patient, when necessary. A general physical examination and mental status examination should be performed, with a search for focal neurologic findings as well as evidence of trauma, aspiration pneumonia, and other complications.

Urinalysis (including myoglobin); measurement of electrolyte, glucose, and creatine phosphokinase levels; and renal function studies should be done. If coma, hyperthermia, or rhabdomyolysis is present, additional workup should include arterial blood gas analysis, complete blood count, coagulation profile, liver function studies, and measurement of calcium, magnesium, and phosphorus levels. Urine drug screening is unlikely to influence acute medical management of patients with PCP intoxication but may help with the subsequent psychiatric management.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment of PCP intoxication consists of behavior control and standard measures for medical complications and supportive care for traumatic injuries. Activated charcoal should be considered for gut decontamination if patients present within 4 to 6 hours of ingestion and are symptomatic. Care should be taken when attempting to administer charcoal with undue force to aggressive or combative patients. Complications such as charcoal aspiration and esophageal perforation may result from forceful attempts at gastric tube placement. Obtunded and combative patients should have activated charcoal instilled by a gastric tube once the airway is secured and appropriate sedation and neuromuscular paralysis have been achieved.

Behavioral control is best achieved with parenteral haloperidol (5 to 10 mg intramuscularly or intravenously every 20 to 60 minutes; up to 30 mg in the first hour).⁶ Chlorpromazine (25 to 50 mg intramuscularly every 30 to 60 minutes, up to 300 mg) is also effective; it is less likely to cause dystonias and more likely to result in hypotension. Oral diazepam has been used successfully for agitation associated with mild intoxications. Intravenous diazepam or midazolam may be effective in calming obtunded patients who are struggling against their restraints.^{2,10}

Neuromuscular paralysis may be needed to control neuromuscular hyperactivity in severe cases. Minimizing stimulation is likely to be more effective than attempting to “talk down” an agitated or psychotic patient. Although physical restraints may be needed to control violent behavior until pharmacologic therapy takes effect, they clearly increase the risk of rhabdomyolysis and should be removed at the earliest possible instance.

Rhabdomyolysis should be treated with adequate intravenous volume replacement, careful attention to electrolyte balance, and monitoring of urine output. Severe hyperthermia should be treated with physical cooling measures, sedation, and neuromuscular paralysis, if necessary.

Hypertension usually responds to sedation with antipsychotic agents or benzodiazepines. If diastolic pressure stays above 115 mm Hg or if the patient is symptomatic or has known coronary or cerebrovascular disease, specific treatment is indicated. Chlorpromazine may be useful because of its alpha-blocking effects.⁹ Persistent hypertension may rarely require treatment with vasodilators (e.g., nitroprusside or hydralazine).

Urinary acidification has not been shown to be of clinical value. It is potentially harmful and is *not* recommended. Although PCP is a weak base, and urinary clearance increases dramatically when the urine pH is lowered from 7.5 to 5.0, urinary acidification has only a minimal effect on overall drug elimination, because PCP is metabolized primarily by the liver, with little active drug excreted in the urine.^{13,15} Further, urinary acidification may increase the renal toxicity of myoglobin (from rhabdomyolysis) and complicate fluid and electrolyte management. Hemodialysis and hemoperfusion are ineffective in removing significant amounts of PCP because of its high volume of distribution, protein binding, and hepatic clearance.

DISPOSITION

Patients with coma, delirium, catatonia, violent behavior, major trauma, hyperthermia (temperature greater than 38.5°C), aspiration pneumonia, sustained hypertension (greater than 200/115 mm Hg), or significant rhabdomyolysis should be hospitalized. Most will require admission to an intensive care unit. Other patients should be observed for at least 1 hour after all symptoms (except nystagmus) have resolved.

Patients with persistent behavior problems who do not require restraints and have no medical complications should be referred to a psychiatrist. All discharged patients should have observation by friends or family, with clear instructions to seek medical assistance if behavior problems recur.

COMMON PITFALLS

- Failure to consider the diagnosis of PCP intoxication, particularly in young patients with agitation, psychosis, or trauma
- Failure to evaluate and treat patients for medical complications (rhabdomyolysis, aspiration pneumonia, hyperthermia)
- Failure to appreciate that PCP-intoxicated patients may have major trauma without apparent pain
- Failure to appreciate that PCP is not detected by commonly used toxicology screening tests and that a specific assay must be requested
- Premature discharge from the emergency department after a brief but transient period of mental clarity
- Acidifying the urine in an attempt to enhance PCP elimination

CHAPTER 364

Phenytoin Poisoning

Thomas E. Kearney

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Phenytoin, formerly called diphenylhydantoin, is an anticonvulsant belonging to the chemical class known as hydantoin, which also includes mephenytoin and ethotoin. It is effective for a variety of seizure disorders, including generalized tonic-clonic, partial-complex, and other focal seizures. It has also been used in the management of trigeminal neuralgia and toxin-induced seizures. It is used as well as a type IB antiarrhythmic, especially for digitalis- and tricyclic antidepressant-induced conduction defects and ventricular dysrhythmias.

Phenytoin, a weak acid with a pK_a of 8.5, is readily soluble only in a highly alkaline medium, and therefore requires formulation in a special diluent (propylene glycol) and adjustment of pH with alkali (sodium hydroxide) for parenteral administration. Although this preparation may precipitate if added to other acidic parenteral solutions, it may be added to normal saline solution if properly diluted and used immediately. Intramuscular injection may result in erratic absorption, muscle pain, and necrosis.

A new preparation and prodrug of phenytoin, fosphenytoin (Cerebyx), has a more neutral pH (8.6 to 9.0) and greater water solubility. It is compatible with common intravenous preparations and lacks the cardiotoxic diluent propylene glycol and the high alkalinity responsible for local soft-tissue injuries; additionally, it may be administered intramuscularly.⁵ Because of its higher cost, however, fosphenytoin has not replaced parenteral phenytoin.

Oral preparations categorized according to their dissolution rates include extended-release and prompt-release capsule formulations of sodium salt, chewable tablets, and suspension of the free acid. Phenytoin poisoning commonly results from acute accidental ingestion by children or from suicidal ingestion and even illicit use by adolescents and adults.^{6,10,14,16,18} In addition, therapeutic misadventures and iatrogenic poisonings frequently result from drug-drug or drug-disease interactions that affect its distribution, protein binding, and clearance; excessive dosing, with administration of a daily amount of phenytoin greater than the patient's metabolic capacity for elimination; or improper parenteral administration.^{8,16}

Toxicity may also result from improper mixing of phenytoin suspensions before use and switching between products with different absorption characteristics. Non-dose-related, idiosyncratic, or hypersensitivity-type toxic effects may be associated with its therapeutic use, particularly in patients with neurologic deficits or occult neurologic lesions.¹⁸

As an anticonvulsant, phenytoin is essentially devoid of hypnotic effects at therapeutic levels. It prevents the spread of abnormal neuronal discharges by stabilizing neuronal membranes. This effect is achieved by altering fluxes of sodium, calcium, and potassium ions in neuronal conducting membranes and by reducing the posttetanic potential of synaptic transmission. It may also deplete folate in the central nervous system (CNS), red blood cells, and bone marrow. In addition, phenytoin may have an excitatory effect on Purkinje cell discharge in the cerebellum that, in turn, activates GABA-nergic inhibitory pathways in the cerebral cortex. Phenytoin may, however, produce or unmask focal neurologic deficits in patients with GABA receptor supersensitivity resulting from hypoxic or ischemic insults. Serotonergic and dopaminergic activity may also be enhanced by phenytoin, as evidenced by its precipitation of movement disorders.

Phenytoin's effects on the myocardium parallel those of lidocaine. It inhibits sodium channels, decreases the effective refractory period and automaticity in Purkinje fibers, and has little or no effect on the QRS and action potential duration.

Phenytoin's anticonvulsant and antiarrhythmic effects are usually achieved at plasma levels in the range of 10 to 20 $\mu\text{g}/\text{mL}$. This level can be quickly attained with an intravenous loading dose of 15 to 20 mg/kg of phenytoin or PE (phenytoin equivalent) units of fosphenytoin. Because of potential toxicity from the propylene glycol diluent (cardiac arrhythmias and hypotension), phenytoin should be given no faster than 50 mg/min.¹²

Fosphenytoin, despite its lack of propylene glycol, may be associated with similar cardiovascular toxicity if administered at high infusion rates and doses. Hence, the rate of fosphenytoin administration should not exceed 150 PE units/min in adults (3 mg/kg/min in children). Phenytoin concentrations should not be monitored until conversion of fosphenytoin to phenytoin is complete, 2 hours and 4 hours after intravenous infusion and intramuscular administration, respectively. The maintenance dose of phenytoin is usually 4 to 6 mg/kg/d as single or divided doses. Neonates may require higher loading doses (15 to 20 mg/kg) and maintenance doses (5 to 8 mg/kg/d).⁴

Phenytoin is poorly soluble, and hence sparingly absorbed, in the acid milieu of the stomach. Absorption from the duodenum and lower gastrointestinal (GI) tract is extremely variable and depends on the oral dosage form, gastric emptying time, and bowel motility. Peak serum levels are observed at 2.6 to 8.9 hours after a single dose of extended-release capsule (i.e., Dilantin). After overdose with this formulation, absorption has continued for up to 12 days.⁶ This lengthy absorption period may be due to the formation of a slowly disintegrating mass of capsules (pharmacobezoar) or decreased GI motility.

Phenytoin is metabolized predominantly in the liver. Up to 70% of a given daily dose is converted by parahydroxylation to 5-(*p*-hydroxyphenyl)-5-phenylhydantoin (HPPH), which is then conjugated with glucuronide into a more water-soluble metabolite and excreted renally.¹⁶ About 1% to 5% of phenytoin is excreted unchanged in the urine. Phenytoin is actively secreted into the gut and undergoes enterohepatic recirculation.

The enzyme system responsible for parahydroxylation of phenytoin is "saturable" at plasma levels around 10 $\mu\text{g}/\text{mL}$. Below this level, phenytoin follows first-order elimination kinetics, with an average half-life of 22 hours (range, 7 to 55 hours) in adults. Above this level, it follows zero-order kinetics, resulting in a much longer half-life. Metabolic enzymes are subject to inhibition or induction by other drugs or may be deficient because of inherited genetic traits or liver disease ([Table 364.1](#)).

Pharmacokinetic Effect	Condition or Concomitant Drug Use	Pharmacologic Effect
Decreased protein binding	Acidosis, age increased Uremia Hepatitis Hypoalbuminemia Valproic acid Nonsteroidal antiinflammatory agents	Increased (higher free fraction of circulating phenytoin)
Decreased clearance	Amodarone, chloramphenicol Isoniazid, disulfiram (metabolic inhibitors) Genetic deficiency of liver enzyme system	Increased (accumulation of phenytoin during chronic dosing due to prolonged half-life)
Increased clearance	Phenobarbital Carbamazepine Ethanol (hepatic enzyme inducers) Pregnancy	Decreased (shortened half-life results in less accumulation during chronic dosing)

TABLE 364.1. Factors That Influence Phenytoin Kinetics

Phenytoin has a relatively low volume of distribution (0.6 L/kg in adults) and preferentially distributes to the cerebellum and brainstem.⁷ It is 90% bound to plasma protein, mostly albumin. Decreased protein binding, resulting from competition with protein receptors by endogenous or exogenous substrates or reduced albumin

levels, increases free (pharmacologically active) drug levels as well as the volume of distribution. Because only total serum phenytoin levels are routinely monitored, decreased protein binding results in therapeutic and toxic effects at lower-than-usual serum concentrations (see [Table 364.1](#)).

Toxic effects result from exaggerated pharmacologic activity, folate depletion, altered collagen metabolism, idiosyncratic reactions, and propylene glycol toxicity with parenteral administration. Numerous teratogenic effects (fetal hydantoin syndrome) have also been reported. ³

Acute poisoning may result from single ingestions of 20 mg/kg or more. Death is rare but has been reported in children aged 3 to 7 years with ingestions of 100 to 220 mg/kg.^{10,17} The cause of death is CNS depression with respiratory insufficiency and hypoxia-related sequelae. Survival has been noted after acute ingestion of 249 mg/kg in a 2.5-year-old child, who had a level of 112 µg/mL at 70 hours.¹⁹ Reported cases of adult phenytoin poisoning have demonstrated moderate CNS toxicity with recovery after ingestion of 12 to 25 g, with the highest recorded level of 130 µg/mL at 96 hours after ingestion. ²

CLINICAL PRESENTATION

Because tolerance to phenytoin has not been described, dose- and level-related toxic effects are similar for both acute and chronic overdosage. ⁴ Phenytoin initially affects cerebellar and vestibular function, with cerebral depression occurring later. At serum levels of 20 to 40 µg/mL, signs and symptoms of mild intoxication include dizziness, ataxia, tremors, lethargy, nausea, vomiting, slurred speech, diplopia, blurred vision, normal-to-dilated pupils, and nystagmus (coarse, horizontal, or vertical).⁹ An initial excitatory phase has also been reported. At levels of 40 to 90 µg/mL, confusion, psychosis, hallucinations, and progressively deeper CNS depression with suppression of nystagmus and sluggish ocular and deep tendon reflexes may be noted. ¹⁶ Levels above 90 µg/mL are associated with severe toxicity and manifest by coma with respiratory depression.¹⁵ “Paradoxical intoxication” with increased seizure frequency, dystonias, dyskinesias, choreoathetoid movements, and decerebrate rigidity may be noted in patients with underlying seizure disorders. ^{14,16} In addition, those with focal neurologic lesions may develop contralateral deficits (e.g., hemianopia, hemianesthesia, and hemiparesis). Other etiologies should be considered for seizures that occur in phenytoin-intoxicated patients without preexisting seizure or neurologic disorders. Laboratory abnormalities are limited to hyperglycemia and decreased thyroxine levels. ²⁰ The electroencephalogram characteristically shows slowing of alpha-wave activity. With severe intoxication, brainstem evoked potentials may be absent.

Unless complications due to anoxia or sepsis ensue, recovery is usually complete once the drug is eliminated. Depending on the phenytoin level, elimination may take longer than a week. In rare cases, chronic poisoning has resulted in encephalopathy and cerebellar degeneration with persistent ataxia. ⁷

With chronic use, folate depletion may occur and result in megaloblastic anemia and peripheral neuropathy. In addition, altered collagen metabolism may lead to gingival hyperplasia, hirsutism, and hypertrichosis.

Idiosyncratic or hypersensitivity reactions include fever, rash, eosinophilia, hepatitis, lupus-like syndrome, lymphadenopathy (“pseudolymphoma”), myositis, rhabdomyolysis, nephritis, vasculitis, and hemolytic anemia. ¹⁸

The rapid infusion of propylene glycol (at phenytoin rates above 50 mg/min) may result in bradycardia, hypotension, ventricular fibrillation and asystole, conduction defects, congestive heart failure, and respiratory arrest. ¹² These effects are usually transient and seldom persist for more than 1 hour after the infusion is stopped. The rapid infusion of high doses of fosphenytoin has also resulted in severe cardiovascular toxicity in infants. ¹¹

Phenytoin may induce the “purple glove syndrome” (limb edema, discoloration, and pain) after peripheral intravenous administration. ¹⁵ It can occur hours after infusion, in the absence of clinical signs of extravasation, and can lead to limb ischemia and necrosis from a compartment syndrome.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of phenytoin intoxication includes intoxication with other anticonvulsants, sedative–hypnotics, and CNS depressants; seizure disorders; postictal states; CNS trauma and tumors; and extrapyramidal disorders. Phenytoin poisoning may also mimic ketotic and nonketotic hyperglycemic coma. ¹⁸ Although it has been stated that nystagmus is pathognomonic of phenytoin toxicity, this finding is neither sensitive nor specific. It can be present with therapeutic levels and absent with toxic levels, and may be present in a variety of other conditions and intoxications.

EMERGENCY DEPARTMENT EVALUATION

The history should include the time, amount, and preparation of phenytoin taken; the onset and nature of symptoms; chronic medications; and past and current medical problems. The clinician should also note previous use of phenytoin and preexisting seizure disorders.

The physical examination should focus on vital signs, cardiopulmonary findings, and a detailed neurologic assessment. Serum phenytoin and glucose levels and an electrocardiogram (ECG) should be included in the initial evaluation. Other routine laboratory studies, toxicology screening, and a chest radiograph should be obtained as clinically indicated. Because phenytoin absorption and elimination may be greatly prolonged after overdosage, two (or more) serum levels taken several hours apart, along with serial clinical evaluations, are necessary to assess the degree and progression of toxicity.

Patients with the purple glove syndrome should be evaluated for limb ischemia; intracompartmental pressure measurement may be useful in guiding therapy in those with manifestations of arterial insufficiency.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures should be instituted as necessary. Patients with a preexisting seizure disorder should be placed on seizure preventives because of the possibility of paradoxical seizures during the acute intoxication phase and breakthrough seizures if serum levels drop too low. Although cardiovascular toxicity has not been reported after oral overdose, cardiac monitoring is advisable for patients with severe CNS toxicity as well as during intravenous administration.

In addition to stopping the infusion, it may be necessary to administer crystalloids to patients who develop hypotension during intravenous administration. Dysrhythmias usually resolve spontaneously upon stopping the infusion but can be treated according to advanced cardiac life-support guidelines, if necessary.

Seizures caused by phenytoin toxicity require discontinuation of the drug and treatment instead with another agent, such as diazepam or a barbiturate. Hyperglycemia usually resolves with discontinuation of phenytoin and seldom requires insulin unless the patient has diabetes.

Administration of activated charcoal is the preferred method of GI decontamination. Multiple oral doses of activated charcoal can enhance the elimination of phenytoin after systemic absorption.¹³ Controlled evidence is lacking, however, that multiple-dose therapy shortens the duration of toxicity or improves outcome. For patients taking phenytoin for therapeutic purposes, an extended observation period may be necessary to ensure that phenytoin levels do not become subtherapeutic.

Because of phenytoin's high degree of protein-binding and hepatic elimination, procedures such as forced diuresis with ion trapping, hemodialysis, and peritoneal dialysis have not been beneficial.¹⁹ Although hemoperfusion has resulted in a minimal increase in clearance in one reported case, ¹ patients with phenytoin poisoning usually have a favorable outcome with good supportive care alone. Hence, the risk of hemoperfusion usually outweighs its possible benefit.

Idiosyncratic or hypersensitivity reactions and complications of chronic therapy are treated by drug withdrawal and supportive measures. A vascular surgeon should be consulted for the management of patients with purple glove syndrome who have signs of vascular compromise.

DISPOSITION

Asymptomatic patients who accidentally ingest less than 20 mg/kg of phenytoin, do not have a preexisting neurologic disorder, and are not taking phenytoin chronically can be observed at home and followed by telephone contact. All other patients should be evaluated at a health-care facility.

Nonsuicidal patients with mild-to-moderate toxicity (those who can sit up, feed themselves, and walk with assistance) can be discharged with home observation after documentation of declining drug levels. Suicidal patients, those with severe toxicity or rising drug levels after several measurements, and those without responsible friends or relatives to assist and observe them at home should be admitted. Inpatient level of care (floor vs. intensive care unit) should be determined by the degree and progression of toxicity and underlying medical problems. Any facility that can provide intensive respiratory therapy should be able to manage uncomplicated cases of phenytoin poisoning. Patients who are transferred should be accompanied by personnel trained in advanced life support.

COMMON PITFALLS

- Failure to recognize that nystagmus is of limited value in the diagnosis of phenytoin poisoning
- Failure to consider alterations in protein binding when interpreting phenytoin levels
- Failure to appreciate that phenytoin can exacerbate preexisting neurologic problems
- Failure to consider the risks of using ipecac, flumazenil, and multiple-dose activated charcoal therapy in patients with seizure disorders and phenytoin toxicity
- Failure to appreciate that phenytoin absorption and elimination may be prolonged after overdosage and that serial drug levels should be obtained
- Failure to appreciate that cardiovascular toxicity can occur with high infusion rates and doses of fosphenytoin as well as phenytoin
- Failure to appreciate that patients with uncomplicated phenytoin poisoning do well with supportive care and that extracorporeal drug removal measures are ineffective or unnecessary
- Failure to appreciate that purple glove syndrome may occur hours after peripheral intravenous administration of phenytoin.

[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)
[Appendices](#)
[Potential Ingestion Hazards](#)
[Nontoxic Houseplants](#)
[Plants That May Cause a Dermal Reaction](#)

Exposures to potentially poisonous plants account for about 10% of calls made to poison centers in the United States. Of the over 100,000 exposures that occur annually, most involve accidental ingestions by children, and only a small number are truly life-threatening.¹⁰ Most adult exposures are intentional, but the intent is usually self-treatment rather than self-harm.

There is no single characteristic that differentiates a poisonous plant ([Appendix 365.A](#)) from a nonpoisonous one ([Appendix 365.B](#)). Plants contain a large number of different toxins, which can affect any organ system. Almost any sign or symptom may be seen. There are rarely specific antidotes or treatments; most commonly, symptomatic and supportive care is the only treatment available or necessary.

Increasingly, herbal medications, commercially available without prescription, are promoted and used for a wide variety of illnesses. While most are relatively innocuous when taken in small quantities and for short duration, serious poisoning can occur with excessive dosing and chronic exposure. Severe idiosyncratic reactions have also been reported.

CLINICAL PRESENTATION

The most common symptoms and signs of plant exposure are referable to the skin, gastrointestinal (GI) tract, and the central nervous system (CNS). Dermal exposure can cause skin irritation as a result of mechanical, chemical, or allergic reactions, or a combination of these ([Appendix 365.C](#)).

Cacti are prime examples of plants that cause mechanical damage to the skin. Once the offending thorn, hair, spine, or glochid has been removed, pain resolves. Secondary infection is also possible.

Nettles and *Mucuna* spp. have hairs that penetrate, causing mechanical skin damage, and then release a chemical irritant into the wound to produce a secondary inflammatory reaction. Some *Euphorbia* spp. have spines as well as chemical irritants or allergens (diterpenes).

Euphorbia myrsinites also contains diterpenes (e.g., euphorbin, phorbol), but they are released on the skin rather than into a wound, causing an irritation that resembles branding.⁹ Other plants in the *Euphorbia* genus, such as the pencil tree, snow-on-the-mountain, and crown of thorns, also have similar effects.

Euphorbia spp. also contain toxins that may produce both a chemical and allergic reaction. Poison ivy, poison oak, and other toxicodendrol-containing plants are additional examples. Exposure typically causes an erythematous papulovesicular eruption, often in streaks.

Plants in the parsley family contain psoralens that cause photodermatitis. An erythematous papular rash, sometimes with blisters, may not occur immediately but only after exposure to the sun. This produces unusual distributions (e.g., rash only on the face, hands, or back of forearms). Psoralens are also found in limes, lemons, and celery.

Many types of phytochemicals cause nausea, vomiting, and diarrhea; only the most common are covered here. Examples of GI toxins are colchicine, emetine, and lycorine. Many other unidentified plants and their toxins cause GI irritation. Abdominal cramping is also common. The toxic principles of daphne (daphnetoxin and mezereon) may cause abdominal symptoms that resemble those of acute appendicitis.

Alkaloids are a diverse group of plant toxins that may cause GI irritation, among other symptoms. Examples include amaryllis, hyacinth, and spider lily, all of which contain lycorine.

A variety of glycosides cause gastroenteritis. The mechanism of action and toxic concentration differ by genus. Sample species are aloe and golden shower (*Cassia fistula*), which contain emodin, and Japanese aucuba, which contains aucubin.

Many plants that initially cause GI symptoms have additional systemic effects. Saponins are glycosides of terpenoid aglycones that also have surfactant properties and may lyse red blood cells. They are widely distributed in the plant kingdom, often occur along with other toxins, and are found in blue cohosh (*Caulophyllum thalictroides*), buckeye (*Aesculus glabra*), horse chestnut (*Aesculus hippocastanum*), and ivies (*Hedera* sp.).

Several cardiac glycoside-containing plants are found in the United States ([Table 365.1](#)).¹⁹ Signs and symptoms are similar to those of digitalis overdose (see [Chapter 332](#)) and include CNS dysfunction and cardiotoxicity as well as GI effects.^{6,7} Digoxin radioimmunoassays can be used to detect digitalis glycoside (from *Digitalis purpurea*) and may be able to detect other cardiac glycosides as well. Interpretation of quantitative results for these other glycosides is impossible.

Common (Botanical) Name	Toxin
European spindle tree (<i>Euonymus europaea</i>)	Evomonoside
Fonglove (<i>Digitalis purpurea</i>)	Digitalis
Lily-of-the-valley (<i>Convallaria majalis</i>)	Convallatoxin
Oleander (<i>Nerium oleander</i>)	Oleandrin
Poison bulb (<i>Acokanthera</i> spp.)	Quabain-like
Yellow oleander (<i>Thevetia peruviana</i>)	Thevetin

TABLE 365.1. Cardiac Glycoside-Containing Plants

Oxalates are found in many common house and garden plants. Representatives are anthurium (*Anthurium andreaenum*), dumbcane (*Dieffenbachia* sp.), elephant's ear (*Alocasia* sp.), jack in the pulpit (*Arisaema triphyllum*), philodendron (*Philodendron* sp.), and Virginia creeper (*Parthenocissus tricuspidata*). In addition to gastroenteritis, they may cause a burning sensation in the mouth, throat, lips, and tongue if chewed prior to ingestion. Erythema and edema may be noted on

examination. The severity of symptoms varies considerably, depending on both the species involved and the plant part ingested. Upper airway obstruction may occur in severe cases.

Baneberry, clematis, and pasqueflower contain protoanemonin, which is a skin irritant and vesicant as well as a GI irritant.

Lectins (toxalbumins) are found in black locust (*Abrus precatorius*), castor bean (*Ricinus communis*), European mistletoe (*Viscum* sp.), North American mistletoe (*Phoradendron* sp.), and monkey pistol (*Hura crepitans*). These proteins can cause severe gastroenteritis, with hematemesis, tenesmus, and bloody diarrhea. Cyanosis, convulsions, and circulatory collapse can also occur.¹¹ Onset may be delayed for 2 to 24 hours.

The chronic ingestion of grain contaminated with weed seeds or certain herbal teas and medications (e.g., comfrey, seneca) containing pyrrolizidine alkaloids can cause venoocclusive hepatic disease. Other plants containing these alkaloids include seaside heliotrope (*Heliotropium curassavicum*), *Senecio* species, rattlebox (*Crotalaria* sp.), and viper's vulgare (*Echium* sp.).

Although the toxin is normally excreted within 24 hours, symptoms may not occur for days or weeks, making the diagnosis difficult. It is often made when other causes of hepatitis are ruled out and a history of herbal use is obtained.¹⁰

In addition to causing GI symptoms, plants containing essential or volatile oils, such as camphor (see [Chapter 372](#)), catnip, citrus oils, eucalyptus oil, eugenol, laurel oil, menthol, and pine oil, may produce CNS depression, followed by CNS stimulation and seizures.

Some plants cause CNS depression, and others cause CNS stimulation. CNS depression may be light to severe, depending on the dose, but most accidental ingestions produce mild-to-moderate effects. A wide variety of chemicals are involved, some known and some not yet identified (e.g., holly).

Plants containing solanine cause delayed-onset CNS depression. Representative species include apple of Sodom (*Solanum sodomaeum*), bittersweet (*Solanum dulcamara*), Carolina horse nettle (*Solanum carolinense*), deadly nightshade (*Solanum nigra*), eggplant (*Solanum melongena*), false Jerusalem cherry (*Solanum capsicastrum*), Jerusalem cherry (*Solanum pseudocapsicum*), nipplefruit (*Solanum mammosum*), potato (*Solanum tuberosum*), and star potato vine (*Solanum seaforthianum*).

The isoquinolone alkaloids are well known for their sedative effect.¹⁸ The extent of the depression depends on the type of toxin, the part of the plant, and the amount ingested. Examples are celandine poppy (*Chelidonium majus*), opium poppy (*Papaver somniferum*), and yellow pea (*Thermopsis montana*).

CNS stimulation can include seizures, which may be sudden in onset. It may be caused by a variety of plants whose mechanisms of action are quite different ([Table 365.2](#)). Camphor is discussed in [Chapter 372](#) and strychnine in [Chapter 366](#).

Common (Botanical) Name	Toxin
Camphor	Volatile oils
Fool's parsley (<i>Aethusa cynapium</i>)	Aethusanol
Poison hemlock (<i>Comum maculatum</i>)	Coniine
Strychnine (<i>Strychnos nux vomica</i>)	Strychnine
Water hemlock (<i>Cicuta</i> spp.)	Cicutoxin

TABLE 365.2. Plants Containing CNS Stimulants

Well-known hallucinogenic or perception-altering plants are marijuana and the peyote cactus; less familiar are the morning glory, four o'clock, and nutmeg (see [Chapter 341](#)). Anticholinergic plants, such as jimsonweed and belladonna, also produce hallucinations (see [Chapter 312](#)). The vomiting associated with nutmeg and morning glory prevents common abuse.

The ingestion of cyanogenic glycosides, contained in the seeds or pits of apple (*Malus* sp.), cherry (*Prunus* sp.), cotoneaster (*Cotoneaster* sp.), loquat (*Eriobotrya japonica*), and peach (*Prunus* sp.), can cause cyanide poisoning (see [Chapter 331](#)).

These compounds, when mixed with water and plant enzymes such as emulsin or prunasin, are hydrolyzed and release cyanide. The amount of glycoside is usually small, and the liberation of cyanide is a slow, incomplete process. Although boiling or roasting may detoxify these toxins, it should not be done in a confined area because of the potential release of hydrogen cyanide gas.

Herbal exposure can cause a wide variety of toxic effects, including allergic reactions, cardiovascular and CNS disturbances, skin and GI irritation, hematologic abnormalities, liver damage, renal dysfunction, and offensive odor and taste ([Table 365.3](#)).^{1,2,3} and ^{4,14,15} and ¹⁶ The administration of herbal teas to young children has resulted in water intoxication, with hyponatremia and seizures.¹² Some herbals are contaminated with drugs or heavy metals (e.g., arsenic, lead).^{13,18} Neonatal jaundice has occurred after *Artemisia scoparia* administration.²⁰ Another means by which a plant herbal can cause toxicity is by drug-plant interaction ([Table 365.4](#)).

[Table content is extremely small and illegible in the provided image]

TABLE 365.3. Examples of Herbal Toxicity

TABLE 365.4. Potential Herbal–Drug Interactions

EMERGENCY DEPARTMENT EVALUATION

A history of exposure is critical in alerting the clinician to the possibility of plant or herbal intoxication. Plant and herbal intoxication can cause any number of signs or symptoms, so questions concerning the use of or contact with plants and herbals should be asked when a patient presents with an illness of uncertain cause. Adults should be asked whether they have taken any homeopathic or folk remedies over the past few weeks. In children, even if an ingestion were not observed, questions should be asked about plant availability. Evidence of plant exposure may include plant material on a child, missing parts on a plant in or around the home, or plant material in the stool or vomitus. Any suspect plant (or a sample) should be brought with the patient, if possible, for identification.

Plants and herbals may have multiple common and scientific names. If the patient provides a common name of a plant, the correct identity should be confirmed by a botanic description. This description should include leaf structure, flower shape and color, fruits, and general size and shape. Because few emergency physicians have the expertise to identify plants, groups such as garden clubs, botanic gardens, floral or garden shops, and university agricultural departments may be of value. Poison centers and other sources, such as a toxicology laboratory, may help with plant identification and possible treatment. [3,4,8,10](#)

Depending on the nature of complaints, a complete or focused physical examination may be appropriate. All patients should have a complete set of vital signs. Depending on the history and physical findings, rhythm or electrocardiogram interpretation may be indicated to evaluate for cardiovascular toxicity, and laboratory testing may be necessary for the assessment of fluid and electrolyte, hematologic, and liver or renal function abnormalities. With few exceptions (e.g., digitalis and heavy-metal poisoning), toxicology testing is unlikely to be helpful.

EMERGENCY DEPARTMENT MANAGEMENT

Supportive care and decontamination are the primary treatment modalities. Although rarely necessary, advanced life-support measures should be instituted when appropriate. Supportive therapy includes replacement of volume deficits with intravenous crystalloids and correction of electrolyte abnormalities. Patients with CNS depression may require airway protection and ventilatory support. Seizures and CNS stimulation usually respond to treatment with benzodiazepines. Phenytoin and phenobarbital can be given for refractory seizures. Allergic reactions and hematologic, liver, and renal toxicity are treated with standard measures.

Decontamination varies with the route and nature of the exposure. Dilution with small amounts of clear liquids or milk is usually sufficient for the ingestion of plants that only cause gastroenteritis. Because many plant toxins are large molecules, activated charcoal should be effective and is the preferred method of GI decontamination for recent ingestions of agents with potential systemic toxicity.

Skin and eye exposures are treated with thorough irrigation. Some cactus spines can be removed with tweezers or forceps. Fine spines (glochids) have been removed with tape, facial masks, glue mixtures, and wood pastes applied to the skin and then peeled off. Oily materials, such as the toxicodendrol oils, should be washed thoroughly with soap and water to prevent spread to other parts of the body or to emergency room staff.

Antihistamines for itching and antiinflammatory agents or analgesics for pain may be required for some dermal exposures. Topical antiseptics and tetanus prophylaxis may be useful if there are puncture wounds.

There are few antidotes for plant poisonings, and when an antidote is considered useful, it is generally similar in effectiveness and dosage to a nonplant exposure to the same toxic substance. For example, cardiac glycoside poisoning due to *Digitalis* species may be treated with digoxin-specific Fab fragment antibodies (see [Chapter 332](#)). Anticholinergic plant poisoning may be treated with physostigmine (see [Chapter 312](#)). Patients with cyanogenic glycoside poisoning should be treated with cyanide antidotes (see [Chapter 331](#)).

DISPOSITION

Patients with acute ingestions of a potentially toxic plant should be observed for 4 hours or until symptoms have resolved. Those with irritant and oxalate ingestions may be discharged as soon as their discomfort is under control, they can take fluids orally, and there is no evidence of airway edema. Patients who are symptomatic after ingesting plants containing cardiac glycoside and CNS toxins should be admitted for observation, monitoring, and, if necessary, treatment. The level of care should be dictated by clinical severity. If severe, patients with allergic reactions and hematologic, liver, or renal toxicity may also require admission. Patients with a history of pyrrolizidine alkaloid plant ingestion and those with abnormal laboratory findings require outpatient referral and follow-up.

COMMON PITFALLS

- Failure to appreciate that plant and herbal poisoning can affect virtually any organ system.
- Failure to ask about self-treatment with plants, herbals, and folk and homeopathic remedies, especially when the clinical picture does not suggest a specific diagnosis
- Failure to recognize potential drug–plant interactions
- Failure to obtain information on plant toxicity from textbooks, poison control centers, or a toxicologist
- Failure to appreciate that, as the use of herbals increases, previously unreported toxicity may be encountered
- Failure to appreciate that the data on plant and herbal poisoning found in textbooks is sometimes conflicting, antiquated, or nonexistent and to consult an expert or perform a literature search for additional information

A large number of chemically distinct compounds with varied toxicities are utilized as rodenticides. One system for classifying rodenticides was developed as part of the federal Insecticide, Fungicide, and Rodenticide Act.⁷ This system categorizes rodenticides as high, moderate, or low toxicity based on their 50% lethal dose (LD₅₀) in rats (Table 366.1). Although useful for comparing the potential human toxicity of the different agents, animals may be more or less sensitive to specific agents than are humans.

HIGHLY TOXIC
(LD ₅₀ < 50 mg/kg in rats)
Arsenic
Oral anticoagulants ("superwarfarin" types)
Sodium monofluoroacetate
Strychnine
Thallium
Vacor
Yellow phosphorus
Zinc phosphide
MODERATELY TOXIC
(LD ₅₀ 50–500 mg/kg in rats)
Alpha-naphthylthiourea
Cholecalciferol
LOW TOXICITY
(LD ₅₀ 500–5000 mg/kg in rats)
Norbormide
Red squill
Oral anticoagulants ("non-superwarfarin" types)

Adapted from Goldfrank L, Hovavbaum N, Weisman ES. Rodenticides. *Hoop Physician* 1981;17:87.

TABLE 366.1. Rodenticide Toxicity

A more clinically useful classification of rodenticides is based on the time of onset of symptoms (Table 366.2). The time of symptom onset, with respect to the time of exposure along with the nature of the symptoms, allows for a presumptive diagnosis in patients with exposure to an unknown rodenticide, a not uncommon clinical scenario.

EARLY ONSET
Alpha-naphthylthiourea
Arsenic
Norbormide
Organophosphates
Red squill
Sodium monofluoroacetate
Strychnine
Thallium
Vacor
Yellow phosphorus
Zinc phosphide
LATE ONSET
Oral anticoagulants
Cholecalciferol

TABLE 366.2. Onset of Symptoms in Rodenticide Poisoning

Medically significant, unintentional rodenticide exposures are uncommon. Most occur in children, especially those under 6 years old, and result in minimal or no toxicity.^{14,18} Adults with intentional ingestions, however, often develop significant morbidity and mortality.

CLINICAL PRESENTATION

Patients exposed to rodenticides with a rapid onset of action can be expected to manifest symptoms within 6 hours of ingestion. Those with exposure to rodenticides that have a delayed onset typically manifest symptoms beginning 12 hours or more after ingestion. Because signs and symptoms differ and depend on the particular toxin involved, agents are discussed individually.

Alpha-Naphthylthiourea

Alpha-naphthylthiourea (ANTU) is relatively nontoxic in humans. Its mechanism of action is unknown, but the lung is the principal target organ. Dyspnea, cough, and pleuritic chest pain can occur but are not typically life-threatening. However, patients with large, acute exposures can rapidly develop noncardiogenic pulmonary edema by an unknown mechanism.

Anticoagulants (Oral)

Oral anticoagulants are the most commonly used rodenticides.^{3,8,12} They are either hydroxycoumarin or indandione derivatives. Toxicity results from inhibition of the cyclic regeneration of vitamin K, a cofactor required for the activation of coagulation factors II, VII, IX, and X.¹⁹ Although vitamin K depletion occurs almost immediately, no anticoagulant effect is seen until the activity of at least one clotting factor is diminished to below 25% of normal.⁶ Because factor VII has the shortest half-life among the clotting factors affected ($t_{1/2} = 5$ hours), at least three half-lives (15 hours) are usually required before any toxicity is manifested.

Conventional anticoagulant rodenticides contain low concentrations of active ingredients. For example, a typical warfarin rodenticide may contain 0.025% to 0.05% of the toxin (100 to 200 mg in a pound of bait). These products were designed to kill rodents who ingest this bait daily over a period of several weeks. Because of this low concentration, acute, single, unintentional exposures in humans are unlikely to cause toxicity.

The widespread use of warfarin-containing rodenticides resulted in many rodent populations becoming resistant to their effects. As a result, higher-potency agents—"superwarfarins"—were developed. These agents can produce toxicity for prolonged periods after ingestions of smaller doses. Although children who unintentionally ingest superwarfarins are unlikely to develop toxicity, adults with intentional ingestions or children with repeated ingestions often develop a coagulopathy within 24 or, at the latest, 48 hours.¹⁸ If this goes untreated, bleeding complications may develop. The most common sites of bleeding are the GI and genitourinary tracts.^{3,8,12}

Arsenic

This heavy-metal rodenticide, used more commonly in the past, was a leading cause of rodenticide-related deaths in the 1950s and 1960s. Professional exterminators still have access to this compound. Arsenic causes rapid onset of toxicity by combining and inhibiting sulfhydryl enzymes. Patients with acute ingestions may be distinguished by a garlic odor on their breath and severe vomiting and diarrhea, dehydration, dysrhythmias, and central nervous system (CNS) and cardiovascular depression (see [Chapter 318](#)).

Cholecalciferol

Cholecalciferol is relatively nontoxic in acute exposures, but with large doses, symptoms consistent with hypervitaminosis D (see [Chapter 359](#)) and hypercalcemia might occur. These symptoms include gastrointestinal (GI) complaints such as nausea, vomiting, constipation, and abdominal pains; mental status depression; and rare cardiac dysrhythmias.

Norbormide

Norbormide is relatively nontoxic in humans, but, in rodents, it causes diffuse vasoconstriction and ischemia. Although the mechanism is not entirely understood, rodent smooth muscle has a specific norbormide receptor that, when stimulated, leads to these effects. No human fatalities have been reported from this agent.

Organophosphates and Carbamates

Organophosphate compounds are not sanctioned for use as rodenticides in the United States. However, they can be used as an active ingredient for this purpose by foreign manufacturers. These products have reached the United States and been sold as rodenticides.¹³ Exposure can occur by the oral, dermal, or inhalational routes. Signs and symptoms include salivation, lacrimation, urination, defecation, nausea, vomiting, GI cramping and/or pain, diarrhea, mental status change, seizures, muscle fasciculations, or weakness.^{9,13} (see [Chapter 361](#)).

Red Squill

Red squill is a cardiac glycoside derived from the plant *Urginea maritima*. Its toxicity relates to its ability to block sodium–potassium ATPase similar to digoxin. This toxin is poorly absorbed in humans because of its potent emetic effects. In rodents, however, whose vomiting mechanism is less well developed, the toxin is fairly effective. If large amounts are ingested, a presentation similar to digoxin poisoning may occur; patients may have GI symptoms, cardiac dysrhythmias, and hyperkalemia (see [Chapter 332](#)).

Sodium Monofluoroacetate

Sodium monofluoroacetate (SMFA) is a white, odorless, tasteless, water-soluble salt typically available as a powder. Although toxicity can occur by inhalation, ingestion is the most common route of severe poisoning. Once absorbed, SMFA (and the closely related compound fluoroacetamide) rapidly enters the Krebs cycle, where it is converted to fluorocitric acid, which inhibits the Krebs cycle, blocking aerobic glycolysis. Initial symptoms include nausea and apprehension, followed shortly by severe lactic acidosis, pulmonary edema, coma, hypokalemia, hypocalcemia, seizures, and dysrhythmias. Poor prognosis is associated with hypotension, early onset of acidosis, and increased creatinine levels.²

Strychnine

Strychnine, a natural alkaloid derived from the native Indian tree *Strychnos nux-vomica*, has been used as a rodenticide since the 1600s. It is a potent neurotoxin that acts by competitively inhibiting glycine postsynaptically. Because glycine is the predominant inhibitory neurotransmitter in the spinal cord, its inhibition results in muscular hyperexcitability. The increased motor activity seen in severe cases results from maximal firing of peripheral muscle groups and can cause opisthotonos, facial spasm (risus sardonicus), and decorticate posturing. Patients are often mistakenly described as having generalized "seizures," but the mental status is normal. Prolonged muscle activity can lead to hyperthermia, rhabdomyolysis, lactic acidosis, and death, often from respiratory dysfunction.

Thallium

Thallium is an odorless, tasteless, highly toxic heavy metal. Although it can penetrate intact skin, it is more readily absorbed when ingested. Thallium, like arsenic, binds to and inhibits sulfhydryl-containing enzymes. Unlike arsenic, however, it preferentially affects mitochondria, and many of its clinical effects may be delayed 12 to 24 hours after ingestion. Initially, GI symptoms such as nausea, vomiting, diarrhea, constipation, and abdominal pain predominate. Characteristically, extremely painful paresthesias then develop in the extremities and are unique in their intensity. In severe cases, dysrhythmias occur and can cause death. Respiratory failure has also been described. Survival is characterized by a period of alopecia and neurologic findings such as neuropathies, paresis, ataxia, choreiform movements, and optic nerve atrophy.¹⁶

Vacor

When first introduced, Vacor was thought to have no human toxicity. After numerous cases of severe poisoning occurred, it was withdrawn from the market in 1979. Vacor is selectively toxic to pancreatic beta islet cells, producing a chemically induced form of insulin-dependent diabetes mellitus. The exact mechanism for the islet cell destruction is unclear, but it may be due to Vacor's ability to deplete beta islet cells of nicotinamide adenine dinucleotide.^{5,15} Exposed patients develop rapid loss of glucose control and the onset of severe diabetic ketoacidosis (DKA). Along with DKA, patients often present with abdominal pain from acute pancreatitis, autonomic instability, and peripheral paresthesias.¹⁵ Survivors of Vacor exposure are characterized by brittle insulin-dependent diabetes as well as accelerated microvascular

diabetic disease.⁵

Yellow Phosphorus

Yellow phosphorus has a garlic odor, is soluble in oils, and is usually sold as a paste. It is often mixed with molasses or peanut butter and spread on bread for rodents to eat. Because it resembles food, the risk of unintentional childhood exposure is high. When yellow phosphorus comes into contact with moisture, it often ignites, and dermal exposures can result in second- and third-degree burns. In addition, this toxin is a protoplasmic poison that uncouples oxidative phosphorylation in the GI tract, liver, kidneys, and bone.

The clinical manifestations of acute ingestions occur in three stages.²⁰ Initially, there is a rapid onset of severe GI symptoms, including nausea, vomiting, hematemesis, diarrhea, and abdominal pain. The stool and vomitus often have a garlic odor and a luminescent appearance (“smoking stools”).¹⁷ If death occurs at this stage, it is typically from cardiovascular collapse. The second stage constitutes a relatively asymptomatic phase lasting 2 to 3 days. In the third stage, hepatorenal syndrome develops, as well as CNS symptoms such as altered mental status and coma.

Zinc Phosphide

A dark gray powder with a “rotten fish” odor, zinc phosphide is highly toxic. Although inhalational toxicity has been reported, it is most toxic after ingestion. In the presence of water and stomach acid, zinc phosphide is degraded to zinc and phosphine gas and is accompanied by the rapid development of profuse, black vomitus and abdominal pain. Phosphine gas is then inhaled and absorbed by the lungs, causing noncardiogenic pulmonary edema, liver and renal damage, dysrhythmias, and circulatory collapse.⁴

DIFFERENTIAL DIAGNOSIS

When a patient presents with an unknown rodenticide exposure, the differential diagnosis includes all of the aforementioned entities. The most useful piece of information is the name of the ingested product. A family member should be asked to return home and try to get this information. The actual container or list of active ingredients is preferred over the commercial name, because many commercial names have been used for several products with different active ingredients.

If this information is unavailable, the time of symptom onset (see [Table 366.2](#)) and clinical manifestations may suggest the identity of the offending agent. When symptoms are rapid in onset, cholinergic findings suggest organophosphate poisoning; muscular hyperactivity suggests strychnine; seizures, coma, and metabolic acidosis suggest SMFA; severe GI symptoms suggest arsenic or yellow phosphorus; respiratory manifestations suggest ANTU or zinc phosphide; hyperglycemia suggests Vacor; and GI symptoms with cardiac dysrhythmias suggest red squill.

The odor may also serve as a clue to the diagnosis. Arsenic and yellow phosphorus smell like garlic. Zinc phosphide smells like rotten fish. Patients with Vacor-induced DKA have a ketone odor on their breath.

Lack of symptoms during the first 6 hours after exposure to an unknown rodenticide suggests a nontoxic exposure to a rapidly acting agent or a potentially toxic exposure to a rodenticide with a delayed onset of toxicity (i.e., an oral anticoagulant or thallium). The most common cause of delayed rodenticide poisoning is superwarfarin anticoagulants.

EMERGENCY DEPARTMENT EVALUATION

The approach to the patient with an unknown rodenticide poisoning is detailed in the differential diagnosis section. The same principles hold true for a known rodenticide exposure, but the evaluation is more focused with the knowledge of the pathophysiology of a specific toxin. While the diagnostic evaluation is proceeding, consideration and institution of therapy (discussion follows) must occur simultaneously, as many of these poisons cause rapid and potentially fatal toxicity.

The initial assessment should always address the airway, breathing, and circulation. Although uncommon, respiratory distress may be a problem with the toxins that have pulmonary effects, such as zinc phosphide and ANTU. Strychnine may cause respiratory failure secondary to tonic muscle contractions and inability to ventilate. Toxicity from several of the other rodenticides can evolve rapidly to produce cardiovascular collapse.

Vital signs should be obtained immediately. Hyperthermia may occur with strychnine poisoning, due to increased muscle activity, or from yellow phosphorus, secondary to the uncoupling of oxidative phosphorylation.

Clinical clues from the physical examination include specific odors associated with the different toxins and the quality and amount of emesis or diarrhea. “Smoking,” luminescent stools have been reported with yellow phosphorus poisoning.¹⁷ Signs of bleeding in the GI or genitourinary tract may indicate oral anticoagulant exposure, although these findings would be delayed in onset.

Blood chemistries and a complete blood count are rarely useful in the absence of clinical findings. A low serum bicarbonate concentration might be found in symptomatic patients with SMFA, yellow phosphorus, strychnine, or Vacor exposures. An elevated serum glucose level, especially in association with a metabolic acidosis, would indicate Vacor-induced DKA. A prothrombin time should be considered in patients with anticoagulant ingestions, although shortly after ingestion, it would most likely be normal. In chronic anticoagulant exposures or in patients who present several days after exposure with active bleeding, this test may be diagnostic.

The need for radiographic assessment should be guided by the toxin involved. Exposure to agents that produce pulmonary toxicity (i.e., ANTU, zinc phosphide) mandate a chest x-ray. Abdominal radiography may help detect opacities in the gut in recent ingestions of the heavy-metal toxins (arsenic, thallium, zinc phosphide). If a sample of an unidentified rodenticide is obtained, a radiograph of it may help to determine its heavy-metal content.¹¹

EMERGENCY DEPARTMENT MANAGEMENT

Treatment begins with stabilization of vital signs; advanced life-support measures are instituted, as appropriate. Once the patient is stable, gastric decontamination should be considered to prevent absorption or to increase elimination of the toxin. For the asymptomatic patient who has ingested an unknown rodenticide, activated charcoal is the preferred method. Although not useful for arsenic poisoning, activated charcoal has minimal toxicity and may reduce the severity of most other exposures, as well as potential coingestants. Syrup of ipecac-induced emesis is contraindicated because numerous toxins can cause rapid decompensation. Orogastric lavage may be used in any patient giving a history of recent ingestion (within 2 to 4 hours) of a highly toxic rodenticide. Although little data exist on the efficacy of orogastric lavage, this intervention seems justified given the severe toxicity and lack of effective antidotes for most of the compounds in the highly toxic group. Activated charcoal should also be given.

Management of asymptomatic patients with unknown ingestions involves checking coagulation studies daily for 48 hours to see if anticoagulant toxicity has manifested. Prophylactic treatment of these cases with vitamin K is not recommended in the absence of documented toxicity.

The treatment of symptomatic patients depends on the specific toxin involved.

Anticoagulants (Oral)

Fresh-frozen plasma is given to patients with life-threatening bleeding. Vitamin K should also be given. If coagulopathy exists but the patient does not have significant bleeding, vitamin K alone should be used. Not all vitamin K preparations are effective; phytonadione (AquaMEPHYTON, vitamin K₁) is recommended for this purpose. The dose needed, as well as the duration of treatment, varies with the type and amount of anticoagulant ingested and the patient's rate of toxin metabolism. Doses of up to 100 mg/d of vitamin K₁ for as long as 10 months have been necessary for superwarfarin poisoning.¹⁰

Alpha-Naphthylthiourea

There is no specific antidotal therapy for this toxin. Treatment involves supportive care.

Arsenic

Management includes supportive care and chelation therapy (see [Chapter 318](#)).

Norbormide

Minimal toxicity is expected; treatment is supportive if any problems develop.

Organophosphates and Carbamates

Treatment includes atropine and pralidoxime along with supportive measure (see [Chapter 361](#)).

Red Squill

Human toxicity is rare. Treatment of cardiac glycoside toxicity is similar to the management of cardiac glycoside toxicity from other causes (see [Chapter 332](#)).

Sodium Monofluoroacetate

Suggested antidotal treatments for SMFA toxicity include the use of glycerol monoacetate and ethanol, although neither approach has been well studied. Glycerol monoacetate is theorized to work by bypassing the site of blockage in the Krebs cycle; ethanol may inhibit the conversion of SMFA to fluorocitrate and allow for excretion of the nontoxic parent compound.¹ Given the availability and relative safety of ethanol administration and the severe toxicity of SMFA, ethanol administration appears warranted.

Strychnine

Treatment of muscle overactivity, the main problem that leads to the life-threatening complications of this toxin, includes high doses of benzodiazepines and, if necessary, neuromuscular paralysis. If the patient is hyperthermic, aggressive rapid cooling (see [Chapter 387](#)) is the most important intervention.

Thallium

The management of this toxin is controversial. There are limited data on the efficacy of proposed treatments. Prussian blue (ferric ferrocyanide) has been advocated by some investigators and is used routinely in Europe, but it is not approved for use in the United States.¹⁵ Other investigators advocate using potassium diuresis to increase thallium excretion; still others propose using hemodialysis or hemoperfusion. Although it is unclear which form of treatment is beneficial, we recommend repeated doses of activated charcoal and Prussian blue (250 mg/kg/d with a cathartic in divided doses), both of which bind thallium and may enhance its elimination as well as prevent its absorption, as the main therapeutic measures.

Vacor

Patients presenting with DKA are managed like other diabetic patients with this presentation. Niacinamide (nicotinamide) has been shown to be an effective antidote in experimental animals. In these animals, the earlier the antidote was given after exposure, the better the outcome. Niacin is not an effective substitute. The dose of niacinamide is 500 mg initially, followed by 100 to 200 mg every 4 hours for 2 days. If an intravenous formulation is not available, it should be given orally.

Yellow Phosphorus

No specific antidote exists for this toxin. Treatment involves aggressive supportive care.

Zinc Phosphide

Because the toxicity of this compound depends on the conversion to zinc and phosphine gas in an acid and aqueous environment (the stomach), treatment involves measures to prevent this conversion, along with supportive care. Alkalinization of the stomach with oral bicarbonate, antacid, and H₂ antagonists is recommended, although the efficacy of these modalities is unclear.

DISPOSITION

The disposition depends on the toxin involved. For symptomatic patients exposed to any rodenticide in the highly toxic group (see [Table 366.1](#)), hospital admission to a monitored setting is warranted. Because of the relative rarity of these exposures, toxicology and poison center consultations are recommended early in the presentation.

Patients with unintentional exposures who remain asymptomatic after a period of observation (6 hours) can be discharged. For patients exposed to superwarfarin or long-acting oral anticoagulants, follow-up coagulation studies are needed at 24 and 48 hours after ingestion. These studies may be performed in the outpatient setting for patients with unintentional ingestions, if adequate family and social supports are in place. All other patients, including those with intentional ingestions, are best managed as inpatients.

COMMON PITFALLS

- Failure to send relatives, paramedics, or friends to the site of exposure to obtain a sample or container for identifying the ingested agent
- Misidentification of the rodenticide because an identical or similar brand or market name is used for more than one agent
- Failure to consider oral anticoagulant and thallium poisoning in a patient with an unknown rodenticide exposure who remains asymptomatic after a period of observation
- Using the wrong type of vitamin K to treat oral anticoagulant toxicity
- Failure to make a laboratory diagnosis of superwarfarin toxicity before beginning vitamin K treatment
- Failure to consider agents that are no longer marketed but still available in homes in the differential diagnosis

CHAPTER 367 Salicylate Poisoning

Christopher H. Linden

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The incidence of pediatric salicylate poisoning has declined steadily since 1965 due to safety packaging, legislation limiting the number of tablets in bottles of children's aspirin, and decreased use because of the association between aspirin use and Reye syndrome. Similarly, the increased use of nonsalicylate aspirin substitutes has resulted in a reciprocal decrease in the incidence of adult salicylate poisoning. Despite these trends, salicylate intoxication continues to be a major cause of poisoning morbidity and mortality. In addition, patients with salicylate poisoning are still mistreated and misdiagnosed with alarming frequency. ^{1,15}

Aspirin (acetylsalicylic acid) is available in tablet, capsule, and suppository formulations, often in combination with anticholinergic, antihistamine, muscle-relaxing, narcotic, and neuroleptic agents. The recommended dosage of aspirin is 10 to 15 mg/kg every 4 to 6 hours, not to exceed 80 mg/kg/d. Aspirin, a weak acid (pK_a 3.5), is mostly nonionized (absorbable) but poorly soluble at gastric pH. Hence, most absorption occurs in the small intestine.

Aspirin is rapidly hydrolyzed by plasma esterases, with a half-life of about 15 minutes, to its active metabolite salicylic acid. ^{11,14} Salicylic acid (salicylate) is also available from other sources ([Table 367.1](#)). Benorylate and diflunisal are conjugates of salicylic acid. Only benorylate is metabolized to free salicylate, but diflunisal may cause a false-positive salicylate reaction on blood or urine testing.

Formulation (Brand Name)	Percentage of Salicylate
Aspirin 75	37
Bismuth subsalicylate (Pepto-Bismol)	76
Choline and magnesium salicylate (Trilisate)	56
Choline salicylate (Anthropan)	51
Homomenthyl salicylate (sunscreens)	90
Magnesium salicylate (Doan's Magan)	89
Methyl salicylate (oil of wintergreen)	100
Salicylic acid (topical keratolytic)	96
Salicylic acid (Disalacid; Salsalate)	84
Sodium salicylate (Pabalate)	

TABLE 367.1. Nonaspirin Sources of Salicylate

The therapeutic effects of salicylates (analgesic, antiinflammatory, and antipyretic) are due to the inhibition of central and peripheral prostaglandin synthesis. ¹¹ In contrast to aspirin, other salicylates do not inhibit platelet aggregation and are less likely to cause gastrointestinal (GI) bleeding. After a single oral dose, pharmacologic effects begin within 30 minutes, peak in 1 to 2 hours, and last for about 4 hours. Peak blood levels of 10 to 20 mg/dL occur 1 to 2 hours after ingestion. Therapeutic concentrations range from 10 to 30 mg/dL. High therapeutic levels, required for maximal antiinflammatory effects, are seen only with chronic dosing. Salicylic acid is extensively (up to 90%) bound to serum proteins, predominantly albumin. The apparent volume of distribution is small (0.15 L/kg), not only because of high protein binding, but also because, at physiologic pH, salicylic acid (pK_a 3.0) is greater than 99% ionized, and hence poorly diffusible across cell membranes. Salicylate is primarily eliminated by hepatic metabolism to inactive metabolites with a half-life of 2 to 3 hours ([Table 367.2](#)). Metabolites are excreted unchanged or after further metabolism, in the urine.

Pathway	Product(s)	Percentage
Conjugation with glycine	Salicylic acid	75*
Conjugation with glucuronic acid	Salicyl phenolic glucuronide	10*
	Salicyl acyl glucuronide	5
Hydroxylation	Genisic acid	<1
Urinary excretion	Salicylic acid	10

*Saturable pathways

TABLE 367.2. Elimination of a Single Dose of Salicylic Acid

Salicylate kinetics differ markedly after the ingestion of multiple therapeutic doses or a single large overdose. ^{11,14,17} After an overdose, gastric emptying is slowed and salicylate tablets may form concretions, resulting in delayed and prolonged absorption. This is particularly true of enteric-coated and sustained-release formulations. As serum levels increase, protein binding decreases (to 50% or less) and both free salicylate concentrations and the volume of distribution increase to more than 0.35 L/kg. In the presence of acidemia, as occurs in poisoning, the fraction of nonionized (diffusible) salicylate also increases, leading to further tissue distribution. Because of increased distribution, tissue salicylate levels increase proportionately more than serum drug levels.

The two main pathways of hepatic metabolism (see [Table 367.2](#)) become saturated when salicylate levels reach or exceed the high therapeutic range and elimination changes from first order (i.e., proportional to the level) to zero order (i.e., constant), as described by the Michaelis-Menton equation. Hence, with chronic dosing, the salicylate "half-life" increases to 6 to 12 hours, and a small increase in dose results in a much (proportionately) greater increase in serum and tissue salicylate levels, with the potential for chronic intoxication. For the same reason, the salicylate "half-life" may increase to 20 to 40 hours after a large acute overdose.

When hepatic metabolism becomes saturated, urinary excretion becomes the major route of salicylate elimination. ^{11,14,17} The amount of salicylate excreted depends on the balance among glomerular filtration of nonionized salicylate, active proximal tubular secretion of ionized salicylate (by the organic anion active membrane transport system), and passive distal tubular reabsorption of nonionized drug. Increasing urine flow increases glomerular filtration and tubular secretion and decreases reabsorption. Raising the urine pH decreases reabsorption by way of ion trapping (conversion of urinary salicylate to the ionized, nondiffusible form). These mechanisms are the rationale for alkaline diuresis in the treatment of salicylate poisoning. Raising the serum pH also increases the ionized fraction and limits tissue distribution. With such therapy, the renal elimination of salicylate can be increased by a factor of 20 or more. Conversely, low urine output and pH, as may occur with illnesses associated with fever, dehydration, and aciduria, decrease salicylate excretion and predispose the patient using salicylates to toxicity. Similar conditions, which develop as a result of salicylate poisoning itself (discussion follows), may lead to increased severity and duration of toxicity.

The mechanisms underlying salicylate poisoning are complex.^{3,8,17,18} When salicylate concentrations exceed therapeutic levels, direct stimulation of the medullary chemoreceptor trigger zone and respiratory center causes nausea and vomiting, and hyperventilation, respectively. Increased carbon dioxide production may also contribute to respiratory stimulation. These effects result in dehydration, not only from GI and insensible fluid losses, but also from diuresis caused by the excretion of bicarbonate in response to alkalemia. Because sodium and potassium are excreted with bicarbonate (in exchange for hydrogen ion reabsorption), there is concomitant depletion of these electrolytes. Alkalosis may also cause functional hypocalcemia (decreased ionized calcium) with cardiac irritability, tetany, and seizures.

As toxicity progresses, the accumulation of intracellular salicylate causes uncoupling of mitochondrial oxidative phosphorylation, inhibition of Krebs cycle enzymes (aminotransferases and dehydrogenases) and amino acid metabolism, and stimulation of gluconeogenesis, glycolysis, and lipid metabolism. These derangements result in increased but ineffective metabolism, with increased glucose, lipid, and oxygen consumption and increased amino acid, carbon dioxide, glucose, ketoacid (acetacetic and beta-hydroxybutyric), and lactic and pyruvic acid production. The accumulation of these organic acids, with a small additional contribution from salicylic acid and its metabolites, leads to an increased anion gap metabolic acidosis.^{2,18} The associated diaphoresis, fever, and osmotic diuresis (due to the renal excretion of organic acids) cause further electrolyte and fluid losses and aciduria.

When high salicylate levels are sustained, progressive metabolic derangements and increasing levels of organic acids may cause increased pulmonary capillary permeability, central nervous system (CNS) and respiratory depression, cerebral and pulmonary edema, cardiovascular collapse, and acute renal failure (acute tubular necrosis).

Acute salicylate poisoning may result from a single ingestion of more than 150 mg/kg of aspirin. Ingestions of 150 to 300 mg/kg may cause mild toxicity, those of 300 to 500 mg/kg may cause moderate toxicity, and those of more than 500 mg/kg may result in severe or fatal poisoning.^{3,18} Salicylate levels may be quite high during the first 6 to 18 hours after an acute overdose without significant clinical or laboratory evidence of toxicity. Conversely, minimally elevated or even “therapeutic” salicylate levels may be seen with severe poisoning after chronic overdose or late in the course of an acute overdose. Hence, the severity of poisoning is defined by clinical and metabolic abnormalities, not by the salicylate level. Decisions regarding management should be based on direct assessments of severity rather than the widely publicized salicylate (Done) nomogram. This nomogram, which attempted to define severity with a timed salicylate level following acute overdose, was never useful for chronic poisoning and sustained-release aspirin overdose, and it has subsequently been shown to have poor predictive value in acute overdoses.⁷

Salicylate poisoning may also result from the topical (skin or gum) application of methyl salicylate or salicylic acid.^{3,17} It may occur in breast-fed infants whose mothers chronically take salicylates and in the fetuses or neonates of mothers who ingested salicylates. The ingestion of salicylic acid preparations (e.g., Compound W) may cause corrosive injury to the GI tract in addition to salicylate poisoning.

CLINICAL PRESENTATION

Vomiting may occur shortly after ingestion as a consequence of direct gastric irritation. The early (postabsorption) phase of salicylate poisoning, which develops 3 to 8 hours after acute overdose (at any time after chronic overdose), is characterized by mild dehydration, respiratory alkalosis, and alkaline urine ([Table 367.3](#)). Signs and symptoms are mild and include nausea, vomiting, abdominal pain, headache, tinnitus (may occur at therapeutic levels), obvious tachypnea or hyperpnea (may be subtle), ataxia, dizziness, agitation, and lethargy. Mild increases or decreases in serum glucose, potassium, and sodium levels may be noted. Blood urea nitrogen (BUN), creatinine, sodium, and potassium levels may remain normal, however, despite total body fluid and electrolyte deficits.^{3,8,17,18,19} and ²⁰

Stage/Severity	Plasma pH	Urine pH	Intravenous Solution	NaCl (mEq/L)	Potassium (mEq/L)
Early/mild	>7.4	>6	D ₅ W	50	0
Intermediate/moderate	>7.4	<6	D ₅ 1/2NS	100	40
Late/severe	<7.4	<6	D ₅ W	150	60-80

*Added to intravenous solution.

TABLE 367.3. Stages and Treatment of Salicylate Poisoning

Moderate poisoning, which usually occurs 12 to 24 hours after an acute overdose, is characterized by an increased anion gap metabolic acidosis with respiratory alkalosis, alkalemia, moderate-to-severe dehydration, and “paradoxical” aciduria (see [Table 367.3](#)). GI and neurologic symptoms worsen. Fever, asterixis, diaphoresis, deafness, pallor, confusion, slurred speech, disorientation, hallucinations, tachycardia, tachypnea, and mild or orthostatic hypotension may be present. Leukocytosis, thrombocytopenia, increased or decreased glucose and sodium levels, hypokalemia, and increased BUN, creatinine, ketone, and lactate levels may be seen on laboratory evaluation.

Severe or late salicylate poisoning usually develops 24 or more hours after an acute overdose and is characterized by severe dehydration, metabolic acidosis, acidemia, and aciduria (see [Table 367.3](#)).^{5,19} Respiratory acidosis and hypoxia also may be present in a few patients. Findings include coma, seizures, papilledema, respiratory depression, hypothermia or hyperthermia, hypotension, pulmonary edema, congestive heart failure, tachycardia, dysrhythmias, and oliguria. The laboratory abnormalities seen with moderate intoxication become more pronounced. The chest radiograph may show pulmonary edema with a normal-size heart, and a computed tomography (CT) scan of the head may reveal cerebral edema and hemorrhage. Electrocardiographic (ECG) abnormalities, other than sinus tachycardia, reflect metabolic abnormalities or the effects of coingested drugs.

GI bleeding, hepatic toxicity, pancreatitis, proteinuria, abnormal urinary sediment, an increased prothrombin time, and a low serum uric acid level (due to salicylate's uricosuric effect) may be seen with therapeutic as well as toxic salicylate levels. Clinically significant bleeding, GI perforation, blindness, and inappropriate antidiuretic hormone secretion are rare complications of acute poisoning. Chronic salicylate intoxication, especially in elderly patients, tends to be more severe than acute poisoning, and children tend to progress to moderate toxicity faster than adults.^{1,8,9} Adults appear to be more prone to pulmonary complications. Although the overall mortality rate is much less than 1%, it may be as high as 15% in patients with severe poisoning.^{17,18}

DIFFERENTIAL DIAGNOSIS

Occult salicylate poisoning should be considered in any patient with an unexplained acid–base disturbance.^{1,8,15} Although an increased anion gap metabolic acidosis is said to be a characteristic feature, it occurs as the sole acid–base abnormality in only about 20% of patients with salicylate poisoning.⁸ Metabolic acidosis with respiratory alkalosis is actually the most common finding (in more than 50% of patients), and respiratory alkalosis alone is seen in another 20% to 25%. Other poisons that cause an anion gap metabolic acidosis include methanol and ethylene glycol, but lactic acidosis may occur in any poisoning that is complicated by hypoxia, hypertension, or seizures. A persistently normal metabolic workup (arterial blood gas analysis and determination of serum levels of electrolytes) in a patient who remains symptomatic many hours after an unknown overdose rules out salicylate poisoning.

Up to 60% of patients with chronic salicylate poisoning are initially (sometimes fatally) undiagnosed.^{1,8,15} These patients are often elderly, are chronically taking nonaspirin salicylates, and have serious underlying medical problems. Unless specifically questioned, the use of salicylates may not be discovered, and signs and symptoms of salicylate poisoning may be attributed to other illnesses (e.g., anxiety, cardiopulmonary disease, cerebrovascular disease, chronic obstructive pulmonary disease, dementia, encephalopathy, alcohol ketoacidosis and withdrawal, viral meningitis, pancreatitis, Reye syndrome, psychiatric disorders, and sepsis).^{1,2,13,15}

Not infrequently patients give a history of aspirin ingestion or overdose when they actually (unknowingly) have taken acetaminophen, or vice versa. Unless the agent or product ingested (or its container) is available for positive identification or the history can be confirmed by a witness, a serum level of both drugs should be obtained.

In children, chronic salicylate poisoning may be indistinguishable from Reye syndrome on the basis of signs, symptoms, and routine laboratory evaluation. Low (subtherapeutic) cerebrospinal fluid salicylate levels and a liver biopsy showing fatty infiltration rule out salicylate intoxication and confirm Reye syndrome.

EMERGENCY DEPARTMENT EVALUATION

The history should include the time of ingestion, the amount ingested, and the specific product ingested in cases of acute overdose. In all cases of intentional ingestion and in those with an unclear history, a serum salicylate level should be obtained. If the patient is symptomatic or the salicylate level is elevated, arterial blood gas analysis; serum levels of electrolytes, glucose, BUN, and creatinine; and a urinalysis should be obtained. If acid–base abnormalities are present, further evaluation should include serum calcium, magnesium, and ketone levels; liver function tests; complete blood count; prothrombin time; partial thromboplastin time; ECG; and a chest radiograph. A toxicology screen may be useful to rule out the coingestion of other detectable poisons.

The physical examination should focus on vital signs, neurologic function, and cardiorespiratory findings. Accurate measurement of the respiratory rate and temperature is important but is often done in cursory fashion. The fundi should be examined for papilledema, and any vomitus and stool should be tested for occult blood. The presence of peritoneal signs necessitates evaluation for surgical complications. Salicylates, especially magnesium and bismuth (Pepto-Bismol) salts and enteric-coated or sustained-release formulations, may be evident on abdominal radiographs.

Because of delayed absorption, serial salicylate levels should be obtained until levels are noted to be declining. A single nontoxic salicylate level soon after ingestion does not rule out a significant overdose, particularly with ingestions of enteric-coated or sustained-release formulations.

If levels continue to rise, repeated metabolic evaluation is necessary.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures are instituted as necessary. Patients with altered mental states should receive intravenous dextrose (or have an immediate fingerstick blood sugar check), naloxone, and thiamine in standard doses. Glucose administration is essential in salicylate poisoning because CNS hypoglycemia may occur with a normal serum glucose concentration.^{3,19} Because nearly all patients with salicylate poisoning are volume-depleted, treatment should begin with intravenous crystalloid administration (e.g., 20 mL/kg of dextrose 5% in 0.45%, or 0.9% sodium chloride with or without sodium bicarbonate, 25 mEq/L; and potassium, 10 to 20 mEq/L, over the first hour or two), provided there is no evidence of cerebral or pulmonary edema. In patients with hypernatremia, a hypotonic solution is used.

Because the immediate goal is to reverse dehydration and establish a good flow of urine, bladder catheterization is usually necessary for monitoring purposes. If hypotension or oliguria is present or persists, central venous or pulmonary artery catheterization is recommended. Patients with elevated right-sided pressures should be treated with dopamine. Furosemide may also be used in an attempt to reverse oliguric renal failure unresponsive to volume replacement.

Seizures should be treated initially with standard agents (glucose, diazepam, phenobarbital, or phenytoin). If there is papilledema or CT scan evidence of cerebral edema, elevation of the head, hyperventilation, and administration of mannitol or furosemide, and dexamethasone should be considered. Diuretics are used cautiously, if at all, in patients with hypovolemia. Pulmonary edema is treated with intubation and positive end-expiratory pressure ventilation. Vitamin K is given to patients with coagulation abnormalities. Those with overt bleeding should also receive fresh-frozen plasma. Underlying metabolic derangements are corrected. Insulin is unnecessary for nondiabetics with hyperglycemia and may be dangerous, particularly if there is coexisting hypokalemia. Similarly, hyperkalemia does not usually require specific therapy and usually resolves with fluid administration and correction of acidosis. Because acetaminophen is unlikely to be effective, physical measures (e.g., cooling blankets and sponging) are preferred for the treatment of fever. Although tetany resulting from respiratory alkalosis may respond to paper-bag breathing, the slow intravenous administration of 10% calcium chloride or gluconate (0.1 to 0.2 mL/kg) is effective, lasts longer, and can safely be given to patients with normal serum calcium levels.

GI decontamination should be done in patients with accidental ingestions of more than 150 mg/kg and in all patients with intentional overdoses. Charcoal alone is superior to ipecac followed by charcoal in simulated overdose patients⁶ and is the preferred method in those with mild-to-moderate overdoses. Because charcoal binds neutral agents better than ionized ones, salicylate may desorb from charcoal in the alkaline milieu of the small intestine.⁵ Therefore, at least two doses of charcoal should be given. Even in patients with spontaneous vomiting, large amounts of salicylate have been recovered as long as 18 hours after ingestion, hence the adage, “It’s never too late to aspirate [the stomach] with salicylate.” Optimal decontamination in patients with large overdoses may be to give a dose of charcoal before and after gastric lavage.⁴ Whole-bowel irrigation should be considered in patients with large ingestions of enteric-coated or sustained-release preparations.²⁰ Serial salicylate levels should be obtained to assess the efficacy of GI decontamination. Levels that continue to rise despite such therapy suggest a gastric drug concretion or bezoar formation. Evaluation and treatment by gastric endoscopy should be considered if drug levels become markedly elevated or clinical toxicity is severe or progressive.

Salicylate elimination can be enhanced by giving repeated oral doses of activated charcoal,¹⁰ alkaline diuresis,^{3,11,16,17,18,19} and²⁰ and extracorporeal removal.¹² Although data from experimental studies are conflicting, multiple-dose charcoal shortened the salicylate half-life to 2 to 4 hours in patients with salicylate levels as high as 66 mg/dL after acute overdosage. However, in this study, the brand of charcoal used (Medicoal) was an effervescent preparation containing bicarbonate. Oral bicarbonate may have trapped salicylate in the gut (decreased its absorption) or been absorbed and caused concomitant urinary alkalization (enhanced elimination). Until further data become available, multiple-dose charcoal therapy is nevertheless recommended.¹⁰ It can be given to almost all patients but may be less effective in those with chronic poisoning or higher levels. Recent evidence suggest that glycine (or *N*-glycylglycine) administration may prevent glycine depletion and saturation of the salicylic acid pathway (see [Table 367.2](#)) and also enhance the elimination of salicylate. Clinical experience is limited, and this therapy should be considered experimental.

Alkaline diuresis can shorten the salicylate half-life to 6 to 12 hours in acute overdose patients with salicylate levels less than 70 mg/dL.¹⁶ Although urinary alkalization alone was reported to be more effective than either diuresis alone or alkaline diuresis, patients treated by “alkalinization alone” actually received 375 to 500 mL/h over the treatment period.¹⁶ Animal studies have shown that alkalization and diuresis are both important. Alkaline diuresis is likely to be less efficacious in patients with chronic salicylism or very high salicylate levels.

Indications for alkaline diuresis include acid–base abnormalities, the presence of symptoms, and elevated salicylate levels (greater than 30 mg/dL) within 18 hours of an acute overdose. Patients who present more than 18 hours after an acute ingestion or have chronic poisoning may require treatment despite “therapeutic” salicylate levels. Contraindications to alkaline diuresis include cerebral and pulmonary edema, oliguric renal failure, and a serum pH above 7.55. It should be performed with caution in patients with a history of congestive heart failure. Adequate hydration and urine output should be established before initiating alkaline diuresis. The rate of fluid administration and amount of sodium bicarbonate administered should be based on the severity of poisoning (see [Table 367.3](#)). Therapy should be individualized according to laboratory findings. Isotonic solutions of sodium bicarbonate at rates of 2 L/h for at least 3 hours have been recommended.

The goal of alkaline diuresis is a urine pH of 7.5 or more and a brisk (3 to 6 mL/kg/h) urine output. However, even during early (mild) intoxication, when the urine pH is alkaline, low doses of bicarbonate should be given to replace ongoing renal losses. Carbonic anhydrase inhibitors (e.g., acetazolamide) should not be used to alkalize the urine, because they also may cause acidemia, increased ionized drug, and enhanced tissue distribution of salicylate. This may result in increased CNS salicylate levels and clinical deterioration, and increased mortality.²⁰ Because potassium reabsorption occurs at the expense of bicarbonate reabsorption and hydrogen ion excretion, it is often stated that alkalization of the urine is impossible until potassium deficits are corrected. Whether this is true or not is controversial.²⁰ In one study, no correlation was found between serum potassium levels and urinary pH.¹⁶ While correction of hypokalemia is clearly indicated, such therapy should not delay the administration of bicarbonate. Complications of alkaline diuresis include excessive alkalemia, hypokalemia, hypocalcemia, hypernatremia, and fluid overload with cerebral and pulmonary edema, particularly in the elderly and those with severe poisoning. Hence, all patients treated with alkaline diuresis should have cardiac monitoring, frequent vital signs, mental status and cardiorespiratory examinations, laboratory evaluation (arterial blood gas analysis and serum electrolytes), and hourly monitoring of fluid intake, urinary output, and urine pH. If intake should persistently exceed output, diuresis may be

enhanced by giving furosemide.

Hemodialysis is the treatment of choice for patients with severe salicylate poisoning.¹² A reduction in the salicylate half-life to 2 to 3 hours can be achieved. Although hemoperfusion is slightly more effective in removing salicylate, it is technically more difficult and does not correct associated acid–base, fluid, and electrolyte abnormalities. Peritoneal dialysis (with 5% albumin added to compete with serum proteins for salicylate binding) and exchange transfusion are less effective and should be used only if hemodialysis is unavailable, contraindicated, or technically impossible (e.g., in infants or in patients with active or recent bleeding complications).

Indications for hemodialysis include coma, seizures, cerebral or pulmonary edema, renal failure, and clinical deterioration or failure to improve despite intensive noninvasive therapy.^{2,12,15} Although, in acute poisoning, severe toxicity is usually associated with very high salicylate levels (greater than 100 mg/dL), patients with high levels without complications do not necessarily need hemodialysis. Conversely, acute or chronic overdose patients with severe toxicity or underlying cardiopulmonary disease should be treated with hemodialysis even if salicylate levels are not markedly elevated.

DISPOSITION

Patients with mild or absent clinical and laboratory toxicity after acute overdose can often be treated in the emergency department if the peak salicylate level is less than 60 mg/dL. Patients with chronic poisoning, higher levels, underlying medical problems, and moderate or severe toxicity should be admitted to an intensive care unit. A nephrologist should be consulted if poisoning is severe. If hemodialysis is unavailable, patients with severe poisoning or moderate poisoning with very high (or rising) salicylate levels should be transferred to a facility where such treatment is available.

COMMON PITFALLS

- Failure to ask specifically about salicylate ingestion and to obtain a serum salicylate level on patients with unexplained acid–base disturbances, particularly in those patients with altered mental status
- Failure to obtain quantitative levels of both aspirin and acetaminophen in patients whose history cannot be verified by a third party or by examination of the drug or its container
- Failure to obtain serial salicylate levels to rule out delayed absorption and to assess the efficacy of decontamination and elimination therapies
- Failure to appreciate the differences between acute and chronic salicylate poisoning
- Failure to monitor for complications of salicylate poisoning and its treatment
- Failure to recognize the limitations of salicylate levels and the salicylate nomogram and to base treatment on clinical and laboratory findings, not drug levels

Seafood poisoning can result from the ingestion of fish, shellfish, or other marine life that contains toxic substances. Often, these toxins originate from dinoflagellates and are closely related. Other toxins are endogenously produced or result from bacterial action. Dinoflagellates, which form the major component of phytoplankton, are unicellular eukaryotic marine algae of the division Pyrrophyta.

Some dinoflagellates proliferate extensively under certain weather conditions, resulting in the surface discoloration of seawater known as a “red tide” or algae bloom. Other species live below the water, attached to macroalgae, and their growth is not as obviously affected by environmental disturbances. They lie at the bottom of a food chain of which humans may be the ultimate consumers. Dinoflagellate toxins are concentrated in the viscera of filter feeders such as shellfish, herbivorous fish, and crustaceans, often causing them no harm. They are among the most potent natural toxins known.

Ciguatera, paralytic shellfish, tetrodotoxin, and scombroid poisoning are relatively well known. Neurotoxic shellfish, diarrhetic shellfish, hallucinatory fish, clupeotoxic fish, fish roe, palytoxin, domoic acid (mussel) and red whelk poisoning, and Haff disease are less commonly recognized and reported. However, expanding international tourism, the importation of exotic seafood, and the harvesting of seafood from more remote waters, as coastal fishing grounds are exhausted, are likely to increase the frequency of seafood poisoning seen in domestic health facilities.

CIGUATERA

Ciguatera poisoning results from eating tropical or subtropical fish contaminated with toxins produced by dinoflagellates living in coral reef waters. *Gambierdiscus toxicus* and several other species produce toxins that accumulate in fish feeding on algae. The toxins, which appear to be harmless to fish, are passed up the food chain from herbivores to their predators and eventually to humans. Ciguatoxin is a heat-stable, lipid-soluble, highly oxygenated polyether. Several other toxins, including maitotoxin and scaritoxin, have been identified. They are concentrated in the visceral organs of fish, particularly the liver and gonads, and can remain for several years.

Environmental factors such as water temperature, salinity, and light affect the growth of *G. toxicus*. Large-scale environmental disruptions such as storms, earthquakes, underwater dredging, pollution, and global climatic changes are also thought to influence toxic dinoflagellate populations. *G. toxicus* and related species are found in coral reef waters between 35° south and 35° north latitude.

Ciguatera is endemic in Australia and the Caribbean and South Pacific islands; French Polynesia has the highest prevalence.⁹ Outbreaks have been reported worldwide, and over 400 species of fish, mostly reef fish, have been implicated. Barracuda, grouper, red snapper, amberjack, eel, sea bass, and Spanish mackerel are most commonly involved. Fish larger than 2 kg are more likely to be contaminated with significant quantities of toxin.

Ciguatoxin is colorless and tasteless and is not destroyed by cooking or gastric acid. It is detectable in affected fish by mouse biologic assay or immunoassay. Ciguatoxin can be transferred across the placenta and by semen or breast milk. It acts by increasing sodium permeability through neuronal voltage-gated sodium channels, resulting in prolonged refractoriness and decreased conduction velocity.⁵ A similar mechanism is suggested to occur in cardiac tissue. Ciguatoxin also may increase central and peripheral cholinergic activity, but this is probably not clinically significant.

PALYTOXIN

Palytoxin is a thermostable terpenoid toxin produced by zoanthid coral of the genus *Palythoa*. The conditions under which corals become toxic are unknown. Poisoning is most common in the South Pacific after ingestion of fish (mackerels, triggerfish, filefish, butterfly fish) and xanthrid crabs that feed on coral.¹¹ Palytoxin may also be found in dinoflagellates. The livers of fish have a high palytoxin content. Palytoxin binds to the ouabain receptor site on Na⁺/K⁺-ATPase, allowing the influx of sodium and resulting in depolarization of nerves and muscles. Although clinical effects are similar to those seen in ciguatera poisoning, additional toxicity results from vasoconstriction, norepinephrine release, and sustained contraction of skeletal and smooth muscle.¹¹

NEUROTOXIC SHELLFISH POISONING

Neurotoxic shellfish poisoning also results in a ciguatera-like syndrome but is generally less severe. It is caused by brevetoxins from *Ptychodiscus brevis*, a dinoflagellate found off the coast of southeastern North America and western Europe during algae blooms. The toxins are accumulated by bivalve mollusks, predominantly clams and oysters. Brevetoxins A, B, and C are polycyclic ethers that bind to the Na⁺ channel near the binding site for ciguatoxin. They are toxic to some marine life and birds and cause extensive losses in susceptible species. Brevetoxins can be aerosolized by wave action and carried several kilometers inland, resulting in respiratory irritation.

PARALYTIC SHELLFISH POISONING

Paralytic shellfish poisoning results from the ingestion of bivalve and gastropod mollusks (mussels, clams, oysters, scallops, and cockles) and occasionally some univalve mollusks, starfish, crustaceans, and fish. These creatures become toxic when dinoflagellates, especially *Gonyaulax* spp., multiply explosively, causing red tides. Toxic shellfish are commonly found in the cold, temperate waters of North America, the western coast of Europe, and the coastal waters of Japan, but are increasingly reported in warmer climates. Saxitoxin, gonyautoxins (I to IV), and neosaxitoxin have been identified.

The relative proportion of toxins varies by geographic region and the dinoflagellate species and life stage. The toxins do not affect shellfish but are concentrated in viscera and can take several weeks to be eliminated. Seabirds, several fish species, and mammals are susceptible to poisoning. Saxitoxin, a potent, heat-stable,

water-soluble neurotoxin, acts by blockading fast sodium channels in nerve and muscle during depolarization, resulting in a conduction block that principally affects motor neurons and muscle. There is no reliable taste, smell, or color to identify contaminated shellfish. Saxitoxin can be detected in shellfish meat by a mouse bioassay. A level above 80 µg of purified saxitoxin per 100 g of raw shellfish meat is considered toxic.

TETRODOTOXIN

Tetrodotoxin, a heat-stable, water-soluble neurotoxin chemically similar to saxitoxin, is found in the skin and viscera of puffer fish (saltwater and fresh-water varieties), porcupine fish, sunfish, toadfish, the blue-ringed octopus, some species of salamanders, and *Atelopia* frogs. A dinoflagellate or bacterial origin has been suggested, but, at least in some species, tetrodotoxin is endogenously produced. It has been identified in a dinoflagellate (*Alexandrium tamarense*), which also contain saxitoxin. Tetrodotoxin has been isolated from scallops, during a bloom of *A. tamarense*, that were associated with paralytic shellfish poisoning.

Puffer fish, the most common source of tetrodotoxin, is eaten as a delicacy in some Southeast Asian countries. Although tetrodotoxin is concentrated in the fish's skin and internal organs, all parts of the fish may contain it. Like saxitoxin, tetrodotoxin inhibits fast sodium channels during depolarization, but at a separate site. The major effect of tetrodotoxin is to reduce conduction of peripheral motor, sensory, and autonomic nerves. Tetrodotoxin also acts on the medulla, stimulating the chemoreceptor trigger zone and possibly depressing the respiratory and vasomotor centers. In high doses, it may have direct effects on cardiac conduction, vascular smooth muscle, and skeletal muscle. Tetrodotoxin can be detected in fish by a bioassay and in serum or urine by gas chromatography or mass spectrometry.

CLUPEOTOXIN POISONING

Clupeotoxinism is a poorly documented but severe poisoning that is more lethal than other forms of seafood poisoning. It is caused by fish of the order Clupeiformes (herrings, anchovies, and sardines), particularly those caught in summer, offshore of tropical islands after heavy rains or floods. The identity of the toxin, which primarily affects the central nervous system, is unknown. A phytoplankton origin has been postulated. It appears to be thermostable and concentrated in the viscera of fish. Toxicity does not depend on the size of the fish or its freshness.¹⁰

SCOMBROID POISONING

Scombroid poisoning is associated with ingestion of fish of the family Scombroidea (mackerel, skipjack, and tuna) and other fish with dark flesh, such as dolphin fish (mahi mahi), bluefish, and amberjack (yellowtail). The muscles of these fish contain large amounts of free histidine. Fish become toxic when left unrefrigerated (above 20°C), allowing bacteria, particularly *Proteus morgani*, to decarboxylate histidine to histamine. This effect can occur during harvesting, transportation, storage, processing, or preparation for consumption.

Ingested histamine is normally metabolized by the intestinal mucosa and has little systemic effect. Other toxins isolated from contaminated fish, putrescine and cadaverine, both short-chain aliphatic diamines, may facilitate the absorption of ingested histamine or compete for its metabolism by diamine oxidase. Patients taking isoniazid, an inhibitor of diamine oxidase, are more sensitive to scombroid. Nonspecific monoamine oxidase inhibitors also inhibit diamine oxidase. The histamine content of spoiled flesh can vary considerably throughout a fish, being highest near the gut cavity. Individual sensitivity to scombroid also varies considerably; females are suggested to be more susceptible.

Scombroid toxins are heat-stable. Affected fish can appear spoiled and have a peppery or sharp taste, but these findings are not always present.⁶ Symptoms are consistent with the known systemic effects of histamine and resemble IgE-mediated food allergies. The histamine content of dark fish flesh is normally less than 5 mg/100 g of flesh. Toxicity can occur at levels above 20 mg/100 g, although the Food and Drug Administration has set a hazard action level of 50 mg/100 g.

OTHER SEAFOOD TOXINS

Diarrhetic shellfish poisoning is caused by consumption of shellfish, particularly mussels, that have eaten dinoflagellates of *Dinophysis* and *Prorocentrum*. These dinoflagellates are widely distributed but do not usually form noticeable algae blooms. Toxins have been identified as dinophysistoxins (okadaic acid and derivatives), pectenotoxins, and yessotoxins and have predominantly gastrointestinal (GI) effects.

Hallucinatory fish poisoning has been described following the ingestion of reef fish from the South Pacific and the Indian Ocean. Toxins similar to indole compounds from the algae *Microcoleus lyngbyaceus* have been implicated as a source of the poisoning.¹⁸

Several other outbreaks of GI and neurologic poisoning have resulted from the ingestion of various kinds of seafood. The causative toxins have not been clearly identified, but clinical toxicity has features of ciguatera or paralytic shellfish poisoning, or a combination of both.

Outbreaks of GI and neurologic toxicity have occurred on the eastern coast of Canada following the consumption of mussels contaminated by domoic acid produced by *Nitzschia pungens*, a phytoplankton associated with algae blooms.¹⁶ Domoic acid is a heat-stable neuroexcitatory amino acid that is structurally related to glutamic acid but is 40 to 100 times more potent. Neuronal loss in the hippocampus and amygdaloid nucleus is seen in severe poisoning. Domoic acid-producing dinoflagellates have been isolated in other parts of the world but have not yet been related to human poisoning.

Raw carp bile is eaten in rural Asia in the belief that it improves visual acuity and treats hypertension and rheumatism. Five species of carp are known to be poisonous. Fish longer than 1 m or heavier than 3 kg are considered more likely to be toxic. Bile salts are thought to be responsible for toxicity.¹⁵ Fish roe poisoning may result from eating the eggs of numerous species of fresh-water and saltwater fish during the reproductive cycle (spring and early summer). The nature of the toxin is unclear, but it does not appear to be destroyed by cooking.¹² Red whelk (*Neptunea antiqua*) and related species, except the common whelk (*Buccinum undatum*), contain tetramine, a heat-stable neurotoxin found in their salivary glands.⁸ Hypervitaminosis A (see [Chapter 359](#)) may occur following the ingestion of the liver of marine mammals and several species of shark.¹⁰

Haff disease is a neuromyodystrophic disease that occurs after ingestion of carp from the Baltic Sea and lakes in Scandinavia and Russia. The causative toxin is heat-stable and is thought to originate from a species of blue-green algae.¹⁹

Several coelenterates (sea anemones) contain proteinaceous toxins that are poisonous only when eaten raw. Species from Samoa contain heat-stable toxins that produce GI toxicity, cardiovascular collapse, and muscle paralysis. Some echinoderms (sea cucumbers) contain saponins, which can cause GI symptoms. Abalone poisoning results from contamination with pyropheophorbide A, a derivative of algal chlorophyll A, which causes a photosensitization reaction. Outbreaks of poisoning with GI and neurologic toxicity due to unknown toxins have resulted from the ingestion of squid and octopus.

CLINICAL PRESENTATION

Ciguatera

Symptoms and signs of ciguatera poisoning typically occur 6 to 12 hours after ingestion, with a range of 30 minutes to 30 hours. GI and neurologic symptoms predominate, typically beginning with vomiting, diarrhea, and myalgias. These are followed by circumoral and peripheral paresthesias, vertigo, and ataxia.⁹ Patients may present initially with only neurologic symptoms; these may be delayed up to 72 hours after ingestion or may occur without GI symptoms. Hypotension is common and may be due to fluid loss, bradycardia, peripheral vasodilatation, or myocardial depression.¹ Symptoms vary between patients and depend on where the fish was caught and what parts of it were eaten.¹ More severe toxicity, especially hypotension and bradycardia, occurs in patients previously poisoned by ciguatera.

A classic feature of ciguatera poisoning is erroneously described as a paradoxical or reversed temperature perception: Cold objects feel hot, and hot objects feel cold. This feature is probably due to hyperstimulation of pain receptors at temperatures below 25°C, manifest by an intense burning sensation on exposure to cold. Warmth relieves these dysesthesias, and patients can accurately sense temperature changes.⁴

Other common neurologic symptoms include asthenia, paresis, tremors, and pain affecting the joints, head, and abdomen.¹ Paresthesias are often poorly defined and do not conform to dermatomal or peripheral nerve distribution. A sensation of looseness of the teeth is another unusual symptom. Insomnia, neurosis, depression, and

hallucinations may occur. Other features include dyspnea, diaphoresis, salivation, tearing, chills, neck stiffness, pruritus, rashes, and tachycardia. ¹ In pregnant patients, violent fetal movements have been described. Less commonly, transient blindness, convulsions, rhabdomyolysis, or paralysis may occur. Death, although uncommon, may result from severe dehydration or cardiac or respiratory failure.

Symptoms are often exacerbated by the ingestion of nontoxic seafood, nuts, grains, or alcohol and by exercise. Medications containing cyclic ethers, such as opiates, barbiturates, and paraldehyde, may exacerbate symptoms.¹⁸ No specific laboratory abnormalities are characteristic. Electrolyte disturbances may occur secondary to dehydration and rhabdomyolysis. Ventricular extrasystoles and T-wave changes may be seen on the electrocardiogram.

Acute GI symptoms usually resolve by 24 to 48 hours, and neurologic symptoms by 3 weeks, but the latter may persist for up to 2 months.

Palytoxin

Features of palytoxin poisoning are similar to those of ciguatera and include weakness, sweating, GI distress, paresthesias, muscle spasms, and tremors. Severe poisoning may result in generalized, painful tonic contraction of muscles, mimicking seizures, and in rhabdomyolysis, myoglobinuria, hemolysis, hyperkalemia, respiratory failure, bradycardia, and renal failure.¹¹

Neurotoxic Shellfish Poisoning

Neurotoxic shellfish poisoning also produces a similar clinical picture but is less severe. Symptoms often begin with circumoral paresthesias, which become more generalized and can be associated with headaches, dilated pupils, tachycardia, and muscle cramps. In severe cases, seizures have occurred, but no cases of paralysis or death have been reported. Symptoms of brevetoxin inhalation include a nonproductive cough, shortness of breath, lacrimation, and irritation of the eyes, nose, and throat. Patients with asthma may develop bronchospasm.

Paralytic Shellfish Poisoning

Symptoms begin 30 minutes to 2 hours after ingestion and typically include numbness of the fingertips, tongue, and lips, often accompanied by nausea and abdominal pain.¹⁷ These symptoms are followed by paresthesias of the face and extremities and progressive muscle paralysis. Bulbar muscles are often affected, causing dysarthria, dysphagia, diplopia, and loss of the gag reflex. Other features include vertigo, ataxia, transient blindness, altered temperature perception, hypotension, headache, and low back pain. Vomiting is not a consistent feature but may result from concomitant bacterial or viral contamination.¹⁷ Ingestion of large doses of saxitoxin can lead rapidly to coma, diaphragmatic paralysis, and respiratory failure. Children appear to be more susceptible.¹⁷ Patients who survive the first 12 hours generally have a complete recovery after 1 to 3 days. Nonspecific T-wave changes and a rise in creatine kinase and its MB fraction have occurred in the absence of myocardial infarction or other signs of cardiac toxicity.

Tetrodotoxin

Patients usually present 10 to 45 minutes after ingesting a tetrodotoxic fish. Very early or mild poisoning reportedly results in a feeling of exhilaration—the reason such fish is eaten in countries such as Japan. Because inadvertent overdose may be fatal, chefs must be licensed in the preparation of this “delicacy.”

Four stages of poisoning have been described. Initially, circumoral paresthesias, salivation, nausea, and vomiting occur, followed by peripheral paresthesias and numbness. Sensory symptoms then become more generalized, with ascending paralysis of the extremities, although deep tendon reflexes remain intact. In the third stage, ataxia and paralysis of peripheral and bulbar muscles occur. Finally, respiratory muscles are affected, although patients may still be conscious. In the most severe cases, patients may become unconscious and completely paralyzed, with dilated nonreactive pupils and loss of all brainstem reflexes. Uncommon complications include neurogenic diabetes insipidus and hypertensive cardiac failure. Patients who survive beyond 24 hours have a good prognosis. Recovery occurs over a period of days and, unless complicated by anoxia, is complete. Death is usually due to paralysis of the respiratory muscles.

Clupeotoxin Poisoning

Symptoms begin with a sharp, metallic taste, followed by severe GI upset and cardiovascular collapse. Violent headaches, paresthesias, muscle cramps, and progressive muscular paralysis may occur. Seizures and coma may intervene rapidly, resulting in death within 15 minutes of ingestion.

Scombroid

The clinical presentation of scombroid poisoning is similar to that of IgE-mediated food allergies. Symptoms typically begin within 1 hour of ingestion and are usually mild.² Common features are flushing of the face and upper trunk, nausea, abdominal cramps, diarrhea, and headache. Pruritus and urticaria, burning sensations of the mouth and throat, fever, and palpitations can occur. Severe reactions, such as bronchospasm, hypotension, and supraventricular tachyarrhythmias, are more likely to occur in patients with preexisting cardiac or respiratory disease. Symptoms usually resolve in 6 to 12 hours (range, 3 to 36 hours).

Other Seafood Toxins

Diarrhetic shellfish poisoning results primarily in GI symptoms. Symptoms of hallucinatory fish poisoning occur within 2 hours of ingestion and typically include ataxia, hallucinations, chest tightness, and a sense of impending doom.¹⁰ GI distress and facial and pharyngeal paresthesias are also common.

Domoic acid mussel contamination results in vomiting, diarrhea, abdominal pain, and headache, occurring about 6 hours after ingestion (range, 15 minutes to 38 hours). Toxic encephalopathy resulting in confusion, disorientation, and memory deficits occurs in one-fourth of patients. Severe poisoning can result in profuse airway secretions, hemiplegia, hypotension, cardiac dysrhythmias, myoclonus, seizures, and coma. Resolution of cognitive deficits can take up to 12 weeks, but memory deficits and peripheral neuropathy appear to be permanent.

Patients poisoned by carp bile present 10 minutes to 12 hours after ingestion, with GI upset and diarrhea, followed by fever, chills, bradycardia, hypotension, hematuria, headache, and oliguria.¹⁵ Acute tubular necrosis and toxic hepatitis may occur; both resolve after 2 to 3 weeks. Symptoms of fish roe poisoning develop within several hours of ingestion, with GI symptoms, hypotension and tachycardia, tinnitus, and weakness.¹² Ingestion of red whelk may result in progressive weakness that may include the respiratory muscles. Also seen are GI symptoms and hypotension due to vagal-induced bradycardia and peripheral vasodilatation.⁸

Haff disease affects motor neurons of the brain, anterior horn cells of the spinal cord, and myocardial muscle cells. Clinical manifestations also include hypertension, tachycardia, diaphoresis, rhabdomyolysis, myoglobinuria, and renal failure.¹⁹

DIFFERENTIAL DIAGNOSIS

The clinical presentation of ciguatera, neurotoxic shellfish, palytoxin, tetrodotoxin, and paralytic shellfish poisoning may be difficult to distinguish, as all may involve symptoms of paresthesias, weakness, and ataxia.¹³ Predominant symptoms and the nature of the fish eaten are used to determine the specific etiology. A common shellfish origin has been found for toxins associated with tetrodotoxin and paralytic shellfish poisoning

The differential diagnosis of toxic seafood poisoning includes infectious gastroenteritis. Common seafood pathogens are hepatitis A, Norwalk virus, *Vibrio* spp. (*V. cholerae*, *V. parahaemolyticus*, and *V. vulnificus*), *Clostridium botulinum*, *Escherichia coli*, *Giardia lamblia*, and species of *Campylobacter*, *Shigella*, and *Salmonella*.⁷

Scombroid poisoning can usually be differentiated from true allergic or anaphylactic reactions by the history of fish ingestion. Rarely, histamine poisoning indistinguishable from that caused by scombroid may result from the ingestion of aged cheese. Symptoms similar to scombroid fish poisoning can result from the ingestion of Japanese Callista clams, the ovaries of which have a high content of choline during the summer spawning season. Additional symptoms include paralysis or numbness of the throat, mouth, and tongue, and recovery takes up to 2 days.

The differential diagnosis of skin flushing also includes poisoning by niacin, vancomycin, rifampin, monosodium glutamate, and ethanol or disulfiram reactions.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of seafood poisoning is based on exposure history, clinical manifestations, and epidemiologic information. A history of seafood ingestion in the past 48 hours should be sought from patients presenting with GI, allergic, or unusual neurologic symptoms. If possible, the origin of the seafood should be identified; this information may help differentiate poisonings specific to certain regions. Public health officials may be able to assist in this process and provide information about similar cases or known quarantined fishing areas.

The physical examination focuses on vital signs, a neurologic evaluation, and assessment of respiratory function. In patients with significant GI symptoms, orthostatic vital signs are taken. The skin is examined for rashes. Peritoneal signs on abdominal examination suggest alternative pathology. Laboratory evaluation includes a complete blood count; measurements of electrolytes, blood urea nitrogen, creatinine, glucose, and creatine kinase; and urinalysis. Unless other diagnoses or complications are considered, additional laboratory tests are of no help. Assays for detecting seafood toxins are not readily available for clinical use but may be used by government agencies for epidemiologic investigations.

EMERGENCY DEPARTMENT MANAGEMENT

General Measures

Patients with bulbar paralysis, respiratory muscle weakness, or depressed consciousness require close observation of airway patency and respiratory function. Intubation and mechanical ventilation are performed, if necessary. The treatment of bradycardia and other cardiac problems should follow standard advanced cardiac life-support guidelines. Volume losses are replaced with intravenous normal saline. Hypotension unresponsive to fluids is treated with dopamine. Dobutamine may be required to treat hypotension in paralytic shellfish poisoning. Calcium gluconate (1 g intravenously over 30 minutes, followed by 2 to 4 g/d as a constant infusion) has also been used to treat hypotension secondary to ciguatera.

Most seafood toxins are readily absorbed by activated charcoal, and this therapy should be used in patients who present within 4 hours of ingestion. Control of emesis may be necessary first. Cathartic agents should be avoided, as they exacerbate diarrhea. Ipecac or gastric lavage is unnecessary.

There are no specific antidotes for any form of seafood poisoning. In most cases, supportive care, with fluid replacement and symptomatic relief, is the mainstay of treatment.

Specific Therapy

Several specific therapies have been tried for ciguatera poisoning. Mannitol appears to be the most effective treatment for control of acute toxicity. Neurologic symptoms often respond within minutes and resolve completely within 48 hours.¹⁴ GI symptoms do not appear to respond as well. Mannitol is given intravenously as a 20% solution in a dose of 1 g/kg, up to 50 g, at 250 to 500 mL/h. Fluid and electrolyte abnormalities must be corrected before it is given. Mannitol is most effective if given within 48 hours of poisoning but may have some effect even when given late or if symptoms return.²⁰

Pralidoxime was originally used because it was erroneously thought that ciguatoxin had anticholinesterase activity. Although pralidoxime can be used to control excessive secretions, it may worsen other symptoms, and its efficacy remains unproved. Amitriptyline, which may act by blocking sodium channels, in doses of 25 to 75 mg/d, usually provides some relief from the chronic neurologic symptoms of ciguatera poisoning. Other agents used with varying degrees of success include fluoxetine, nifedipine, vitamins B₁₂ and C, calcium gluconate (1 to 3 g intravenously over 24 hours), lidocaine, and tocainide. Indomethacin and cyproheptadine are commonly used to relieve arthralgias and pruritus. Opiates and barbiturates should be avoided. Steroids are ineffective. Seafood, nuts, grains, alcohol, and exercise should be avoided for 3 to 6 months after exposure.

Patients with systemic anaphylactoid reactions secondary to scombroid poisoning should be treated with intravenous epinephrine, inhaled albuterol, and steroids. Less severe reactions can be treated with antihistamines. Type 2 histamine receptor blockers such as cimetidine appear more effective than type 1 blockers such as diphenhydramine.³ Nausea and vomiting may respond to prochlorperazine. Once stabilized, patients with scombroid poisoning can be discharged on oral antihistamines for 48 hours.

Edrophonium and neostigmine have been used to reverse motor paralysis due to tetrodotoxin poisoning but have not been studied in controlled trials. Diuresis and transfusion of red cells may be necessary in patients with palytoxin poisoning who have rhabdomyolysis and hemolysis, respectively.

For all toxic seafood poisonings, prevention is the best treatment. In areas where ciguatera poisoning is endemic, people should avoid eating fish larger than 2 kg or those known to be frequently affected; for instance, the sale of barracuda is banned in Miami. Eating any viscera, especially the liver and gonads, should always be avoided. Outbreaks of paralytic shellfish poisoning are prevented by periodic testing of susceptible mollusks. When toxin levels are high, affected areas are quarantined. In some areas, harvesting of susceptible shellfish is banned during the summer. Quarantines also may be introduced during algae blooms. Failure to heed quarantines invites disaster.

Puffer fish should be eaten only if prepared by a licensed chef. Scombroid poisoning can be prevented by proper refrigeration of fish. Obviously, any fish that appears spoiled or has an unusual taste should be avoided.

DISPOSITION

Most patients can be treated in the emergency department and then discharged with outpatient follow-up. Those with abnormal vital signs, persistent or severe dehydration, systemic anaphylactoid reactions, and neurologic symptoms should be hospitalized. The level of care required depends on clinical severity. A toxicologist, regional poison control center, or public health agency can be consulted for current trends and treatment advice. Local or state departments of health should be notified of all cases of suspected seafood poisoning, because timely intervention may prevent additional exposures.

COMMON PITFALLS

- Failing to obtain a history of seafood ingestion, including the identity and source, in patients presenting with gastroenteritis or allergic symptoms
- Failing to consider seafood poisoning in patients presenting with unexplained or atypical neurologic symptoms
- Failing to assess airway control and respiratory function in patients with bulbar paresis, muscle weakness, or altered mental status
- Failing to replace fluid losses
- Failing to report cases of possible seafood poisoning to public health agencies

CHAPTER 369 Sedative–Hypnotic Poisoning

Barbara Insley Crouch and Fred M. Henretig

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Nonbarbiturate, nonbenzodiazepine “sedative–hypnotic” agents are used for the relief of anxiety and as sleeping aids. They include buspirone, chloral hydrate, ethchlorvynol, glutethimide, meprobamate, methaqualone, zolpidem, and gamma-hydroxybutyrate (GHB) and its congeners, gamma-butyrolactone (GBL) and 1,4-butanediol (BD). GHB and related agents were originally marketed as sleep aids and body-building nutritional supplements but are currently widely abused as recreational substances.

Overdoses of ten- to 20-fold the recommended dose may cause life-threatening central nervous system (CNS) depression and coma for many of these agents. All may be toxic at a relatively low dose in combination with alcohol or other CNS depressants. Most have a lower margin of safety than the benzodiazepines, although buspirone and zolpidem, the newest members of this class, appear to have a more favorable safety profile. As a class, sedative–hypnotics are notorious for their abuse potential, given their propensity to cause tolerance and dependence. Abstinence may cause severe effects, including a delirium tremens–like syndrome and convulsions. Methaqualone in particular had such a high abuse potential that it was made a class I agent and withdrawn from the market in the United States in 1983. GHB has no current medical indications, and its sale in the United States was banned in 1991.

All sedative–hypnotics are metabolized in the liver, and several induce hepatic enzymes, so that drug interactions with other liver-dependent agents must be borne in mind (i.e., decreased response to warfarin in patients taking ethchlorvynol), and they should not be used in patients with porphyria (particularly ethchlorvynol and meprobamate). Pharmacokinetic data for these agents are summarized in [Table 369.1](#).

	t _{1/2}	t _{1/2} (h)	V _d (L/kg)	Bound (%)	Active metabolite	Bio/chem		
						Th	F ₁	L
Buspirone	2	16	6.7	1	Pyrimidinyl piperazine	NA	NA	NA

NA, none; Th, protein-binding (%); F₁, volume of distribution; L, plasma protein-binding; V_d, volume of distribution; TCE, trichloroethanol; 4-HPG, 4-hydroxy-2-phenylglutathimide; 5-Methylpyridinyl, 5-methylpyridinyl.

TABLE 369.1. Summary of Pharmacokinetic Data for Nonbarbiturate, Nonbenzodiazepine Sedative–Hypnotic Agents

Buspirone, an azaspirodecanedione derivative, does not seem to interact with the benzodiazepine–gamma-aminobutyrate (GABA) receptor complex. Rather, it is thought to act primarily as a partial serotonin 1A agonist.² The drug is completely absorbed in the gastrointestinal (GI) tract, with peak concentrations reached in 40 to 90 minutes. It is 95% protein-bound, with a volume of distribution in excess of 400 L, and it is metabolized in the liver to pyrimidinyl piperazine (active), with a plasma half-life of 2 hours. A typical adult daily dose is 20 to 30 mg.

Chloral hydrate is one of the oldest known hypnotics. It was first synthesized in 1832 and used as a hypnotic as early as 1869.¹⁷ The first cases of poisoning were reported in 1890. Chloral hydrate use in adults has declined considerably in recent years, but it is still popular for procedural sedation in children at doses ranging from 50 to 100 mg/kg. The toxic dose in adults is 5 to 10 g. As little as 1.5 g has resulted in significant toxicity in a toddler. It is rapidly absorbed, has a volume of distribution of 0.6L/kg, and is rapidly metabolized to trichloroethanol (TCE), which is believed responsible for its hypnotic effects. The half-life of TCE is 8 hours at therapeutic doses, but may be prolonged to 12 to 35 hours after overdose. The combination of alcohol and chloral hydrate (“Mickey Finn”) is particularly potent, as these agents not only have additive CNS depressant effects, but also inhibit each other’s metabolism. In 1997, 461 cases of chloral hydrate exposure were reported to the American Association of Poison Control Centers’ Toxic Exposure Surveillance System (TESS); three were fatal.¹²

Ethchlorvynol, an agent with a rapid onset and relatively short duration of action, has been used for more than 30 years. It is available in capsule sizes of 100, 200, 500, and 700 mg. The usual adult hypnotic dose is 500 to 700 mg. In 1997, 100 ethchlorvynol overdoses were reported to TESS; none was fatal.¹² GI absorption is rapid after therapeutic doses, with onset of effect in 15 to 30 minutes and peak concentrations in 60 to 90 minutes. The drug is initially distributed to fatty tissue, with a redistribution phase occurring at 7 to 10 hours. Protein binds 50% to 60% of free drug in plasma. The elimination half-life is about 10 to 25 hours after therapeutic dosage, but as much as 100 hours after overdose. Generally, 4 to 5 g will lead to toxic effects in an adult. A 5-g overdose has been fatal, but a patient who ingested 50 g has survived after a prolonged coma. As little as one capsule has caused toxic symptoms in toddlers, and 2.5 g coingested with alcohol has caused death in an adult. Symptomatic patients usually have concentrations above 19 to 20 mg/L, and concentrations above 38 mg/L are associated with coma. Ethchlorvynol can cross the placenta, and a neonatal withdrawal syndrome has been described.

Illicit use of GHB was reported in 1990.⁴ Prior to 1991, it was available in health-food stores and by mail order as a supplement for body-building (presumably due to its growth hormone–stimulating properties), as well as a diet and sleep aid. Until very recently, it was widely available by mail order or over the Internet as kits for home production. Such kits provided GBL, sodium hydroxide, and instructions for converting GBL to GHB. Abuse of GBL itself, which is rapidly converted to GHB *in vivo*, and BD, which are still legal for sale in many states and produce effects nearly identical to those of GHB, has obviated the need for purchasing these kits.

GHB is structurally related to the inhibitory neurotransmitter GABA, and GHB receptors (probably GABA_B receptors) have been identified in animal models. GHB may also have neurotransmitter and neuromodulator effects. GHB appears to increase brain dopamine levels and to effect endogenous opioids. GHB may also induce a normal sequence of rapid eye movement (REM) and non-REM sleep and has been investigated in the treatment of narcolepsy. It has also been evaluated as an anesthetic agent, but its value was limited by its lack of analgesic effects and its tendency to induce both petit mal and grand mal seizures. It is typically available as the sodium salt in a white powder or tablet form. One teaspoon of the powder provides 2.8 g of GHB. Doses range from one-fourth teaspoon to several tablespoons. GBL and BD are typically sold as liquids. Amnesia occurs after GHB doses of up to 10 mg/kg, somnolence and euphoria after 20 to 30 mg/kg, and anesthetic coma after 50 mg/kg. Doses above 50 mg/kg may be associated with seizures and cardiorespiratory depression. GHB is well absorbed orally. Onset of effects is typically within 15 minutes.¹⁰ Peak concentrations occur in 1.5 to 2.0 hours. The volume of distribution is 0.4 to 0.58 L/kg, the elimination half-life is 1 to 2 hours, and the duration of action ranges from 2 to 8 hours.

Glutethimide, introduced in 1954, was popular as a substance of abuse prior to its being withdrawn from U.S. markets. It was often taken orally with codeine (with cough syrup, called “pancakes and syrup,” or with Tylenol Compound 3 or 4, known as “loads,” “packs,” or “4s and Dors,” from the Doriden brand of glutethimide), a combination that purportedly simulates the high of heroin. In 1997, only ten glutethimide overdoses were reported to TESS, with no deaths.¹² GI absorption is relatively erratic for this poorly water-soluble drug. Plasma protein binding is about 50%. The elimination half-life varies from 5 to 22 hours in therapeutic doses but may be 40 to 100 hours or more after overdose. There are two active metabolites. One (4-hydroxy-2-ethyl-2-phenylglutathimide) was thought to correlate with clinical effects and to be responsible for the characteristic fluctuation in level of coma seen with this agent. However, a subsequent case report has documented a lack of

correlation between the 4-hydroxy metabolite concentrations and depth of coma.⁵ The fluctuating level of consciousness is now felt to be due to erratic absorption, perhaps related to anticholinergic effects on GI motility. Thus, as the drug concentration falls, coma lightens, and gut activity increases, absorption of residual intraluminal drug occurs and results in deepening coma. Glutethimide induces hepatic microsomal enzymes. The toxic effects of glutethimide are due primarily to global CNS depression. It also has significant anticholinergic activity. Death is usually due to cardiovascular collapse. An acute dose of 500 mg in a young child or 5 g in an adult will produce severe poisoning. The lethal dose is reportedly 10 to 20 g, although survival after prolonged comas has occurred after ingestion of 45 g. Fatal overdoses have been associated with concentrations of 2 to 80 mg/L. Tolerance and physical dependence are characteristic of chronic abuse. Glutethimide can cross the placenta, and neonatal withdrawal has been reported.

Meprobamate, originally synthesized and used as a muscle relaxant in the late 1940s, was introduced in the United States for use as an anxiolytic agent in 1955. Although still used today for this purpose, there is little evidence that it is effective. It is available in 200-, 400-, and 600-mg tablets, and in 200- and 400-mg sustained-release capsules. In 1997, there were 229 poison exposures to meprobamate reported to TESS; four had fatal outcomes.¹² A carbamate ester, meprobamate is structurally related to the skeletal muscle relaxants carisoprodol, methocarbamol, and chlorphenesin, and to the anticonvulsant felbamate. Meprobamate itself has anticonvulsant and skeletal muscle relaxant properties. Its mechanism of action is similar to that of barbiturates, although it is thought to be more selective in its depression of areas in the cerebral cortex. It also suppresses polysynaptic reflexes in the spinal cord, which probably contributes to its skeletal muscle relaxation properties. The therapeutic dose of meprobamate for adults is usually 1.2 to 1.6 g daily, in three or four doses; the maximal daily dose is 2.4 g. Therapeutic blood concentrations are said to be between 5 and 30 µg/mL, although therapeutic drug monitoring is usually not performed. Meprobamate is well absorbed from the GI tract, with peak plasma concentrations within 1 to 3 hours after ingestion. It binds very little to plasma proteins and has volume of distribution of 0.7 L/kg. Meprobamate induces hepatic microsomal enzymes to some degree. The half-life is reported to be about 12 hours, although this may be markedly prolonged after an overdose. Toxic effects may occur after ingestions of as little as 2 to 4 g. Death has been reported with as little as 12 g, but survival has been reported after ingestions of up to 40 g.¹ Drug concentrations do not correlate well with clinical effects, although concentrations above 100 µg/mL are associated with severe toxicity. Fatal concentrations in 12 cases ranged from 142 to 346 µg/mL, with a mean concentration of 226 µg/mL.⁶

Methaqualone, a quinazoline derivative, was introduced in 1965 as a nonaddicting substitute for the barbiturates. It rapidly became popular as a drug of abuse, however. Abused for its euphoric and aphrodisiac effects, methaqualone was nicknamed the "love drug." In 1997, only 19 poison exposures were reported to TESS.¹² The therapeutic dose is 150 to 300 mg of the methaqualone base or 200 to 400 mg of the hydrochloride salt. Methaqualone is rapidly absorbed from the GI tract. Effects are noted within 30 minutes and peak at 1 to 2 hours. Methaqualone is widely distributed, especially adipose tissue, and is slowly eliminated. The distribution half-life is about 2 to 4 hours, and the elimination half-life is more than 24 hours. Protein binding is 70% to 80%. Toxic effects usually occur with ingestions of more than 2 g. Ingestion of 8 g has resulted in death, but survival was noted after ingestion of 22 g.¹⁶ Patients with reported overdoses of 2.5 to 7.5 g of methaqualone in the form of Mandrax (methaqualone and diphenhydramine) were minimally responsive or unresponsive to deep painful stimuli and had plasma concentrations of 9 to 47 µg/mL.⁹ Serum concentrations appeared to correlate with clinical findings in this study but not in another.¹⁴

Zolpidem, an imidazopyridine derivative that is structurally unrelated to the benzodiazepines, selectively bind to the central benzodiazepine receptor subtype BZ₁ located in the GABA_A receptor complex. Unlike benzodiazepines, it does not appear to possess significant anticonvulsant or muscle relaxant properties. Oral bioavailability is 70%, due to significant first-pass metabolism. It is rapidly absorbed, and peak concentrations are reached within 30 to 120 minutes following an oral dose. It is highly protein bound (92%) and has a volume of distribution of 0.54 L/kg and a half-life of approximately 2 hours following 5- to 200-mg therapeutic doses. Ingestions of up to 300 mg without the development of symptoms have been reported.¹⁶ An ingestion of 1,000 mg resulted in tachycardia and agitation only.⁷ No deaths attributable to zolpidem alone have been reported.

CLINICAL PRESENTATION

Experience with buspirone overdose is limited. Amounts up to 300 mg have been reported to cause dysphoria, transient CNS depression, miosis, vomiting and diarrhea, and mild decreases in heart rate and blood pressure. Paresthesias and dystonic reactions have also been described. CNS depression usually resolves within 6 hours. One recent report, however, describes generalized seizures 36 hours after the ingestion of 420 mg.²

Chloral hydrate overdose resembles that due to barbiturates, with coma, miosis and hypotension.¹⁷ It is also a GI irritant and commonly causes nausea and vomiting. Hemorrhagic gastritis and gastric necrosis or perforation occur rarely. As a halogenated hydrocarbon, chloral hydrate can also cause hepatic injury, renal failure, and cardiotoxicity. It reduces myocardial contractility, shortens the refractory period, sensitizes the myocardium to circulating catecholamines, and can precipitate cardiac dysrhythmias.

With an acute ethchlorvynol overdose, symptoms range from lethargy, ataxia, and nystagmus to deep coma with respiratory and cardiovascular depression. A hallmark of massive ethchlorvynol overdose is prolonged coma.¹⁹ Pulmonary edema can occur, especially after intravenous overdose, but also 24 to 48 hours after an oral overdose. Hypothermia, bradycardia, hypotension, and excess salivation are seen in severe cases. Gastric fluid is pink, with a minty odor. Skin bullae similar to those seen with barbiturate poisoning may also be noted.³ Complications include those of prolonged coma, especially pneumonia and pressure necrosis of the extremities.

Ingestion of GHB, GBL, or BD results in vomiting, drowsiness, hypotonia, and dizziness within 15 to 60 minutes.^{4,10} These effects may soon be followed by coma, mydriasis (miosis has been noted infrequently), irregular and slowed respirations, tremor, agitation, hallucinations, myoclonus, and, possibly, seizures. Bradycardia and hypotension have also been described. Effects typically resolve within 8 hours, although dizziness may last for several days. Pulmonary aspiration is very uncommon.⁴ Death has been reported, but coingestants and underlying medical conditions have complicated the interpretation of many of these cases.

Prolonged, fluctuating coma is the predominant effect of severe glutethimide overdose.¹³ Anticholinergic manifestations may include mydriasis, ileus, urinary bladder retention, and hot, flushed, dry skin. Cerebral and pulmonary edema is regularly reported in severe overdoses. Ocular and neurologic signs can be dramatic: papilledema; nystagmus; unilateral or bilateral pupillary dilation; ataxia; tonic spasms and seizures; coma progressing to loss of deep tendon, corneal, gag, and pupillary light reflexes; and an isoelectric electroencephalogram. Both hypothermia and fever may be encountered. Bullous skin lesions analogous to those seen in barbiturate overdose may be noted. Hypotension can occur, and apnea may develop suddenly. The effects of coingestants (e.g., codeine with or without acetaminophen) may also be present. Complications include those of severe coma, particularly pneumonia and pulmonary edema.

Meprobamate overdose may produce lethargy, ataxia, slurred speech, and coma. Depending on the level of consciousness, respirations may or may not be depressed. Meprobamate is unique among sedative-hypnotic agents in that it often causes hypotension.¹ The observation that hypotension may occur without respiratory depression suggests a direct myocardial depressant effect. Tachycardia is also common. Miosis, mydriasis, nystagmus, respiratory depression, disconjugate gaze, seizure activity, hallucinations, and hypothermia have been reported. Meprobamate has a tendency to clump in the stomach, resulting gastric pharmacobezoar formation. Methaqualone commonly causes muscle hyperactivity, including hyperreflexia, twitching, and clonus, in addition to CNS depression.^{9,14} Hypotension and respiratory depression occur infrequently. Dysrhythmias and myocardial infarctions have been noted in a few patients. Fixed drug eruptions have been noted in methaqualone abusers; lesions resolved once the drug was withdrawn. Bleeding tendencies, believed to be caused by coagulopathy and abnormal platelet count or aggregation, have been reported, with retinal hemorrhage being described in one case.

Zolpidem overdose appears to be relatively benign. In a series of 35 patients, 51% developed no symptoms.¹⁵ The remainder had mild CNS effects, including dizziness, slurred speech, and lethargy. Four patients complained of nausea, vomiting, and abdominal discomfort. Only two patients in this series had deep sedation. Of cases reported to a poison center, 28% did not have symptoms, and over half of those that did had concomitant ingestions.⁷ Of patients who ingested zolpidem alone, the majority experienced only drowsiness. Vomiting occurred in seven; coma without respiratory depression in four; mydriasis, agitation and tachycardia in three each; and confusion and hypotonia in two. Effects noted in only a single patient included hyporeflexia, gait disturbances, incoherent speech, memory impairment, tachypnea, visual hallucinations, blurred vision, bradycardia, dizziness and hypotension.

DIFFERENTIAL DIAGNOSIS

Poisoning by alcohols, anticonvulsants, barbiturates, benzodiazepines, beta blockers, calcium channel blockers, centrally acting antihypertensives, cyclic antidepressants, opioids, and skeletal muscle relaxants can cause similar signs and symptoms. Hypotension out of proportion to the degree of CNS depression suggests meprobamate, a cardiovascular agent, or a cyclic antidepressant. Cyclic coma suggests glutethimide or a gastric drug bezoar. CNS infection and trauma,

hypoglycemia, hypernatremia, hypercalcemia, and hypermagnesemia should also be considered.

EMERGENCY DEPARTMENT EVALUATION

The history should include the time and amount of drug(s) ingested, the time of onset and the nature of symptoms, and medical history, including the pattern and extent of sedative–hypnotic drug use. The physical examination focuses on vital signs and the neurologic and cardiopulmonary status.

Symptomatic patients should have baseline blood work (oxygen saturation or arterial blood gas analysis, complete blood count, and determination of electrolyte, blood urea nitrogen, creatinine, and glucose concentrations), urinalysis, an electrocardiogram (ECG), a chest radiograph, and liver function tests, as indicated by clinical severity. Patients with deeper comas should also be evaluated for possible rhabdomyolysis by serum creatine phosphokinase and urine myoglobin tests. Comprehensive urine toxicology screening tests can confirm the presence of all sedative–hypnotics except GBH and its derivatives. Drugs of abuse immunoassays will not detect these agents. In general, quantitative serum drug levels are neither readily available nor clinically useful.

EMERGENCY DEPARTMENT MANAGEMENT

Generally, therapy involves stabilization and support of vital signs and gut decontamination, with the administration of activated charcoal being the preferred modality. Patients normally respond well to good supportive measures. If a patient starts to deteriorate after apparent recovery, or is deteriorating despite good supportive care, a drug mass in the stomach should be suspected. Endoscopy can be both diagnostic and therapeutic in such cases. Gastrotomy has been used for meprobamate pharmacobezoar removal.¹⁶ If hypotension fails to respond to fluids, or if the patient is already fluid-overloaded, a trial of agents with positive inotropic activity, such as dopamine and epinephrine, is indicated. Unless hypoxic injury is present, full recovery can be expected once these drugs have been eliminated. Hence, invasive cardiovascular support (e.g., partial or full bypass and intraaortic balloon pump therapy) should be included in the supportive care of hemodynamically unstable patients.

Ventricular dysrhythmias due to chloral hydrate are often refractory to treatment.¹⁷ Lidocaine, magnesium (especially for torsades de pointes), beta blockers, and overdrive pacing have been used with success. Pressor agents should be avoided, if possible, to decrease the risk of precipitating refractory dysrhythmias. Hemodialysis may be considered in extremely severe cases with profound hypotension and unstable arrhythmias.

The use of extracorporeal methods for enhancing the elimination of ethchlorvynol is controversial. Plasma half-life can be decreased with hemodialysis. Resin hemoperfusion, although not widely available, is even more efficacious.¹⁸ Such therapy should be considered only in patients with high drug levels and life-threatening toxicity unresponsive to intensive supportive care.

Patients with GHB poisoning may require endotracheal intubation for airway protection or for respiratory support while obtunded and vomiting. Because the duration is short, many can be managed effectively with noninvasive airway support (recovery position with suction, oxygen, close monitoring, and stimulation) and careful observation for up to 6 hours in the emergency department.¹⁰ Benzodiazepines may be required for seizures, and atropine for bradycardia.

Glutethimide's anticholinergic effects may cause delayed gastric emptying and absorption, so decontamination may be useful many hours after ingestion. Repeated doses of activated charcoal may also be helpful, given the prolonged and fluctuating degree of intestinal absorption. Efforts to enhance elimination with hemodialysis and hemoperfusion have shown limited benefit, probably due to the agent's extensive tissue distribution. In patients who have coingested codeine, the administration of naloxone (see [Chapter 360](#)) may be partially effective. Those who have coingested a codeine product containing acetaminophen should have an acetaminophen concentration measured and be treated accordingly.

Fluids should be given with caution in treating the hypotensive effects of meprobamate, because its myocardial depressant properties increase the risk of pulmonary edema. Hemodialysis, resin and charcoal hemoperfusion, and continuous arteriovenous hemoperfusion (CAVHP) have been used successfully in the treatment of life-threatening meprobamate overdoses.^{8,11} These methods should be reserved for patients who are unresponsive to supportive measures. Proponents of CAVHP note its efficacy in hypotensive patients, as well as its potential availability in smaller community hospitals.

Patients with methaqualone poisoning may require pharmacologic paralysis for control of neuromuscular hyperactivity.

The benzodiazepine antagonist, flumazenil (see [Chapter 319](#)), can reverse CNS depression due to zolpidem.

DISPOSITION

Patients with mild symptoms may be observed in the emergency department until asymptomatic. Except with GHB and related compounds, those with moderate or severe symptoms require admission, because prolonged close monitoring and supportive care are necessary. Intensive care unit admission is advisable. Patients with unstable vital signs or very deep coma may be candidates for extracorporeal elimination procedures and should be transferred to a facility that is capable of such treatment. Advanced life-support equipment and staff should accompany the patient during transfer.

COMMON PITFALLS

- Failure to consider the possibility of gastric drug bezoar and continuing drug absorption in patients with progressive, prolonged or cyclic coma, particularly that due to glutethimide and meprobamate, and to consider interventions such as endoscopy and multiple-dose charcoal
- Failure to appreciate that meprobamate can cause hypotension in the absence of severe CNS depression
- Failure to appreciate that buspirone, GHB and its congeners, and methaqualone can cause agitated coma (i.e., neuromuscular hyperactivity or seizures in addition to CNS depression)
- Failure to appreciate that the effects of GHB, GBL, and BD are short-lived and that endotracheal intubation and intensive care unit admission may not be necessary
- Failure to monitor for pulmonary edema, especially in patients who require fluid resuscitation for hypotension
- Failure to perform toxicology testing to rule out occult coingestants (e.g., acetaminophen), especially in comatose patients
- Failure to consider invasive hemodynamic support and elimination therapies in patients with severe poisoning unresponsive to noninvasive treatment
- Failure to anticipate and treat withdrawal syndromes in patients chronically taking these drugs

CHAPTER 370 The Serotonin Syndrome

Andis Graudins

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The serotonin syndrome is due to pharmacologic overstimulation of central nervous system (CNS) 5-hydroxytryptamine (5-HT) or serotonin receptors. It may result from drug interactions during therapeutic dosing or from overdose with one or multiple serotonin-specific antidepressant agents. These antidepressants include the selective serotonin reuptake inhibitors (SSRIs) fluoxetine, sertraline, paroxetine, citalopram, and fluvoxamine; the nonselective serotonin (and norepinephrine) reuptake inhibitors (NSRIs) venlafaxine and nefazodone; and the reversible inhibitor of monoamine oxidase A (MAO-A), moclobemide. ^{1,5,6,12,13,17}

Most reports of the syndrome are either single case reports or small case series. There is no obvious gender or age preference.

In a study of 204 patients exposed to serotonergic antidepressants, there was a 10% incidence of serotonin syndrome. Seventy percent of the cases were the result of overdose; the remainder were due to therapeutic drug interactions. A single agent was involved in 50%, and two were involved in 45%. ⁴ Drug interactions often result from substituting a new antidepressant for one with a long elimination half-life (e.g., fluoxetine) or duration of action (e.g., a monoamine oxidase inhibitor [MAOI]; see [Chapter 354](#)) without an adequate wash-out period (i.e., allowing the previously used agent to be completely eliminated).

Drug interactions also may be precipitated by the addition of a second serotonergic antidepressant when a patient is already taking one. Finally, patients may be taking an antidepressant and unknowingly be given another medication with serotonergic activity (e.g., the use of meperidine or dextromethorphan in a patient taking an MAOI or serotonergic antidepressant). ^{3,7,20} The severe hyperthermic response sometimes seen following methylenedioxymethamphetamine (MDMA, “ecstasy”) abuse may also be due to the serotonin syndrome. ⁹

Serotonin is a neurotransmitter found widely throughout the body. Large amounts are stored in the enterochromaffin cells of the gastrointestinal tract (greater than 90% of body stores), where it produces stimulation of vascular and gastrointestinal smooth muscle contraction. Lesser amounts (8% of body stores) are found in platelets, where it causes their aggregation. In the CNS, which contains a relatively small amount of serotonin (2% of body stores), its main action is the inhibition of excitatory neurotransmission. Animal models of serotonin syndrome suggest that excessive stimulation of brainstem 5-HT-1a and cortical 5-HT-2 receptors is responsible for the serotonin syndrome. ^{10,19} Various drugs and mechanisms of action may be involved ^{15,16} ([Table 370.1](#)).

Increased serotonin production	L-tryptophan
Increased presynaptic serotonin release	Amphetamines MDMA Cocaine
Decrease serotonin breakdown by monoamine oxidase	Irreversible inhibitors of MAO-A and MAO-B Phenelzine, tranylcypromine, isocarboxid Reversible inhibitors of MAO-A Moclobemide Reversible inhibitors of MAO-B Selegiline
Inhibition of serotonin reuptake	Serotonin-specific reuptake inhibitors Fluoxetine, citalopram, paroxetine, venlafaxine, fluvoxamine, cyclic antidepressants, meperidine, dextromethorphan Serotonin-norepinephrine reuptake inhibitors Venlafaxine, nefazodone
Direct agonists of postsynaptic receptors	Bromocriptine, lithium, levo-DOPA, electroconvulsive therapy

Data from refs. 1, 9, and 16.

TABLE 370.1. Drugs Affecting Central Nervous System Serotonin Concentrations with the Potential to Produce Serotonin Syndrome

The high and increasing frequency of serotonergic drug use requires that caution be exercised in prescribing other serotonergic agents, particularly meperidine, for patients seen in the emergency department. Meperidine is absolutely contraindicated in patients taking MAOIs. ^{15,20} Morphine does not have any serotonin reuptake inhibition properties and should be used as the analgesic of choice in this population.

CLINICAL PRESENTATION

Original criteria proposed for the diagnosis of the serotonin syndrome included a recent increase or addition of a serotonergic agent to a medication regimen and at least three of the following clinical features: mental status change, agitation, myoclonus, hyperreflexia, diaphoresis, shivering, tremor, diarrhea, incoordination, and fever. In addition, they required that other etiologies be excluded; additionally, the patient must not have been exposed to neuroleptic agents. ¹⁹ These criteria may exclude a number of patients who have the serotonin syndrome, particularly those exhibiting severe toxicity. ¹⁶

It is now recognized that signs and symptoms fall into three major categories: altered mental status, autonomic nervous system instability, and neuromuscular hyperactivity ([Table 370.2](#)). Milder forms of the syndrome may present with abnormalities in only one or two of these categories. A review of 127 cases of the serotonin syndrome found that the most common clinical findings were myoclonus, hyperreflexia, confusion, hyperthermia, diaphoresis, and sinus tachycardia. ¹⁶ The diagnosis remains one of exclusion and should be considered in patients with a history of recent exposure to serotonergic agents and findings in any of the major categories.

Autonomic Instability	Altered Mental Status	Neuromuscular Hyperactivity
Tachycardia	Anxiety	Myoclonus
Fluctuating blood pressure	Confusion	Hyperreflexia
Diaphoresis	Drowsiness	Muscle rigidity
Flushed skin	Hallucinations	Tremor
Hyperthermia	Coma	Agitation
Tachypnea	Insomnia	Restlessness
Mydriasis	Dizziness	Ataxia
Unreactive pupils		Mydriasis
Diarrhea		Trismus
Abdominal pain		Ophthalmolus
Excessive salivation		

TABLE 370.2. Summary of Potential Clinical Findings Associated with Serotonin Syndrome

The time of onset of symptoms following exposure to serotonergic agents is variable. Symptoms are often reported to develop within 1 to 2 hours of ingestion. ^{6,12} The

syndrome has also been reported to occur after several days following gradual increases in dosing of antidepressant medications.² There appears to be no relationship between the amount of drug ingested and the risk of serotonin syndrome, as it can occur both with therapeutic dosing and in overdose. Reported serum levels of drugs measured in patients with the serotonin syndrome have been either at therapeutic or below therapeutic levels in up to 90% of cases.¹⁶

The clinical course of the serotonin syndrome is usually self-limiting. Symptoms and signs tend to subside with withdrawal of the offending drugs. Milder forms of the syndrome may resolve after a period of 6 to 12 hours. More severe cases may be symptomatic for 24 to 48 hours. Death has been reported but is rare.^{17,19}

DIFFERENTIAL DIAGNOSIS

Meningitis, encephalitis, septicemia, hypoglycemia, and neurotrauma should be considered in the differential diagnosis of patients presenting with mental status changes, autonomic instability, or hyperthermia. Intoxication with amphetamine, cocaine, or hallucinogens and withdrawal from alcohol and benzodiazepine should be considered when agitation, hallucinations, and sympathetic excess are present. In these conditions, the characteristic neuromuscular features of serotonin syndrome are usually absent.

Neuromuscular hyperactivity may be seen in dystonic reactions, tetanus, strychnine poisoning, and lithium intoxication. Lithium toxicity and tetanus may have additional features suggestive of the serotonin syndrome. The most similar condition, however, is the neuroleptic malignant syndrome (NMS; see [Chapter 356](#)). In contrast to patients with the serotonin syndrome, those with NMS have a history of recent commencement of, or increase in, dosage of neuroleptic medications. Symptoms tend to develop (and later resolve) over days rather than hours; muscular hyperactivity is characterized by sustained “lead pipe” rigidity rather than by myoclonus; and hyperreflexia is rarely, if ever, seen.¹⁶

EMERGENCY DEPARTMENT EVALUATION

The history should focus on drug use. Specifically, any evidence of drug overdose and use of multiple serotonergic medications, drugs of abuse, and over-the-counter medications containing dextromethorphan should be sought. The time course of onset and progression of symptoms is important in discriminating between NMS and serotonin syndrome.

Both the history and physical examination should focus on excluding other causes of the clinical picture. Vital signs should include an accurate temperature. A thorough search for evidence of trauma should be made. Features of serotonin syndrome that are present should be documented. The vital signs should be repeated frequently, as autonomic instability can result in fluctuating blood pressure and pulse. Patients should be questioned about the presence of visual or auditory hallucinations and examined for neuromuscular features of serotonin syndrome. A finger-stick blood sugar should be performed on patients with altered mental state.

Laboratory investigation should focus on excluding other causes of the clinical picture as well as evaluating for potential complications of the serotonin syndrome. A complete blood count, electrolytes, glucose, blood urea nitrogen, creatinine, and urinalysis and creatine kinase (to rule out rhabdomyolysis) are suggested. A coagulation profile, liver function tests, cultures, chest x-ray, head computed tomography scan, and lumbar puncture may be necessary in severely ill or hyperthermic patients to exclude sepsis, cranial trauma, meningitis, and complications such as multiorgan failure and coagulopathy (disseminated intravascular coagulation). Although toxicology testing is unlikely to be of any benefit in the acute management, detecting a serotonergic agent can support the diagnosis when a history of drug ingestion cannot be obtained.

EMERGENCY DEPARTMENT MANAGEMENT

First and foremost, management consists of supportive care. Advanced life-support measures should be instituted, as necessary. Airway control and assisted ventilation may be required in obtunded patients with severe forms of serotonin syndrome to maintain oxygenation and prevent aspiration pneumonia. Patients presenting with agitation, myoclonus, hypertonia, or hyperpyrexia should initially be treated with intravenous benzodiazepines, crystalloids, and external cooling measures. If no response is observed, chemical neuromuscular paralysis with sedation should be used to reduce muscle tone and decrease hyperthermia.^{6,7}

Seizures should be treated with intravenous benzodiazepines and barbiturates. Continuous electroencephalographic monitoring should be considered in paralyzed patients with suspected seizures. In milder forms of the syndrome, benzodiazepines can be used in an attempt to reduce anxiety, restlessness, and tremor, but they may be ineffective on their own.¹⁶ Serotonergic medications must be discontinued and avoided. Gastrointestinal decontamination, using activated charcoal, should be considered for patients with acute overdoses.

Serotonin-receptor antagonists can be considered as adjunctive therapy. Cyproheptadine (Periactin), a first-generation antihistamine with 5-HT_{1A} and 5-HT₂ receptor-blocking effects, has been used in a number of cases of serotonin syndrome with apparent success.^{12,13 and 14,19} It appears to be relatively free of potential major adverse effects. The initial adult dose is 4 to 8 mg, orally or by gastric tube, with repeat doses every 2 to 4 hours until a response is noted. It is then continued at a dose of 4 mg every 6 to 8 hours for a period of 24 hours. The maximum recommended dose is 32 mg in 24 hours. In patients with signs and symptoms of mild-to-moderate severity, a response is typically noted in 1 to 2 hours.¹² Cyproheptadine may not produce an obvious response in severe cases.

Chlorpromazine, a nonspecific serotonin receptor antagonist, has been used successfully in doses of 50 to 100 mg intravenously and intramuscularly.^{8,11,19} Administration should be preceded by adequate intravenous fluid hydration to prevent hypotension. Other side effects include anticholinergic effects and dystonic reactions. The use of chlorpromazine in patients with NMS wrongly diagnosed as serotonin syndrome has the potential to worsen this condition. Conversely, the use of bromocriptine, a dopaminergic agonist with indirect serotonergic effects, in the treatment of serotonin syndrome misdiagnosed as NMS may result in worsening of serotonergic symptoms.⁹ Other medications used with varying success in the treatment of serotonin syndrome include propranolol, methysergide, and dantrolene.^{9,19}

DISPOSITION

Most patients with serotonin syndrome require admission and 12 to 24 hours of close observation and cardiac monitoring in a telemetry or intensive care unit until symptoms and signs resolve. Severe cases or those with evidence of complications require intensive care. In mild forms of the syndrome, symptoms may resolve spontaneously, or following use of a specific serotonin antagonist such as cyproheptadine, in a shorter time. All patients with a history of intentional overdose require psychiatric assessment prior to discharge. The risk of recurrent serotonin syndrome must be weighed against the benefits of therapy and alternative treatments when considering reinstitution of serotonergic medications.

COMMON PITFALLS

- Failure to appreciate the variety of drugs with serotonergic activity and to take a detailed history of recent drug exposure
- Failure to recognize the serotonin syndrome and to exclude other conditions causing similar signs and symptoms
- Failure to provide aggressive supportive care; overreliance on antidotal therapies
- Prescribing meperidine for pain relief or dextromethorphan as a cough suppressant to patients taking serotonergic medications, particularly MAOIs

CHAPTER 371 Sympathomimetic Poisoning

Christine Haller and Paul R. Pentel

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The sympathomimetic drugs discussed in this chapter are structural analogues of catecholamines that share their ability to stimulate adrenergic receptors. These drugs are less rapidly metabolized than catecholamines and have half-lives long enough to make oral administration feasible. The activity of sympathomimetics at various adrenergic receptors varies and, in part, explains their clinical uses ([Table 371.1](#)). Alpha-mediated vasoconstriction of the nasal mucosa is responsible for decongestion. Beta₂ stimulation causes bronchodilation. Anorectic effects are centrally mediated, but the mechanisms involved are unclear. The dopaminergic action of amphetamines may be an important determinant of amphetamine abuse. The cardiovascular toxicity of sympathomimetics is largely due to alpha- and beta₁-agonist activity.

Drug	Common Uses
PRESCRIPTION	
Amphetamine, dextroamphetamine, levorphanolamine, methamphetamine	Narcolepsy, anorectic agents
Methylphenidate, pemoline	Narcolepsy, attention deficit disorder
Diethylpropion, phentermine, phendimetrazine, fenfluramine	Anorectic agents
Terbutaline, albuterol	Bronchodilators
NONPRESCRIPTION	
Ephedrine	Decongestant, bronchodilator
Pseudoephedrine	Decongestant
Phenylpropanolamine	Decongestant, anorectic agent
Propylhexedrine, desoxyephedrine	Inhaled bronchodilator

TABLE 371.1. Sympathomimetics

Several sympathomimetics occur as optical isomers. Dextroamphetamine is a more potent central nervous system (CNS) stimulant than racemic or *l*-amphetamine. Ephedrine is a more effective bronchodilator than its isomer, pseudoephedrine. Phenylpropanolamine (PPA) is a racemic mixture sometimes referred to as *d,l*-norephedrine. *l*-PPA is more active than *α*-PPA in animals, but the relative activities of the isomers in humans are unknown. Some Australian compounds called PPA (and reported as such in the literature) may have been single isomers of PPA or another compound with the same chemical formula, norpseudoephedrine. Literature regarding these compounds must, therefore, be interpreted cautiously.

When used as decongestants, sympathomimetics are usually formulated in combination with antihistamines, anticholinergics, analgesics, or caffeine. Each of these additional drugs may add to the toxicity of sympathomimetic overdose by increasing heart rate or contributing to cardiac dysrhythmias or seizures.

Prescription sympathomimetics, particularly amphetamines, may be abused for their stimulant properties. Toxicity results from excessive doses or prolonged periods of use. Nonprescription (over-the-counter [OTC]) stimulants are often sold illicitly to buyers who think they are getting amphetamine or cocaine. Because their CNS actions are weak compared with amphetamine or cocaine, unpleasant peripheral effects (tremors and tachycardia) or toxicity is common when these drugs are abused for their weak stimulant properties. Sympathomimetic overdose may also result from excessive use of diet pills, inadvertent use of several different OTC products that all contain sympathomimetics, or suicidal ingestion.

Ephedrine and related isomers are the active constituents extracted from botanical *Ephedra* species and sold commercially as *ma huang*. Combinations of *ma huang* and plant-derived caffeine (e.g., kola nut and guarana), as well as other herbs, such as ginseng and willow bark, are currently marketed as herbal weight loss aids and sold as dietary supplements. Also known as “fat burners,” “herbal fen-phen,” and “herbal ecstasy,” these products are widely promoted and used to stimulate weight loss, increase energy, build strength, and enhance athletic performance. There is no scientific basis to the claim that ephedrine alkaloids derived from a botanical source would have different biologic activity than synthetic compounds. In fact, the toxicity of ephedrine may be greater in combination with caffeine and multiple other ingredients found in herbal supplements because of synergistic effects and alterations in clearance and metabolism. Since 1993, the Food and Drug Administration (FDA) has received more than 800 reports of adverse events associated with the use of ephedrine-containing dietary supplements. Adverse events ranged in severity from insomnia and nervousness to seizures, strokes, cardiac arrhythmias, and death. The FDA has issued a number of public health warnings and proposed requirements for warning statements and dose limits of 8 mg of ephedrine per serving.¹⁶ Approximately 21 states have limited or banned sales of ephedrine-containing products.

Various other forms of, or derivatives of, sympathomimetics are also subject to abuse. “Ice,” relatively pure crystalline methamphetamine hydrochloride, is volatile enough that it can be smoked.¹³ A naturally occurring amphetamine-like compound, cathinone, is the active substance in khat.⁸ The leaves of the khat shrub are commonly chewed in East Africa for their stimulant properties. A derivative, methcathinone (CAT) is a drug of abuse that is growing in use and popularity in the United States and has been classified as a schedule I substance.⁷ Many other “designer drug” derivatives of amphetamine have been synthesized; they are psychoactive at lower doses but may produce sympathomimetic effects with overdose (see [Chapter 341](#)).

OTC sympathomimetics are usually safe when taken by healthy people in recommended doses, but their therapeutic index is low. Although dose-response relations for toxicity are not well documented, available data suggest that ingestion of as little as four or five times the usual dose may produce toxicity.^{5,11} Patients with orthostatic hypotension due to autonomic neuropathy exhibit marked sensitivity to the pressor effect of both prescription and OTC sympathomimetics, even in subtherapeutic doses, and should avoid these drugs. Concurrent use of monoamine oxidase inhibitors may also exaggerate the effects of sympathomimetics.

With chronic use of prescription sympathomimetics such as amphetamine or methylphenidate, considerable tolerance may develop. A toxic dose is therefore difficult to establish. When chronic use is discontinued, users may demonstrate fatigue, hunger, and dysphoria. Unlike withdrawal from sedative-hypnotics, this syndrome poses no medical risk except for the possibility of suicidal depression.

Sympathomimetic toxicity is typically greatest 1 to 4 hours after oral drug ingestion and lasts for 4 to 8 hours, but sustained-release formulations may alter this time course. Onset of toxicity with intravenous use is within minutes. Ephedrine, pseudoephedrine, and PPA are eliminated almost entirely by renal excretion.²⁰ Because these drugs are weak bases, excretion is quickest when the urine pH is low. At the usual urine pH (5.0 to 6.5), half-lives are about 3 to 6 hours.¹⁰ Renal failure or a very alkaline urine could prolong the duration of toxicity. Amphetamine undergoes both hepatic and renal elimination, and metabolites may contribute to toxicity. The elimination half-life of amphetamine and methamphetamine is 4 to 5 hours when the urine is acidic but considerably longer (up to 20 hours for amphetamine) when it is alkaline.⁶

Sympathomimetic toxicity is primarily mediated by excessive adrenergic stimulation. Hypertension is the most common and most important feature. Hypertension is due primarily to alpha-mediated vasoconstriction and may be aggravated by concomitant beta₁-mediated increases in heart rate or cardiac contractility. Hypertension caused by PPA alone is usually accompanied by reflex bradycardia or atrioventricular block; however, coingestion of drugs such as anticholinergic agents that increase heart rate may aggravate hypertension by preventing the reflex slowing of heart rate.¹⁷ Most other sympathomimetics have more beta₁ activity than does

PPA, and hypertension is usually accompanied by sinus tachycardia. Atrial tachyarrhythmias, premature ventricular beats, and ventricular tachycardia are presumably due to excessive beta₁ stimulation.

The mechanisms by which sympathomimetics produce CNS toxicity are less clear. Symptoms of CNS stimulation, including insomnia, agitation, mania, psychosis, and seizures, may result from sympathomimetic triggered release of dopamine and other neurotransmitters in the brain. Hyperthermia is associated with increased heat production caused by agitation or seizures, and impaired heat loss is caused by cutaneous vasoconstriction. Toxicity may rarely result from contaminants of illicitly synthesized drugs, as in one episode of lead poisoning from methamphetamine.¹

CLINICAL PRESENTATION

The most common life-threatening toxic effect of sympathomimetics is hypertension. If severe, hypertension may result in headache, hypertensive encephalopathy, or intracerebral hemorrhage.^{4,9} However, hypertension may be asymptomatic, even at blood pressures that require urgent treatment. Most deaths from sympathomimetic overdose are due to hypertensive intracerebral hemorrhage. Dysrhythmias include sinus or supraventricular tachycardia, premature ventricular beats, and ventricular tachycardia.¹⁹ Patients may present with palpitations or with hypotension due to hemodynamic compromise. Sympathomimetic overdose may rarely produce transient chest pain, ischemic electrocardiographic (ECG) changes, and elevation of the creatine kinase MB isoenzyme, simulating myocardial infarction.¹⁸ This lesion may be due to diffuse myocardial necrosis rather than to focal coronary artery disease. Chronic intravenous use of propylhexedrine has been associated with cardiomyopathy and biventricular congestive heart failure.³

CNS toxicity of amphetamine overdose includes anxiety, agitation, confusion, psychosis, and seizures.¹⁴ Psychotic behavior usually occurs during drug use but has been noted to persist during abstinence in chronic amphetamine abusers. Seizures have been reported when overdoses of OTC sympathomimetics are taken in combination with antihistamines or caffeine.¹⁵ Patients may present with focal neurologic signs or symptoms, most commonly caused by intracerebral hemorrhage. Several cases of ischemic stroke with angiographic changes suggestive of cerebral vasculitis have been reported in patients taking amphetamine or PPA.¹² Chronic amphetamine abuse has also been associated with renal or systemic vasculitis, mimicking polyarteritis nodosa.² The mechanisms of these toxic effects are unknown.

Pupils may be dilated or normal. Hyperthermia is most common in patients who are agitated, active, or seizing. Rhabdomyolysis and myoglobinuric renal failure may occur due to these same factors.

DIFFERENTIAL DIAGNOSIS

The dominant feature of sympathomimetic overdose is hypertension. Differentiation from essential hypertension is important, because patients with sympathomimetic overdose are at risk for intracerebral hemorrhage at blood pressures much lower than those of patients with accelerated or malignant hypertension of other causes (see [Emergency Department Management](#) section). Essential hypertension can be distinguished by history or the finding of fundoscopic changes indicative of long-standing hypertension. Patients with acute cerebrovascular accidents may have secondary hypertension. These patients may be recognized by the finding of focal neurologic deficits, or focal lesions on a head computed tomography (CT) scan. Diagnosis of a cerebrovascular accident is important, because treatment of hypertension in patients with ischemic stroke may worsen the neurologic deficit, and may be contraindicated. Other causes of drug-induced hypertension include cocaine poisoning, phencyclidine poisoning, monoamine oxidase inhibitor interactions with drugs or food, tricyclic antidepressant or anticholinergic overdoses, clonidine withdrawal (or, rarely, overdose), and alcohol or sedative-hypnotic withdrawal syndromes.

Headache is a common, nonspecific finding in patients with sympathomimetic-induced hypertension, but it may also be due to intracerebral hemorrhage. Seizures may also occur as a direct toxic effect or due to secondary complications such as intracerebral hemorrhage.

EMERGENCY DEPARTMENT EVALUATION

Sympathomimetic toxicity should be considered in patients with unexplained hypertension, dysrhythmias, or CNS stimulation. Blood pressure monitoring is essential. Core temperature should be measured immediately. A 12-lead ECG should be obtained and continuous cardiac monitoring instituted. The physical examination is directed toward evaluating the optic fundi and performing a neurologic examination. Laboratory evaluation should include electrolytes, blood urea nitrogen, creatinine, glucose, creatine kinase, and urinalysis. If intracerebral hemorrhage is suspected because of focal neurologic findings, seizures, a depressed level of consciousness, severe headache, or headache that persists after hypertension resolves, a head CT scan is indicated. Most sympathomimetics can be detected in urine by thin-layer chromatography or enzyme-multiplied immunoassay technique (EMIT). Methods for measuring serum concentrations are not usually available.

EMERGENCY DEPARTMENT MANAGEMENT

Initial management is directed at treating severe hypertension, life-threatening dysrhythmias, seizures, and hyperthermia. This should take precedence over gastric decontamination or a head CT scan. Patients with sympathomimetic overdose usually do not have chronic hypertension, nor do they have the shift in cerebral blood flow autoregulation that allows patients with chronic hypertension to tolerate very high blood pressures. Encephalopathy or intracerebral hemorrhage may therefore develop with blood pressures as low as 170 mm Hg systolic or 110 mm Hg diastolic. A blood pressure exceeding these values should be treated as an emergency, with a goal of lowering the blood pressure to less than 170/110 mm Hg within 15 minutes. This can be done with intravenous nitroprusside (0.5 to 5.0 µg/kg/min) or phentolamine (1- to 5-mg bolus initially, repeated at 5- to 10-minute intervals as needed). If intravenous access cannot be established rapidly, “sublingual” or chewed nifedipine is an alternative. Propranolol is not recommended as a single agent for treatment of hypertension caused by sympathomimetics, because paradoxical worsening of the hypertension may result from blockade of beta₂-mediated vasodilatation. Supraventricular tachycardias seldom require therapy. Premature ventricular beats or ventricular tachycardia may be treated with the short-acting beta₁-selective blocker esmolol (loading dose 500 µg/kg; maintenance dose 50 to 100 µg/kg/min intravenously). Reflex bradycardia or atrioventricular block in patients with PPA overdose is a normal response that serves to limit hypertension; reversal of the bradycardia (e.g., with atropine) can worsen hypertension and is not indicated. Hyperthermia may be managed by sedation or paralysis to decrease heat production, and active external cooling with sponge bathing and evaporative cooling.

Agitation or psychotic behavior does not usually necessitate drug therapy but may be managed with intravenous benzodiazepines (diazepam 0.1 to 0.2 mg/kg, lorazepam 0.05 to 0.1 mg/kg, midazolam 0.02 to 0.05 mg/kg, or haloperidol 2 to 5 mg in adults), if needed, with a goal of calming the patient but not obscuring the neurologic examination. Seizures may be treated with a benzodiazepine, although data regarding efficacy are lacking.

Gastric decontamination is best accomplished with oral activated charcoal. Gastric lavage may be indicated for patients with massive, recent ingestions, but it should be performed only after initial treatment to lower the blood pressure. Urine acidification is not usually needed, because the normal urine pH is normally already low and because toxicity is normally brief and can be managed with the previously mentioned measures.⁴ Moreover, if rhabdomyolysis occurs, acidification of the urine may aggravate renal injury. For similar reasons, there is little benefit from hemodialysis or hemoperfusion for sympathomimetic toxicity.

DISPOSITION

When toxicity resolves, monitoring is no longer needed, and admission is indicated only for evaluation or management of concurrent psychiatric diagnoses. Patients with mild signs or symptoms may be monitored in the emergency department, because the duration of toxicity is often brief. Patients with persistent or severe hypertension, dysrhythmias, or CNS stimulation should be monitored in a medical intensive care unit. Patients with headache or neurologic signs that persist when hypertension resolves may need an urgent CT scan of the head and neurologic consultation.

COMMON PITFALLS

- Failure to measure the temperature in seizing or agitated patients and to diagnose and treat hyperthermia
- Failure to evaluate symptomatic patients, especially those with agitation, hyperactivity, seizures, hyperthermia, and vital signs abnormalities, for the presence of rhabdomyolysis
- Failure to appreciate that persistent headache, even without focal signs or symptoms, may be due to intracerebral hemorrhage and should be evaluated with a CT scan of the head
- Failure to appreciate that a blood pressure above 170/110 mm Hg in a previously normotensive person should be treated as an emergency

- Failure to appreciate that bradycardia or atrioventricular block in patients with hypertension due to PPA is a normal (reflex) response that serves to limit hypertension and that treatment with atropine will probably aggravate hypertension and is not indicated
- Failure to inquire about the use of herbal remedies or dietary supplements as part of the medication history

CHAPTER 372

Terpene Poisoning

Louis J. Ling

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Terpenes are a class of unsaturated, aliphatic cyclic hydrocarbons. These volatile substances are found naturally in oils and oleoresins of plants and flowers. Camphor, pine oils, and turpentine are the most common terpenes involved in poisoning. Terpenes also are present in volatile oils of plants (see [Chapter 365](#)).

Camphor, a naturally occurring cyclic ketone obtained from the camphor tree or synthesized from turpentine oil, has minimal medicinal value¹ but is still widely available in up to a 10% concentration in over-the-counter products. It is used as a rubefacient in external analgesic rubs, causing vasodilatation and a sensation of warmth. When inhaled, it causes a cooling sensation, and the odor gives a strong, reassuring effect. Turpentine is a pine tree distillate consisting of pinene, diterpenes, and other terpenes. It is commonly used as a thinner for paints and varnishes. Pine oils contain a variety of terpene alcohols and are found in household cleaners (e.g., Pine Sol) in concentrations of up to 20% to 35%. The toxicity of naphthalene, a terpene found in mothballs, is discussed in [Chapter 316](#).

Camphor is well absorbed orally. Absorption also may occur through the skin.¹⁸ It is classified as very toxic (class 4); lethal doses in humans range from 50 to 500 mg/kg.¹¹ The smallest lethal dose was reported in a 19-month-old child, who died after a 1-g ingestion,³ but an adult has survived after ingesting 42 g.¹² Typically, ingestions of 10 to 30 mg/kg—equivalent to one swallow of camphorated oil—may result in minor symptoms. Major symptoms are uncommon with ingestions below 50 mg/kg.⁸ The acute toxic dose of turpentine has never been well defined, and case reports have given a wide range of effects; vomiting makes dose estimates unreliable. Gastrointestinal (GI) symptoms have occurred in children after ingestions of 15 to 60 mL, and 120 to 180 mL is a potentially lethal dose in adults.⁶ Turpentine ingestions of more than 2 mL/kg should be considered potentially toxic.⁶ Pine oils have about one-fifth the toxicity of turpentine in animals,² and a suggested lethal dose for adults is 60 to 120 g,¹⁵ although survival after a 400-mL ingestion has been reported.⁶

Camphorated oil, with 20% camphor, was removed from the market in 1982, and camphor products are now limited to 11%. Turpentine is highly volatile. Vapors are easily inhaled, and aspiration of the liquid may occur during ingestion. It is well absorbed from the GI tract.¹⁰ Most ingestions are accidental and involve small amounts. It is rare to see toxicity from GI absorption of pine oil, but aspiration is a common problem.

CLINICAL PRESENTATION

Patients with terpene ingestion frequently have a strong odor of camphor, turpentine, or pine oil on the breath, in vomitus, or in the urine. Mild camphor poisoning results in GI symptoms such as nausea, vomiting, and a burning sensation in the mouth, esophagus, and stomach. In some cases, central nervous system (CNS) toxicity initially presents as stimulation and restlessness. CNS depression with delirium, hallucinations, confusion, muscle irritability, and seizures may follow.¹ Symptoms can occur as soon as 5 to 30 minutes after ingestion,¹⁹ and seizures have occurred as soon as 4 minutes after ingestion.¹⁸

Turpentine causes similar GI irritation and CNS symptoms; however, seizures appear to be less common than with camphor. Direct skin contact with turpentine can be irritating. A single case of acute renal failure and hemorrhagic cystitis several days after ingestion has been reported.¹³ Turpentine has been implicated in the pathogenesis of thrombocytopenic purpura.²⁰

The breath odor of a patient with pine oil ingestion is characteristically violet-like, from the metabolites that are excreted in exhaled air.¹⁵ Patients usually present with gastrointestinal symptoms and respiratory symptoms from aspiration. CNS toxicity (e.g., somnolence, ataxia) is usually mild and develops within 90 minutes. Ataxia is much more common in children, but lethargy and coma may be present in children or adults.³ Facial erythema has been reported.¹⁵ Renal failure is rare.

Patients with camphor poisoning may show a transient leukocytosis and modest abnormalities on liver function tests.¹⁹ Hepatotoxicity has also been reported after massive pine oil ingestions.¹⁹ Patients who ingest turpentine or pine oil may have concomitant aspiration and resultant respiratory symptoms (see [Chapter 362](#)).

DIFFERENTIAL DIAGNOSIS

If the history is vague or unavailable, the odor of the patient's breath, vomitus, or urine may be a valuable diagnostic clue. Naphthalene, paradichlorobenzene, and other volatile oils have a vaguely similar aroma.

EMERGENCY DEPARTMENT EVALUATION

As in all toxic exposures, the product name and contents, the amount ingested, the time since exposure, and symptoms must be sought. Physical examination should focus on CNS and GI symptoms. Patients should be assessed for signs and symptoms of aspiration (see [Chapter 362](#)).¹⁷ Any emesis should be tested for blood. Routine laboratory studies for symptomatic patients include a baseline complete blood count with platelets; determination of electrolyte, blood urea nitrogen, creatinine, and glucose levels; and urinalysis. Arterial blood gas analysis or oxygen saturation measurement and chest radiography should be performed if aspiration is suspected (see [Chapter 362](#)).

EMERGENCY DEPARTMENT MANAGEMENT

Because the onset of seizures and pulmonary toxicity may be rapid with camphor, an ambulance should be used to transport these patients.¹⁹ Advanced life-support measures are instituted, as necessary. Patients who are symptomatic and have ingested more than 2 g¹⁸ or 30 mg/kg of camphor⁶ or 2 mL/kg of turpentine⁶ should have gastric emptying. Because of the risk of aspiration with CNS depression and seizures, syrup of ipecac should not be used after camphor ingestion. Gastric lavage very early after ingestion may be considered.¹⁵ A small tube may be adequate for a liquid preparation. Activated charcoal has not absorbed camphor well in animals.⁴ Terpenes have hydrocarbon characteristics, which make them unlikely to be absorbed by activated charcoal.^{4,19} Mineral oil and vegetable oil were formerly recommended as solvents or cathartics for camphor, but because their use may increase the risk of aspiration and enhance the absorption of camphor, they are no longer recommended.¹⁵

Renal, hepatic, and bone marrow complications are treated supportively. Lipid hemodialysis against soybean oil⁹ and Amberlite resin hemoperfusion¹⁴ have been used in patients with severe camphor poisoning. These measures are not of benefit in patients who have ingested pine oil because of its large volume of distribution.¹⁵ Patients with pine oil aspiration recover faster; these aspirations are not as serious as other hydrocarbon aspirations.³

DISPOSITION

Patients who remain asymptomatic or have only mild GI symptoms during the 6 hours after ingestion are at low risk for serious complications and may be discharged.^{8,15} Patients with systemic symptoms, those with aspiration with persistent or progressive symptoms,¹⁶ and those who have clearly ingested more than 3 g of camphor should be admitted for observation.¹⁵ Patients with seizures or CNS depression should be admitted to an intensive care unit. Symptomatic patients should also be monitored for hematologic, renal, and hepatic complications. Patients with persistent seizures or coma after camphor ingestion should be considered for hemodialysis or hemoperfusion. Although rare deaths have been reported, patients with pine oil ingestion should be expected to recover readily with minimal

supportive care.^{3,7}

COMMON PITFALLS

- Failure to appreciate that small amounts of camphor may be toxic (e.g., a swallow of 10% camphor)
- Failure to establish intravenous access and to be prepared to treat seizures, which can occur early and without warning
- Failure to recognize the risk of aspiration with syrup of ipecac or gastric lavage
- Failure to check hematologic, renal, and hepatic function parameters in symptomatic patients
- Failure to advise patients who are discharged to return if any respiratory symptoms develop

CHAPTER 373

Thyroid Hormone Poisoning

Milton Tennenbein

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Thyroid hormones are used as replacement therapy for hypothyroid states and as pituitary suppressants in the treatment or prevention of euthyroid goiters. The two available types are tetraiodothyronine (thyroxine, or T_4) and triiodothyronine (T_3). A given preparation may be of natural (beef or pork thyroid extract) or synthetic origin and contain one or both of these hormones ([Table 373.1](#)).

Thyroid Preparation	Thyroid Hormone Content
NATURAL PREPARATIONS	
Thyroid extract Armour Thyroid (USV) S.P.T. (Boering)	T_4, T_3
Thyroglobulin Proloid (Parke-Davis)	T_4, T_3
SYNTHETIC PREPARATIONS	
Levothyroxine sodium Synthroid (Iliot) Levothyroid (USV)	T_4
Liothyronine sodium Cytomet (SKF)	T_3
Liotrix Luthroid (Parke-Davis) Thyroal (USV)	T_4, T_3 (4:1)

TABLE 373.1. Thyroid Hormone Preparations

In addition to being important in the regulation of growth and development, thyroid hormones increase heat production and oxygen consumption by body tissues and stimulate the cardiovascular system. The usual daily adult replacement dose is 100 to 300 μg of T_4 , 25 to 75 μg of T_3 , and 60 to 180 mg of thyroid extract or its liotrix equivalent. The normal serum concentration is 4 to 12 $\mu\text{g}/\text{dL}$ for T_4 and 110 to 250 ng/dL for T_3 . T_3 is well absorbed from the stomach (greater than 90%), but the absorption of T_4 is less efficient (50% to 90%). Peripheral tissues convert T_4 to T_3 , the metabolically active thyroid hormone. More than 99% of circulating thyroid hormones are metabolized by deiodination; most of the remainder are conjugated before excretion, with some being excreted intact. The half-life of a therapeutic dose of T_4 is 4 to 7 days; it is about 1 day for T_3 .

Acute oral overdose of thyroid hormones seldom produces serious toxicity, and no deaths have been reported. Thus, the minimal toxic and lethal doses are unknown, and there is no correlation between serum T_4 concentration and clinical severity. Children are resistant to the effects of large overdoses.²⁰ Elderly patients with compromised cardiovascular function may be more sensitive, but there are no data to support this speculation.

To assess toxic risk, it is important to differentiate between the different types of thyroid hormone supplements. Because T_3 is the active thyroid hormone, acute toxicity would be predicted. Only one case of its ingestion has been reported,⁴ and although the onset of toxicity was within a few hours, it was minor and of brief duration (12 hours) despite a documented serum concentration 50 times normal. Eighty tablets were ingested (or 80 therapeutic doses); this patient coingested significant amounts of an antidepressant and an antihistamine, which may have contributed to the observed toxicity.

In contrast, T_4 overdose is relatively common.^{6,8,10,11,13,14,17,20} There has been no evidence of toxicity in children who have ingested up to 1.5 mg of T_4 .¹⁴ Ingestions of up to 30 mg have produced negligible toxicity,²⁰ as have serum T_4 concentrations of 84.7²⁰ and 90 $\mu\text{g}/\text{dL}$.¹⁷ Thus, there is a large tolerance for acute massive ingestion of levothyroxine. Several factors contribute to this inherent low toxicity. Conversion of T_4 to T_3 takes several days, and is regulated by a negative-feedback loop. The presence of excess T_4 inhibits endogenous secretion of this hormone, inhibits the peripheral conversion of T_4 to T_3 ,² increases the disposal rates of both T_4 and T_3 ,² and downregulates the T_3 nuclear receptors.¹⁹ Also, elevation of serum concentrations of reverse T_3 (an inhibitor of thyroid hormones) has been observed in two T_4 overdose patients.^{11,16} Therefore, it is expected that the occurrence of toxicity would be less likely and its onset later (several days).

The only reported case of serious toxicity occurred in a 2-year-old boy who took 18 mg of levothyroxine.¹⁰ At about 6 hours after ingestion, his serum thyroxine concentration was 117.4 $\mu\text{g}/\text{dL}$, and he had two seizures 7 days later. There have been reports of minor toxicities such as asymptomatic tachycardia, low-grade fever, diarrhea, and hyperactivity.^{6,8,13,14}

The ingestion of products that contain both T_3 and T_4 may theoretically result in biphasic toxicity with early (within hours) and late (after several days) phases. In fact, only one of the six reported patients with acute combined overdose developed significant toxicity.^{5,9,12} This 15-month-old boy was seriously ill within 6 hours, but asymptomatic by 24 hours.¹²

The repeated ingestion of excessive amounts of thyroid hormones on a daily basis (chronic overdose or abuse) will probably produce toxicity. Overt hyperthyroidism and even death may occur.^{1,7,15,18} Such patients may be abusing thyroid hormones to lose weight or because of emotional instability or frank psychiatric illness. They often deny thyroid ingestion.

CLINICAL PRESENTATION

Most patients with acute thyroid overdoses are asymptomatic on presentation, and it is uncommon for signs and symptoms to develop. The few patients who manifest toxicity have the features of hyperthyroidism (fever; tachycardia; warm, moist skin; diarrhea; restlessness; and anxiety). For T_4 , the onset is between many hours and several days; for T_3 , the onset is within a few hours. However, chronic rather than acute overdose is more likely to produce this picture. Such patients may have virtually all the signs of hyperthyroidism except for exophthalmos.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of chronic thyroid hormone abuse includes metabolic conditions (e.g., pheochromocytoma and hypoglycemia), central nervous system infection, organic brain syndrome, overdose with psychoactive drugs (e.g., amphetamine, cocaine, anticholinergics, and hallucinogens), acute withdrawal states, and acute psychotic illness. For patients with elevated serum T_4 concentrations, the chief differentiation is from endogenous hyperthyroidism, in which the serum thyroglobulin concentration is elevated. It is depressed in patients with exogenous hyperthyroidism.¹⁵

EMERGENCY DEPARTMENT EVALUATION

The history includes the identity of the ingestant, the dose, the time of ingestion, symptoms of hyperthyroidism, the reason for ingestion, and prior medical conditions. The identity of the hormones involved is important because of their differing clinical courses after overdose. The physical examination is directed toward eliciting the findings of hyperthyroidism. In the case of acute ingestions, the T_4 concentration is measured 4 to 6 hours after ingestion if the patient has ingested more than 2 mg of levothyroxine or its equivalent. This amount identifies patients who require follow-up; this measurement should be done in all patients with chronic thyroid overdose.

EMERGENCY DEPARTMENT MANAGEMENT

Supportive measures are instituted as necessary. Gastrointestinal decontamination should be considered for patients who have ingested more than 2 mg of thyroxine or its equivalent. For the uncommon patient who develops symptoms after acute ingestion, acetaminophen for fever and propranolol for sympathetic hyperactivity can be considered.^{6,8,13} The oral administration of iopanoic acid (Telepaque, 125 mg per day in a 2.5-year-old), an iodine-containing radiocontrast agent that inhibits the conversion of T_4 to T_3 , has also been used with apparent success.³ The use of prophylactic antithyroid therapy (cholestyramine, prednisone, propylthiouracil, and propranolol) in asymptomatic patients is controversial, but experience has demonstrated that it is unnecessary.^{6,11,14,20} For the symptomatic patient with chronic thyroid ingestion, thyroid supplements should be discontinued, and the patient should be treated as for endogenous hyperthyroidism and thyroid storm. Enhanced elimination by extracorporeal removal has not been shown to be of benefit.²⁰

DISPOSITION

Patients with significant T_3 overdoses (20 therapeutic doses or more) should be admitted to an observation or inpatient unit. Vital signs, cardiac rhythm, and clinical status should be monitored for 12 to 24 hours. Because patients with acute T_4 overdose are at risk only for delayed toxicity, immediate inpatient observation is unnecessary. Toxicity after acute T_4 overdose has not been reported with serum concentrations under 25 $\mu\text{g/dL}$; daily assessment for the next 10 days is required if this value is exceeded. Symptomatic patients should be treated, as necessary. Patients who present with hyperthyroidism due to chronic abuse usually require admission. Consultation with an endocrinologist is advisable.

COMMON PITFALLS

- Failing to differentiate between T_3 and T_4 overdose
- Failing to differentiate between acute and chronic overdose
- Failing to appreciate that acute overdoses of levothyroxine or thyroid extract may result in delayed toxicity. Arrangements should be made for close follow-up.
- Using overzealous therapy (prophylactic antithyroid drugs, extracorporeal removal) in asymptomatic patients

CHAPTER 374

Valproate Poisoning

Gregory G. Gaar

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Valproic acid, valproate sodium, and divalproex sodium are used either alone or in combination with other anticonvulsants primarily in the treatment of absence seizures, both simple and complex. Although not currently included in the labeling approved by the Food and Drug Administration, they are also used to treat temporal lobe seizures, myoclonic seizures, and generalized tonic-clonic seizures. They are now approved for use in the treatment of migraine headaches and the manic phase of bipolar illness.

The compounds are carboxylic acid derivatives that differ structurally from any of the other commercially available anticonvulsants.¹⁴ Although valproic acid's mechanism of action has not been fully elucidated, it is believed to exert some effects through modulation of levels of gamma-aminobutyric acid (GABA), an inhibitory central nervous system (CNS) neurotransmitter.

In the United States, forms for oral use include capsules of valproic acid (250 mg), a solution of valproate sodium (250 mg valproic acid per 5 mL), a "sprinkle capsule" containing coated granules of divalproex sodium (equivalent to 125 mg of valproic acid), and enteric-coated tablets of divalproex sodium (equivalent to 125, 250, and 500 mg of valproic acid).¹⁴ Depakene and Depakote are the most widely used brands of valproate sodium and divalproex sodium, respectively. The initial starting dosage is 15 mg/kg/d (maximum, 600 mg/d). Once weekly, the dosage may be increased by 5 to 10 mg/kg/d until adequate seizure control is established or adverse effects necessitate smaller dosages. The manufacturer does not recommend a dosage of more than 60 mg/kg/d. Although definite therapeutic or toxic serum levels have not been established, it is generally accepted that therapeutic concentrations are in the range of 50 to 100 µg/mL.¹⁴

Absorption of valproic acid is rapid and complete from either capsule or solution formulation. Although valproate sodium must be converted to valproic acid to be absorbed, this reaction occurs rapidly in the stomach. Peak plasma concentrations occur within 1 to 4 hours of a single oral dose of valproic acid. Food in the gastrointestinal (GI) tract decreases the rate of absorption but not the total amount.¹⁴ When enteric-coated tablet or granule preparations are used, the compound must dissociate into valproate in the jejunum before absorption can occur. The enteric coating slows this process, so the peak plasma level occurs later, usually within 3 to 5 hours of a single oral dose.^{7,14}

The volume of distribution ranges from 0.1 to 0.4 L/kg.¹⁴ Therefore, distribution is mostly into plasma and extracellular water. Protein-binding is significant in the therapeutic range; at concentrations of 80 µg/mL, almost 90% is bound to proteins.^{7,14} At concentrations above 100 µg/mL, saturation of these proteins occurs and the percentage of drug bound to plasma protein decreases.¹⁴ Accordingly, after the acute ingestion of toxic amounts, the percentage of circulating "free" drug increases markedly.⁸

The elimination half-life ranges from 7 to 15 hours.^{7,14} Valproic acid is metabolized by the liver; the metabolites are usually conjugated with glucuronide and then eliminated in the urine. Small amounts of drug are excreted unchanged in the urine and feces.¹⁴ Other antiepileptic drugs used concomitantly can alter the half-life of valproic acid, usually reducing it.⁷ In contrast, concomitant use of valproate may inhibit the metabolism of phenobarbital and increase phenobarbital levels.¹¹

Valproic acid can be toxic both after acute overdoses and during chronic therapy. In acute ingestion, there are no absolute guidelines for predicting toxicity based on the amount ingested. A 19-month-old infant survived an ingestion of 204 mg/kg, with a serum drug level of 185 µg/mL, and adults have recovered from ingesting as much as 75 g.^{9,13,16} In one large series, patients were likely to be unconscious only after ingesting more than 200 mg/kg.⁹ Death from complications of pneumonia has been reported after an ingestion of 15 g (705 mg/kg) in a 20-month-old boy.¹⁷

Toxic manifestations have occurred during chronic use at therapeutic dosages. Blood levels above 100 µg/mL may cause unusual neurologic effects or potentiate seizures. Dosages of 2.2 to 2.5 g/d have caused CNS effects.⁶ Hepatotoxicity can occur with chronic therapy and may be fatal.⁵ Hyperammonemia and hyperglycinemia have occurred secondary to inhibition of enzymes involved in intermediate cell metabolism, independent of hepatotoxicity. Acute pancreatitis is rare.³

CLINICAL PRESENTATION

The predominant symptoms and signs of toxicity after acute overdosage with valproate relate to the CNS. Drowsiness, confusion, and change in mental status are the most common.^{6,13} Coma may ensue, with subsequent respiratory failure.^{9,13,17} Seizures and myoclonic movements have been reported.⁹ Pupils may be pinpoint and sluggishly reactive to light.¹ GI toxicity includes nausea, vomiting, and diarrhea. Hypotension and cardiorespiratory arrest are rare.¹⁷

Toxicity during chronic valproate usage includes mental status changes such as drowsiness, confusion, and social withdrawal.⁶ Nausea, emesis, and abdominal pain have been observed. Elevated liver enzyme levels, hepatocellular necrosis, and fatal cholestatic hepatitis are rare. Hyperammonemia has been noted.¹² Hematologically, thrombocytopenia and impaired platelet aggregation have been seen.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a patient with impaired mental status due to the acute ingestion of a toxic amount of valproate includes trauma, hypoglycemia, hypoxia, other toxins (barbiturates, opiates, tricyclic antidepressants), infections, metabolic disorders (diabetic ketoacidosis and Reye syndrome), intracranial tumors, and the postictal state. An elevated serum valproate level and the exclusion of other causes confirm the diagnosis.

EMERGENCY DEPARTMENT EVALUATION

The history includes questions about the amount of valproate presumed to be ingested, other substances available for ingestion in the patient's environment, and the time of the ingestion (or the last time the patient was in his or her usual state of health). The patient's preexisting health status is noted. The events that occurred between the time of the ingestion and presentation to the emergency department are documented.

The physical examination initially focuses on the CNS and cardiorespiratory function. Cardiorespiratory monitoring and pulse oximetry are instituted in patients with a known ingestion of toxic amounts or in patients demonstrating toxic effects. A quantitative valproate level is ordered to confirm the diagnosis. Serial levels are obtained after an acute overdose. As most patients with seizure disorders have access to multiple medications, an "anticonvulsant screen" is often useful. Full toxicology testing should be considered in patients with intentional overdoses. In symptomatic patients, routine laboratory evaluation includes a complete blood count; measurement of serum electrolytes, blood urea nitrogen, creatinine, and glucose; and hepatic function tests. A chest x-ray and arterial blood gas analysis should be obtained in patients with severe poisoning.

For patients on chronic valproate therapy, monitoring should include a complete blood count with differential, a platelet count, liver function tests (including serum ammonia), and serum electrolyte measurements.

EMERGENCY DEPARTMENT MANAGEMENT

Initial management of the patient suspected of having ingested an overdose of valproate is immediate support of vital functions. In patients with coma of unknown cause, appropriate doses of naloxone, glucose, and thiamine are given. Naloxone reportedly reverses CNS depression secondary to valproate poisoning,¹ but no study of a series of patients has replicated this finding, and responses have been inconsistent.

Prevention of absorption is the next consideration. Activated charcoal is the preferred method of preventing absorption of valproic acid. Charcoal adsorbs valproate.¹⁶ Emesis with syrup of ipecac is not recommended, as the patient could develop an altered mental status from drug effects during emesis. Gastric lavage should be reserved for patients who are comatose and present within 30 minutes to 1 hour after the ingestion. In patients who have ingested large amounts of enteric-coated tablets, whole-bowel irrigation might, theoretically, be advantageous.²

Hemodialysis and hemoperfusion were used in an adult who ingested 75 g¹⁵ of valproate and in another who had a valproic acid level of 1,262 µg/mL.¹⁸ Although both recovered, pharmacokinetic data were not available to prove the efficacy of extracorporeal removal. Given the complications of these procedures and the fact that toxicity is usually responsive to good supportive care, extracorporeal removal is not routinely recommended.¹⁰ Forced diuresis is ineffective.

There is evidence supporting the use of repeated doses of activated charcoal. In one case, continuous nasogastric infusion of charcoal appeared to increase the elimination of valproic acid.⁸ However, the effect of this therapy on other drugs must be considered in the management of patients who may be on multiple anticonvulsants.

Most patients recover fully. Sequelae are rare, although a report of visual disturbances has been published.⁴

DISPOSITION

All patients with changes in mental status or respiratory function after an acute overdose of valproic acid should be hospitalized in a facility capable of providing continuous cardiorespiratory monitoring. Appropriate consultation from physicians trained in clinical toxicology, intensive care, and pulmonary medicine may be indicated, depending on the clinical course. If intensive care necessitates transfer to another facility, stabilization—including appropriate airway management, intravenous access, and maintenance of circulatory status—should precede advanced cardiac life-support-capable transport to the appropriate institution.

Patients who have ingested rapidly absorbed products should have valproate levels monitored for at least 6 hours after the overdose; those who have ingested enteric-coated preparations should be monitored for 8 to 10 hours. If drug levels are decreasing and there are no clinical signs of toxicity, they can be discharged. Psychiatric consultation should be obtained before discharge on all patients with intentional overdose.

COMMON PITFALLS

- Failure to appreciate that the onset of toxicity may be delayed, particularly after overdose of enteric-coated or granule formulations of divalproex sodium
- Failure to obtain serial drug levels after an acute overdose, in order to determine whether further observation is necessary
- Failure to appreciate that therapy is primarily supportive and depends on the clinical condition, not the drug level
- Failure to appreciate that the benefit–risk ratio does not justify the routine use of extracorporeal elimination procedures, even with markedly elevated drug levels

CHAPTER 375 Withdrawal Syndromes

Paul M. Wax

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The clinical presentation of the withdrawal syndrome varies significantly among patients. Patients who present with symptoms and signs of withdrawal and admit to a history of substance abuse are easily identified; those who present with withdrawal symptoms (e.g., seizures) but initially deny ethanol and drug use are not. In patients who present with medical and surgical complications of ethanol and drug abuse, such as pneumonia, pancreatitis, skin abscess, or subdural hematoma, the physician must carefully look beyond the primary process to recognize manifestations of a withdrawal process. Finally, patients may present with an unrelated problem, such as a myocardial infarction or motor vehicle accident, and develop withdrawal symptoms while waiting for admission. To recognize and manage these diverse groups of patients expeditiously, emergency physicians must be familiar with the clinical manifestations and treatment strategies of ethanol and drug withdrawal.

Ethanol withdrawal is the most common withdrawal syndrome seen in the emergency department ([Table 375.1](#)). Ethanol withdrawal, as well as the less commonly seen withdrawal from sedative–hypnotics such as benzodiazepines, barbiturates, chloral hydrate, glutethimide, ethchlorvynol, and meprobamate, may result in life-threatening manifestations. Anticipating and recognizing the early signs of ethanol and sedative–hypnotic withdrawal allow for timely treatment and prevent the development of serious withdrawal manifestations. Opioid withdrawal tends to follow a much more benign course. Withdrawal from cocaine may result in lethargy, dysphoria, and depression; withdrawal from tricyclic antidepressants may result in anxiety, insomnia, malaise, and gastrointestinal (GI) symptoms, but the importance of emergent recognition and treatment of these conditions is less well defined.

Type of Withdrawal	Onset of Symptoms
Ethanol	6–8h
Sedative-hypnotic (e.g., benzodiazepines, barbiturates)	3–7 d (long-acting drugs)
Opioids	4–8h (heroin); 36–72h (methadone)
Cocaine	Within hours after binge
Tricyclic antidepressants	few days

TABLE 375.1. Withdrawal Syndromes Seen in the Emergency Department

Physical tolerance and dependency to a drug are a prerequisite for the development of a withdrawal syndrome from that drug. The dose of the drug, duration of effect, frequency of administration, and duration of abuse all contribute to the development of dependency. More severe withdrawal phenomena may be associated with a longer period of abuse or a history of previous withdrawal episodes. Sporadic use of a drug does not generally cause the altered pharmacodynamic and pharmacokinetic responses required for the development of withdrawal symptoms.

Withdrawal from ethanol and other sedative–hypnotics is characterized by intense sympathetic stimulation. The exact mechanism has not been fully elucidated, but it has been theorized that this hyperadrenergic state may result, in part, from unopposed compensatory central nervous system (CNS) mechanisms that counteract the depressant effects of ethanol intoxication. Elevated levels of plasma and urinary catecholamines and a decrease in the inhibitory activity of presynaptic α_2 receptors have been demonstrated in patients withdrawing from ethanol.

Other contributory mechanisms to ethanol withdrawal may involve changes in gamma-aminobutyric acid (GABA; an inhibitory neurotransmitter), glutamate (an excitatory neurotransmitter), and dopamine-receptor activity.¹ Chronic ethanol abusers have been shown to have a decrease in GABA activity. Ethanol withdrawal results in reduced sensitivity to GABA inhibition. The “excitotoxicity” associated with ethanol withdrawal may also be partially due to upregulation in *N*-methyl-D-aspartate (NMDA) glutamate receptors, thereby increasing calcium flux through these receptors.⁵ Increased dopaminergic transmission may contribute to ethanol withdrawal hallucinations.¹⁰

Withdrawal from opioids may also involve an increase in sympathetic discharge, but to a lesser extent than ethanol withdrawal and by a different mechanism. Unlike ethanol, opioids have a specific, well-defined receptor. A decrease in exogenous opioid binding to opioid receptors increases catecholamine release in the locus ceruleus of the CNS. Severe catecholamine storm, however, is not observed during opioid withdrawal.

In all withdrawal scenarios, the precipitant is a decrease or elimination of the dependent drug. An absolute serum drug level of zero is not required to make the diagnosis of ethanol or drug withdrawal. In chronic alcoholics who routinely maintain high ethanol blood levels, withdrawal symptoms may occur at serum levels of 100 mg/dL or more.

CLINICAL PRESENTATION

The clinical presentation of ethanol withdrawal varies in intensity and duration. There are four different symptom stages: tremulousness, seizures, hallucinations, and delirium.¹⁹ Because these stages may coexist and overlap, the physician should categorize ethanol withdrawal as mild, moderate, or severe.

Tremulousness and anxiety characterize mild ethanol withdrawal. Because ethanol is a short-acting agent, withdrawal may begin relatively quickly, within 6 to 8 hours after the patient stops or reduces ethanol intake. Other symptoms may include insomnia, anorexia, nausea, and vomiting. The physical examination may be remarkable for mild autonomic and CNS hyperactivity characterized by tachycardia, hypertension, irritability, and hyperreflexia. Unlike patients with delirium tremens, patients with mild ethanol withdrawal have a clear mental status. Most patients with mild withdrawal recover uneventfully after a few days, but 20% to 25% develop more serious withdrawal manifestations.

Seizures and hallucinations are evidence of moderately severe withdrawal. About 25% of patients with ethanol withdrawal demonstrate seizure activity. Seizures usually occur within 48 hours of decreased ethanol intake. These patients may or may not have tremulousness and other sympathetic hyperactivity before seizure activity begins. Seizures tend to be of the generalized tonic–clonic type. They may occur singly or as a brief flurry with normal sensorium between seizures. Status epilepticus is uncommon. As many as a third of patients with seizures progress to delirium tremens.

About 25% of patients with ethanol withdrawal experience some form of false perceptions, including hallucinations and illusory experiences. Most of the hallucinations appear to be visual (e.g., insects crawling on the wall). Some patients complain of auditory hallucinations, often of a persecutory nature. This distinctive presentation, known as acute alcoholic hallucinosis, may not be accompanied by sympathetic hyperactivity. Acute alcoholic hallucinosis usually lasts for at least several days but

may persist for months; it may resemble paranoid schizophrenia.¹⁸

Delirium tremens, characterized by an altered sensorium and dramatic sympathetic hyperactivity, is the most severe form of ethanol withdrawal. Although only 5% of patients with ethanol withdrawal progress to delirium tremens, a study of inpatients admitted for ethanol detoxification or withdrawal showed that 24% developed delirium tremens.⁶ It appears to be more common in patients with a long history of ethanol use, a prior history of significant withdrawal, more days since last ethanol use, and concurrent acute medical illness.

Delirium tremens usually begins 48 to 72 hours after cessation or reduction of ethanol. These patients are truly delirious, demonstrating global confusion, agitation, hallucinations, and delusions. Picking at the bedclothes is common. Tachycardia, hypertension, tachypnea, hyperthermia, diaphoresis, and mydriasis may occur, as may tachyarrhythmias. In the untreated patient, mortality usually results from severe dehydration, coexisting medical conditions, or hyperthermia. Although, in the past, mortality rates have been as high as 35% in untreated patients, early recognition of the problem and aggressive treatment should eliminate mortality in patients without significant underlying disease.

Other sedative–hypnotic withdrawal syndromes may be indistinguishable from ethanol withdrawal except for differences in the time course. Because most benzodiazepines have a much longer elimination half-life than ethanol and have active metabolites, withdrawal manifestations may be delayed up to 1 week or more after cessation of drug use. Mild withdrawal symptoms include anxiety, apprehension, irritability, dysphoria, and insomnia.¹⁴ These symptoms may be difficult to distinguish from an underlying anxiety disorder. Hallucinations, delusions, myoclonus, seizures, and agitation may appear with more severe withdrawal. Symptoms from long-acting benzodiazepine withdrawal may persist for weeks. Severe withdrawal symptoms, including seizures, may occur after the administration of flumazenil to patients chronically taking benzodiazepines.

The clinical manifestations of opioid withdrawal are usually different. Symptoms of mild opioid withdrawal include lacrimation, rhinorrhea, yawning, diaphoresis, anxiety, restlessness, and dysphoria. Piloerection is particularly characteristic. The patient may exhibit mild elevations in pulse, blood pressure, and respiratory rate, but these changes are usually not very significant. More severe opioid withdrawal is characterized by vomiting, diarrhea, abdominal pain, and dehydration. Severe agitation, seizures (except in neonatal withdrawal), mental status changes, and hyperthermia are not seen with opioid withdrawal, as they are in ethanol and sedative–hypnotic withdrawal.

The severity and time course of the opioid withdrawal syndrome depends on the pharmacokinetics of the opioid. Shorter-acting agents (e.g., heroin) tend to have a more intense course than longer-acting agents (e.g., methadone). Heroin withdrawal usually begins within 4 to 8 hours after the last dose, peaking by 36 to 72 hours. In contrast, the onset of methadone withdrawal may be delayed 36 to 72 hours after the last dose, and symptoms may persist for up to 2 weeks.⁷

In the emergency department, the sudden onset of opioid withdrawal may occur after an opioid antagonist such as naloxone is given to an unsuspected opioid-dependent patient. Due to naloxone's short half-life, withdrawal symptoms do not usually persist beyond 20 to 60 minutes. Treatment with additional opioid to reverse these effects is not indicated. Giving opioids with agonist–antagonist properties, such as pentazocine (Talwin), nalbuphine (Nubain), and butorphanol (Stadol), to the opioid-dependent patient may also precipitate withdrawal symptoms. Opioid withdrawal from the long-acting opioid antagonists naltrexone and nalmefene may result in a markedly prolonged withdrawal period lasting upwards of 1 to 2 days.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the withdrawal state is broad and includes many other serious conditions that may require different therapy ([Table 375.2](#)). Because drug-dependent patients are particularly prone to develop many of these conditions, careful exclusion of other etiologies is critically important. Ethanol-induced hypoglycemia must be differentiated from ethanol withdrawal. Clinically, both conditions may feature diaphoresis, tachycardia, confusion, agitation, and an odor of ethanol on the breath. However, only the patient with hypoglycemia will have rapid improvement with the intravenous administration of 50 g of glucose.

Symptom	Ethanol Withdrawal	Opioid Withdrawal	Other Causes
Agitation	Common	Common	Delirium, Anxiety, Infection
Confusion	Common	Uncommon	Delirium, Hypoglycemia, Hypoxia
Diaphoresis	Common	Uncommon	Hyperthermia, Infection
Mydriasis	Common	Uncommon	Hyperthermia, Infection
Tachycardia	Common	Common	Hyperthermia, Infection, Anemia
Hypertension	Common	Common	Hyperthermia, Infection, Anemia
Tachypnea	Common	Uncommon	Hyperthermia, Infection, Pulmonary Embolism
Vomiting	Uncommon	Common	Gastroenteritis, Infection
Diarrhea	Uncommon	Common	Gastroenteritis, Infection
Abdominal Pain	Uncommon	Common	Gastroenteritis, Infection
Seizures	Common (Delirium Tremens)	Uncommon	Epilepsy, Hypoglycemia, Hypoxia
Yawning	Uncommon	Common	None
Lacrimation	Uncommon	Common	None
Rhinorrhea	Uncommon	Common	None
Piloerection	Uncommon	Common	None
Restlessness	Uncommon	Common	None
Dysphoria	Uncommon	Common	None
Anxiety	Uncommon	Common	None
Apprehension	Uncommon	Common	None
Irritability	Uncommon	Common	None
Dysphoria	Uncommon	Common	None
Insomnia	Uncommon	Common	None
Hallucinations	Common (Delirium Tremens)	Uncommon	Delirium, Infection
Delusions	Common (Delirium Tremens)	Uncommon	Delirium, Infection
Myoclonus	Uncommon	Uncommon	None

TABLE 375.2. Differential Diagnosis of Major Withdrawal Symptoms

Differentiating ethanol withdrawal seizures from other types of seizures may be particularly difficult. Not all seizures in the alcoholic patient are due to ethanol withdrawal: Other common causes include preexisting idiopathic epilepsy, posttraumatic epilepsy, and other complications of ethanol abuse (e.g., hypoglycemia, hypomagnesemia, hyponatremia, head trauma). Poor anticonvulsant compliance in chronic alcoholics with underlying seizure disorders may add to the diagnostic confusion.

Opioid withdrawal must be distinguished from ethanol and other sedative–hypnotic withdrawal because of the significant differences in therapy. Symptoms of significant ethanol withdrawal, such as confusion, agitation, and seizures, are not generally seen with opioid withdrawal; opioid withdrawal symptoms such as piloerection, yawning, lacrimation, and rhinorrhea are not seen with ethanol and sedative–hypnotic withdrawal. Some patients, however, may be withdrawing from both substances. GI manifestations of opioid withdrawal must be differentiated from other causes of gastroenteritis.

EMERGENCY DEPARTMENT EVALUATION

Patients presenting with possible ethanol or drug withdrawal require a comprehensive assessment. All patients initially should be connected to a cardiac monitor. A fingerstick glucose and oxygen saturation analysis should also be performed. The physician must obtain a complete history of substance abuse, previous withdrawal episodes, and all current and former medications. If possible, family, friends, and prehospital personnel are interviewed to gain additional information. Alcoholics tend to underreport their substance use; drug abusers may overreport it.

All vital signs, including rectal temperature, are recorded and closely monitored. Examination of the skin, abdomen, eyes, and pulse rate may help to distinguish an anticholinergic toxidrome (dry skin, decreased bowel sounds, urinary retention, mydriasis, tachycardia) from a sympathomimetic toxidrome (moist skin, normal bowel sounds, no urinary retention, mydriasis, tachycardia). Close attention should be directed to any stigmata of chronic liver disease or evidence of intravenous drug use.

Because these patients are at high risk for concomitant trauma, a full assessment for obvious and occult traumatic injury should be done. These patients should also be evaluated for other complications of ethanol and drug abuse, such as pneumonia, skin abscesses, bacterial endocarditis, acquired immunodeficiency syndrome, pancreatitis, liver disease, and GI bleeding.

Laboratory studies should include a complete blood count; measurement of electrolytes, glucose, blood urea nitrogen, and creatinine levels; liver function tests; coagulation profile; and ethanol level. Ethanol levels in patients with ethanol withdrawal may be 100 mg/dL or more; likewise, a urine drug screen may be positive or negative for the offending agent. In patients with significant agitation, a creatine phosphokinase determination may help detect rhabdomyolysis.

An elevated temperature requires a full sepsis workup, including urine and blood cultures, chest radiograph, and, often, a lumbar puncture. Obtaining a head

computed tomography scan before lumbar puncture is critical in patients presenting with either focal neurologic deficits or high risk for intracranial hemorrhage. Patients with a first-time seizure in the setting of withdrawal should be evaluated the same as any other patient with a new seizure (see [Chapter 206](#)). Subsequent withdrawal seizures do not require reevaluation unless there are extenuating circumstances.

EMERGENCY DEPARTMENT MANAGEMENT

Withdrawal syndromes, particularly in the case of ethanol and sedative–hypnotic withdrawal, must be recognized and treated in a timely fashion. Because treatment may prevent withdrawal from progressing to a more serious stage, early treatment may significantly affect the subsequent clinical course. A successful strategy of treating withdrawal in the emergency department must address several basic goals: alleviating symptoms, preventing progression, avoiding complications, and recognizing and treating coexisting medical problems. Planning for long-term rehabilitation and drug independence is usually better done as part of inpatient management.

Initial treatment should be directed at readily correctable causes of altered mental status. Oxygen should be given if the oxygen saturation is low, and an intravenous line should be established. Fifty grams of glucose should be immediately given intravenously if hypoglycemia is present. In a patient with a borderline normal glucose level and altered mental status, glucose should also be given, in case the glucose determination is inaccurate.

To treat possible Wernicke's encephalopathy, 100 mg of thiamine should be given intravenously. If the mental status is clear, thiamine may still be given as a nutritional supplement. A "vitamin cocktail" of 100 mg of thiamine, one ampule of multivitamins, 1 mg of folate, and 2 g of magnesium sulfate is often added to the initial liter of intravenous fluid given to chronic alcoholics, due to their increased risk for malnutrition. Volume resuscitation is often necessary, particularly in patients with severe withdrawal manifestations and dehydration.

Significantly agitated patients may initially need to be physically restrained to prevent injury, establish intravenous access, and facilitate sedation. Soft restraints should be used. Prolonged use of restraints is discouraged, because continued struggling against them may lead to rhabdomyolysis, hyperthermia, and metabolic acidosis. Once intravenous access is obtained and chemical sedation has achieved behavioral control, physical restraints should be discontinued.

Achieving adequate sedation is the cornerstone of successful treatment of ethanol and other sedative–hypnotic withdrawal ([Table 375.3](#)). Sedation alleviates the excitatory manifestations of the hyperadrenergic state and may prevent progression to delirium tremens with its attendant complications.

ETHANOL OR SEDATIVE–HYPNOTIC WITHDRAWAL	
1st Choice:	Diazepam
2 mg i.v. bolus q1h. Titrate until sedated	
Alternative agent for 20 mg q1h. Titrate as sedation occurs	
Total dose 24 h period may = 3,000 mg	
Do not exceed 3 mg/min	
2nd Choice:	Lorazepam
1–2 mg i.v. bolus q1h. Titrate until sedated	
Titrate as long as long as necessary	
Preferable in cases of hepatic failure or recurrent seizures	
1st Choice:	Phenobarbital
100 mg i.v. bolus	
Continue titration to sedation to 600 mg total	
Potential for more respiratory depression than benzodiazepines	
Do not exceed 30 mg/min	
Alternatives:	
Chlordiazepoxide, secobarbital, phenobarbital	
OPIOD WITHDRAWAL	
1st Choice:	Clonidine
0.1–0.2 mg PO 3–4 times in emergency department	
If tolerated well this dose may be continued q4–6h for several days	
2nd Choice:	Acetaminophen
3–20 mg/kg, up to 600	
Give if needed (patients who require admission do not use for patients sent home)	

TABLE 375.3. Pharmaceutical Management of Ethanol and Drug Withdrawal

Substitution with a cross-tolerant drug is required to achieve proper sedation and replace the dependent agent. Many agents have been used over the years, but benzodiazepines have proven to be the most effective.^{11,13} Compared with other sedative–hypnotic agents, benzodiazepines are safer and produce less respiratory depression. Their dosage is easier to titrate and the effects are more predictable. Diazepam (Valium), chlordiazepoxide (Librium), and lorazepam (Ativan) are the most commonly used agents for ethanol withdrawal and can also be used for sedative–hypnotic withdrawal. These agents are preferred over benzodiazepines with shorter half-lives, which require frequent dosing, because they allow gradual drug elimination over several days.

Compared with short-acting agents, long-acting agents may be more effective in preventing withdrawal seizures and contribute to smoother withdrawal with fewer rebound symptoms.¹³ Active metabolites of diazepam and chlordiazepoxide prolong their therapeutic effect. In elderly patients and those with hepatic dysfunction, lorazepam, which has no active metabolites, may be preferred. In other cases, lorazepam does not appear to offer any distinct advantage over diazepam or chlordiazepoxide.²

Intravenous dosing is preferred in all but the mildest cases of ethanol withdrawal: Agitation may preclude oral administration, and gastritis may impair drug absorption. Intravenous therapy can be readily titrated. Lorazepam (but not diazepam or chlordiazepoxide) is predictably absorbed intramuscularly. This route may be useful in the wildly agitated patient before intravenous access is established.

The dose of benzodiazepines required to achieve proper sedation must be individualized and varies considerably, depending on the patient's tolerance to the drug. Symptom-triggered therapy is as efficacious as fixed-schedule therapy and decreases both the amount of benzodiazepine used and treatment duration.¹⁶ Frequent intravenous boluses should be given until the patient has achieved a restful state. When using diazepam, 5 to 20 mg can be given every 5 to 15 minutes until the patient is sleepy but arousable. Sometimes, very large doses of diazepam (1,000 mg or more over 24 hours) are necessary to achieve adequate sedation. Usually, sedation is obtained before respiratory depression develops, but close airway observation is always required.

Failure to obtain immediate sedation need not prompt switching to an alternative agent. Mixing different drugs or different routes of administration may increase the risk of adverse effects, particularly respiratory depression. However, if a patient does not respond completely to the chosen benzodiazepine, the use of another cross-tolerant agent may be valuable. Intermediate-acting or long-acting barbiturates such as pentobarbital, secobarbital, or phenobarbital are recommended in these situations. Doses of 100 mg of pentobarbital may be given intravenously every 5 to 10 minutes until sufficient sedation is achieved or a total dose of 600 mg is given.

Phenobarbital may also be used, although its onset of action may be delayed. Phenobarbital's long duration of effect, however, requires less frequent dosing and allows gradual self-tapering. Phenobarbital may be particularly helpful in withdrawal patients with idiopathic or posttraumatic epilepsy who require maintenance anticonvulsant levels. The barbiturates are more likely to cause excessive sedation and respiratory depression.²⁰

The use of midazolam (a short-acting benzodiazepine) by continuous intravenous infusion has been suggested to treat for ethanol withdrawal.¹² This approach, however, requires more vigilant monitoring, especially in the patient who is not intubated, and does not provide the advantages of a long-acting agent. More recently, propofol has been suggested as an effective alternative to benzodiazepines for refractory delirium tremens.³ Such an approach, however, has not been subject to controlled trials. Paraldehyde and ethanol itself, both used in the past, are considerably more toxic and difficult to titrate than the benzodiazepines and are no longer recommended.¹³

Withdrawal seizures should also be treated with benzodiazepines. Lorazepam, which has a longer anticonvulsant effect than does diazepam, has been shown to decrease the risk of recurrent seizures related to ethanol and is the agent of choice in this situation.⁴ Phenobarbital is a useful alternative. Phenytoin is ineffective in treating or preventing withdrawal seizures.¹⁵ It should be reserved for patients with a history of an underlying chronic seizure disorder who require maintenance phenytoin therapy.

Neuroleptics such as the phenothiazines and butyrophenones (e.g., haloperidol) should never be used as monotherapy in the treatment of ethanol and sedative–hypnotic withdrawal. Although sometimes used for severe agitation, these neuroleptics are not cross-tolerant with ethanol or sedative–hypnotics and do not prevent or suppress withdrawal. Hypotension, impaired thermoregulation, a lowered seizure threshold, and dystonic reactions may result from their use. Uncontrolled clinical experience suggests that neuroleptics may be considered as adjunctive therapy for patients with refractory agitation and hallucinations.¹⁷ They may also be

useful in treating concomitant nausea, vomiting, and GI cramps.

Sympatholytic therapy with beta blockers (e.g., propranolol) and central adrenergic agonists (e.g., clonidine) has been used for ethanol or sedative–hypnotic withdrawal, but these agents offer little benefit in the emergency department setting. Sympatholytics are not cross-tolerant with ethanol or sedative–hypnotics and do not prevent agitation, confusion, or seizures. Their ability to normalize vital signs may mask a deteriorating clinical situation.

For opioid withdrawal, clonidine may offer symptomatic relief because it decreases sympathetic activity in the locus ceruleus. An initial oral dose of 0.1 to 0.2 mg is recommended. Because hypotension may be particularly problematic after the first dose, the blood pressure should be monitored for 2 hours while the patient remains in the emergency department. A dose of 0.1 to 0.2 mg every 4 to 6 hours may help prevent recurrence of opioid withdrawal symptoms.⁷ Nonspecific sedation with benzodiazepines is also an option.

For patients who will be hospitalized with other medical problems, methadone may be given to relieve the symptoms of significant opioid withdrawal.⁸ A dose of 5 to 25 mg intramuscularly or orally blocks most manifestations of physiologic withdrawal. Parenteral administration guarantees absorption in the vomiting patient. Symptomatic improvement usually occurs within 30 to 60 minutes. Daily maintenance doses average 50 mg and range from 25 to 150 mg. Shorter-acting preparations such as morphine or meperidine are not indicated.

Federal regulations restrict the use of methadone to Food and Drug Administration–designated programs.⁷ While this legislation does not prohibit the use of methadone in opioid addicts who are admitted for other reasons, unless the facility has an approved program, methadone should not be given to those admitted solely for the treatment of opioid withdrawal. Similarly, legislation prohibits prescribing methadone for the outpatient treatment of withdrawal without a specific license.

DISPOSITION

Patients with moderate-to-severe ethanol and sedative–hypnotic withdrawal should be admitted. Because withdrawal usually persists for several days, admitted patients should be closely monitored for signs of progression and treated as necessary. The level of care necessary depends on clinical severity. Because of potential complications, patients requiring intravenous sedation are best managed in an intensive or intermediate care unit. Patients with less severe withdrawal may be managed and observed on a medical floor, psychiatric floor, hospital-based detoxification unit, or detoxification unit outside of the hospital. Patients with mild withdrawal may also need to be admitted for the evaluation and treatment of concomitant medical problems that have not been adequately addressed in the past due to poor use of outpatient services. The inpatient setting also provides a protected environment away from the temptations of ethanol and street drugs.

Prescriptions for benzodiazepines should not usually be given to patients with ethanol withdrawal who are being discharged home from the emergency department. The ingestion of ethanol by a patient taking benzodiazepines may result in fatal respiratory depression, or the benzodiazepines may simply be sold on the street. Outpatient management should be attempted only if the patient can be discharged home with a supportive family member or friend and appropriate outpatient follow-up can be arranged. Supervised withdrawal in the home setting, under the direction of a visiting nurse, may be appropriate in some of these circumstances.⁹

Patients who present to the emergency department with opiate withdrawal may be discharged home if they do not have other concomitant medical problems that require hospital admission and they can tolerate oral fluids. Offering the patient a limited supply of clonidine (if tolerated in the emergency department) may help prevent further withdrawal symptoms. Prescriptions for opioids should not be given.

Social service, detoxification, or substance-abuse counseling and psychiatric referrals should be offered to all patients with a history of substance abuse.

COMMON PITFALLS

- Failure to consider the possibility of ethanol and drug withdrawal in all patients with altered mental status and elevated vital signs
- Failure to appreciate that ethanol and sedative–hypnotic withdrawal are potentially life-threatening, whereas opioid withdrawal, although bothersome, does not usually cause significant morbidity
- Failure to appreciate that ethanol withdrawal is not synonymous with delirium tremens but that those with other withdrawal symptoms are at risk of progressing to delirium tremens if not treated
- Failure to exclude other etiologies of fever and altered mental status (e.g., hypoglycemia, head trauma, infection) in patients with suspected withdrawal
- Failure to appreciate that long-acting intravenous benzodiazepines such as diazepam or lorazepam are the treatment of choice for ethanol and sedative–hypnotic withdrawal
- Failure to appreciate that neuroleptics do not cross-react with ethanol and are generally not indicated in the treatment of ethanol withdrawal
- Failure to evaluate for and treat the dehydration that often accompanies withdrawal
- Failure to admit patients with signs and symptoms of moderate or severe ethanol and sedative–hypnotic withdrawal, particularly those with underlying medical problems

CHAPTER 376

Black Widow Spider Envenomations

Steven C. Curry and Thomas J. Higgins, Jr.

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The common name “black widow spider” was initially limited to *Latrodectus mactans*, but several other species of the genus *Latrodectus* are now referred to as black widow spiders.⁷ Although the males are too small to produce significant envenomation, both immature and adult female spiders can produce significant envenomation after a bite.

Mature females have globular abdomens and leg spans ranging up to 40 mm. *L. mactans* of southern North America and *Latrodectus hesperus* of the western United States are shiny black, with a red hourglass on the ventral surface of the abdomen. In *Latrodectus variolus*, found in the eastern United States and Canada, the triangles of the hourglass do not quite meet. The red widow, *Latrodectus bishopi*, found in central Florida, has an orange carapace, sternum, and legs, with a black abdomen. The abdomen may have red spots surrounded by a yellow border. The brown widow, *Latrodectus geometricus*, is found in southern Florida. There may be regional variations in appearance of all black widow spiders.⁷ Furthermore, immature yet venomous spiders may be brown or cream-colored with spots, and sometimes exhibit broad red markings on the dorsal surface of the abdomen.

Most bites occur in the warmer months and result from accidental encounters between humans and spiders. In Arizona, the spiders can be found in almost every crawl space, fence corner, storage shed, or other partially concealed location. They commonly nest in porch furniture or in the metal tubing of lawn chairs and baby strollers kept outside or in the garage.

Latrodectus venom from all species appears to have identical action, although structural differences can be demonstrated on electrophoresis.^{5,7} The most important action of the venom is to cause the release of neurotransmitters from both noradrenergic and cholinergic nerve endings.^{2,6,7} Ca⁺⁺ may be mobilized from intracellular stores to cause neurotransmitter release.⁷ Early studies suggested that neurotransmitter release was accompanied by Ca⁺⁺ influx into nerve endings, but other studies have failed to document this. *Ex vivo* studies document greater neurotransmitter release when extracellular Ca⁺⁺ concentrations are increased, suggesting that it is irrational to give calcium to patients suffering from black widow spider bites.⁸ Excessive release of acetylcholine from cholinergic nerve endings results in diaphoresis and muscle cramping. Although frequently not recognized as such by the patient, it is the cramping that is thought to cause the severe pain that characterizes serious envenomations. Excessive release of catecholamines from adrenergic nerve endings and the adrenal medulla can result in hypertension and tachycardia.

Older literature alludes to deaths after black widow spider bites, but mortality is extremely rare with modern supportive care. From 1983 through 1997, there were 30,782 black widow spider bites reported without a single death.¹ However, stress from severe pain and catecholamine release may compromise the very young, the elderly, and those with cardiopulmonary disease.

CLINICAL PRESENTATION

Bites by black widow spiders are usually felt, although not necessarily recognized as such. A brief, sharp pain resembling a needle stick is often noted. Over the next 30 minutes to several hours, pain described as deep, burning, aching, or numbing may begin near the bite, such as in an arm or a leg. Children may present with unexplained persistent crying. A history of onset of crying shortly after the child was placed in a stroller or other item kept in the garage or outside should raise the possibility of a black widow spider bite in areas where these spiders are common.

Examination of the bite site may reveal two minute puncture wounds but no necrosis or significant swelling. A close examination also frequently reveals a halo lesion consisting of a circular area of pallor surrounded by a ring of erythema.¹⁰ Multiple bites are fairly common, and halo lesions may be noted at each site.¹⁰ Halo lesions are especially helpful in making the diagnosis in the absence of a history of a spider bite (e.g., in young children).

Most patients who seek medical care do so to obtain relief from pain. In those suffering significant envenomations, symptoms may not peak for 12 to 18 hours and can last up to several days. Mild-to-moderate symptoms may then persist for 2 to 3 weeks. Muscle cramping and pain typically occur in major muscle groups such as the back, neck, thighs, flanks, abdomen, and chest. Patients frequently move about intermittently in attempts to find comfortable positions. On occasion, abdominal muscles may become rigid and tender, sometimes mimicking an acute abdomen. Diaphoresis is frequently noted over the site of the bite. Sometimes, diaphoresis is localized to areas distant to the bite. For example, a bite to the arm could result in diaphoresis limited to the nose or to the lower legs and feet without other evidence of sweating. An occasional patient suffers severe diaphoresis over the entire body, drenching sheets and covers. Mild-to-moderate hypertension is common but usually not severe enough to require treatment. Less frequent findings include vomiting, headache, chest tightness, hyperesthesias, weakness, priapism, lacrimation, salivation, and, especially in children, bilateral periorbital ecchymosis. Rare reports describe paresthesias, weakness, and atrial fibrillation. Herpes zoster has been reported after envenomation, although a causal relation has not been established.

Pregnant women who suffer black widow spider bites may develop uterine muscle contractions and abort the fetus.⁸ We have seen one woman in her first trimester of pregnancy develop vaginal bleeding while suffering severe pain and muscle cramping after a bite. Antivenin completely relieved symptoms and halted further bleeding, resulting in successful delivery at 40 weeks.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes almost any illness that can produce severe pain. Pain localized to the back or flanks may suggest renal colic or infection, but the urinalysis is normal. Severe muscle pain from envenomation may be confused with rhabdomyolysis; a normal or minimally elevated total serum creatine kinase level rules out the latter. Severe abdominal pain has resulted in unnecessary exploratory surgery. In older patients with prolonged chest pain, myocardial ischemia may need to be ruled out, even if a black widow envenomation is known to have occurred. The presence of fever should suggest an alternative or accompanying diagnosis.

Patients who suffer black widow spider envenomations often stay in one position for a few seconds or minutes before moving to a new position. In contrast, severe scorpion envenomation results in constant writhing and abnormal eye movements. In addition, scorpion stings do not produce halo lesions.

EMERGENCY DEPARTMENT EVALUATION

The physician should ask about the circumstances surrounding the suspected bite (e.g., witnessed bite, unexplained crying after the child was placed in a stroller), the description of the spider, and the progression of symptoms.

The physical examination should include a search for minute puncture wounds or halo lesions suggestive of black widow envenomation. The skin should be examined for unexplained diaphoresis, even in areas remote from the bite site. Vital signs should be examined for the presence of hypertension and tachycardia. No laboratory studies specific for black widow spider envenomations are available. Evaluation for other causes of pain may be necessary, even in patients with known black widow spider bites.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures should be instituted, as necessary. As with any puncture wound, a primary tetanus immunization or booster should be given, if indicated. Efforts should then be directed at relieving pain. Patients with mild pain can usually be treated with oral analgesics. Those with moderate pain may require agents such as hydrocodone or hydromorphone. Those with severe pain or moderate pain refractory to oral analgesics require parenteral agents. We prefer morphine for analgesia and lorazepam for sedation and amnesia. Doses of these drugs vary tremendously, depending on the patient's age and weight, other central nervous system (CNS) depressants the patient may be taking, preexisting diseases, and individual responses to these agents. An initial intravenous dose of 6 mg of morphine sulfate and 1 mg of lorazepam may be given to an otherwise healthy adult in severe pain. Further doses of morphine sulfate may be given every 2 to 5 minutes until the pain is controlled or until excessive CNS depression limits further doses.

L. mactans antivenin, a horse serum product, is effective in reversing all signs and symptoms caused by envenomations by any species of *Latrodectus*. The main indications are severe pain or dangerous hypertension. It is also reasonable to give antivenin to pregnant women who suffer moderate-to-severe envenomations and to those with mild symptoms and threatened abortion. Antivenin is contraindicated in patients allergic to horse serum, and it is ill-advised in patients taking beta-adrenergic blocking agents, as these drugs may predispose to anaphylactic reactions that can be refractory to treatment.

The manufacturer recommends skin testing before administration, although information obtained from skin testing may not be reliable in predicting who will or will not suffer an anaphylactic response to the antivenin (unless the skin test itself produces anaphylaxis). Therefore, it is prudent to administer the antivenin in a controlled critical care setting such as the emergency department or intensive care unit and to be prepared to immediately treat life-threatening anaphylaxis. We mix one vial of antivenin in 50 mL of crystalloid solution and give it intravenously over 20 to 30 minutes, regardless of the patient's age or weight. Symptoms usually begin to resolve in about 40 minutes, and the patient is usually completely asymptomatic within 60 to 90 minutes. Rarely, if ever, is a second vial of antivenin required. There have been case reports of antivenin being effective in the treatment of latrodectism as long as 12 days after envenomation in patients who remain symptomatic.¹¹

Because of the minimal volume of horse serum in a single vial of *Latrodectus* antivenin, serum sickness is an uncommon late occurrence.⁹ If it does occur, symptoms are easily controlled with oral corticosteroids and hydroxyzine.

Patients not treated with antivenin may require therapy to control hypertension or excessive diaphoresis. Hypertension may be treated with a vasodilator (e.g., nitroprusside, nifedipine, hydralazine). Severe diaphoresis may be treated with low doses of subcutaneous atropine sulfate.

Patients suffering from *L. hesperus* envenomation benefit little, if at all, from intravenous calcium salts.³ There are anecdotal reports of dramatic pain relief from intravenous calcium after envenomations by other species, but there are no meaningful studies documenting calcium's efficacy. The same is true for centrally acting muscle relaxants (e.g., methocarbamol), which have little or no muscle-relaxing activity independent of their CNS depressant activity. In fact, methocarbamol has been reported to be even less effective than calcium.⁴

DISPOSITION

Patients with mild-to-moderate symptoms who respond to oral analgesics may be discharged from the emergency department with prescriptions for analgesics. They should be warned that symptoms may continue to worsen for 12 to 18 hours after envenomation and should be told to return if symptoms are not relieved with medication. Patients who receive antivenin without complications may also be discharged when asymptomatic. They should be told that they are likely to be allergic to horse serum in the future, should be warned of the signs and symptoms of serum sickness, and should be instructed to see a physician if this complication develops.

Patients who require parenteral narcotics and do not receive antivenin should be admitted to the hospital. They can be discharged when the pain has lessened enough that it can be controlled with oral analgesics, usually in 2 to 4 days.

COMMON PITFALLS

- Sending patients with moderate-to-severe pain home with a prescription for oral analgesics without ensuring that they respond to such agents in the emergency department
- Risking anaphylaxis and serum sickness by giving antivenin to patients with only mild symptoms
- Giving antivenin to a patient taking a beta-adrenergic blocking agent, which can make anaphylaxis, if it occurs, difficult to treat
- Mistaking severe abdominal, back, or chest pain for other disease processes
- Failure to appreciate that chest pain in a patient at risk for heart disease may be due to myocardial ischemia, even if a black widow spider bite is known to have occurred

EMERGENCY DEPARTMENT MANAGEMENT

Treatment of necrotic or cutaneous arachnidism should be the same, regardless of the culprit. A “benign neglect” approach nearly always results in an excellent outcome. It is impossible to make an early prediction about which bite will result in a disfiguring lesion. General wound care usually suffices. Corticosteroids injected locally or systemically, as well as vasodilators, have not proved helpful.¹ Antibiotics are not needed routinely, but they may be needed for secondary bacterial infection. An antipruritic or antianxiety drug is often comforting, as well as cool compresses (avoid heat, because it may stimulate a cascade of inflammatory reactants).

Analgesics can be given for pain, but nonsteroidal antiinflammatory drugs are contraindicated because of possible bleeding problems. Although still performed by some surgeons, early wide excision is ineffective, unnecessary, and expensive; produces complications (such as allowing venom to penetrate deeper into tissues); and may cause disability or worsen scarring. Corrective surgery should be delayed for 6 to 8 weeks, when the necrosis is clearly demarcated.^{18,19} Necrotizing fasciitis or abscess would warrant emergency surgery.

Some authorities suggest that a polymorphonuclear leukocyte inhibitor such as dapsone (25 to 100 mg orally twice a day for 1 to 2 weeks) may prevent ulceration if started early.¹² Dapsone should be reserved for nonpregnant, healthy adults with rapidly progressive blistering and hemorrhage or impending ulceration in a cosmetic area such as the face or digits, and a strongly suggestive or confirmed history of spider envenomation. Glucose-6-phosphate dehydrogenase deficiency is a contraindication for dapsone therapy, and patients treated with this agent must be carefully monitored for drug toxicity (hemolysis, methemoglobinemia, superinfection, leukopenia, rash). There is no controlled study proving the effectiveness of hyperbaric oxygen, although it may be beneficial in a subgroup of patients with a history of poor wound healing.

The treatment of systemic arachnidism is mainly aggressive, symptomatic, and supportive care. Corticosteroids (methylprednisolone, 10 to 40 mg intravenously every 6 hours) ameliorate hemolysis and are needed for only 3 to 7 days. Alkalinization of the urine can protect against renal failure secondary to hemoglobinuria. Anemia and thrombocytopenia should be treated with component therapy (e.g., platelets, packed red cells), as needed. As complement or unknown factors in whole blood may react with venom components and contribute to red blood cell destruction, this product is not recommended.¹⁰

DISPOSITION

Physicians unfamiliar with arachnidism should consult a regional poison control center or toxicologist for advice. A telephone call to an envenomation expert may be necessary. Patients who present immediately after a bite should be followed as outpatients with 24- to 48-hour rechecks for 3 to 5 days. Patients who present with or develop large ulcers should be referred to a plastic surgeon for follow-up. Patients with significant systemic symptoms, clinical toxicity, or hematologic abnormalities should be admitted with an appropriate level of monitoring. Those with a benign course and stable physical and laboratory evaluations can be discharged with follow-up in 24 to 48 hours. Liberal admission for observation may be prudent in very young or debilitated patients and in those judged to be unreliable regarding follow-up.

COMMON PITFALLS

- Diagnosing “brown recluse spider bite” rather than “necrotic arthropod bite or sting” or “necrotic or cutaneous arachnidism” when positive identification of the offending species has not been made
- Failure to appreciate that hemolysis secondary to *L. reclusa* envenomation may occur rapidly or be insidious
- Failure to perform laboratory evaluations on patients with skin lesions highly suspicious of loxoscelism
- Failure to warn patients about potential but unpredictable complications, such as hemolysis, coagulopathies, and secondary infections
- Failure to provide adequate follow-up
- Failure to discuss therapeutic options, controversies, and complications

CHAPTER 378

Crotalid Snake Envenomations

Richard C. Dart and John B. Sullivan, Jr.

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

There are several thousand poisonous snakebites in the United States each year, resulting in approximately five deaths.¹⁰ Most of these bites involve members of the Crotalidae family and include the genera *Crotalus* (rattlesnakes), *Agkistrodon* (copperheads and water moccasins or cottonmouths), and *Sistrurus* (pygmy rattler and massasauga). Although all states except Alaska, Hawaii, and Maine have poisonous snakes, most bites occur in the southeast, southwest, and western regions. The incidence is greatest between March and October, when snakes and victims are the most active.

Crotalidae have a temperature (prey)-sensing pit below and in front of the eye (the pupil of which is elliptical)—hence the common name “pit viper.” Venom is injected through a pair of fangs attached to the maxilla. Venom is mainly a mixture of digestive enzymes that cause local tissue necrosis and systemic vascular damage, hemolysis, fibrinolysis, and neuromuscular dysfunction. Venom shock and pulmonary injury result from increased vascular permeability and coagulopathy, leading to edema and hemorrhage. Direct cardiac depressant effects may also contribute to shock.¹² Venom composition varies with the species.

Up to 25% of bites do not result in envenomation (dry bites).¹² Most envenomations result in a combination of local and systemic effects. However, some populations of Mojave rattlesnakes have a venom (type a) that may cause presynaptic neuromuscular blockade with delayed respiratory failure and mild or absent local effects.^{2,6,8} Envenomations by *Agkistrodon* and *Sistrurus* species tend to be less severe than those of *Crotalus* species.

The size and species of snake, the location and depth of the bite, the victim's size and health, first-aid measures performed, the time to definitive therapy, and the type of therapy influence the severity and outcome. The worst scenario is a small, unhealthy victim deeply bitten by a large snake in the central body. Improper first-aid measures, delay in arriving at medical care, delayed diagnosis, and inadequate or unnecessary treatment adversely affects the outcome.

Bites by exotic snakes may occur in zoo and pet snake handlers and require specific antivenoms. A regional poison center or zoo can provide information on snake identification, expected toxicity, and antivenom location. A 24-hour Antivenom Index Service can be reached by calling your certified regional poison center. Physicians unfamiliar with the management of snake envenomation should consult a toxicologist or regional poison center.

CLINICAL PRESENTATION

Dry bites produce no signs or symptoms other than those of a puncture wound. If envenomation has occurred, the victim (often an intoxicated male) typically notes sudden, severe pain at the bite site, soon followed by progressive swelling and, sometimes, paresthesias.

Examination may show two puncture wounds exuding bloody fluid. However, there are many reports of serious envenomation associated with scratches and single or multiple puncture wounds. Other local findings include erythema, ecchymosis, bullae, and, eventually, necrosis and ulceration. Severity is graded using several factors ([Table 378.1](#)). Bites about the face may lead to airway obstruction; those of the extremities may lead to compartmental syndromes. Wound infection is a potential complication.⁷

Bite	Mild	Moderate	Severe
Puncture wound, pain, little or no swelling, no systemic symptoms or progression	Localized pain, edema, erythema	Progressive pain, edema, erythema, stable systemic symptoms	Marked edema, erythema, bullae, respiratory depression
Normal laboratory studies	Progression, Normal laboratory studies	Mild laboratory abnormalities	Marked laboratory abnormalities

TABLE 378.1. Grading of Envenomation by Signs and Symptoms

Systemic symptoms include nausea, vomiting, diarrhea, perioral paresthesias, salivation, lethargy, and weakness. Severe envenomations may lead to cardiovascular collapse, coma, seizures, dyspnea, respiratory depression, and gastrointestinal and pulmonary hemorrhage. Initial vital signs often show tachycardia and mild hypertension. Laboratory evaluation may reveal hemolysis, anemia, thrombocytopenia, coagulopathy (including severe fibrinolysis), and blood, protein, and glucose in the urine in severe cases. In severe cases, the chest radiograph may reveal pulmonary edema, and the electrocardiogram (ECG) may show dysrhythmias or ischemic changes. Systemic findings are also used to assess the severity of envenomation (see [Table 378.1](#)). An initially mild envenomation may progress over a period of hours to become moderate, severe, or even life-threatening. Coagulation abnormalities may peak as late as 3 days after envenomation.

DIFFERENTIAL DIAGNOSIS

Victims at the extremes of age, those with altered mental states, and those who are bitten while reaching into concealed areas may not realize they have been bitten. Snakebite may be misdiagnosed as a nonvenomous bite or sting or as puncture wounds and scratches from thorns and brush. The possible diagnosis of snake venom poisoning can be excluded only by prolonged observation, documenting a lack of progressive local and systemic manifestations.

EMERGENCY DEPARTMENT EVALUATION

On the patient's arrival in the emergency department, vital signs and a rapid patient survey should be performed to determine the patient's clinical stability. The time and circumstances of the bite, the nature and severity of symptoms, the first-aid measures taken before arrival, and any history of allergies, medical problems, previous bites, and antivenom therapy are noted. The bite site should be examined, noting the nature and extent of local findings. Distal neurovascular status should be noted in extremity bites. In the early course, the local evaluation should be repeated every 15 minutes. The general examination should focus on the cardiovascular, pulmonary, and neurologic systems. Laboratory tests in questionable or initially minimal bites should include complete blood count; determination of electrolytes, blood urea nitrogen, and creatinine levels; prothrombin time; platelet count; and urinalysis. In severe cases or in patients who worsen, creatine kinase, fibrinogen, fibrin split products, arterial blood gas analysis, and blood typing should be included. A chest radiograph and an ECG should be obtained in patients with systemic signs or symptoms.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures should be instituted, as necessary. Prehospital personnel should be directed to establish intravenous access, to give oxygen, and to transport victims of venomous snakebites to a medical facility that possesses antivenom. If a tourniquet has been placed, it should not be removed until intravenous access has been established. The limb should be maintained in a neutral position. Loose (lymphatic) tourniquets, incision and suction, and cooling an extremity may be effective if used within 30 minutes of envenomations, but they are not substitutes for definitive care. Local wound care and tetanus prophylaxis should be provided. Worsening of local or systemic manifestations provides a guide for appropriate administration of Wyeth equine polyvalent Crotalidae antivenom. Immunoglobulins in the antivenom neutralize venom proteins by antigen–antibody complex formation. If, after several hours, pain and edema remain localized to the bite site and coagulopathy is not progressing, antivenom is unnecessary. Continued observation for signs of local progression and laboratory abnormalities cannot be overemphasized. The extent of swelling should be outlined with a marking pen, and the limb circumference should be measured at several sites above and below the bite. If any of these parameters worsen, antivenom therapy is usually warranted.

The skin test should not be performed unless a definite decision to give antivenom has been made. Unstable patients and those with obvious systemic involvement should be tested immediately. A negative skin test suggests, but does not guarantee, that an antivenom reaction will not develop. Although a positive test (erythema or induration) is an important warning, it does not absolutely preclude administration of antivenom.¹³ Patients with moderate or severe envenomation who require antivenom can be pretreated with diphenhydramine, cimetidine, and, if necessary, epinephrine.^{11,12}

Each vial of antivenom should be diluted to 10 mL, using the diluent supplied with the vial. This requires 20 to 30 minutes of gentle mixing, so preparation should begin at the same time as skin testing. Each vial is further diluted twofold to fivefold in intravenous fluid before infusion, and tenfold in patients with an allergic response.

Initially, the antivenom should be given slowly, while observing for allergic or hypotensive reactions. If none occurs, the infusion rate should be rapidly increased so that the antivenom dose is completed in 1 hour. Antivenom should be given only in a critical care setting with epinephrine and antihistamines readily available. It can reverse coagulopathy up to 72 hours after envenomation.

Patients with minimal envenomations with progression and those with moderate envenomations should receive five to ten vials of antivenom initially. Patients with severe envenomations require ten to 20 vials initially. Life-threatening envenomations require higher dosages. Management decisions are outlined in [Fig. 378.1](#). Subsequent antivenom doses are guided by clinical response.

Figure 378.1. Algorithm for the management of crotalid snakebite.

Concomitant supportive care (e.g., fluids and pressors for hypotension, blood component replacement for severe hematologic abnormalities, and respiratory support) is extremely important but often neglected.⁹ Blood products should be used only if the patient is actively bleeding or cannot receive antivenom.¹

The effectiveness of antivenom in the treatment of snake venom poisoning has been extensively documented. However, fasciotomy and supportive care without antivenom have been proposed in some areas as definitive treatment of snakebite. Experimental evidence in animals shows no beneficial effect.^{4,5} Only in patients with documented increased intracompartmental pressure unresponsive to limb elevation, mannitol (1 to 2 g/kg intravenously), and antivenom (five to ten vials) should fasciotomy be considered. Cultures and antibiotic therapy should be initiated if clinical signs of infection develop.

DISPOSITION

Patients with dry bites may be discharged after an 8- to 12-hour observation period. Those with severe or life-threatening bites and those receiving antivenom should be admitted to an intensive care unit. Admission to a floor bed is appropriate for the observation of patients with mild or moderate envenomations. Mobilization of the affected extremity can begin when the progression of swelling has ceased. Discharge is appropriate when swelling is decreasing, any coagulopathy has completely reversed, and the patient is ambulatory. Outpatient follow-up may be necessary for several days to monitor for infection and serum sickness. Serum sickness may range from a mild viral-like illness to severe urticarial rash, arthralgias, and other complications. Most patients who receive more than five vials will develop serum sickness.³ Most cases can be treated as outpatients, with antiinflammatory analgesics, antihistamines, and corticosteroids.

COMMON PITFALLS

- Failure to diagnose envenomation because of a lack of history or inadequate observation of patients with suspicious wounds of unclear cause
- Performing inappropriate skin testing in patients who do not need antivenom
- Failure to monitor closely for allergic reactions in patients receiving antivenom, even though they may have had a negative skin test. Epinephrine and diphenhydramine must be available at the bedside.
- Using antivenom unnecessarily, or giving inadequate doses
- Failure to provide supportive care as well as antivenom to patients with severe reactions
- Failure to recognize that horse serum allergy is not an absolute contraindication to antivenom administration

CHAPTER 379

Elapid Snake Envenomations

Richard C. Dart and John B. Sullivan, Jr.

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

North American representatives of the elapid family are the coral snakes. These brightly colored snakes are known for the potency of their venom. Fortunately, few bites occur, because these snakes are usually small, nocturnal, and reticent.

Coral snakes found in the United States include the Eastern coral snake (*Micrurus fulvius fulvius*), the Texas coral snake (*Micrurus fulvius tenere*), and the Arizona (Sonoran) coral snake (*Micruroides euryxanthus*). The Eastern coral snake is found in the deep southeast United States; the Texas and Arizona subspecies are found primarily in the states whose name they bear.³ All these snakes are brightly colored, with black, red, and yellow rings that encircle their bodies. The red and yellow rings touch in coral snakes but are separated by black rings in nonpoisonous snakes, hence the rhyme, "Red on yellow, kill a fellow; red on black, venom lack." Unfortunately, victims may confuse the rhyme, especially when intoxicated (e.g., "Red on yellow, good fellow."). Elapids lack facial pits and have nearly round pupils.

Coral snakes are docile. When biting, they hold on or chew, allowing them to envenomate. Their venom is discharged through grooves on two small, fixed anterior fangs. Their small size makes it difficult, but not impossible, to envenomate humans seriously. The Eastern and Texas subspecies are larger and have seriously envenomated many patients, but the Sonoran coral snake has not caused severe envenomation.³

CLINICAL PRESENTATION

Coral snake envenomation can be difficult to diagnose and easy to underestimate. The typical bite shows little local damage and few initial systemic symptoms. Minor pain without swelling may be present. This may be followed by numbness and weakness of the affected part as the envenomation syndrome advances. Systemic symptoms, which may take hours to develop, include drowsiness, apprehension, weakness, fasciculation, tremors, difficulty swallowing, dyspnea, salivation, nausea, and vomiting.¹

Physical examination may show fang marks and associated scratches. It is often possible to express a drop of blood. However, the history is particularly important, because significant envenomation without any apparent marks, despite close examination, has occurred. In such cases, injecting lidocaine under the suspected area may show minute beads of serosanguineous fluid exuding from fang punctures. Signs of systemic toxicity may be delayed in onset and include weakness of extraocular muscles, miotic pupils, bulbar paralysis, respiratory depression, and convulsions. In severe cases, arterial blood gas analysis may show hypoventilation and an elevated creatine kinase level.

DIFFERENTIAL DIAGNOSIS

The diagnosis of coral snake envenomation is usually clear, because the snake frequently hangs on to the victim and has bright, identifiable coloring. When the patient cannot clearly communicate, the rapidity of onset and usually short duration of venom poisoning distinguish it from other motor neuron diseases. Laboratory testing may be necessary to rule out poisoning by agents such as botulism, heavy metals, and central nervous system depressant medications.

EMERGENCY DEPARTMENT EVALUATION

The time and circumstances of the bite, a description of the snake, first-aid treatment before arrival, allergies, previous bites and antivenom therapy, medical history prior to presentation, and the onset, progression, and nature of symptoms should be established. The physical examination focuses on neurologic assessment, particularly the cranial motor nerve, and respiratory muscle function. Tidal volume, arterial blood gas analysis, and other routine studies (laboratory, chest radiograph, electrocardiogram) are obtained, if clinically indicated. Although positive identification of the offending snake is helpful, it should not delay treatment.

EMERGENCY DEPARTMENT MANAGEMENT

Prehospital care should consist of intravenous line insertion, maintenance of airway, and timely transport to a health-care facility capable of full life-support and antivenom therapy. Constriction bands or pressure bandages to retard venom spread may be useful.

Wound cleansing and tetanus prophylaxis are provided. Patients who have clearly been bitten or who have developed symptoms or signs of envenomation are given at least five vials of *M. fulvius* antivenom (equine) by intravenous infusion. Waiting until systemic manifestations develop before giving antivenom may not always reverse them or prevent further deterioration. If symptoms progress, the dose of antivenom is repeated. Although *M. fulvius* antivenom is neither effective nor necessary in Sonoran coral snake envenomation, the aforementioned protocol should be followed unless a positive identification of this species has been made. The elective intubation of patients with bulbar signs or symptoms may prevent aspiration pneumonia.¹

The prognosis is excellent. There is normally no tissue loss or permanent neurologic dysfunction. Even without antivenom treatment, recovery can be expected if appropriate supportive care is provided.² Hence, patients with allergic reactions to horse serum or antivenom can be managed successfully without antivenom.

DISPOSITION

All patients in whom the diagnosis of coral snake envenomation is entertained should be admitted to an intensive care area for at least 12 hours of close monitoring of vital signs and neurologic function. This disposition applies to patients with a definite bite, either by history or examination, regardless of whether they are symptomatic. Patients with no evidence of envenomation after 12 hours of observation may be discharged. Those with severe envenomations may require several days of hospitalization.

COMMON PITFALLS

- Delaying antivenom administration until systemic signs and symptoms are present
- Failure to admit and monitor all patients with possible coral snake envenomation
- Failure to monitor for progression of toxicity after antivenom administration, and failure to provide concurrent, aggressive supportive care
- Using antivenom inappropriately in patients with documented Arizona (Sonoran) coral snake envenomation and in those with allergic reactions to horse serum or antivenom
- Failure to take the same precautions as described for crotalid antivenom when giving coral snake antivenom

Mammal Bites and Associated Infections

Stephen J. Playe and Richard V. Aghababian

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Role of the Consultant](#)
[Indications for Admission](#)
[Transfer Considerations](#)
[Common Pitfalls](#)
[Chapter References](#)

Thousands of people throughout the world are killed each year by sharks, crocodiles, pachyderms, big cats, and other large carnivores.⁴ Ten to 20 fatal dog attacks occur in the United States each year, almost always involving children. Morbidity is extensive. More than a million Americans seek care for animal bites each year, accounting for about 1% of emergency department visits. One percent to 2% of these patients require hospital admission. Dogs and cats inflict 95% of the bites, and tend to bite the extremities of adults and older children and the face and scalp of younger children and infants. Infectious complications are often responsible for serious morbidity and mortality.

Bite wounds are unique in several respects. Dog bites are usually crush-type lacerations with devitalized adjacent tissue. About 10% of full-thickness dog bites become infected.^{1,2} Cat bites tend to be puncture wounds, with an infection rate of up to 50%.¹ Human bites are thought to be third most frequent after dog and cat bites. Although occlusional human bites of the extremities or trunk are mechanically similar to dog bites, the epidemiology and microbiology of human bites are different. Occupational exposure can occur in dental professionals, caretakers of the mentally impaired, daycare workers, and medical personnel involved in airway management or the care of seizing or combative patients. "Love bites" can be incurred, often involving the neck, breasts, or genitalia, during passionate sexual encounters. Biting off the tip of the nose as punishment for adultery is reported in some cultures. Teeth marks (wound imprints) have been used by forensic dental pathologists to help identify assailants. Clinched-fist injuries ("fight bites"), which occur when a fist strikes teeth during altercations, are the most serious of human bites. The microbes contained in plaque and deposits around teeth may be carried to deep structures and relatively avascular tissue planes. The patient may present with an innocuous-appearing laceration, initially offer an alternative explanation of the mechanism of injury, and subsequently develop tenosynovitis, septic arthritis, or osteomyelitis. Persistent infections can necessitate amputation. Animal bites may inoculate the site with a host of potentially pathologic microorganisms, including tetanus and rabies viruses, *Staphylococcus* spp., *Streptococcus* spp., *Corynebacterium* spp., and anaerobes.¹⁴ The human oral flora frequently includes *Eikenella corrodens*. Transmission of hepatitis B, hepatitis C, and human immunodeficiency virus (HIV) must also be considered.

Pasteurella species, small gram-negative rods that are part of the normal mouth flora of many animals, have been implicated in up to 50% of infected dog bites (most often *P. canis*) and in up to 75% of infected cat bites (most often *P. multocida* subspecies *multocida* and *septica*).^{5,12,14} These organisms typically produce a rapidly developing inflammatory response in the wound, often with purulent drainage, within 24 hours. *Pasteurella* species may also cause cellulitis, abscess, osteomyelitis, septic arthritis, meningitis, and septicemia.

Capnocytophaga canimorsus (DF-2), a fastidious gram-negative bacillus, can infect dog and cat bites and can lead to often rapidly fatal bacteremia, disseminated intravascular coagulation, or meningitis. Although most common in immunocompromised patients,¹⁵ these infections have been reported in normal hosts.^{13,16}

The organism thought responsible for cat-scratch disease, *Bartonella henselae*, is a small pleomorphic bacillus identified by Warthin-Starry stain of lymph node or skin biopsies.⁷ The gram-negative organisms *Streptobacillus moniliformis* and *Spirillum minus* cause rat-bite fever. *Francisella tularensis* is a gram-negative coccobacillus that causes tularemia.

Herpesvirus simiae (B virus) is carried by rhesus and other macaque monkeys. It is spread to humans by bites or scratches and can lead to fatal encephalitis.⁹

CLINICAL PRESENTATION

Animal bites can lead to trauma of the skin, tendons, joints, bones, major vessels, viscera, brain, and other organs. Death in immediately fatal cases is usually due to hemorrhagic shock. Crush lacerations over the dorsum of the proximal phalanges or metacarpophalangeal joints should be presumed to be due to clenched-fist bites, even when patients are reluctant to offer this history. Patients who present more than 24 hours after injury usually have signs of established local or systemic infection. This is often the case with clenched-fist injuries.

Patients with cat-scratch disease present with headache, fever, malaise, and tender regional lymphadenopathy about a week (range, 3 days to 6 weeks) after a cat scratch or bite.⁷ A tender papule that develops at the inoculum site and subsequently blisters and heals with eschar formation or a transient macular or vesicular rash may be noted. A significant number of patients give a history of cat exposure without a wound or primary lesion. Lymph nodes may suppurate and drain spontaneously or become nontender but remain palpable over a period of weeks to months. Complications and associated conditions include encephalitis, Parinaud syndrome (granulomatous conjunctivitis), mesenteric adenitis without splenomegaly, osteolytic bone lesions, purpura with both normal and low platelet counts, and erythema nodosum.

Patients with rat-bite fever caused by *S. moniliformis* typically develop sudden fever, chills, headache, and myalgias several days (range, 1 to 22 days) after a bite by a wild, laboratory, or pet rodent or carnivore, or the ingestion of food contaminated by rat excreta.⁴ A rash (macular, petechial, purpuric, or pustular; centripetal or generalized) and asymmetric polyarthralgia or arthritis may also be present. Complications include soft-tissue and brain abscesses and endocarditis. Patients with *S. minus* infection usually develop relapsing fever, headache (with nausea, vomiting, and photophobia), and signs of nonpurulent local infection with regional lymphangitis and adenopathy several weeks (range, 1 to 36 days) after the initial healing of the bite wound. A rash (macular, brown or purple) may be noted on the extremities. Endocarditis has been reported.

Patients with tularemia usually present with fever, chills, headache, malaise, myalgias, tender hepatosplenomegaly, wound ulcer, and regional adenopathy 2 to 5 days after a bite or direct or indirect skin contact with virtually any animal (e.g., amphibians, birds, fish, or mammals).⁴ Skin inoculation most frequently results from exposure to wild rabbits (usually cottontails) during skinning and preparation for eating and from bites from insect vectors (e.g., ticks, deer flies, mosquitoes). Other animals that commonly harbor *F. tularensis* include beavers, cats, cattle, muskrats, sheep, and squirrels. The initial skin lesion (a bite or puncture wound or contaminated scratch) develops into a well-defined ulcer with a black base and yellow exudate. A macular rash may be present, and lymph nodes may suppurate and drain spontaneously. Contamination of the eye, throat and intestines (ingestion), or lung (inhalation) may also lead to conjunctivitis, pharyngitis, gastroenteritis, or pneumonia, all of which are associated with regional lymphadenopathy. Complications include endocarditis, meningitis, osteomyelitis, pericarditis, and peritonitis.

The presentation of human rabies varies with the time elapsed after exposure. An asymptomatic incubation period (generally 20 to 60 days) is followed by a prodrome of 2 to 10 days characterized by symptoms that may include pain, paresthesias, or pruritus at the site of the bite and nonspecific symptoms such as fever, headache, nausea, vomiting, and malaise. The ensuing acute neurologic phase lasts 2 to 10 days. In about 80% of cases, the "furious" signs of hyperactivity predominate; these include agitation, hallucinations, thrashing, biting, and the classic hydrophobia caused by an exaggerated respiratory tract protective reflex. In about 20% of cases, paralytic signs predominate; this is termed *dumb rabies* and is characterized by progressive paralysis with intact sensorium. If patients do not succumb during the acute neurologic phase, they then become comatose and die within 2 weeks.⁸

Routine laboratory findings in cat-scratch disease, rat-bite fever, and tularemia are nonspecific (e.g., elevated leukocyte count and erythrocyte sedimentation rate). Cat-scratch disease is confirmed by antigen skin testing or microscopic examination of the primary skin lesion or lymph node. Rat-bite fever is confirmed by culture or antibody response to *S. moniliformis* or examination (Wright's stain or dark-field microscopy) of blood, skin lesion, or lymph node drainage in *S. minus* infections.

These infections may result in false-positive syphilis tests. Tularemia is confirmed by serologic response.

DIFFERENTIAL DIAGNOSIS

Concomitant envenomations should be considered in bites by lizards (i.e., Gila monster), snakes, marine animals, and the short-tailed shrew. The differential diagnosis of cat-scratch disease, rat-bite fever, and tularemia is extensive and includes infections such as plague, syphilis, lymphogranuloma venereum, sporotrichosis, anthrax, histoplasmosis, coccidioidomycosis, infectious mononucleosis, toxoplasmosis, brucellosis, bacterial adenitis, and infections with *Mycobacterium*, *Rickettsia*, *Staphylococcus*, and *Streptococcus*. Sarcoid, lymphoma, and cysts and tumors of the neck should also be considered.

Rabies must be differentiated from other infectious causes of encephalitis, including herpes, arbovirus, tetanus, malaria, rickettsia, typhoid, poliomyelitis, and botulism. Noninfectious diseases that must be considered include Guillain-Barré syndrome, poisoning, alcohol withdrawal, acute porphyria, and behavioral disorders. ⁸

EMERGENCY DEPARTMENT EVALUATION

Initial evaluation of acute injuries should include a primary survey, with attention to the basics of trauma care, particularly when a small victim is attacked by a large animal. The history should include details of the biting event: the time, the offending animal and its identity (wild or domestic, immunization and health status, captured or not), and the nature of the attack (provoked or unprovoked). The patient's underlying health status should also be determined.

The patient should be assessed not only for skin wounds, but also for deep-structure injury, particularly of the brain, vessels, viscera, nerves, tendons, joints, bones, and spinal cord. Puncture wounds are particularly prone to cause deep and often undiagnosed injuries. Location of the wound on the hand, wrist, foot, or joint or on the face and scalp of an infant increases the likelihood of deep-structure injury. Because clenched-fist injuries occur in flexion, they must be carefully explored throughout flexion in addition to extension to identify retained tooth fragments or tendon, joint, or bone injury. Radiographs should be obtained.

Local infectious complications include wound infection, cellulitis, abscess, osteomyelitis, prosthesis infection, and septic arthritis (even when the joint is not penetrated). Local wound infections that develop less than 24 hours after the bite are probably caused by either *P. multocida* or streptococci. Local infections that develop more than 48 hours after the bite are most frequently caused by *S. aureus*. Systemic complications include bacterial sepsis, meningitis, disseminated intravascular coagulation, cat-scratch disease, rat-bite fever, tetanus, tularemia, and rabies. The risk of infection is high in patients who are very young, very old, or immunocompromised (alcoholism, splenectomy, diabetes mellitus, liver dysfunction, acquired immunodeficiency syndrome, or immunosuppressive medication); those who have prosthetic joints or valves; and those who have peripheral vascular or lymphatic compromise. Other risk factors include cat bites; puncture wounds; location on a hand, wrist, foot, or joint; and treatment delay beyond 8 hours.

Although Gram stain and culture of fresh bites do not predict infection, a Gram stain and culture (aerobic and anaerobic) should be obtained in clinically infected wounds. If sepsis is suspected, the Gram stain of the peripheral blood should be examined for evidence of *C. canimorsus*, and blood cultures (anaerobic and aerobic) should be obtained. Complete blood count; determination of blood urea nitrogen, glucose, electrolyte, and creatinine levels; prothrombin time; partial thromboplastin time; fibrin split products; and lumbar puncture with cerebrospinal fluid (CSF) analysis and culture should be obtained, if clinically indicated.

Extremity radiographs are useful to evaluate the possibility of joint penetration, fracture, foreign body, and osteomyelitis. Skull radiographs and computed tomography scanning of the head are indicated for infants with face and scalp bites.

The patient who presents with fever, constitutional symptoms, and regional adenopathy should be questioned about animal bites, scratches, or exposures and a history of rash or skin lesions. The extent of adenopathy and tenderness and the size of the lymph nodes, liver, and spleen should be noted. The patient should also be examined for evidence of endocarditis, meningitis, and other complications. Further assessment should include complete blood count, serum electrolyte levels, liver and kidney function studies, blood cultures, and a chest radiograph. Lumbar puncture, peripheral blood smear, lymph node and skin biopsy examination, skin testing, and antibody titers (acute and convalescent) may be necessary.

EMERGENCY DEPARTMENT MANAGEMENT

For acute injuries, prehospital care should initially focus on life-support measures. Wound care should include copious irrigation with sterile saline solution or clean tap water. Wounded extremities should be immobilized and elevated.

In the emergency department, extremity wounds should be assessed for distal function and neurovascular status before local or regional anesthesia. Extremity tourniquets may facilitate exploration and repair. The most important aspect of wound care is copious irrigation with sterile saline solution, 1% povidone-iodine solution (1:10 dilution of the commercial 10% solution), or Pluronic-68. Devitalized tissue should be debrided with a scalpel or fine dissection scissors. Excision of puncture wounds has been recommended but never proved to be effective. Abrasions should be cleansed and treated with topical antibiotics.

Primary closure of animal bite wounds is controversial. When successful, the benefits are early return of function and optimal cosmetic results. As a rule, normal hosts with relatively clean lacerations, especially of the face, can safely be sutured, primarily if seen within a few hours of injury. Alternatively, sterile skin tapes may result in a lower incidence of infection. Delayed primary closure, often a prudent alternative, and healing by secondary intention are less apt to result in infection. Buried sutures should be avoided whenever possible. All wounded extremities should be immobilized, and strict elevation should be advised.

Clenched-fist bite wounds are best treated by delayed primary closure or secondary intention. In gaping wounds, the edges can be loosely approximated with a minimum of sutures, provided that sufficient space is allowed for drainage. All wounds should be carefully explored, copiously irrigated, splinted, and elevated. Admission to the hand, orthopedic, or plastic surgery service should be considered if there is any injury to the tendon, joint, or bone or if signs of infection are present. Intravenous antibiotics should be administered in all cases. Abscesses and infections that involve deep structures such as tendon sheaths and joints should also be referred to a surgeon, because they may require concomitant operative management. Antibiotics should again be administered intravenously. Patients may be discharged only after consultation and only when reliable, early follow-up can be assured.

Although "prophylactic" antibiotics are often prescribed, there are no prospective controlled studies with sufficient numbers of patients to demonstrate their effectiveness definitively or the superiority of a particular regimen. It seems, however, that antibiotics significantly decrease the incidence of infection in high-risk situations.^{3,6}

Antibiotics, whether "prophylactic" or as empirical treatment of established infections, should cover *Pasteurella* spp. streptococci, staphylococci, *C. canimorsus*, and anaerobes. Amoxicillin-clavulanic acid (Augmentin 875 twice a day), a second-generation cephalosporin with anaerobic activity (e.g., cefuroxime 500 mg twice a day), or penicillin combined with a first-generation cephalosporin or with a semisynthetic penicillin, all offer an appropriately broad spectrum of activity.¹⁴ Many authors have suggested semisynthetic penicillins or first-generation cephalosporins alone. These agents are not sufficiently effective against *P. multocida*. Penicillin-allergic patients can be given the combination of clindamycin (300 mg three times a day) with a fluoroquinolone (e.g., levofloxacin 500 mg daily) or doxycycline alone (100 mg twice a day for 7 days). Azithromycin (10 mg/kg, up to 500 mg on day 1; then 5 mg/kg, up to 250 mg daily for up to 4 more days) can be used in penicillin-allergic patients who are pregnant, nursing, or under 9 years old. Intravenous antibiotic administration (e.g., ampicillin-sulbactam 2 g; penicillin G 1 million units, plus nafcillin 1 g; or doxycycline 100 mg; or azithromycin 500 mg) before wound closure, although never formally studied in bites, can produce adequate penetration of the wound coagulum and is advisable in high-risk situations.

If used prophylactically, the course of therapy should be limited to 3 to 5 days, with a follow-up wound check scheduled during this period. Seven to 10 days of oral therapy is usually sufficient for the treatment of superficial wound infections. Close follow-up should be arranged. Deeper infections should be treated initially with intravenous antibiotics. In reliable patients, this can be accomplished on an outpatient basis by scheduling them to return to the emergency department or outpatient clinic. Daily reassessment should be performed until there is improvement, at which time, therapy can be continued with an oral agent and follow-up can be done less frequently.

Septic patients with a history of recent animal bites should be given broad-spectrum intravenous antibiotics initiated in the emergency department as soon as the Gram stain and culture are obtained from wounds, blood, and CSF, if indicated. Meropenem (1 g intravenously) is a reasonable choice for initial therapy pending

culture results.³

Cat-scratch disease resolves spontaneously in 1 to 2 months or can be treated with ciprofloxacin, gentamicin, erythromycin, or trimethoprim–sulfamethoxazole.¹⁰ Needle aspiration of fluctuant lymph nodes can alleviate constitutional symptoms as well as local pain.

Uncomplicated rat-bite fever should be treated with a 10-day course of penicillin, tetracycline, or erythromycin (500 mg orally four times a day).

Treatments of choice for tularemia are streptomycin (10 to 15 mg/kg intramuscularly twice a day) or gentamicin (2 mg/kg intravenously for loading dose) for 7 to 10 days.

Treatment of patients exposed to B-virus (*H. simiae*) should include prophylactic acyclovir (15 mg/kg intravenously every 8 hours).⁹

Bites are tetanus-prone, and immunoprophylaxis should be provided.

Rabies is fatal, and only supportive care can be offered once symptoms develop. Prevention depends on control of exposure, aggressive local wound care, and knowledge of transmission, which is usually by means of saliva contacting a laceration, scratch, abrasion, or mucous membrane. Postexposure prophylaxis is indicated if the offending animal is known or clinically suspected to be rabid or if it is a bat or wild carnivore (e.g., a bobcat, coyote, fox, raccoon, skunk, or wolf).^{4,7} The silver-haired bat variant of rabies virus is able to replicate in the superficial dermis and has been associated with several recent cases of human rabies without known history of conventional exposure. For this reason, postexposure prophylaxis is now recommended for persons who may have come in contact with a bat (e.g., an infant or a sleeping adult in a room with a bat, even if a bite or scratch wound is not apparent).¹¹ Livestock and unprovoked dog and cat bites should be considered individually in consultation with public health officials.

Patients bitten by healthy dogs and cats do not require immunization, provided the animal can be observed for 10 days for signs of illness. Rabbit and rodent (e.g., hamster, mouse, rat, squirrel) bites do not require treatment unless the animal is wild and rabies is endemic in the offending species. Patients who have not been previously immunized should receive both human rabies immune globulin (20 IU/kg), up to half the dose infiltrated at the bite site, if anatomically feasible, and the remainder given intramuscularly (e.g., deltoid), and human diploid cell rabies vaccine (1 mL intramuscularly on days 0, 3, 7, 14, and 28).

Because hepatitis B can be transmitted by saliva, all bites must be considered for hepatitis B prophylaxis according to the risk evaluation of the source. While saliva contains only low concentrations of HIV, there is often admixture of blood in bite situations. This is the case in occlusional bites by persons with friable gingiva or seizing patients who have bitten their tongue. Clenched-fist injuries have significant risk for HIV transmission, especially when a lip laceration was sustained at the time of the altercation. In these situations, postexposure HIV treatment should be offered.

DISPOSITION

Role of the Consultant

Consultation with an infectious disease specialist and a microbiologist (for a careful search for organisms unique to animal bites) is advisable in cases of septicemia. Infectious disease consultation should be considered in cases of possible HIV, hepatitis B, or B-virus transmission. A surgeon (general, hand, plastic, or orthopedic, depending on local practices) should be consulted when there is violation of a deep structure (such as a joint, bone, tendon, or internal organ), extensive facial damage, tissue loss, or a clenched-fist bite. Bites by potentially rabid animals should be reported to state public health officials. All bite wounds should be reported to local agencies.

Indications for Admission

Patients who sustain major trauma, significant blood loss, or injuries that require operative intervention usually need to be admitted. Those who require intravenous antibiotics (i.e., systemic, central nervous system, hand, joint, or other deep-structure infection or any infection in a high-risk patient) or who cannot receive proper care as outpatients should also be admitted. Clenched-fist bites with involvement of tendon, joint, or bone should be considered for admission. All patients who do not require admission should be rechecked in 24 to 72 hours for signs of infection. If signs of infection develop, sutures must be removed and the wound left opened for drainage.

Transfer Considerations

Transfer to another institution should be arranged whenever appropriate inpatient facilities or consultants are unavailable.

COMMON PITFALLS

- Failure to diagnose deep-structure or vital organ injury
- Failure to diagnose, fully explore, and refrain from primary closure in clenched-fist bites
- Failure to identify and admit infected immunocompromised patients
- Failure to close low-risk wounds
- Failure to immobilize and elevate injured extremities
- Failure to recheck all wounds in 24 to 72 hours
- Failure to provide rabies immunization after possible bat exposure

CHAPTER 381

Hymenoptera Envenomation

Paul A. Janson and Richard J. Iseke

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Hymenoptera envenomations are commonly referred to as bee stings, although the order Hymenoptera also includes wasps, hornets, yellow jackets, and ants. Honeybees and bumblebees belong to the family Aphididae; yellow jackets, hornets, and wasps are of the Vespidae family; and ants, of which only a small number are venomous, belong to the Formicidae family.

There is a strong cross-reactivity between the venoms within each family, but less so between families. Stinging or “fire ants” are found predominantly in the southern United States, but winged species are ubiquitous. Yellow jackets build nests in the ground. Hornets' nests are large and are found in trees and under branches. Wasps build honeycombed nests, often under roofs. Only the honeybee leaves its stinger, often with the venom gland attached, in the skin of victims of envenomation.

The venoms of winged species contain mixtures of biogenic amines (e.g., acetylcholine, dopamine, histamine, norepinephrine, serotonin), polypeptides or protein toxins (e.g., apamin, melittin, kinins), and enzymes (e.g., hyaluronidase, phospholipases). That of bees and wasps may be more potent during the cooler autumn months. The venom of fire ants consists mostly of piperidine alkaloids, with small amounts of low-molecular-weight protein. ^{3,5}

Hymenoptera envenomation may result in local inflammatory reactions, immediate and delayed hypersensitivity reactions, atypical reactions, and direct systemic toxicity. Nonallergic local reactions result from alkaloid-, polypeptide-, and protein-induced histamine release from mast cells, as well as the direct action of injected amines. Immediate (type I) hypersensitivity reactions may be either local or systemic. They occur when basophils or mast cells react with antigenic venom polypeptides, proteins, and enzymes (or alkaloid haptens) and cause the release or production of intracellular histamine, serotonin, leukotrienes, and other chemicals.

Physiologic effects include bronchiolar constriction, vasodilatation, myocardial depression, increased capillary permeability, and production of mucus. Sensitized people usually have elevated levels of venom-specific serum IgE. However, different winged species have similar venom constituents, and people sensitized to one species may also react to a sting by another species, particularly one of the same family, even though those people have not been previously stung by the latter. Anaphylaxis to insect stings affects up to 0.5% of the U.S. population and accounts for about 40 deaths annually. ¹³

Delayed (type III) hypersensitivity reactions are caused by IgG and IgM antibody–antigen complex–mediated local (Arthus) and systemic (serum sickness) toxicity. ¹¹ Delayed atypical reactions, suspected to be allergic in etiology, include hematologic and neurologic disorders such as hemolytic anemia, thrombocytopenic purpura, Guillain-Barré syndrome, multiple sclerosis, optic neuritis, parkinsonism, and transverse myelitis. ^{11,15,19}

Direct systemic toxicity results from the absorption of large amounts of venom after multiple stings. Although most multiple stings occur when a nest has been disturbed, African honeybees (“Brazilian killer bees”), now indigenous to Central America and the southwestern United States, are notorious for large, aggressive swarms, with encounters and often resulting in multiple stings. ^{9,13,19} Their venom, however, is no more potent than that of other honeybees.

Hymenoptera envenomation usually causes only a transient reaction at the site of the sting. A few victims develop an excessive local inflammatory response or a generalized systemic reaction. ^{7,12,13,16,19} A sting in someone with no history of previous systemic reaction (including those with pronounced local reactions) results in an anaphylactic reaction less than 1% of the time. ¹¹ However, because most victims of fatal stings have no history of a prior systemic reaction, a negative history does not rule out the possibility of a severe reaction in the future.

Adults with a history of a previous systemic reaction have up to a 60% chance of a similar reaction after subsequent envenomation. Those with a severe local reaction have about a 5% chance of a future anaphylactic reaction. Children with a systemic reaction limited to non–life-threatening urticaria or angioedema have a subsequent systemic reaction rate of less than 10%. Venom immunotherapy is 98% effective in preventing subsequent systemic reactions. ¹⁰

Most anaphylactic fatalities are due to laryngeal edema and bronchospasm and occur within an hour of the sting. ¹ Vascular collapse, coma, and seizures can also occur. Direct venom toxicity (Braphylactoid reaction) may result in vascular collapse with renal or cardiac failure. Death may occur hours to weeks after multiple stings. Depending on the size of the victim and the offending species, 20 to 300 simultaneous stings may be serious or fatal. ¹⁹ Both children and adults have survived single episodes that involved more than 1,000 honeybee stings.

CLINICAL PRESENTATION

Nonallergic local reactions are characterized by pain, wheal and flare formation, warmth, and pruritus at the sting site. Reactions to stings by winged species begin immediately and last for several hours. Fire ant stings, often in clusters, frequently develop into painful vesicles and pustules during the first 24 hours and require up to 10 days for resolution. ⁶ Puncture marks may be invisible without the aid of a magnifying lens.

Local allergic reactions are manifested by persistent swelling, pain, and erythema at the site of the sting. These reactions may progress to involve a large area (e.g., an entire extremity) over the first 2 to 3 days and may last for more than a week. Stings after insect inhalation or ingestion may result in swelling and obstruction of the pharynx, larynx, or esophagus.

Most anaphylactic reactions develop within minutes of envenomation and peak within an hour. ^{2,6,15} Rarely, they may be delayed as long as 6 hours after the sting. Recurrent reactions may occur for up to 2 days. Mild reactions are characterized by generalized flushing and urticaria. Weakness, chest or throat tightness, nausea, vomiting, diarrhea, and generalized angioedema indicate a moderate reaction. Cyanosis, dyspnea, stridor, hoarseness, confusion, coma, and collapse are seen in severe cases. Physical findings may include hypotension, tachycardia, laryngeal and pulmonary edema, and wheezing, as well as skin manifestations. Secondary complications include cerebral and myocardial infarction and coagulopathy. ^{9,15,18}

Delayed atypical and hypersensitivity reactions are rare. ⁸ Symptoms normally occur within 1 week of envenomation. Serum sickness is characterized by fever, arthralgia, myalgias, rash, adenopathy, headache, glomerulonephritis, nephrotic syndrome, and necrotizing vasculitis. Cutaneous vasculitis (“palpable purpura”) may indicate an Arthus reaction. Hematologic and neurologic abnormalities may suggest one of the previously mentioned disorders or syndromes.

Signs and symptoms of direct systemic toxicity usually begin within minutes and include vomiting, diarrhea, generalized edema, collapse, loss of consciousness, confusion, headache, muscle spasms, and seizures. Hepatotoxicity and encephalopathy mimicking Reye syndrome has been described. Vital signs may reveal hypotension, tachycardia, and fever. Severe cases may be complicated by hemolysis, rhabdomyolysis and acute renal failure. ^{13,16,19}

DIFFERENTIAL DIAGNOSIS

Because Hymenoptera envenomation can cause a variety of reactions, the differential diagnosis is extensive. Fortunately, there is usually a history of a sting to indicate the correct diagnosis. The challenge is making the diagnosis when the history is unclear.

Limited local reactions of similar appearance may be produced by virtually any stinging or biting insect (see [Chapter 382](#)). Extensive local reactions must be differentiated from infection: Hymenoptera envenomations seldom become infected. Progressive extension of the initial reaction beginning shortly after the sting indicates an allergic reaction, whereas inflammation with fever, leukocytosis, and lymphangitis beginning more than 24 hours after envenomation suggests infection.

Anaphylactic reactions may be caused by a wide variety of proteins (e.g., pollen, food), drugs, dyes, and diagnostic and therapeutic agents. This diagnosis should be considered in any unconscious patient with hypotension and signs of airway obstruction during warm months, particularly if the patient is discovered outdoors. A careful skin examination may suggest the correct diagnosis.

Patients who present with symptoms and signs of delayed or atypical reactions should be asked about recent insect bites or stings, illnesses, and medication use (particularly passive immunization therapy) within the previous month, as it is unlikely they will volunteer such a history.

Direct systemic toxicity must be differentiated from anaphylaxis. Toxic reactions progress more slowly, require many stings, and may produce fever. Urticaria, pruritus, and wheezing suggest anaphylaxis.

EMERGENCY DEPARTMENT EVALUATION

The history should include the time and number of stings, the offending species (if known), previous Hymenoptera reactions, preexisting medical conditions, and the time of onset, progression, and nature of symptoms. The physical examination should focus on the vital signs, upper airway patency, the lungs, the cardiovascular system, and the skin. With honeybee envenomation, the stinger and venom sac may be apparent at the sting site. Patients with hypotension, chest pain, or loss of consciousness should have an electrocardiogram to rule out myocardial injury.

If the physical examination is equivocal, upper airway patency may be assessed by soft-tissue neck radiographs. Patients with persistent respiratory signs and symptoms should have arterial blood gas analysis and a chest radiograph. Patients with hypotension, loss of consciousness, or more than ten stings should have measurements of serum creatine phosphokinase, blood urea nitrogen, and creatinine levels; prothrombin time; partial thromboplastin time; and urinalysis. A complete blood count may help to differentiate local allergic reactions (eosinophilia) from infection (leukocytosis with left shift) as well as to detect hemolysis and thrombocytopenia.

EMERGENCY DEPARTMENT MANAGEMENT

The treatment for anaphylaxis due to Hymenoptera stings is the same as that for anaphylaxis of other etiologies (see [Chapter 217](#)). Advanced life-support measures should be instituted, as necessary. Epinephrine should be given at the first sign of an anaphylactic reaction, preferably by prehospital personnel. ^{4,6,15} The dose and route depend on the severity and nature of symptoms, as well as on the victim's underlying medical problems (see [Chapter 217](#)).

Aggressive volume replacement with crystalloid should be part of the management of patients with anaphylaxis, particularly those with hypotension. Adjunctive therapy should include oral or intravenous diphenhydramine (0.5 to 1.0 mg/kg) and oral prednisone (0.5 to 1.0 mg/kg) or intravenous methylprednisolone (1 to 4 mg/kg), depending on the severity and response to epinephrine. ^{14,17} Whether an H₂ blocker such as cimetidine would also be helpful is unknown.

Severe anaphylactic reactions or marked local reactions that involve the nose, mouth, and throat may require immediate airway control. Because most deaths are due to airway obstruction, early endotracheal intubation may be lifesaving in patients with respiratory distress from either upper or lower airway obstruction. Intubation should also be considered in patients with significant central nervous system depression or severe shock.

Measures to consider in recurrent or refractory anaphylaxis include continuous infusions of epinephrine or isoproterenol, and norepinephrine for hypotension. Higher-than-usual doses of adrenergic agents may be required in patients taking beta-adrenergic blocking agents and those on chronic beta-agonist medications. Isoproterenol may be preferred in patients taking beta blockers. ⁷

The treatment of local reactions includes wound care and symptomatic therapy for pain, swelling, and pruritus (with analgesics; cool soaks, ice packs, and elevation; and antihistamines). Cleansing of the puncture site and tetanus prophylaxis are routine measures. Stingers with attached venom sacs should be removed, to avoid further envenomation, by brushing or scraping with the sharp edge of a needle or scalpel. Stingers without sacs may also be removed with forceps. ²⁰ The use of topical papain (meat tenderizer), aluminum-containing antiperspirants, and parenteral heparin is controversial and of uncertain benefit.

The treatment of toxic reactions after multiple envenomations is entirely supportive. Delayed hypersensitivity reactions can usually be treated with analgesics and antihistamines. Corticosteroids may be necessary in severe cases. Complications and atypical reactions should be treated with standard measures.

DISPOSITION

Patients who present immediately after envenomation should be observed for 1 to 2 hours for signs and symptoms of anaphylaxis. Asymptomatic patients may then be discharged. Because milder anaphylactic reactions may be delayed, patients should be instructed to return immediately if systemic symptoms ensue. In asymptomatic patients with a history of previous anaphylactic reactions or severe local ones, it may be prudent to prescribe a prophylactic 3-day course of antihistamines and corticosteroids, beginning with a dose before discharge.

Patients with anaphylaxis should be treated and observed for 4 hours. Those who become asymptomatic may be discharged. Patients with persistent or recurrent symptoms (excluding isolated urticaria) and those with life-threatening reactions should be hospitalized. Similarly, those with ischemic complications, those with toxic reactions and multiple envenomations, and those without reliable home observation should be admitted. All patients with anaphylactic reactions should be treated with a 3-day course of antihistamines and corticosteroids to prevent a relapse.

Those with anaphylactic or severe local reactions should be given a prescription for epinephrine (e.g., EpiPen or Ana-kit) and referred to an allergist (directly or through the primary care physician) so that they can receive instruction regarding the self-use of epinephrine and evaluation for desensitization immunotherapy. Victims of anaphylaxis should be cautioned about outdoor work and recreation (particularly gardening, fruit picking, and eating) and advised to avoid wearing bright colors and perfumes. The use of insect repellents may be helpful. An allergy identification bracelet is also recommended.

Patients with local or delayed hypersensitivity reactions can be treated as outpatients, with emergency department or primary care follow-up. Atypical reactions may require admission and referral to an appropriate specialist. Although the role of desensitization therapy in patients with severe local reactions is controversial, such patients should be referred to an allergist.

COMMON PITFALLS

- Failure to suspect anaphylaxis caused by Hymenoptera envenomation in an unconscious patient with cardiovascular collapse during an outdoor activity in warm seasons
- Failure to recognize delayed and atypical reactions and secondary complications of anaphylaxis and massive envenomation
- Failure to intubate patients with severe upper or lower airway reactions
- Failure to give epinephrine to patients with life-threatening anaphylaxis
- Failure to prescribe antihistamines and corticosteroids for 3 days after anaphylaxis, to prevent its recurrence
- Failure to prescribe an emergency epinephrine kit for victims of severe local and anaphylactic reactions
- Failure to refer patients with severe local and anaphylactic reactions to an allergist

CHAPTER 382

Insect Bites and Infestations

Constance G. Nichols

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Common Pitfalls](#)
[Chapter References](#)

Insects are members of the phylum Arthropoda. Those commonly causing bites or infestations in the United States include fleas, flies, lice, mites, and ticks. Insect bites are frequently not recognized as such. Those frequently affected are the young, the elderly, or the mentally or physically impaired who are unable to give a history, cannot care for themselves, and live under crowded conditions (e.g., nursing homes, chronic care institutions or daycare centers).

Fleas (order Siphonaptera) are small wingless insects that carry diseases such as typhus or plague. Fleas have specially adapted legs that allow them to jump several feet at a time. They feed on the blood of animals but can survive (e.g., on carpets) for several months without a meal. Flea-bite dermatitis is an inflammatory reaction to flea saliva.^{3,5}

Lice (Anoplura) are crablike, crawling parasites that require a human blood meal every 12 to 24 hours. The female lice deposit eggs (“nits”) at the base of hair shafts and “cement” them to the shaft. The scalp and body are infested by the *Pediculus humanis*, while the pubic area is infested by *Phthirus pubis*. Transmission of lice occurs through such fomites as clothing, caps, hairbrushes, and linens or through direct contact. In the case of pubic lice, the patient is usually sexually active and may have other coexisting venereal diseases. Body lice are usually found in those with poor personal hygiene. The bites and saliva of the lice are responsible for symptoms. These insects are also vectors of epidemic typhus, trench fever, and relapsing fever.^{8,9 and 10}

Flies and mosquitoes (Diptera) are ubiquitous winged insects that require a moist environment for larval and pupal development and feed on warm-blooded animals, including humans. The blood-sucking apparatus is a syringe-like proboscis through which the insect injects salivary material that has allergenic, vasodilatory, and anticoagulant activity. These insects range in size from 2.5-mm midges, sandflies, and “no-see-ums” to 2.5-cm horseflies and deerflies. Some are vectors for diseases such as dengue fever, encephalitis, filariasis, leishmaniasis, malaria, trypanosomiasis, and tularemia.

Assassin bugs, bedbugs, and wheel bugs (Hemiptera) are large (2 to 4 cm) and winged. The assassin bug (*Triatoma protracta*), also known as the kissing, reduviid, or western cone-nosed bug, has a long proboscis with which it sucks blood painlessly from the victim. It usually lives in conjunction with mammals in the wild but can adapt to human environs. Bedbugs (*Cimex* species) have nonfunctional wings, feed on blood, and inflict painless bites. The larvae are found in clothing, bedding, and furniture; they attack at night. A wheel bug (*Arilus cristatus*) inflicts injury by rubbing its snout on the skin, inflicting a transient abrasion and local reaction.^{8,10}

Blister beetles (Coleoptera) are winged insects that live on vegetation and are in contact with humans only when disturbed. These insects do not bite or sting. Exposure to them occurs when handling plants on which the insects live. When the beetle is crushed, it releases hemolymph, a vesicant.⁸

Centipedes (Chilopoda) are long, crawling insects with one pair of legs on each body segment and fangs for injecting venom on the first segment. Millipedes (Myriapoda) excrete defensive fluid that contains a number of toxic chemicals. They have two pairs of legs per body segment. Centipedes and millipedes are most common in the tropics.¹⁰

Insects of the Arachnid order include mites, such as scabies and chiggers, and ticks. Scabies is caused by the barely visible female of the species, *Sarcoptes scabiei* var. *hominis*, which, after fertilization, burrows into the epidermis and lays eggs at the rate of two to three per day. The mite dies after laying a total of ten to 25 eggs, resulting in an inflammatory reaction. Scabies is spread through close contact, as the mite cannot survive more than 24 to 48 hours without human contact. Normally, only a small number of mites are present on the skin. In patients with compromised immune systems, thousands of mites may be present.^{10,15}

Chiggers, the larvae of harvest mites, are prevalent in the South and Midwest. The adults live on plants and deposit their eggs there. After the larvae hatch they migrate to the ends of leaves, waiting for a vertebrate host so they may attach, feed, molt, and continue the life cycle as vegetarian adults. When the chigger attaches to the skin, it bites and feeds, releasing digestant substances that cause an allergic reaction.^{2,8,15}

Ticks are divided into two morphologic types: hard (Ixodidae) and soft (Argasidae). This classification is based on the presence or absence of the scutum, a protective covering of chitin on the dorsal surface of the tick. They are found worldwide and feed on the blood of warm-blooded animals and some reptiles. Bites occur when the tick attaches itself painlessly to the skin surface. The tick is attached by its teeth and by a cement-like substance that it excretes onto the host. Soft ticks tend to feed for several hours and drop off, whereas hard ticks may remain attached for days. After the tick attaches, its saliva contaminates the host.

Ticks may transmit a variety of diseases caused by viruses or bacteria (Table 382.1). Tick paralysis occurs when a tick has been attached for 4 to 5 days; it is due to neurotoxins present in the saliva of some species. Prevention of tick-borne diseases is possible by careful examination of people who have been exposed to the outdoors, especially children.^{8,13,14}

Disease	Tick Vector	Agent	U.S. Distribution
Babesiosis	Ixodes	Babesia spp.	Northeast
Lyme disease	Ixodes	Borrelia burgdorferi	Northeast, Wisconsin, Minnesota, California
Ehrlichiosis	Dermacentor	Ehrlichia chaffeensis	South Central, South Atlantic
Rocky Mountain spotted fever	Dermacentor	Rickettsia rickettsii	Southwest, West, South Central
Tularemia	Dermacentor, amblyomma	Francisella tularensis	Arkansas, Missouri, Oklahoma
Tick paralysis	Dermacentor, amblyomma	Toxin	Northwest, South
Relapsing fever	Ornithodoros	Borrelia spp.	West
Colorado tick fever	Dermacentor	Coltivirus spp.	West

TABLE 382.1. Tick-borne Diseases

Swimmer's itch (cercarial dermatitis) is caused by the invasion of the dermis by avian blood flukes or schistosomes. Released by intermediate hosts (snails and other mollusks) and unable to find natural hosts (e.g., ducks, geese), cercariae burrow into the skin; however, unable to penetrate the dermis, they die.^{6,11} Seabather's eruption is caused by the bite of planula larvae of the phylum Cnidaria, with different species responsible in varying locales.⁴

CLINICAL PRESENTATION

Flea bites are grouped welts, papules, and vesicles surrounded by urticarial areas, usually on the exposed parts of extremities. In children, the vesicles can become generalized and confused with varicella. Although the lesions usually resolve after several days, they may be intensely pruritic, with scratching leading to secondary

infections. Repeated exposure to bites in sensitive people, especially children, results in more severe reactions. [5,8,10](#)

Lice bites are often pruritic and can cause urticaria. They can become secondarily infected from excoriation. Head lice are commonly found in schoolchildren, usually in the temporal and occipital regions. Often, the children present with lymphadenopathy and a secondarily infected area of the scalp with matted hair. They may complain of something "crawling" on their scalp. Body lice do not live on the skin but in the clothes or bedding of the affected individual. Nits can often be found in the seams of clothing. The lice are present on the person during feeding but leave after a blood meal. Lesions are often found on the back, waist, and buttocks. [8,9](#) and [10](#)

Pubic lice live at the base of hairs in the perineum, abdomen, and thighs. They can also be found in the eyelashes, axillae, and beards. Occasionally, maculae cerulae, blue-pigmented lesions up to 1 cm in diameter, thought to be due to alteration in blood pigment, can be seen at sites of louse feeding. [1,8,9](#) and [10](#)

Fly and mosquito bites initially cause intensely pruritic, painful papules. By age 5, almost all children react to such bites. Erythema, edema, and urticaria may develop later as a result of delayed hypersensitivity. Bites may become secondarily infected. [8,10](#)

The bites of assassin bugs are usually discovered the morning after they have occurred. They are clustered, erythematous, pruritic nodules found in areas not covered by clothing. The lesions can be large (2 to 6 cm) and often last for more than a week. Some people have more severe reactions, such as light-headedness, gastrointestinal upset, and frank anaphylaxis.

Bedbug bites, also first noted in the morning, generally appear as reddened and sometimes hemorrhagic lesions in a linear distribution. Anaphylaxis has been reported but is extremely rare. Wheel bugs cause minute, painful lacerations with transient swelling. [8,10](#) Patients with blister beetle bites present 2 to 5 hours after gardening, with the development of large (5- to 50-mm) vesicles or bullae on the exposed skin. [10](#)

Centipede envenomation results in pain, itching, and, sometimes, local necrosis with lymphadenitis and myonecrosis. Millipede secretions initially cause a brown-stained area with some burning, which can progress to blistering with subsequent exfoliation. If the toxin gets in the eyes, there is immediate irritation, usually accompanied by pain, lacrimation, chemosis, periorbital edema, and corneal ulceration. [10](#)

Patients with scabies present with severe pruritus. Examination of the skin reveals excoriated, dry, scaly patches. The diagnostic lesion is a serpentine burrow usually found on the hands, especially in the finger webs. Erythematous papules occur on the skin, and nodules can appear on the penis and scrotum. A severe form of scabies found frequently in the immunocompromised patient is called "Norwegian scabies"; it presents with severe, crusting lesions. Secondary bacterial infection is common. [1,10,15](#)

Chigger bites cause intense, pruritic, papular, or vesicular erythematous lesions with a central punctum. The reaction begins within 3 to 24 hours of exposure. After a few days, the lesions become red, flat, and conical. [2,8,10,15](#) Chigger bites to the penis can result in local swelling, pruritus, dysuria, and decreased urine stream (the "summer penile syndrome"). Half of patients with this syndrome have a papule or bite puncture mark on the penis. [12](#)

Tick bites result in a pruritic papule that resolves in 2 to 3 days. Patients commonly present with the tick still attached to the skin. If mouthparts are left in the bite site after removal of the tick, a nodular granuloma can form. With tick paralysis, there is a 24-hour prodrome of malaise, followed by an ascending symmetric paralysis similar to that of the Guillain-Barré syndrome, often with respiratory compromise. Other neurologic findings include difficulty swallowing and involuntary eye movements. The patient is afebrile and reflexes are absent, but sensation is intact. Laboratory tests, including cerebrospinal fluid analysis, are usually normal. [8,10,14](#)

Patients with swimmer's itch have only a slight pruritus immediately after exposure to fresh water. Twelve hours to 2 weeks later, an intense pruritus develops along with a maculopapular or papulovesicular erythematous rash. [6,11](#) Seabather's eruption, often confused with insect bites, occurs after exposure to salt water and is characterized by a papular rash that is typically more intense on areas covered by a bathing suit.

DIFFERENTIAL DIAGNOSIS

Insect bites are commonly confused with contact dermatitis (allergic or chemical) and viral exanthems. Generalized vesiculation from flea bites may resemble varicella, but fever and systemic symptoms are absent. Bullous impetigo and burns may have the same appearance as reactions to blister beetles. Potential exposure by history is frequently the only diagnostic clue. Tick bite nodules may resemble tumor visually and histologically. The Guillain-Barré syndrome, myasthenia gravis, and other causes of weakness or peripheral neuropathy may be confused with tick bite paralysis if the tick is not discovered. The rash of swimmer's itch may resemble chigger bites, mosquito bites, and poison ivy or oak, scabies, or sea bather's eruption. [6,11](#)

EMERGENCY DEPARTMENT EVALUATION

The history should include inquiries regarding activities that occurred prior to or at the time of onset of skin lesions, exposure to animals and others with similar skin lesions, the description of any insects observed, similar reactions in the past, and what treatments have been tried prior to presentation. Evaluation should include a complete examination of the entire skin surface, as well as a general examination, to exclude systemic diseases, particular anaphylactic reactions, and infectious diseases with insect vectors. Self-medication with steroids and topical diphenhydramine (itself a cause of allergic reactions), excoriations from scratching, and secondary bacterial infection can result in atypical lesions.

EMERGENCY DEPARTMENT MANAGEMENT

General measures include cool soaks, showers, baths, and antihistamines for itching; topical steroids for inflammatory reactions; and topical or systemic antibiotics for secondary infections. Treatment should also include eradication of the insect source and prevention of reexposure, when possible. Insecticides, insect repellents, and protective clothing may be helpful for environmental control.

Flea control requires vacuuming, washing of rugs and pet beds, and, often, the use of insecticides (foggers, sprays, flea collars). [7](#)

Lice and scabies control often requires the treatment of institutional contacts and sexual partners, as well as the laundering of bedding and clothing. Treatment of lice and scabies infestation has historically been topical 1% lindane (gamma benzene hexachloride; Kwell, Scabene) lotion or shampoo. Toxic reactions to lindane, such as nausea, vomiting, irritability, convulsions, respiratory failure, and blood dyscrasias, have been reported when it is used improperly, especially in young children.

Permethrin cream (5%), a newer scabicide with little potential for neurotoxicity, may be preferred for children. In infants less than 2 months old, pregnant women, nursing mothers, and patients with underlying skin diseases and neurologic disorders, the recommended treatment is 10% crotamiton. This cream or lotion is rubbed into the skin on two consecutive nights and can itself cause dermatitis. [8](#) Alternatives for scabies include 5% to 10% sulfur in petrolatum (very messy), benzyl benzoate emulsion, and NBIN (benzyl benzoate, DDT, benzocaine, and polysorbate 80, used by the World Health Organization in underdeveloped countries). Other pediculosis treatments include malathion, benzyl benzoate, and NBIN. Hospitalized patients with scabies need to be placed on skin precautions, and hospital personnel must be gowned and gloved. Lice infestation of the eyelashes is treated by application of thick layers of petrolatum twice daily for 8 days, with mechanical removal of the nits. [1,8,9](#) and [10](#)

Tick paralysis is treated supportively. Following removal of the tick, there is rapid recovery (within 24 to 48 hours). One method of removal is to grasp the tick with forceps close to the mouthparts, flip (not twist) the tick over so that its backside is closest to the skin and pull. Other methods include suffocation of the tick with mineral oil, nail polish, petrolatum, or chloroform. Hot objects may be applied, but care must be taken to avoid causing thermal burns. During the agonal struggle from suffocation, the tick's gastric contents may be forced into the bite wound. The site should be explored for retained mouthparts. Retained mouthparts and tick-bite nodules should be removed by excision. [8,10](#)

Treatment of swimmer's and seabather's itch is symptomatic. Antipruritic agents are useful, along with antihistamines, and, in severe cases, corticosteroids will relieve the intense pruritus. [6,11](#)

COMMON PITFALLS

- Failure to elicit a history of activities with the potential for insect exposure
- Failure to consider insect bites and infestations in the differential diagnosis of rashes
- Failure to consider the possibility of concomitant insect-transmitted infections or disease in patients with insect bites
- Failure to institute infection control measures for lice and scabies and to offer treatment to those who have had close but unprotected contact with such patients

About 1,200 species of venomous or poisonous marine animals are found throughout the oceans and seas of the world. These animals usually do not cause major medical, public health, or socioeconomic problems, but untoward encounters with these animals present unique and challenging clinical situations. Such encounters have increased in frequency in recent years because of greater use of the marine environment for recreational, commercial, and scientific activities. Unfortunately, these situations are not always medically managed most effectively.

This chapter reviews the most common marine animal envenomations, focusing briefly on the biology of the animals, their venom apparatus and mechanism of envenomation, and the clinical presentation and management of the injury. Infection is always a potential complication, and tetanus prophylaxis should be given as needed.

INVERTEBRATES

Coelenterates

The phylum Coelenterata is a diverse group of more than 9,000 species, all of which possess the basic coelenteron structure: a gastrovascular cavity that functions in both digestion and circulation and has a single opening. Coelenterates also have tentacles and a highly developed venom apparatus, used primarily to capture prey and secondarily for defense.

About 100 coelenterate species are dangerous to humans, and they collectively account for more marine envenomations than any other phylum.^{1,6,9,13} These species, generally known as Cnidaria, have venom-containing stinging cells (cnidocytes) near their mouths or on the outer surface of their tentacles. Cnidaria that cause the most human envenomations are the hydrozoans (fire coral and Portuguese man-of-war), scyphozoans (true jellyfish), and anthozoans (sea anemones).

Cnidocytes contain organelles known as nematocysts, composed of a venom-filled capsule (the cnidoblast) that contains a spiral-coiled, harpoon-like eversible tube. On the cnidoblast, there is a trigger (the cnidocil) and a trapdoor-like operculum over the opening, through which the nematocyst is discharged. The cnidocil is sensitive to pressure and changes in osmolarity, so both mechanical and chemical stimulation will trigger its discharge. On penetrating the upper dermis, the viscous venom coating the harpoon is released and picked up by the victim's circulation. The amount of venom contained in a single nematocyst is extremely small, but envenomation by jellyfish or Portuguese man-of-war typically involves the discharge of hundreds of thousands or even millions of nematocysts. Venoms are complex mixtures of heat-labile peptides and proteins, including deoxyribonuclease, ribonuclease I, adenosine triphosphatase, phospholipases, catecholamines, histamine, hyaluronidase, fibrolyns, kinins, and various hemolytic, cardiotoxic, and dermatonecrotic fractions.^{5,6,9,16}

Mollusks

Mollusks comprise the single largest group (45,000 species) of potentially toxic marine invertebrates. Most mollusk poisonings result from ingestion (see [Chapter 340](#)). The main molluscan envenomations of concern are cone shell stings and blue-ringed octopus bites (see subsequent discussion).

Conidae

Conidae, beautiful cone-shaped, univalve gastropods, are found primarily in the shallow tropical waters of the Indian and Pacific oceans; they are prized by shell collectors. Cones are nocturnal predatory carnivores that kill their prey by the injection of paralyzing conotoxins, delivered by a venomous radular tooth that inflicts a puncture wound.¹³

The venom consists of conotoxins, which attack neural and muscular impulse transmission at several points.^{14,16} One conotoxin acts by preventing entry of calcium into presynaptic nerve terminals, thus inhibiting the release of acetylcholine. Another conotoxin inhibits acetylcholine receptors, and others block sodium channels in cell membranes, thereby abolishing action potentials.

Eighteen species of the genus *Conus* have been implicated in human envenomations, which usually result from careless handling of live specimens or from accidental encounters with burrowed animals while rummaging through sand or debris in the area of coral reefs.

Octopuses

Although octopuses are usually reclusive creatures that pose no threat to humans, severe and even fatal reactions may result from bites of the Australian blue-ringed octopus (*Hapalochlaena maculosa*). The blue-ringed octopus seldom exceeds 20 cm in length and is yellow-brown with barely visible blue rings. The rings become a brilliant iridescent blue when the animal is provoked. The principal active venom component is tetrodotoxin, which blocks sodium conduction in both central and peripheral nerves.^{13,19}

Echinoderms

About 80 species of echinoderms, which include sea cucumbers, urchins, and starfish, are known to be venomous or poisonous to humans.^{2,13} Only sea urchins are discussed here.

Sea urchins are globular or flattened creatures whose vital organs are encased in a calcareous shell covered with regularly arranged spines. The spines are sharp, movable, and brittle, easily breaking off after puncturing a victim's skin; they may exceed a foot in length (e.g., *Diadema* spp.). Some sea urchin spines are venomous (e.g., *Asthenosoma* and *Areosoma* spp.). In addition, some species have small, triple-jawed, pincer-like seizing organs known as pedicellariae, which also may be venomous (e.g., *Tripneustes* and *Toxoneustes* spp.). Most sea urchins that are hazardous to humans are found in the Indian and Pacific oceans and the Red Sea.

The venom consists primarily of steroid glycosides, serotonin, and acetylcholine-like substances.¹⁶ Envenomation causes reactions that are painful but rarely life-threatening.

VERTEBRATES

There are about 200 species of fish that envenomate by spines located on their gill covers or dorsal, pelvic, or anal fins. The spine-puncture wound may be quite serious in itself. Although venomous species include sting rays, scorpionfish, catfish, weeverfish, and sea snakes, this discussion is limited to sting rays and scorpionfish.

Sting Rays

Sting rays, commonly found in tropical and subtropical waters, are peaceful, reclusive bottom feeders that usually lie buried in the sand or mud, with only their eyes, spiracles, and tail exposed. Envenomations usually occur when an unsuspecting swimmer, fisherman, wader, or scuba diver steps on the animal, causing the animal to reflexively thrust its barbed tail upward and forward, impaling the victim's leg or foot.^{1,10,12,15} When the tail penetrates the skin, the integumentary sheath over the spine ruptures and venom passes along the spine's ventrolateral grooves into the wound. Wounds are usually deep, jagged, and contaminated with debris. The barb is typically retroserrate and causes further injury as it is withdrawn. Sting ray venom is a complex mixture of heat-labile peptides and proteins.

Scorpionfish

Envenomations by bony fish of the family Scorpaenidae are relatively common, extremely painful, and, depending on the species, potentially deadly. This large, diverse family consists of about 30 genera and 350 species, at least 80 of which have caused venomous injuries in humans.^{10,11} They are widely distributed throughout the world but are especially prevalent in the Red Sea and the Indian and Pacific oceans, where they are usually found around coral reefs. They are masterfully camouflaged, and envenomation usually occurs when an unsuspecting scuba diver, swimmer, or fisherman naively handles or unknowingly grasps or steps on the fish. A finger or the palm is most often envenomated. In addition, thousands of lionfish are imported into the United States every year for private or commercial fish collections, resulting in envenomations of aquarists and tropical fish enthusiasts.¹¹

Scorpaenids envenomate victims by erectile spines on their dorsal, anal, and pelvic fins; these pierce the victim's skin and release venom from glands located in grooves on either side of the spine. The Scorpaenidae are typified by three genera: *Pterois* (e.g., lionfish, zebrafish, and turkeyfish), *Scorpaena* (e.g., scorpionfish and bullrouts), and *Synaceja* (the stonefish). *Pterois* spp. have long, slender spines and small venom glands; *Scorpaena* spp. have long, heavy spines and moderate-sized venom glands; *Synaceja* spp. have short, thick spines and very large, well-developed venom glands. Stonefish are the most dangerous of the Scorpaenids, accounting for a number of fatalities, but they are indigenous only to the Indo-Pacific region.

Scorpaenid venom is a complex mixture of peptides and proteins that are not well characterized. The principal toxic fraction of stonefish venom (stonustoxin) is a nondialyzable, heat-labile protein that causes an inflammatory reaction and potentially lethal hypotension.¹⁰

CLINICAL PRESENTATION

Coelenterates

The clinical manifestations of coelenterate envenomation are both toxic and antigenic in etiology.^{1,4,5,9} The most common presentation is localized dermatitis at the points of tentacle contact. For hydroids and fire coral, burning pain occurs immediately on contact with the animal; this is typically followed by development of an erythematous, papular, or urticarial eruption, which may become quite pruritic and last for several days.

In cases of jellyfish or Portuguese man-of-war stings, intense burning or stinging pain is usually followed by the appearance of linear red papules, beaded streaks, or urticaria in the areas of tentacle contact. These lesions are of variable duration, usually lasting for minutes to hours, and they may become vesicular, hemorrhagic, necrotizing, or ulcerative. The initial cutaneous eruption may be followed by localized or regional hyperhidrosis, angioedema, or lymphadenopathy.

Systemic symptoms include malaise, generalized weakness, pallor, myalgias and muscle spasms, diaphoresis, nausea, vomiting, headache, dizziness, low-grade fever, hyperpnea and respiratory distress, paresthesias and other sensory disturbances, ataxia, emotional lability, tachycardia, hypotension, and, rarely, cardiovascular collapse and death.³ Conjunctivitis, chemosis, corneal ulcerations, visual disturbances, and lid edema have been reported in cases of eye contact. Ingestion may produce abdominal pain and cramps and a generalized cutaneous eruption.

In addition to the acute reactions, persistent, recurrent, and delayed reactions may occur. These may take the form of papular urticaria, granuloma annulare, granulomatous nodules, fat atrophy, keloid formation, hyperpigmentation, contractions, gangrene, scarring, vasospasm, mononeuritis, autonomic nerve paralysis, and renal failure.⁴ Recurrent eruptions involve both type I and type IV hypersensitivity.

Fatal coelenterate envenomation may result from anaphylaxis or venom-induced cardiac or respiratory arrest or from hyperkalemia secondary to acute renal failure. Deaths from envenomation by the Pacific box jellyfish (*Chironex fleckeri*) or sea wasp (*Chiropsalmus quadrigatus*) may occur within minutes and are believed to be due to direct cardiotoxicity.⁵

Conidae

Envenomation initially causes a stinging or burning sensation, numbness, localized ischemia, and cyanosis about the wound.^{1,13,15} Depending on the severity of the envenomation, swelling, numbness, and paresthesias may rapidly extend from the wound. Local paralysis may progress to generalized weakness, paralysis, and respiratory failure. Severely envenomed victims may develop dysphagia, dysphonia, diplopia, blurry vision, generalized pruritus, and nausea. Rarely, disseminated intravascular coagulation, coma, or cardiovascular collapse follows. Death may occur within 2 hours of envenomation, although symptoms more often resolve in 6 to 8 hours.

Octopuses

Most envenomations occur when the victim is handling the animal—something that should not be done. Venom is injected painlessly but under sufficient pressure that it spreads rapidly through the dermis and into the muscle fascia.^{1,13,15,19} Victims are often unaware that they have been bitten. Within 10 minutes, local burning or throbbing pain is noted. Marked erythema, edema, pruritus, and pain may soon develop and spread to involve part or all of the extremity. Severe envenomations may result in systemic symptoms such as oral and lingual paresthesias, nausea, vomiting, blurred vision, dysphonia, dysphagia, generalized paresthesias, and ataxia. Neurologic symptoms may progress to generalized paralysis and respiratory failure.

Echinoderms

An immediate reaction consists of intense, localized burning pain, accompanied by erythema, swelling, and bleeding. Subcutaneous staining (e.g., purple or black) may result from dye in the spines. Without treatment, the affected area typically aches, is numb, and bleeds for several minutes to several hours. Infrequent systemic symptoms include nausea, generalized paresthesias or weakness, myalgias, ataxia, syncope, and bronchospasm.^{1,2,13,15} Local swelling and discomfort may occasionally recur periodically for a year or more after the initial envenomation.

A delayed reaction sometimes occurs 1 to 2 months after the injury, consisting of either localized granuloma formation or a diffuse inflammatory process. Embedded spines can also lead to wound infection and damage to nerves or joints.

Sting Rays

Victims of sting ray envenomation usually experience immediate, sharp, excruciating pain and bleeding. Without treatment, the pain rapidly spreads to involve the entire extremity, peaking 1 to 2 hours after inoculation. Pain is usually more severe than with similar nonvenomous injuries. Marked erythema or cyanosis and swelling may also develop. Systemic manifestations include nausea, vomiting, fever, chills, tremors, myalgias and muscle cramps, weakness, paresthesias, lymphadenopathy, and syncope. Rarely, dyspnea, hypotension, cardiac dysrhythmias, convulsions, and even death may occur.^{1,10,12,15}

Scorpionfish

The clinical manifestations of envenomation are relatively mild for lionfish and related species, moderate for scorpionfish, and potentially life-threatening for stonefish.^{1,10,11} and ¹² Intense, sharp, throbbing pain occurs immediately and rapidly radiates centrally. The wound and surrounding area typically become erythematous, ecchymotic or cyanotic, and swollen. Paresthesias or anesthesia about the wound and in the affected extremity and regional lymphadenopathy are relatively common. Localized tissue necrosis and sloughing may occur over several days. Systemic symptoms include nausea, vomiting, abdominal cramps, headache, dizziness, tremors, cardiac dysrhythmias, hypotension, myalgias, weakness or paralysis, dyspnea, pulmonary edema, syncope, and convulsions.¹¹ Delayed complications include neuropathies, cutaneous granulomata, and indolent ulcers. Without treatment, the pain and other local manifestations typically peak in 60 to 90 minutes and last for 8 to 12 hours, but sometimes they persist for days or weeks.

DIFFERENTIAL DIAGNOSIS

Allergic reactions, traumatic injuries, wound botulism and infections ([Table 383.1](#)), and bites and envenomations by other marine animals are the main considerations in the differential diagnosis.

FRESH-WATER CRUSTACEANS	SALT-WATER CRUSTACEANS
<i>Amphipoda</i>	<i>Amphipoda</i>

TABLE 383.1. Marine Pathogens

Seabather's eruption ("sea lice") is an intensely pruritic maculopapular or vesicular eruption caused by contact with larvae of the jellyfish (*Linuche unguiculata*).¹⁷ It begins within 24 hours of swimming, affects skin surfaces covered by bathing suits, and lasts 3 to 5 days. Treatment consists of antipruritics and topical or systemic steroids. Other measures used for coelenterate envenomation may be tried but are unlikely to be helpful, due to the typically late presentation. Contact with bristleworms, which have numerous silky, spine-like setae, can cause a similar eruption on exposed surfaces.¹

Catfish envenomation can occur when these fish are handled when caught or stepped on while wading in both salt and fresh water.²⁰ The dorsal and pectoral fins have barbed spines with venom glands. Pain, erythema followed by cyanosis and edema, and muscle fasciculations are typical manifestations. The spines are radiopaque. Secondary infection may occur. Treatment consists of immersion in hot water, spine removal, and antibiotics for infection (discussion follows). Some shark species also have venomous dorsal fin spines.¹⁰

Corals, although not venomous, can produce painful cuts when the victim brushes against the reef.^{1,13,15} Pruritus, erythema, urticaria, and cellulitis with ulceration and necrosis occur. Foreign-body granuloma can occur. Irrigation with hydrogen peroxide has been used to remove coral particles from the wound. Additional treatment includes routine wound care and antibiotic therapy covering *Vibrio* and *Aeromonas* species (see previous discussion).¹

Sea snakes are found primarily in coastal waters of the Indian and Pacific oceans. All sea snakes are venomous.¹⁸ Their venoms contain protein mixtures similar to those found in land snakes (see [Chapter 378](#) and [Chapter 379](#)). The principal component is a neurotoxin that binds to acetylcholine and the neuromuscular junction and causes muscle weakness, pain, stiffness, spasm, and, finally, paralysis. The bite itself is usually painless and may go unnoticed unless a careful search is made for fang marks. Fangs can break off and may be visible on x-ray. Symptoms may be delayed in onset up to 2 days. Rhabdomyolysis is a common complication. Treatment consists of supportive care and antivenom administration. Australian sea snake antivenom is available from the Commonwealth Serum Laboratory in Melbourne, Australia.

Sponges can cause irritant and contact dermatitis.^{1,13,15} Erythema multiforme and anaphylaxis can also occur. Spicules can be removed with adhesive tape. Soaking with vinegar may provide some relief. Treatment with topical or systemic steroids also may be necessary.

EMERGENCY DEPARTMENT EVALUATION

The history includes the identity or a description of the offending animal, the geographic location and circumstances surrounding the envenomation, and the time of onset, nature, and progression of symptoms. The physical examination focuses on vital signs and cardiovascular, respiratory, and neurologic functions. The skin is examined for puncture wounds, teeth marks, rashes, and signs of infection. All wounds are explored and x-rayed for foreign bodies. Infected wounds are cultured. Patients with abnormal vital signs or altered mental status should have routine laboratory evaluation, including a complete blood count; measurement of electrolytes, blood urea nitrogen, creatinine, glucose, and creatine phosphokinase; and an arterial blood gas or oxygen saturation measurement.

EMERGENCY DEPARTMENT MANAGEMENT

Coelenterates

Management requires recognition of envenomation, identification of the offending species, general supportive care, and specific detoxification measures.^{1,4,5,9,15} Initial management includes reassurance, rinsing the involved area with sea water or isotonic saline solution (not fresh water), and species-specific measures to suppress

additional nematocyst firing. Cold packs or ice is an effective first-aid measure for the treatment of pain.⁸ Spraying or immersing the affected area in vinegar or other dilute acetic acid solution is effective if the offending animal is the jellyfish *C. fleckeri* or the Atlantic Portuguese man-of-war, *Physalia physalis*; a slurry of baking soda should be used for *Chrysaora quinquecirrha*. The application of a slurry of isopropyl alcohol and powdered papain (e.g., Adolph's unseasoned meat tenderizer or papaya latex) appears to be clinically effective for the Pacific Portuguese man-of-war, *Physalia utriculus*, and some jellyfish species, although alcohol has been observed to prompt nematocyst firing *in vitro*.

After the nematocysts have been inactivated, adherent tentacles are manually removed with forceps or by shaving the area. Surgical gloves should be worn for protection. The envenomed area should be immobilized for at least 30 to 60 minutes, because muscle activity tends to mobilize the venom from the inoculation site. Although some venom components are heat-labile, the application of local heat or cold is not helpful.

Systemic reactions are treated according to the severity of the reaction and the species involved. Anaphylaxis is treated in the standard manner. Severe *C. fleckeri* envenomations usually require respiratory and cardiac support. Intravenous verapamil may be useful in these cases, although this therapy is controversial.⁷ Hyperimmune serum and antivenom specific for *Chironex* is available from the Commonwealth Serum Laboratory in Melbourne, Australia. Systemic corticosteroids are ineffective for toxin-mediated effects. Analgesics may be necessary for prolonged or persistent local reactions.

Conidae

Treatment is empiric, relying on nonspecific symptomatic and supportive measures.^{1,13,15} Immersing the affected area in hot water (110°F to 115°F) for 30 to 60 minutes sometimes provides pain relief. Careful observation for at least 12 hours after injury is essential.

Octopuses

Treatment is symptomatic; respiratory support is crucial.^{1,19} Recovery is usually rapid, with complete resolution within 24 hours.

Echinoderms

Treatment of spine-puncture injuries is primarily symptomatic.^{1,2,13,15} Immersing the affected area in hot water (110°F to 115°F) for 30 to 90 minutes usually produces substantial pain relief. Systemic analgesics can also be given. Spines are carefully removed: They easily fracture. Spines are removed after they have been clearly localized by appropriate radiologic procedures and with the aid of a bloodless field and operating microscope. Retained spines may produce a local foreign-body, sarcoid-like granulomatous reaction. There is no justification for blindly probing these wounds or pounding the affected area to break up the spines. Topical agents are ineffective in relieving pain. Antibiotics are not indicated unless infection has developed, which, at times, may be difficult to differentiate from the toxic inflammatory reaction. Systemic corticosteroids are of no proven value.

Sting Rays

Treatment should begin immediately and focuses on inactivating the venom, providing symptomatic relief and necessary vital function support, and preventing infection.^{1,10,12,15} Initial therapy includes immersing the affected area in hot water (110°F to 115°F) for 30 to 90 minutes, followed by thorough wound irrigation. After maximal pain relief has been achieved by hot water, systemic analgesics can be given for residual pain. Many of these wounds become secondarily infected and require treatment with a broad-spectrum antibiotic.¹ Systemic manifestations are treated symptomatically.

Scorpionfish

Initial management consists of immediate immersion of the affected area in hot water (110°F to 115°F) for 30 to 90 minutes.^{1,10,11} and ¹² Systemic analgesics can be given for residual pain. Other symptomatic and supportive measures are used as necessary. An antivenom is available in Australia and at a few public aquariums in the United States for stonefish stings; it is almost never needed for other types of Scorpaenid envenomations.

Secondary Infection

Given the variety of gram-positive and gram-negative organisms present in both fresh and salt water (see [Table 383.1](#)), broad-spectrum antibiotics should be given for infection that develops in wounds acquired in aquatic environments. For oral therapy, ciprofloxacin, levofloxacin, or trimethoprim-sulfamethoxazole can be used. Ceftazidime, a second-generation fluoroquinolone, or imipenem can be given for infections requiring intravenous therapy.

DISPOSITION

Patients with systemic signs and symptoms should be admitted. The level of care is dictated by the clinical severity. Patients with wound infections also may require admission. Those with skin eruptions can be managed as outpatients. Antivenoms can often be located through regional poison centers or aquariums. A poison center or toxicologist can be consulted for treatment advice.

COMMON PITFALLS

- Failure to appreciate that the pain from most spine-induced envenomations can be effectively treated with hot-water immersion
- Failure to appreciate that the pain from most coelenterate envenomations can be effectively treated by 5% acetic acid (vinegar) soaks
- Failure to appreciate that irrigation of jellyfish or coelenterate envenomations with fresh water may cause worsening of pain
- Failure to diagnose and treat associated traumatic injuries
- Failure to consider bacterial infection in the differential diagnosis and to reorganize that broad-spectrum antibiotics may be necessary
- Failure to observe for systemic toxicity
- Failure to appreciate that antivenoms are available for *Chironex* jellyfish, sea snake, and stonefish envenomations
- Failure to appreciate that envenomation may lead to anaphylactic as well as toxic reactions

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of Kenneth W. Kizer who wrote the previous versions of this chapter.

CHAPTER 384

Scorpion Envenomation

Jeffrey R. Suchard and Steven C. Curry

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Although nearly 40 scorpion species are found in the United States, *Centruroides sculpturatus* is the only scorpion reported to produce potentially life-threatening illness after a sting. This species, also known as *Centruroides exilicauda*, or the bark scorpion, is found throughout Arizona and in parts of Texas, New Mexico, small areas of California, the northern shore of Lake Mead in Nevada, and northern Mexico.³ *C. sculpturatus* stings may occur elsewhere, as scorpions have been known to stow away in a person's belongings (e.g., shoes, duffel bags) and be transported long distances before stinging their victims. Most other American scorpion stings produce only local pain and inflammation, which respond well to minimal supportive therapy and wound care, though the common striped scorpion, *Centruroides vittatus*, causes mild-to-moderate systemic effects in 20% of cases.¹¹

C. sculpturatus specimens generally measure about 5 cm (range, 1.3 to 7.6 cm) long; have a streamlined appearance, with a thin tail and claws; and are a uniform tan, yellow, or light brown. The last (sixth) tail segment, termed a *telson*, contains a venom apparatus and stinger (Fig. 384.1). *C. sculpturatus* prefers to reside in or near trees, especially sycamore, mesquite, cottonwood, and palm. They may also hide in ground debris, camping equipment, or clothing left unattended in natural desert areas, or even in areas long-inhabited by humans. Scorpions spend the daylight hours undercover and are active at night in warm weather, lying quietly while waiting to ambush prey. In defending themselves, they grasp the victim's flesh with pincers and repeatedly sting by thrusting their tails over their bodies.

Figure 384.1. The sixth tail segment of *C. sculpturatus* (bark scorpion) contains venom apparatus and stinger.

Although a sting from any scorpion can produce local pain, *C. sculpturatus* venom contains protein neurotoxins that cause repetitive firing of neurons by binding to sodium channels and preventing channel inactivation during depolarization or after repolarization.³ No destructive enzymes are present in the venom, accounting for lack of inflammation or necrosis. Prolonged and excessive firing of parasympathetic, sympathetic, and somatic motor neurons produces various autonomic effects and uncoordinated and spontaneous activity in voluntary muscle.

Scorpion stings are fairly common in endemic areas. About 10% of all calls to the Samaritan Regional Poison Center in Phoenix, Arizona, are regarding scorpions, with several thousand stings reported annually. Fortunately, the majority of envenomations are not serious enough to warrant medical attention. Children tend to be more seriously affected by *C. sculpturatus* stings, however, and may require aggressive intervention to avoid morbidity and mortality. Death has not been reported in Arizona for many years. The lack of recent fatalities probably reflects advances in supportive medical care.

Severe envenomations by *C. sculpturatus* are seen almost entirely in children under age 10 and occur in 15% to 20% of this group. In contrast, 95% of envenomations in those older than age 10 result in only mild-to-moderate effects. The life-threatening effects (myocarditis, pulmonary edema, shock) associated with adrenergic storm and caused by the venom from scorpion species found in other parts of the world are not noted after envenomations by *C. sculpturatus*.

CLINICAL PRESENTATION

Scorpion envenomation results in the immediate onset of a painful tingling or burning sensation at the sting site. Tapping the site of the sting may produce severe pain, although no lesion is usually visible. Over minutes to several hours, pain and paresthesias may become generalized. Victims may complain of "thick tongue" and "trouble swallowing," yet lack objective abnormalities on examination. Young children frequently rub their noses, eyes, and ears, and may present with unexplained crying.

Autonomic dysfunction is characterized by tachycardia, excessive secretions, and, occasionally, vomiting and wheezing. Somatic motor abnormalities include roving eye movements, blurred vision, fasciculations (especially of the tongue), and poor control of pharyngeal muscles. Continuous jerking of extremities may be noted and misinterpreted as restlessness, seizures, or hysteria. The combination of uncoordinated pharyngeal musculature and muscles of respiration, increased secretions, and occasional wheezing may produce stridor, hypoxia, aspiration, and respiratory arrest in severe cases.

Severe envenomations may also be accompanied by metabolic acidosis, respiratory failure, sterile cerebrospinal fluid pleocytosis (9 to 20 white blood cells per microliter), coagulopathy, pancreatitis, and rhabdomyolysis.^{1,2 and 3}

Envenomations can be graded on the basis of signs and symptoms (Table 384.1). In serious envenomations, abnormal motor activity may last 10 to 20 hours.^{3,8} Paresthesias may last up to 3 weeks.

Grade	Description
I	Local pain and/or paresthesias at site of envenomation
II	Pain and/or paresthesias remote from the site of sting
III	Either cranial nerve or somatic skeletal neuromuscular dysfunction Cranial nerve dysfunction: Blurred vision, wandering eye movements, hypersalivation, trouble swallowing, tongue fasciculations, stridor, slurred speech Somatic skeletal neuromuscular dysfunction: Jerking of extremities, restlessness, severe involuntary shaking and jerking which may be mistaken for seizures
IV	Both cranial nerve and somatic skeletal neuromuscular dysfunction

TABLE 384.1. Scorpion Envenomations: Signs and Symptoms

DIFFERENTIAL DIAGNOSIS

Bites or stings from other arthropods should be considered in the differential diagnosis of scorpion envenomation. The pain at the site of envenomation may be similar to that seen after a black widow spider bite. However, severely ill patients who suffer from scorpion stings appear unable to lie still, whereas those bitten by black widow spiders can maintain a position for short periods of time before moving in an attempt to become comfortable. Black widow envenomations do not produce abnormal eye movements, fasciculations, and paresthesias. Tapping over the site of envenomation produces severe pain in the patient stung by a scorpion, but not in someone bitten by a spider. Black widow spider bites frequently produce a characteristic halo lesion at the site of the bite; no lesion is usually visible after a *C. sculpturatus* sting.

Tachycardia, excessive secretions, wheezing, and respiratory distress accompanying serious scorpion stings may be mistaken for asthma, airway obstruction from a foreign body, or poisoning with cholinergic agents such as organophosphate insecticides. In the absence of a witnessed scorpion sting, other entities to be considered include central nervous system infections, tetanus, dystonic reactions, seizures, and intoxication with sympathomimetics, phencyclidine, and nicotine. Methamphetamine toxicity, for instance, is sometimes mistaken for *C. sculpturatus* envenomation when young children from scorpion-endemic areas present with unusual neurologic findings such as agitation or choreiform movements; this has occasionally led to the inappropriate use of antivenin. ^{6,8}

EMERGENCY DEPARTMENT EVALUATION

If a sting was not witnessed, it should be determined whether there are scorpions near where the patient became ill. The physical examination should focus on vital signs, the airway, and neuromuscular function. Although no specific diagnostic tests are available, patients with suspected aspiration should have an arterial blood gas analysis and a chest radiograph. Patients with severe envenomation should also have serum amylase and creatine kinase determinations and coagulation studies.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures, with particular attention to airway management, should be instituted as necessary. As with any puncture wound, a primary tetanus immunization or booster should be given, if indicated.

Patients with grade I or II envenomations are treated symptomatically. Application of ice to the sting often provides relief in lower grade envenomations. Oral analgesics are effective in most cases, but parenteral analgesia may be needed in rare cases. There are no rational or therapeutic benefits in giving barbiturates, benzodiazepines, steroids, epinephrine, calcium, or antihistamines to patients with scorpion envenomations. Barbiturates have not been found effective in lessening motor activity or in shortening the course of the illness, and they often produce serious or life-threatening respiratory depression. ¹⁰ Propranolol has anecdotally been reported to lessen the tachycardia in a severely envenomated child without affecting other neuromuscular abnormalities. ⁹ Beta-adrenergic blockers are not recommended, because tachyarrhythmias do not cause morbidity, bronchospasm can be seen in severe scorpion envenomations, and such therapy does not correct neurologic abnormalities.

C. sculpturatus goat serum antivenin is available for the treatment of severe envenomations. The only current source of this antivenin in the United States is the Antivenom Production Laboratory at Arizona State University, which distributes the product free of charge to hospitals within the state. This antivenin is very effective in alleviating symptoms of grade III or IV envenomations, reversing severe neurotoxicity usually within 30 to 60 minutes. Abnormal motor activity usually resolves within 60 to 90 minutes. ^{3,4} Patients who do not receive antivenin will continue to have symptoms for 4 to 20 hours. Antivenin has no role in the treatment of grade I or II envenomations.

Patients with grade III or IV envenomations can be successfully treated with antivenin after the institution of supportive care. Supportive measures include continuous monitoring of the airway, with respiratory assistance as needed; intravenous hydration; and loose restraints to prevent self-harm. One or two vials of antivenin mixed in 50 mL of a crystalloid solution is given intravenously over 20 to 30 minutes. Although skin testing with antivenin is suggested, it is not completely reliable in predicting which patients will suffer allergic reactions. ⁴ Those with a history of prolonged exposure to goats or goat's milk and those who have previously received goat serum antivenin are at increased risk for allergic reactions and should not be given antivenin. The use of beta blockers is a relative contraindication to the administration of *C. sculpturatus* antivenin, because beta-adrenergic blockade complicates the treatment of anaphylaxis, a potential complication of antivenin administration. The Samaritan Regional Poison Center in Phoenix (602-253-3334) may be contacted before giving antivenin if the physician is not completely familiar with the technique and potential risks of antivenin therapy.

Some physicians in scorpion-endemic areas do not use antivenin, but prefer to treat severely envenomated patients with supportive and symptomatic care in the intensive care unit (ICU). Such treatment requires close respiratory monitoring, as the patients are often given benzodiazepines to control neuromuscular hyperactivity and to induce sedation and amnesia. ⁵ We believe that routine admission unnecessarily increases cost, and that administering sedatives to patients who already have tenuous airway control unduly increases the risk of respiratory depression and aspiration in those who could potentially be safely discharged home from the emergency department if treated with antivenin. ² The main argument against antivenin is that using animal-derived serum products places the patient at risk for potentially serious immunologic reactions. Anaphylactic reactions to antivenin can occur, but they are usually mild and can be reversed with appropriate treatment. ^{2,3,7} Serum sickness occurs in about 60% of patients treated with scorpion antivenin, though the symptoms typically resolve within 3 days when treated with antihistamines and corticosteroids. ^{2,7}

DISPOSITION

Patients with grade I or II envenomations should be observed for 3 to 4 hours after a sting for evidence of progression of symptoms. Those who do not manifest increased envenomation severity can be discharged home with oral analgesics and follow-up with their personal physician, if needed.

Patients with grade III or IV envenomations can be discharged after receiving antivenin if they are asymptomatic and aspiration pneumonia or other complications from envenomation are ruled out. Children with grade III or IV envenomations who have not received antivenin, or who have evidence of a complication after receiving antivenin, should be admitted to an ICU. Adults without respiratory difficulties who require admission for pain control may be admitted to an unmonitored bed. Those with more severe envenomations generally require intensive care.

All patients who receive antivenin should be advised of the signs and symptoms of serum sickness, which could appear 3 to 14 days after the administration of antivenin. In addition, they should consider themselves allergic to goat serum in the future. Serum sickness is easily controlled with nonsteroidal antiinflammatory agents, hydroxyzine, and tapering doses of oral corticosteroid.

COMMON PITFALLS

- Mistaking symptoms of severe envenomation for hysterical or uncooperative behavior or for seizures, especially in children
- Relying on the absence of a visible lesion at the site of the sting to rule out scorpion envenomation
- Routinely giving barbiturates, steroids, epinephrine, antihistamines, benzodiazepines, or calcium
- Using antivenin as a substitute for good supportive care
- Failure to inform patients about potential allergic reactions to antivenom and to monitor for such reactions

CHAPTER 385

Cold-Induced Tissue Injuries

Federico Gonzalez and Kenneth Leong

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Historically, cold-induced tissue injuries have been most prevalent in military personnel. In the civilian population, those involved in outdoor sporting activities, industrial workers in cold environments, and the homeless compose the majority of individuals who suffer injury due to cold exposure. Altered mental status due to either medical illness or drugs, advanced age, malnutrition, and peripheral vascular disease are added risk factors for cold injury. ^{2,3,9,20}

Frostnip, the mildest form of cold-induced tissue injury, results from cold-induced vasoconstriction and resolves without epidermal or dermal damage with rewarming. *Chilblain*, or *perniosis*, a more severe form of cold injury, results from exposure to cold temperatures above freezing. This injury is characterized by a chronic vasculitis of the dermis and often results from repeated exposures to cold, usually humid air. Tissue changes are felt to reflect vascular inflammation from hypoxia secondary to cold-induced vasoconstriction. *Trenchfoot*, or *immersion foot*, is tissue injury at temperatures between 0°C and 20°C, resulting from prolonged exposure to a cold, wet environment. Tissue injury is due to skin edema and microvascular damage secondary to water absorption and cold temperatures. The role of secondary infection is controversial.

Frostbite is the destruction of tissue due to freezing and commonly occurs at temperatures below 2°C. Tissue injury can be divided into two phases: cooling or initial freeze injury, and reperfusion injury with thawing and rewarming. The first physiologic response to peripheral cooling is vasoconstriction resulting from the release of tissue factors and the generalized sympathetic response. ^{4,11} When tissue temperature falls to 10°C, the “hunting response” occurs. This phenomenon is characterized by 5- to 10-minute cycles of vasoconstriction and vasodilation in an attempt to preserve tissue viability while conserving core temperature. When core temperature is threatened, the hunting response is superseded by vasoconstriction alone. Once tissue temperatures reach -2°C to -4°C, extracellular ice crystals form. This usually requires an ambient temperature of -6°C. Ice crystal formation increases extracellular colloid osmotic pressure and draws fluid from the intracellular space, resulting in cellular dehydration. If tissue freezing is rapid (greater than 10°C per minute), intracellular ice formation results in cell death. ^{12,13} Intravascular ice crystal formation concurrent with interstitial ice formation results in hemoconcentration, leading to red blood cell sludging and cessation of blood flow. In addition to ice crystal formation, freezing temperatures also have direct effects on endothelial cell integrity, with sloughing of the endothelium from the internal elastic membrane. ¹¹ Tissue injury due to freezing may be partially reversible with rapid warming. ^{12,15,18,19}

Reperfusion following rewarming results in endothelial cell damage that causes leakage of protein and fluid from endothelium damaged by freezing. Vascular intimal damage leads to increased platelet affinity, with resultant erythrocytosis and vessel thrombosis. Histologic studies have revealed thrombus clogging venules within 10 minutes of thawing. By 1 hour, capillaries are thrombosed and most blood flow is through arteriovenous anastomoses. Elevated numbers of neutrophils have also been demonstrated in skin following thawing. Neutrophil aggregation and adhesion to endothelium has been hypothesized to play a critical role in tissue injury. Experimental data and clinical observation indicate that the major mechanism for tissue loss in frostbite is likely due to microvascular disruption. This hypothesis is supported by the observation that frozen and then thawed skin grafted onto normal tissue usually results in graft survival, whereas normal skin grafted onto previously frozen tissue results in graft loss. ¹⁹

Vasoactive substances released from damaged tissue may also cause microvascular injury. Analysis of blister fluid from frostbite reveals high levels of thromboxane metabolites, which may mediate tissue ischemia through vasoconstriction. Animal and clinical studies have demonstrated a decrease in tissue ischemia after treatment with cyclooxygenase inhibitors such as ibuprofen and aspirin as well as with the thromboxane inhibitor aloe vera. ^{14,17}

As with other reperfusion injuries, frostbite-induced tissue damage may also be mediated by the release of oxygen free radicals. Animal models using the free radical scavengers, superoxide dismutase and deferoxamine, have shown improved tissue survival. However, clinical studies have not been as promising. ¹¹ Studies with the use of hyperbaric oxygen, effective in reducing oxygen free radical formation, have been promising in both clinical and animal studies. ^{8,16}

CLINICAL PRESENTATION

Manifestations of *frostnip* include numbness, pain, paresthesias, and pallor. The fingers, toes, ears, and nose are the most common sites affected. Symptoms usually resolve within 30 minutes of rewarming.

Symptoms associated with *chilblain* include erythema, pruritus, and burning, usually of appendages, including the ears and nose. Blistering and ulceration is uncommon but may occur. Recurrence is common, particularly in patients with underlying peripheral vascular disease. Symptoms usually resolve in 1 to 3 weeks.

Patients at risk for *immersion foot* include soldiers, sailors, fishermen, and, increasingly, the homeless. Complaints may include itchiness, numbness, pain, and paresthesia, along with leg muscle cramping. Early findings include coolness, pallor, insensitivity, and wrinkling of the soles. With dorsal involvement, papules, purpura, vesicles, and edema may be present. Cyanosis, mottling, and erythema present later. Maceration with secondary infection, fever, and femoral adenopathy is common. In severe cases, blisters, ulcers, and gangrene may be present. Tissue loss is unusual, although healing with return of normal skin color, temperature, and sensation may take months.

The history given by victims of *frostbite* is usually sufficient to make a diagnosis and estimate the extent of tissue damage. The patient may present with totally or partially frozen parts. In general, the tissue is white and waxy when frozen. The subcutaneous tissue is soft and pliable prior to thawing in superficial frostbite. In more deeply injured tissues, there is little resilience in the subcutaneous tissues. The frozen part is cold and lacks sensibility. Some victims demonstrate a superimposed burn injury from attempts to rewarm the frozen, insensate part. Classification of the depth of injury is done after thawing, when frostbitten tissue takes on an appearance that is characteristic of the depth of injury ([Table 385.1](#)).

Severity	Symptoms
First degree: partial thickness Erythema, edema, hyperemia No blisters or necrosis Occasional skin desquamation (5-10 d later)	Stinging, burning Possible bubbling and aching Possible hyperhidrosis
Second degree: full thickness Erythema, significant edema Clear vesicles Blisters may disapppear and form blackened eschar	Numbness
Third degree: involves subcutaneous tissue Vascular thrombosis; blisters due to injury to the reticular dermis and subdermal plexus Skin necrosis Blue-gray skin	Initially insensate; later, shooting pains, burning, throbbing, aching
Fourth degree: involves muscle, tendon, and bone Little edema Initially mottled, deep red, or cyanotic Later dry, black, mummified	Possible joint discomfort

TABLE 385.1. Classification of Frostbite Severity

DIFFERENTIAL DIAGNOSIS

The appearance of frostbite or cold immersion may be confused with a devascularizing injury, envenomation, or a thermal or chemical burn. The history usually reveals the correct cause of tissue injury. In patients who are not communicative, the temperature of the body or the extremity will assist in making the diagnosis.

EMERGENCY DEPARTMENT EVALUATION

The early evaluation of cold-injured tissue is difficult and can be deceiving. Often, the full extent of injury may not be apparent for days after the injury. Because only 10% to 15% of patients arrive in the emergency department with the involved part still frozen, the physician must recognize the injury at various stages in its presentation. A careful history, including exposure temperature, duration of exposure, the extent of wetting involved, and the wind conditions at the time of exposure, is critical. Risk factors such as trauma, peripheral vascular disease, smoking, alcohol use, and other systemic illnesses should be investigated.

Physical examination should include the patient's core temperature and a full description of the injured part. Color, blister formation, the color of the blister fluid, temperature, consistency, capillary refill, movement, two-point discrimination, and vibratory sensibility should be observed serially, because these signs may change rapidly. The presence of peripheral pulses should be ascertained by palpation or by Doppler examination. Rarely, cold injury to the cornea may occur, necessitating visual acuity and fluorescein examination. Laboratory studies are of minimal assistance in diagnosing the frostbite injury. The frostbite patient should, however, be evaluated for hypothermia, trauma, and concomitant illness. Angiography is contraindicated due to potential injury to the vasculature. Technetium three-phase bone scanning may be helpful in determining the extent of injury and in planning surgical debridement, but does not change early therapy.

EMERGENCY DEPARTMENT MANAGEMENT

Prior to arrival, there should be no rubbing or manipulation of the frozen part, as this can exacerbate tissue injury. Refreezing of thawed parts can cause greater damage than the initial injury, so rewarming should be delayed until there is no risk of refreezing.^{2,7}

Nonadherent wet or cold apparel should be removed and the patient placed under warm blankets. Clothing frozen to the skin should be trimmed and removed only after it is loosened with rewarming. Systemic hypothermia should be treated prior to thawing of frozen extremities. Tetanus toxoid should be administered, if indicated. Intravenous hydration may be beneficial for hemodilution in the dehydrated patient and for redistribution of blood flow to underperfused areas to minimize tissue loss secondary to ischemia.¹

Rewarming with dry heat is sufficient for the treatment of *frostnip*, *chilblain*, and *immersion foot*. Elevation and avoidance of manipulation and pressure, cleansing, topical antimicrobials (e.g., Neosporin ointment and silver sulfadiazine cream), and dressings for denuded areas are also recommended for immersion foot. Prophylactic systemic antibiotics are not indicated. Treatment of infections should be based on clinical examination as well as microscopic examination and culture results for both fungi and bacteria.

The initial care of *frostbite* is rapid thawing of the involved part in a water bath at 40°C to 42°C.¹⁰ The water temperature should be kept constant, as cooling of the bath could allow refreezing and further tissue damage. Thawing usually takes 15 to 20 minutes; during this period, rubbing or manipulation should again be avoided. Thawing with dry heat should be avoided, because it has been associated with larger areas of tissue loss. Ultrasound therapy is contraindicated as an adjunct to thawing, because it has been associated with earlier development of wet gangrene.

With rewarming, symptoms of pain with gradual evolution to numbness may present. Throbbing pain may develop 48 to 72 hours postthaw and may persist for several weeks. With nerve regeneration, a tingling sensation may be present. Return of normal sensibility depends on the depth and extent of injury. Postthaw pain may be managed with narcotic analgesia as well as elevation and avoidance of abrasion or pressure.

Bullae containing clear fluid should be opened to remove the fluid, as prostanoid derivatives contained within may cause further tissue damage. Hemorrhagic bullae indicate injury to the subdermal vascular plexus and should be left intact to minimize further injury to the remaining viable tissue.

Additional therapies for frostbite include aloe vera (applied topically to the injured tissue every 6 hours) and ibuprofen (400 to 800 mg orally every 6 to 8 hours). Ascorbic acid (1 g orally every 12 hours), a free radical scavenger, is also recommended.^{5,7} Small-vessel vasodilation and blood flow can be maximized with nifedipine (10 mg orally every 8 hours).⁶ Smoking is prohibited for both patient and visitors. The patient should be restricted to bed and the injured part elevated, with no external garments or bedclothes touching it. Although clinical experience with the use of hyperbaric oxygen is limited, this therapy warrants consideration when it is available.

Other frostbite therapies should be considered experimental or of unproved benefit. Dextran has been shown to reduce tissue loss after frostbite in animal studies. There is experimental support for use of the thrombolytic agents (streptokinase and urokinase, but not tissue plasminogen activator) in frostbite injuries. The calmodulin antagonists, thioridazine and trifluoperazine, have been found to reverse frostbite tissue damage. Studies of sympathectomy, both medical and surgical, have not been conclusive. Reserpine and guanethidine have yielded long-term benefits in frostbite patients.

The amount of tissue loss following cold injury depends on the depth and extent of injury. Appropriately treated, second-degree or less frostbite or immersion foot seldom results in tissue loss. However, hypesthesia or dysesthesia may be present for a long time postinjury. Surgical intervention and debridement of tissues should be reserved for wet gangrene or late gangrene. Early surgery may injure marginally viable tissue and result in an extension of tissue necrosis.

DISPOSITION

All but the most superficially injured frostbite patient should be admitted. Surgical consultation (plastic, vascular, or general, depending on local practices) should be obtained. Corneal injuries warrant an ophthalmology consult. Discharged patients should be reevaluated within 24 to 48 hours, as tissue necrosis may be progressive and infectious complications may develop. Protective clothing and footwear, as well as avoidance of future cold exposure, should be advised due to the increased sensitivity and susceptibility to subsequent exposures. Smoking should be prohibited.

COMMON PITFALLS

- Failure to evaluate and treat for concurrent systemic hypothermia
- Rubbing or manipulating frozen tissue
- Failure to rapidly warm affected parts
- Failure to monitor the temperature of the rewarming bath, which can result in refreezing or burn injury
- Failure to obtain surgical consultation
- Failure to admit patients with significant frostbite injuries for observation
- Failure to consider adjunctive therapy (e.g., thromboxane inhibitors and vasodilators)
- Failure to appreciate that the extent of irreversible tissue damage may not be evident until many days after exposure
- Failure to warn patients about the hazards of reexposure

CHAPTER 386

Hypothermia

Joseph J. Currier

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Hypothermia is defined as a core temperature less than 35°C (95°F).^{3,8,11,12,20} It may be acute (less than 6 hours' duration) or chronic (greater than 6 hours' duration); mild (32°C to 35°C), moderate (28°C to 32°C), or severe (less than 28°C); and primary or secondary. Primary, or "exposure," hypothermia is usually acute and occurs in healthy persons following immersion in cold water or exposure to low environmental temperatures.

In contrast, secondary, or "urban," hypothermia is generally chronic and occurs in those with predisposing illness, infirmity, intoxication, or extremes of age.^{3,4} Secondary hypothermia is much more common than primary hypothermia and has a very high mortality rate (approaching 100% in severe cases). In contrast, recovery is the rule for young, healthy adults with primary hypothermia. Survival has been reported with a core temperature as low as 16°C (61°F).¹⁷

Body temperature is a function of the production and loss of heat.^{3,10,11} and ^{12,20} Heat is produced by metabolism, muscular activity, and shivering. Newborns can also produce heat by nonshivering thermogenesis, in which specialized adipose tissue (brown fat) can directly transform substrate into heat due to the unusually high density of mitochondria.¹⁸ Heat is conserved by peripheral vasoconstriction and the insulation provided by clothing.

Heat is lost by conduction (direct contact with colder objects, such as ground, snow, and water), convection (air motion across body surfaces), evaporation (from skin, lungs, or wet clothing), and radiation (from exposed surfaces). Normal heat dissipation occurs predominantly by radiation. The rate of heat loss is proportional to the difference between body and environmental temperature. Convection losses are also a function of ambient air velocity (the wind-chill factor) and humidity.

Humans, like other warm-blooded animals, normally maintain core body temperature within a very narrow range (37°C ± 0.2°C). Thermosensors in the skin, spinal cord, and gastrointestinal tract detect changes in body temperature. Efferent impulses are integrated within the spinal cord and transmitted to the hypothalamus, the central thermoregulatory center. Both neural (vasomotor) and hormonal (e.g., catecholamines, thyroxine) hypothalamic efferents control heat production and heat loss.

Any condition that results in decreased heat production, increased heat loss, or impaired temperature regulation may result in hypothermia ([Table 386.1](#)).^{3,8,11,12,20} Very low ambient temperatures are not required. Without adequate insulation and intact thermoregulatory mechanisms, exposure to any temperature below 35°C can result in hypothermia. Neonates are at risk because of a relatively large body surface relative to total mass and ineffective shivering and heat production. Low fat stores, medication effects, lower metabolic rate, relative inability to detect temperature changes, and deteriorating adaptive responses place the elderly at risk.

DECREASED HEAT PRODUCTION	INCREASED HEAT LOSS
CNS depression (metabolic or traumatic)	Environmental exposure: inadequate clothing/shelter, wind chill, low humidity, perspiration, wet clothing
Immobility (age, neuromuscular disorders)	Exfoliative skin disease
Endocrine failure (adrenal/pituitary/thyroid)	Vasodilatation
Hypoglycemia/malnutrition	Drugs
	Neuropathy
	Sepsis
	Shock
	Burns
HYPOTHALAMIC DYSFUNCTION	IATROGENIC COOLING
Acidosis/anosmia	Use of large volumes of cool (<35°C [95°F]) fluids for lavage or i.v. administration
CNS hemorrhage/infarction	overly aggressive treatment of hyperthermia
Drugs (e.g., phenothiazines)	
Encephalopathy	

TABLE 386.1. Predisposing Factors in Hypothermia

Ethanol and drug use may increase heat loss due to cutaneous vasodilatation and impaired shivering. Hypothalamic dysfunction and decreased ability to seek shelter from the cold also may contribute. Sepsis, endocrine dysfunction (diabetic ketoacidosis, hypoglycemia, hypothyroidism, hypopituitarism, hypoadrenalism), central nervous system (CNS) disorders (stroke, brain tumors, spinal cord injury), and skin conditions (burns, erythroderma, psoriasis, ichthyosis) are additional predisposing factors. Lengthy exposure times, cool intravenous fluid infusions, and general anesthesia contribute to the hypothermia often seen in trauma victims.^{4,13,18}

The initial response to cooling includes cutaneous vasoconstriction, shivering, and increased metabolic activity.^{3,4,8,10,11} and ^{12,20} Heart rate and respirations are usually increased, but facial immersion in cold water can cause vagally mediated bradycardia (the diving reflex) and apnea. Generalized organ dysfunction with CNS, cardiac, and respiratory depression occurs with core temperatures below 35°C. Acid–base status may vary. Mild hypothermia is accompanied by respiratory alkalosis, while more severe hypothermia is associated with respiratory acidosis.

Decreased tissue oxygenation results from hypoventilation, vasoconstriction, increased blood viscosity, ventilation–perfusion mismatch, shifting of the oxyhemoglobin dissociation curve to the left, and volume depletion due to cold-induced diuresis and ileus. Furthermore, shivering increases lactate production, which, along with poor perfusion of tissues, decreased acid excretion, and impaired hepatic metabolism, causes a metabolic acidosis. The threshold for ventricular fibrillation is decreased at temperatures below 28°C.

CLINICAL PRESENTATION

The physiologic changes that occur during hypothermia are summarized in [Table 386.2](#).^{3,4,8,10,11} and ^{12,20} Manifestations of mild hypothermia include apathy, confusion, lethargy, fatigue, forgetfulness, incoordination, shivering, slurred speech, withdrawal, and increased pulse and respirations. A fine, at times unilateral, muscle tremor may also be present. With progressive hypothermia, shivering stops and pulse, blood pressure, and respirations are decreased. Disorientation, stupor, inappropriate behavior, ileus, polyuria, rhonchi, and wheezing may be noted.

Sign of Hypothermia	Organ System				
	Central Nervous System	Cardiovascular	Respiratory	Dermatologic/Neuromuscular	Renal/Gastrointestinal/GI
Mild (32°C-33°C) Excitatory Phase	Apathy Hyperreflexia Disorientation	Tachycardia Hypertension Increased CO	Tachypnea Bronchospasm Bradycardia	Shivering Tachymyoclonia Increased tone	Coiled renal stones Decreased GI motility Constipation
Moderate (30°C-32°C) Sedating Phase	Hyperreflexia Paradoxical ventilation	Bradycardia Hypotension Increased and irregular arrhythmias	Bradypnea Decreased gag reflex Decreased O ₂ consumption	Decreased shivering Spasm	Renal Oliguria Hypotension Hypocoagulability
Severe (<30°C)	Coma Anisocoria Patent EC	Asystole Ventricular arrhythmias	Pulmonary edema Spasms	Rigidity Compartment syndrome	Oliguria Decreased renal blood flow

EC = extensor carpi radialis; EC = extensor carpi ulnaris

TABLE 386.2. Physiologic Changes during Hypothermia

The electrocardiogram (ECG) commonly shows atrial fibrillation. Paroxysmal atrial tachycardia, interval prolongation (P-R, QRS, Q-T), decreased P-wave amplitude, T-wave changes, premature ventricular contractions, or a humped ST segment adjacent to the QRS complex (Osborn wave) may also be seen.¹⁵ Findings in severe hypothermia include coma, dilated unreactive pupils, absent reflexes, a flat electroencephalogram, muscle rigidity, hypotension, weak or absent pulse, and slow, barely detectable respirations. Rarely, transient focal neurologic findings can be seen.¹⁷ The ECG may show marked bradycardia, asystole, or ventricular fibrillation.

Laboratory findings include respiratory alkalosis in mild hypothermia, and hypoxia, metabolic and respiratory acidosis, increased amylase and hematocrit, and leukopenia, thrombocytopenia, coagulopathy, and variable electrolyte abnormalities in moderate and severe hypothermia. Hyperglycemia and, less commonly, hypoglycemia can be seen. The chest x-ray may disclose pulmonary infiltrates characteristic of aspiration or pneumonia. Other abnormalities may be present in patients with coexisting illness or injury.

DIFFERENTIAL DIAGNOSIS

Unless an accurate core (rectal or esophageal) temperature is obtained, hypothermia may be confused with virtually any endocrine, metabolic, toxic, traumatic, or vascular condition causing CNS depression. Even after the diagnosis has been made, it is necessary to distinguish between primary and secondary hypothermia by ruling out predisposing pathology.

ECG J waves may be misidentified as early repolarization or the T-on-R phenomenon seen in cyanide poisoning. The J wave is a distinct deflection during the downstroke of the QRS complex, not an early T wave. The lack of detectable vital signs on physical examination in severe hypothermia may lead to a misdiagnosis of death; careful and prolonged observation, an ECG, intraarterial blood pressure monitoring, core temperature measurement, and reassessment after warming can prevent this error.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of hypothermia may be suggested by the setting in which the patient was found (e.g., cool or cold, indoor or outdoor environment). The length and conditions of exposure, underlying medical problems, recent illnesses, and medications are documented. Any patient with altered mental status should have a core temperature measured; the same is true for initially normothermic or hyperthermic patients treated with cooling measures or large volumes of intravenous or lavage solutions.

The physical examination initially focuses on vital signs and the neurologic, cardiovascular, and pulmonary systems. In severe cases, observation for 2 minutes or longer may be required to detect a pulse or respirations. An esophageal or rectal probe (thermocouple) or a thermometer capable of measuring low temperatures (below the usual 34°C) is required for an accurate diagnosis. A detailed examination should then be performed, searching for coexisting pathology. An ECG and chest x-ray are usually indicated.

In moderate and severe hypothermia, routine laboratory tests should include arterial blood gas measurement; a complete blood count; measurement of amylase, electrolytes, glucose, blood urea nitrogen, and creatinine; a coagulation profile; and urinalysis. Additional tests, such as a bacteriologic culture; measurement of calcium, magnesium, phosphate, lactate, ketones, cortisol, and cardiac enzymes; liver and thyroid function tests; and toxicology screening, may also be necessary to elucidate concomitant medical problems.²⁰

The interpretation of arterial blood gas results in hypothermia is controversial. Because the pH increases (0.015 U/°C) and the P_{CO₂} (4.4%/°C) and PO₂ (7.2%/°C) decrease at temperatures below 37°C as the result of changes in gas solubility, measurement of these parameters in samples warmed to 37°C will result in a falsely decreased pH and increased P_{CO₂} and PO₂ levels if not corrected for temperature. However, the pH of neutrality increases as temperature decreases. Therefore, the normal pH at room temperature (7.40) is relatively acidic in a hypothermic state, and the uncorrected results of an arterial blood gas analysis may better guide therapy for acid-base disturbances.^{8,9}

EMERGENCY DEPARTMENT MANAGEMENT

All patients should receive oxygen and have cardiac and temperature monitoring. An intravenous line should be established. In the prehospital setting, the patient should be protected from further cooling. Wet clothes should be removed, the ambulance should be heated, and the patient should be covered with blankets.

If a pulse is detected, cardiopulmonary resuscitation (CPR) and endotracheal intubation should not be performed, because these procedures may precipitate ventricular tachycardia, fibrillation, or asystole. Ventilations should be assisted by a bag-mask device, and the patient should be moved as little as possible. Hyperventilation should be avoided, as it may induce alkalosis and result in ventricular fibrillation.

Emergency department management depends on severity.^{3,4,8,10,11} and ^{12,20} Nearly all patients require volume expansion. Normal saline with dextrose is preferable to lactated Ringer's, because lactate may not be metabolized during hypothermia. The volume of fluid should be determined by tissue perfusion and vital signs. Intravascular monitoring (e.g., arterial central venous, pulmonary artery) may be required in severe cases. Room-temperature intravenous fluids are acceptable for mild hypothermia, unless the rapid infusion of large volumes is necessary (e.g., patients with bleeding or severe dehydration). Otherwise, intravenous fluids should be warmed to 45°C, because room-temperature intravenous fluids are relatively hypothermic compared with most patients suffering from hypothermia. If a blood warmer is unavailable, 1 L of room-temperature intravenous fluid may be warmed in a standard microwave oven (high setting for 1 to 2 minutes, depending on wattage).⁵

Patients who require intubation for airway protection, hypoxia, or respiratory depression (CO₂ retention) should first receive 100% oxygen, topical anesthesia, and sedation. Acid-base abnormalities should be corrected. Prophylactic administration of lidocaine or bretylium may be helpful. Intubation should be done with as little airway manipulation as possible to avoid inducing dysrhythmias. Nasal intubation may be preferable to the oral route if spontaneous respirations are present.

Chemical or electrical treatment of dysrhythmias is usually ineffective at temperatures below 30°C, so warming should take precedence. Supraventricular dysrhythmias will generally convert spontaneously during or within 24 hours of rewarming. Pulseless rhythms should be treated according to advanced cardiac life-support guidelines. Because bretylium (but not lidocaine) has been shown to increase the threshold for ventricular fibrillation and to increase the success of defibrillation during experimental hypothermia, it should be considered a first-line agent for this rhythm.¹⁴ Although open cardiac massage in conjunction with mediastinal lavage using warm saline has been advocated for pulseless rhythms, its efficacy remains to be determined.

Passive (spontaneous) rewarming is appropriate for adults with mild, primary hypothermia. Warm blankets and shivering will generally increase body temperature by an average of 0.4°C per hour. Neonates and adults with secondary hypothermia should be treated by active rewarming, as should victims of moderate and severe hypothermia. Active rewarming may be accomplished by providing warm intravenous fluids; humidified air or oxygen (by mask or ventilator) heated to 42°C to 45°C

(mouth temperature); immersion in a 40°C water bath; peritoneal, gastric, bladder, or colonic lavage with 45°C fluid; covering the patient with a plastic circulating hot-air blanket (e.g., Bair Hugger); blood warming by hemodialysis (with an in-line heat exchanger) or femoral–femoral (partial) cardiopulmonary bypass pump; and pleuromediastinal lavage via thoracostomy or thoracotomy. ^{1,2,3 and 4,7,8,10,11 and 12,19,20}

Inhalational warming, using a cascade humidifier, is safe, easy, and readily available and can increase the temperature by about 1°C per hour. Gastric, bladder, colonic, and pleuromediastinal lavages are less efficacious. Bath rewarming is more effective than inhalation rewarming but makes monitoring difficult. Peritoneal lavage can increase the temperature by 2°C to 4°C per hour, whereas extracorporeal techniques can achieve rates of up to 10°C per hour. Cardiopulmonary bypass can support the circulation in lieu of prolonged CPR. Although not as rapid as cardiopulmonary bypass, hemodialysis may be advantageous in the hypothermic patient who also has a coincident drug overdose responsive to dialysis. ⁶ Resuscitation should not be considered unsuccessful until the core temperature has been raised to at least 32°C. ¹⁹

The optimal rate of rewarming depends on the cardiopulmonary status and the degree of hypothermia. Animal studies suggest that slow rewarming (maintaining an intramyocardial temperature gradient of less than 2°C) minimizes the risk of ventricular fibrillation. Hence, invasive procedures should generally be reserved for hemodynamically unstable patients with severe hypothermia. When used in such instances, the most effective techniques available should be employed in order to minimize the rewarming time.

Decreases in core temperature (afterdrop) and, possibly, acidosis and hypotension due to peripheral vasodilatation and the exchange of cool peripheral blood for warm core blood have been noted during spontaneous, inhalation, or immersion rewarming. ¹⁶ Because there are both central and peripheral thermosensors, afterdrop is theoretically possible with any rewarming technique.

The magnitude and duration of afterdrop appears to be lower with bath rewarming than with spontaneous or inhalation techniques. ¹⁶ In addition, metabolic rates are increased with surface rewarming but not by inhalation. ⁶ It thus appears that active surface rewarming is not contraindicated, as previously speculated. Uneven surface warming (e.g., warm packs to axilla and groin), however, is not recommended. The concurrent use of multiple rewarming techniques is probably most effective and safest.

Additional measures should include correction of underlying metabolic derangements and the treatment of coexisting or secondary medical or surgical problems.

DISPOSITION

Patients with mild hypothermia should be observed until they are asymptomatic and normothermic. Those with extremes of age or coexisting underlying pathology should be admitted for further evaluation and treatment. Patients with moderate or severe hypothermia should be admitted to an intensive care unit. Those with unstable vital signs or a core temperature below 28°C should be transferred by an advanced life-support unit to a facility capable of performing extracorporeal rewarming, if such services are not available at the current facility.

COMMON PITFALLS

- Failure to consider the diagnosis of hypothermia in patients with altered mental status
- Failure to obtain an accurate (core or rectal) temperature
- Failure to search diligently for underlying causes of secondary hypothermia
- Failure to recognize that chemical and electrical treatment of dysrhythmias is generally ineffective at temperatures below 28°C
- Failure to appreciate that rough handling, airway manipulation, and invasive procedures may precipitate dysrhythmias
- Failing to continue resuscitation attempts until the core temperature is at least 32°C
- Failure to include volume replacement in resuscitative efforts
- Failing to monitor for core temperature afterdrop

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of Paul H. Klainer and Brian Mongillo who wrote the previous version of this chapter.

Phytophotodermatitis is due to skin exposure to furanocoumarins (psoralens) from fruits and vegetables, followed by sun exposure. It is an occupational hazard of harvesters and grocery workers.¹¹

UVB frequencies (290 to 320 nm) are up to 1600 times more injurious than UVA (320 to 400 nm), but there is a preponderance of UVA in the environment.^{4,10}

CLINICAL PRESENTATION

Heat cramps are painful spasms of heavily used muscle groups. They often occur in acclimatized persons, during or up to several hours after exertion. The victim often has been sweating heavily, with insufficient or hypotonic fluid replacement for several days. Serum sodium levels are normal.^{3,13}

Heat edema is manifest by ankle and wrist swelling. It occurs in the first few days of heat exposure and sometimes results in pitting.^{3,13}

Heat rash (prickly heat) is most common early in acclimatization, in tropical areas, and in those wearing tight clothes. It is an intensely pruritic, red, papular, occasionally vesicular dermatitis. Complications include infection and the formation of large nonpruritic plugs, which take several weeks to desquamate. Persons with advanced heat rash are at risk for heat exhaustion or heatstroke due to loss of sweat gland function.⁴

Heat syncope is a transient loss of postural tone, with or without brief loss of consciousness, occurring early in exposure to a new heat stress. It is often preceded by dehydration or the presence of drugs that affect the body's normal compensatory mechanisms.² By the time victims are examined, vital signs are usually normal.

Heat tetany presents as carpopedal spasm and is frequently seen in conjunction with other heat syndromes or other causes of hyperventilation. In contrast to heat cramps, it does not involve the heavily used proximal muscles. Arterial blood gas analysis may reveal a respiratory alkalosis.^{3,9}

Victims of *heat exhaustion* are usually nonacclimatized persons who have been working in the heat for several days. Symptoms caused by water depletion include thirst, weakness, dizziness, anxiety, muscular incoordination, agitation, confusion, palpitations, oliguria, and elevated temperature. Those caused by salt depletion include fatigue, weakness, headache, anorexia, vomiting, diarrhea, and skeletal muscle cramps; thirst is absent. Body temperature is usually normal or subnormal in both types of heat exhaustion; the skin is cool and clammy. Tachycardia and hypotension are common. Most victims present with a combined picture of water and salt depletion. Laboratory findings may include hyponatremia, high urinary specific gravity, and mildly elevated serum creatine phosphokinase and liver enzyme levels. Without termination of the heat stressor and immediate treatment, heat exhaustion may progress to frank heatstroke.^{3,9}

Classic heatstroke usually affects the very young or the debilitated elderly and develops over several days, mostly during heat waves.^{3,9} The gradual onset may result in severe dehydration and hot, dry skin. Exertional heatstroke usually occurs in an unacclimatized younger person after a few hours of severe heat stress. Victims usually can still sweat.

Vital signs show hyperthermia (usually greater than 40°C), tachycardia, tachypnea, and hypotension. Family or witnesses may describe a malaise or flulike prodrome.^{2,4,13}

Because a high core temperature for a short period of time can produce the same injury as a relatively lower temperature for a longer period, the presenting temperature may not predict severity or outcome.¹⁴ Widespread damage to almost every organ system, especially the cerebellum, has been described. The central nervous system (CNS) is one of the first systems involved and the last to recover. Mental confusion begins with a core temperature of 38°C, with cessation of function at temperatures above 42°C. Any CNS change from confusion and coma to seizure activity and posturing has been described.¹³ The liver is particularly susceptible to heat injury. Serum transaminase levels may initially be in the thousands and peak up to 2 weeks later at more than 10,000. Coagulopathies and hypoglycemia are common. The kidneys are at high risk for acute tubular necrosis. Rhabdomyolysis may contribute to renal injury in victims of exertional heatstroke.^{3,9,13} Arterial blood gas measurements usually reveal a respiratory alkalosis. Lactic acidosis may also be seen following heavy exertion. Death is usually secondary to disseminated intravascular coagulation, acute renal failure, liver failure, or adult respiratory distress syndrome.^{3,17}

DIFFERENTIAL DIAGNOSIS

The key to diagnosing any heat illness is a history of a heat stress. During a heat wave, the diagnosis is easily considered. Vigorous exercise in moderate temperatures, or working in a closed, hot environment, may also result in significant heat stress. The clinician should remember the predisposing factors in [Table 387.1](#). Rhabdomyolysis should be excluded in patients with heat cramps. Electrolyte abnormalities should be ruled out in victims of heat cramps and tetany. An extensive evaluation may be necessary to exclude other causes of edema and syncope. The differential diagnosis of heatstroke includes infection, particularly meningitis, thyroid storm, drug intoxication, and the neuroleptic malignant syndrome (malignant hyperthermia). In contrast to heatstroke, patients with the neuroleptic malignant syndrome have muscular rigidity that responds to dantrolene.^{13,15}

EMERGENCY DEPARTMENT EVALUATION

The history includes the duration, magnitude, and conditions of heat exposure; recent activity; the nature, progression, and duration of symptoms; medications; drug use; and underlying medical problems. In young, healthy victims, a typical history and physical examination that reveal no other pathology are all that is necessary for a diagnosis of minor heat-related problems. Normal laboratory findings will confirm the diagnosis in questionable cases and in those with advanced age or coexisting medical problems.

In victims of heat exhaustion and heatstroke, vital signs include orthostatic pulse and blood pressure measurements and a rectal temperature. Depending on the severity, laboratory evaluation should include arterial blood gas analysis; a complete blood count; measurements of electrolytes, blood urea nitrogen, creatinine, glucose, creatine phosphokinase and liver enzymes; and urinalysis. Those with elevated levels of creatine phosphokinase, abnormal electrolyte or liver enzyme levels, or high temperatures should also have coagulation studies; calcium, magnesium, phosphorus, and uric acid measurements; an electrocardiogram and a chest x-ray.³

EMERGENCY DEPARTMENT MANAGEMENT

Heat cramps are treated with oral or intravenous fluid and salt replacement. Fruit juices or Gatorade by mouth is sufficient for mild cases. Intravenous normal saline is recommended for severe symptoms. Heat edema is self-limited and will resolve with time if the limb is elevated and support hose are worn. Patients with heat rash should keep their skin cool and dry and avoid tight clothing. Antihistamines may be given for pruritus, but, to prevent further plugging, powders should be avoided. Desquamating agents (e.g., salicylic acid) and antibiotics effective against staphylococci may be prescribed for secondary infection. Heat syncope is treated with rest, fluids, salt, and gradual return to activity. Heat tetany should resolve with the reversal of hyperventilation (e.g., bag breathing).

The treatment of heat exhaustion centers around replacement of fluid and electrolyte losses with isotonic saline. Orthostatic patients may require 4 L or more of intravenous fluids. Oral fluids can substitute for or supplement intravenous fluid in mild cases. Rare cases will present with severe hyponatremia requiring hypertonic saline infusion.^{3,9,13}

The cornerstone of heatstroke therapy is rapid cooling. Immersing or covering the patient in ice is not recommended, because skin cooling causes both vasoconstriction and shivering and could increase the core temperature.³ Cooling rates similar to ice immersion can be achieved by using immersion in 15°C water.⁷ Applying ice packs in the areas of large vessels, such as the groin and axillae, and infusing large volumes of cool intravenous fluids are useful for field management but insufficient for definitive cooling.^{3,5}

Although the fastest cooling rates (0.5°C/min) have been reported with peritoneal and even thoracic lavage using iced dialysate, using evaporation (0.3°C/min) and iced gastric lavage (0.2°C/min) with water or saline is a more practical combination.^{6,13,16} Evaporation is maximized without inducing shivering by keeping the patient

wet with lukewarm water or wet towels and blowing air over him or her with a fan. Helicopter blade fanning has also been used.¹² The rectal temperature should be monitored with a probe capable of measuring high temperatures (up to 44°C).

Cooling is continued only until the temperature drops to 38.5°C to 39.0°C, to avoid overshoot hypothermia. Rectal temperature monitoring should be continued, as the patient may rebound hours later and be thermally unstable for days. Along with cooling, these patients frequently need sedation and intubation and large volumes of intravenous normal saline. A central venous pressure line and Foley catheter are recommended to monitor fluid therapy. Acid–base, electrolyte, and coagulation abnormalities should be corrected. Alkaline diuresis may be helpful if rhabdomyolysis is present.³

Shivering may be treated with chlorpromazine (25 mg intravenously), benzodiazepines, or thiopental. Seizure activity is best treated with diazepam or phenobarbital. Phenytoin is ineffective. Dantrolene sodium has not been proved efficacious in canine studies, although anecdotal reports of success do exist.¹⁵ Poor prognostic indicators are a serum glutamic–oxaloacetic transaminase level above 1,000 after 24 hours, a coma that lasts more than 8 hours, or a presenting temperature of 42.2°C or higher.^{3,5}

Prevention of sunburn is the best therapy and can be done by avoiding unnecessary sun exposure (especially between 10 a.m. and 3 p.m.); wearing protective clothing, hats, and sunglasses; using broad-spectrum sunscreens with a sun protection factor of 15 or higher on exposed areas; and avoiding artificial tanning lights.¹⁰ Treatment is otherwise supportive. Antiinflammatory drugs and topical aloe vera and steroid spray may be useful for mild cases. More severe cases may require therapy similar to that for thermal burns (see [Chapter 125](#)).

DISPOSITION

Patients with minor heat-related problems may be discharged. Patients with heat exhaustion should be admitted to a floor bed if they have abnormal vital signs or laboratory findings or remain symptomatic after fluid therapy. Patients with heatstroke should be admitted to an intensive care unit. Discharged patients should be advised to avoid the conditions that precipitated their illness. Acclimatization with frequent water breaks and rest periods during hot-weather activity should prevent future problems. Consultation with a dermatologist may be helpful in patients with photosensitivity reactions.

COMMON PITFALLS

- Failure to recognize heat-related illness and to appreciate its nonenvironmental causes
- Failure to assess carefully for mental status changes in potential heatstroke victims
- Failure to obtain an accurate temperature (by rectal thermoresistor probe, if necessary) in patients with suspected heat illness
- Failure to cool heatstroke patients aggressively
- Overaggressive rehydration of heatstroke victims
- Failure to warn victims to avoid reexposure until acclimatization has occurred
- Prescribing medications that predispose patients to or exacerbate heat or UV reactions

CHAPTER 388

Arterial Gas Embolism

Christopher H. Linden

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Arterial gas embolism (AGE) is the most feared complication of compressed-gas diving. Second only to drowning as a cause of dive-related deaths, it accounts for 12% to 55% of patients treated at centers that specialize in the treatment of diving emergencies.⁸

AGE occurs for the same reasons as all barotrauma of ascent. Scuba equipment is designed to deliver compressed gas at ambient pressure. As a diver ascends, he or she moves to an environment of progressively lower pressure. According to Boyle's law, at a constant temperature, the volume of a gas varies inversely with ambient pressure ($PV = k$, where k is a constant). Thus, all gas breathed at depth will attempt to expand as the diver approaches the surface. If compressed gas is not allowed to vent from an enclosed space, pressures may eventually rise enough to rupture that space.

Whenever transpulmonic pressure exceeds a critical value, gas may dissect into surrounding tissue and produce a "pulmonary overpressurization syndrome" (POPS). In dogs, the critical pressure is as low as 60 mm Hg.¹⁴ Human cadaver studies and anecdotal reports suggest that a depth change of as little as 4 to 6 ft of seawater may be enough to produce significant overpressurization.^{2,4} People with poor lung compliance (due to structural abnormalities or pulmonary disease) are at higher risk for such a problem.³ Most cases of POPS are of minor clinical importance. Local extravasation of gas commonly results in interstitial, mediastinal, and subcutaneous emphysema. Pneumothorax is rare, and tension pneumothorax even more so.

Penetration of gas into the pulmonary venous circulation is more serious. If gas bubbles survive passage through the left side of the heart, they may travel via the arterial circulation to distant organs. AGE may also develop as systemic venous gas bubbles that paradoxically embolize into the arterial system via right-to-left shunts (e.g., patent foramen ovale).¹³ When such emboli are large enough, catastrophic complications may ensue.

The distribution of gas emboli seems to be determined by the same gravitational and hemodynamic forces that affect the movement of other types of emboli. Clinical manifestations are determined by a target organ's tolerance of arterial occlusion and its overall importance to homeostasis. Although coronary artery embolism has been reported, cerebral air embolism (CAE) is the most common and devastating manifestation of AGE. Thus, despite the fact that AGE to many different organs has been described, from a practical standpoint, AGE is synonymous with CAE.

CLINICAL PRESENTATION

The classic presentation of AGE was long thought to be hemoptysis and unilateral neurologic findings that occurred soon after a rapid ascent. Although studies are complicated by the frequent coincidence of embolic and decompression syndromes,⁷ it is now clear that AGE may present in several ways. By definition, AGE can occur only in the setting of a compressed-gas dive. Most cases are associated with some violation of standard dive protocols (e.g., rapid ascent and failure to exhale during ascent), but failure to identify such risk factors should not rule out the diagnosis. Virtually all significant cases of AGE become clinically apparent within 10 minutes of ascent, but most within 5 minutes.^{4,5,8,9}

Pulmonary symptoms play a surprisingly small role in the presentation of AGE. Only 25% to 50% of patients report dyspnea, 5% to 15% note hemoptysis, and pneumothorax is rare.^{8,9} Neurologic symptoms are the hallmark of AGE, which is essentially a dive-related stroke. Clinical presentation is determined by the arterial distribution(s) occluded and by whatever secondary inflammatory response may develop in surrounding brain tissue. Symptoms range from subtle mental status changes to headache, cranial nerve abnormalities, focal paralysis or paresis, altered consciousness, seizures, and total vasomotor collapse.^{4,5,8,9} and ¹⁰ Some authorities have found loss of consciousness to be the most common presentation of AGE (up to 40%).⁴ Others find focal limb paralysis or paresis to be far more frequent (up to 65%).⁸

Neuroimaging may or may not reveal abnormalities in patients with neurologic deficits.^{12,18} Magnetic resonance imaging is more sensitive than computed tomography scanning in detecting ischemic cerebrovascular lesions, but it is often normal. Transcranial Doppler sonography can sometimes detect arterial bubbles and may sometimes be diagnostic of CAE if performed early.¹³

In addition to neurologic findings, crepitus heard on auscultation of the heart (Hamman's sign), or signs of pneumothorax, hemoptysis, or subcutaneous air should suggest pulmonary barotrauma and thereby raise suspicion of AGE. Rarely, air bubbles seen in the retinal arteries or sharply circumscribed areas of glossal pallor (Liebermeister's sign) provide direct evidence of embolization.

An elevated serum creatinine kinase level (predominantly MM isoenzyme) is common in dive-related AGE. Levels above 900 U/L may be diagnostic in an appropriate clinical setting.¹² Other laboratory abnormalities include hemoconcentration with subsequent decline in the hematocrit and elevated serum transaminases and lactate dehydrogenase.^{16,17} Chest radiographs may demonstrate pulmonary infiltrates (hemorrhage), pneumothorax, pneumomediastinum, or subcutaneous emphysema.⁶ Gas embolization to a coronary artery or to cerebral autonomic centers may produce electrocardiographic (ECG) abnormalities such as dysrhythmias, ischemia, and infarction.

Some divers who suffer symptomatic AGE experience spontaneous recovery within minutes to hours of onset (the so-called lucid period). Without treatment, as many as 20% to 35% of these patients relapse.¹¹ Therefore, even in the absence of physical, radiographic, or ECG abnormalities, any diver with a history suggestive of AGE must be assumed to have suffered it and must be managed accordingly.

DIFFERENTIAL DIAGNOSIS

When AGE presents as altered mental status, it may be difficult to distinguish from trauma, near-drowning, or hypothermia. Victims of trauma or near-drowning often ascend or are taken to the surface rapidly and may develop AGE as a secondary complication. Thus, it is best to assume that anyone with a history of altered mental status immediately after a compressed-gas dive has suffered CAE.

Neurologic decompression sickness (DCS) usually becomes manifest later than CAE and classically presents as a spinal cord rather than a cerebral syndrome. However, the two may be difficult to distinguish, and up to half of all divers who present with AGE do so in the setting of a more generalized "dysbarism syndrome."⁸ Clinically, the point is moot: CAE and neurologic DCS are managed identically.

Thrombotic or vasospastic arterial occlusion and paradoxical arterial embolization of venous air, amniotic fluid, fat, foreign bodies, or thrombi cause similar clinical findings but occur in different settings.

EMERGENCY DEPARTMENT EVALUATION

Even in the presence of other likely causes, a history of altered neurologic status within 10 minutes of ascent from a compressed-gas dive must be interpreted as

presumptive CAE. A history of improper or rapid ascent or evidence of pulmonary barotrauma may be supportive, but their absence does not rule out the diagnosis.

Because patients may deny symptoms, the testimony of diving partners or witnesses is often useful. Complaints of headache or weakness should raise suspicion of AGE. A history of diminished consciousness, seizures, paralysis, paresis, dizziness, vertigo, nausea, ataxia, visual problems, or difficulty speaking is virtually diagnostic. In patients with chest discomfort, dyspnea, or hemoptysis, the presence or absence of neurologic symptoms must be specifically investigated.

Although all patients should receive a complete physical examination, special attention must be given to the neurologic evaluation. Mental status, cranial nerves, motor pathways, sensation, and cerebellar function are critically important. The patient is also evaluated for evidence of pulmonary barotrauma, hypothermia, and signs of head or spinal trauma.

All patients require a complete blood count, biochemical profile (including electrolytes, blood urea nitrogen, creatinine, glucose, creatine kinase, and liver function tests), chest radiograph, and ECG. If a patient demonstrates respiratory symptoms or altered mental status, arterial blood gas analysis is indicated. History or evidence of trauma may dictate additional radiographic studies.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures are instituted as necessary. All victims of AGE must be treated in a recompression chamber as soon as possible. Any diagnostic or therapeutic interventions that unnecessarily delay such therapy are unjustifiable. *In vitro* and animal studies suggest that a high inspired Fi O_2 level increases tissue oxygen levels and also increases the nitrogen pressure gradient between air bubbles and blood, thereby speeding reabsorption. ¹ Patients should, therefore, be given the highest available oxygen concentration. Beyond this, in the absence of acute cardiopulmonary decompensation, most patients require only supportive care (e.g., airway, cardiac monitoring, intravenous fluids, and rewarming) while awaiting transfer to a hyperbaric facility.

Dysrhythmias are treated according to advanced cardiac life-support protocols. Seizures that do not respond to oxygenation are treated with intravenous diazepam. An empiric trial of thiamine, dextrose, and naloxone is indicated if the patient demonstrates altered mental status.

In anticipation of recompression, all AGE patients with a simple pneumothorax should have a prophylactic chest tube placed to prevent progression to a tension pneumothorax. Endotracheal tube and Foley catheter cuffs should be filled with water or saline solution, not air.

All other interventions are controversial. Many authorities believe that AGE victims should be maintained in the Trendelenburg or Durant (left lateral decubitus) position to decrease risk of further embolization. Others believe that this maneuver is more likely to harm the patient by increasing intracranial pressure.

Anecdotal reports of efficacy have led to widespread use of high-dose corticosteroids in the management of CAE and DCS. ^{7,9} As yet, there have been no prospective, controlled trials to document their therapeutic value in diving accidents. Enthusiasm for such agents should be tempered by their failure to prove beneficial in the management of most types of cerebral insult (e.g., trauma, infarction, hemorrhage, and infection).

When AGE is managed appropriately, the prognosis is surprisingly good. Although overall mortality is as high as 5% to 15%, only 1% to 5% mortality should be anticipated among patients who reach medical attention. ^{5,8,9,15} Complete recovery is seen in 60% to 65% of survivors; persistent neurologic deficits of varying severity may be seen in the rest. Eventual neurologic outcome seems to correlate well with the magnitude of hemoconcentration serum creatinine kinase elevation. ^{15,16} Victims who present with loss of consciousness and those who require resuscitation represent a subset at high risk for a poor outcome. ⁴

DISPOSITION

All patients suspected of suffering AGE must be referred for recompression. Transfer to the closest hyperbaric facility should be done as soon as possible. If transfer is by air, further decompression should be minimized. Aircraft capable of full pressurization (1 atm absolute) or of flight below 1,000 feet are best suited for such transfers. Consultations regarding the management of diving-accident victims or the location of recompression facilities are available 24 hours a day from the Diver's Alert Network, (919)684-8111.

COMMON PITFALLS

- Failure to consider the diagnosis of AGE in a patient with a history or clinical evidence of central nervous system injury occurring within 10 minutes of ascent from a compressed-gas dive
- Failure to consider concomitant trauma, near-drowning, and hypothermia in the differential diagnosis of AGE
- Failure to recompress all AGE victims, regardless of their condition at the time of presentation. Those who experience spontaneous recovery may later relapse.
- Failure to treat AGE victims with 100% oxygen, supportive measures, and rapid transfer to the nearest hyperbaric facility
- Failure to appreciate that the Divers Alert Network is available day and night to assist in questions of management or transfer

ACKNOWLEDGMENT

CHAPTER 389

Barotrauma

Christopher J. Degnen

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Injuries due to changes in ambient pressure result primarily from two basic mechanisms: changes in volume of free gas and changes in solubility of dissolved gas. Injuries resulting from changes in volume of free gas are classified as barotrauma. Expansion (or relative contraction) of gas within a closed anatomic space results in mechanical injury. Injuries resulting from changes in solubility of dissolved gases are classified as decompression sickness (DCS). Gas coming out of solution in body fluids causes pain (in joints, bones, soft tissues) or neurologic changes (in brain, spinal cord, blood vessels).

Often, these mechanisms and their presentations overlap. For example, expansion of free gas in the pulmonary cavity (pulmonary barotrauma) can force free gas into ruptured pulmonary vessels (air embolism), which may cause neurologic symptoms (mimicking DCS). Although the etiology and pathophysiology of neurologic injuries are diverse, the therapy for all such injuries is similar.

A third category of injury occurs when pressurized air or gas mixtures are inhaled, as with scuba (self-contained underwater breathing apparatus) diving or hyperbaric chambers. Under such conditions, the partial pressure of oxygen and nitrogen in plasma can reach toxic levels (see [Chapter 390](#)).

Scuba diving accidents occur in all regions of the United States. Although sport diving is most common along both coasts, lake diving and swimming pool training sessions are universal. Cerebral air embolism from a 12-ft pool dive has been reported.¹⁵ Scuba divers sometimes travel by air soon after a dive, and aircraft cabin pressures less than the pressure at sea level may precipitate injury in those travelers.

The weight of the gases in the earth's atmosphere at sea level, 760 mm Hg of pressure, is arbitrarily defined as 1 atmosphere (1 atm). For every 33 ft of seawater that a diver descends, the ambient pressure increases by an additional 1 atm. Boyle's law (the volume of a gas is inversely proportional to the absolute pressure) describes how the volume of a free gas varies in response to ambient pressure. The rate of change of volume proportional to change of depth is most rapid near the surface.¹ Major volume changes are possible on a shallow dive; hence, significant barotrauma can be seen even in a swimming pool dive.^{2,3}

Barotrauma during descent can cause injury even on a breath-holding dive, or free dive, in which no scuba or other breathing apparatus is used. This condition is commonly called a "squeeze" and generally causes only pain unless the diver continues deeper without correcting the problem. The areas of the body most commonly affected in this situation are the ears and facial sinuses. Because external pressure on the tympanic membrane (TM) increases with increasing depth and middle ear and sinus cavity pressures remain at about 1 atm, TM rupture can result. Cerebrospinal fluid and inner ear fluid pressures also increase. Small vessels may rupture into the middle ear or sinuses, and the round or oval windows may rupture into the middle ear if adequate equalization of pressures is not accomplished.

Divers who breathe pressurized air can correct these imbalances with a modified Valsalva maneuver, in which the glottis is open and the nares and lips are held closed. A safer technique is the Frenzel maneuver, in which the glottis is closed and nasopharynx pressure is increased by facial muscle manipulation.¹¹ Both of these techniques are also useful during airplane descent.

Barotrauma of ascent is seen only when divers inhale air (or other gaseous mixtures) under pressure. With such equipment, divers can fully inflate their lungs (including sinuses, middle ears, and so on) at depth; these compartments can then overexpand if they remain closed during ascent. Ruptures of the TM, round or oval windows, sinus bones, and alveoli or visceral pleura are all possible. This typically occurs during a panic ascent, in which the diver forgets to exhale.

Swallowing air at depth creates the potential for abdominal viscus rupture as well. Pockets of infection with gas-producing organisms have the potential for painful squeezes on descent or ascent. Periodontal abscess is the usual source of such pain.¹³ Wearing a face mask creates a potential closed space on descent only and may result in facial petechiae.

Every person who wishes to participate in compressed-air diving should first have a thorough physical examination. Medical conditions such as asthma, sinusitis, or chronic otitis media might predispose the diver to air trapping.^{5,10,16} Active allergic rhinitis or upper or lower respiratory infections are also contraindications to diving.

CLINICAL PRESENTATION

Pain is typically the first and most common symptom of barotrauma. Bleeding from the nares, ears, mouth, or lungs may accompany the pain. Hearing loss, tinnitus, and potentially disabling vertigo can occur with rupture of any of the ear membranes. A transient spinning sensation, called alternobaric vertigo, may result from a disequilibrium in middle ear pressures, even when all ear membranes are intact. Pneumothorax, pneumomediastinum, and perforated viscus may also occur.

Because barotrauma is a mechanical phenomenon, symptoms are likely to be maximal as soon as, or shortly after, a diver surfaces. Unusual exceptions occur when slow leaks of air trapped in the lungs or bowel produce a progressive tension pneumothorax or pneumoperitoneum.⁴

The physical examination is consistent with the injuries. Hearing loss may be either conductive (TM rupture) or sensorineural (oval or round window rupture or fistula). Subcutaneous emphysema may be palpated about the sinuses or chest. Radiography of the affected area (e.g., chest, abdomen, sinus, skull) is the most helpful diagnostic study.

DIFFERENTIAL DIAGNOSIS

Alternate diagnoses include almost any pathologic condition that can affect a given body compartment. For this reason, divers should never descend when they have an acute illness.⁸ The history of acute onset of symptoms in a previously well individual exposed to atmospheric pressure changes suggests barotrauma. The inability to establish a nondysbaric diagnosis may commit the patient to an expensive, time-consuming, and potentially dangerous recompression.

EMERGENCY DEPARTMENT EVALUATION

In divers, the history should indicate a rapid descent or ascent. Although the dive profile (see [Chapter 390](#)) should be obtained, on any single dive, a patient is equally at risk for a *de novo* barotraumatic event. The patient should describe the following: any problems in clearing the ears or sinuses on descent, swallowing air at depth, failing to exhale on ascent, when the symptoms began, and whether the dive was a breath-holding or compressed-air dive.

In addition to receiving a complaint-oriented physical examination, any victim of a dysbaric event should receive thorough ear, nose, and throat (ENT); cardiopulmonary; abdominal; and neurologic evaluations. Severe pain from a benign sinus squeeze may cause a patient to overlook minor sensory changes with a more ominous prognosis (i.e., DCS).

Plain radiographs of the affected area provide a good initial screen. Even skull films may be useful in a patient with significant headache following ear or sinus squeeze; pneumocephalus has been detected in such patients.⁷ A computed tomography scan may be indicated in patients with severe unexplained headache. If plain films reveal pneumothorax or pneumoperitoneum, further laboratory tests for arterial blood gases and preoperative blood work, for example, are indicated.

If the physical examination and plain films are normal, significant barotrauma can be ruled out.

EMERGENCY DEPARTMENT MANAGEMENT

Unlike air embolism or DCS, barotrauma can often be managed definitively in the emergency department. Advanced life-support measures should be instituted, as necessary. In cases of true barotrauma, the only probable life-threatening process is tension pneumothorax, in which case, needle decompression followed by tube thoracostomy is indicated. Because barotrauma is not a spontaneous injury and other complications may develop, patients with pneumothorax or pneumomediastinum should be admitted to the hospital. Similarly, patients with free intraperitoneal air require gastric decompression via nasogastric tube and surgical evaluation and treatment. Patients with pneumocephalus require assessment and management by a neurosurgeon. Patients with severe headaches require frequent neurologic checks, and patients with severe headaches of unexplained cause should be referred for hyperbaric chamber treatment when DCS is a possible cause.

Minor ENT problems, including small TM ruptures, are best treated with decongestants and prophylactic antibiotics. Severe vertigo or unexplained hearing loss require emergent ENT referral for round or oval window evaluation. Ruptures of these membranes are generally observed and require surgery only if symptoms do not resolve.^{6,12}

DISPOSITION

Patients with pulmonary, gastrointestinal, and central nervous system barotrauma should be admitted to the hospital, and patients with associated air embolism or DCS should be transferred to a hyperbaric treatment center for management. Patients with ENT problems can be discharged with referral to an ENT surgeon.

The prognosis for purely barotraumatic injuries is very good. Previous ENT barotrauma is a relative contraindication to further diving. The diver generally has warning symptoms when descending and can take corrective action or resurface. Pulmonary barotrauma is an absolute contraindication, however, because recurrences tend to be more severe.^{9,14}

A local hyperbarics expert or the Diver's Alert Network ((919)684-8111) may be consulted. The Diver's Alert Network is a resource for statistics and for locations and telephone numbers of hyperbaric treatment centers.

COMMON PITFALLS

- Failure to elicit a history of rapid ascent or descent and to diagnose barotrauma as the cause of a sudden illness in patients with recent diving or air travel
- Failure to appreciate that significant barotrauma can occur even in shallow depths and even on breath-holding dives
- Failure to rule out associated decompression sickness or air embolism in patients who have been scuba diving
- Failure to advise patients with significant barotrauma of the risks of further diving and to discourage them from such activity in the future

CHAPTER 390

Decompression Sickness

Christopher J. Degnen

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Records suggest that divers have used air bells (which compress air by being open to seawater) since 330 B.C.^{1,3} Diving helmets became practical in 1819, and compressed air technology for caissons and tunnels was developed in 1839. In the late 1800s, decompression sickness was first recognized and was termed *caisson disease*, the *bends* (for the doubled-over gait), or the *staggers* (presumably reflecting inner-ear involvement).

The development of the self-contained underwater breathing apparatus (scuba) allowed commercial divers increased freedom and gave birth to the sport of recreational diving. About 5 million divers are certified in the United States,¹⁰ and easy air travel allows them quick access to remote dive sites. Emergency physicians practicing anywhere in the United States may encounter patients with complications of scuba diving.

There are two types of decompression sickness (DCS). Type I, called “pain only” or musculoskeletal DCS, primarily affects the joints, bones, and soft tissues. Type II, called central or neurologic DCS, affects the brain, the spinal cord, and the cardiopulmonary process. Diving complications also include barotrauma (see [Chapter 389](#)) and nitrogen toxicity (discussion follows).

The pathophysiology of DCS is not clearly established. Evidence suggests that bubble formation on a microscopic, even subcellular, level is the initial insult.³ Bubbles form in tissue when the ambient pressure is decreased too rapidly to allow supersaturated gases to be released from plasma into the pulmonary alveoli.

The pressure of the atmosphere at sea level (760 mm Hg) is defined as one atmosphere (1 atm). The ambient pressure on a diver increases by 1 atm for each 33 ft of seawater (FSW) descended. The scuba regulator is designed to deliver compressed air at increased (ambient) pressure as the diver descends. Hence, the alveolar gas pressure in a scuba diver is the same as ambient pressure. High external pressures would otherwise prevent normal chest expansion.

Most sport divers breathe compressed air (21% oxygen, 78% nitrogen, 0.03% carbon dioxide). Because the amount of gas dissolved in a liquid is proportional to the pressure of that gas in contact with the liquid, increasing amounts of each component of air are dissolved in plasma with increasing depth. Excess oxygen can be metabolized, but excess nitrogen cannot and is released from solution on decompression. Because helium is less toxic than nitrogen, mixtures of oxygen and helium are generally used in commercial (deep) diving.

Increased partial pressures of nitrogen are intoxicating and cause confusion and euphoria (“rapture of the deep”). This short-lived effect resolves with resurfacing but may precipitate poor judgment and slow reflexes while the diver is at depth.

In a controlled ascent, supersaturated gases are slowly released from plasma at the alveoli. If the diver ascends too rapidly, the gas can “boil out” of the liquid phase anywhere in the body, both intravascularly and extravascularly. A similar phenomenon can occur if a person at sea level ascends too rapidly in an airplane or altitude chamber.

Dissolved nitrogen can accumulate in plasma and tissues over several dives. Divers are trained to keep exact records (dive profiles) that specify the maximum depth achieved, time spent at that depth, decompression stops made during ascent, and time spent on the surface before the next dive.

Tables can tell divers how long they may stay at different depths before decompression stops (rest periods on ascent to allow off-loading of nitrogen) are required. At depths of 0 to 33 FSW, a diver can spend unlimited time without the need for a decompression stop. Descending more than 33 FSW requires stops after variable periods of time; the deeper the dive, the shorter the maximum allowable time until a decompression stop is required.

Constructing these tables is not an exact science, however: They were empirically prepared on the experience of British and U.S. Navy divers. Consequently, rare divers suffer DCS even though they adhered to the tables. DCS has also been reported in a diver who stayed within the allowable 33 FSW.¹² Also, fatal barotrauma, a different mechanism of injury, is possible at much shallower depths (see [Chapter 389](#)).

CLINICAL PRESENTATION

Decompression sickness may manifest initially as profound but nonspecific fatigue. In type I DCS, pain is most common in the large joints. Pain may be deep, mild to severe, and radiate to surrounding areas. In some cases, tenderness, edema, and paresthesias may also occur. Type I DCS can also involve the skin (itching, erysipelas-like rash or mottling) and the lymph nodes (peau d'orange edema). Avascular necrosis of bone can be seen on radiographs after a single episode of DCS. These lesions are usually asymptomatic, but crippling osteonecrosis of the large joints can occur.

Type II DCS may present with a variety of neurologic manifestations, such as back pain (radiating around to the abdomen), confusion, deafness, dysphasia, headache, fecal incontinence, paresthesias, weakness, scotoma, vertigo, and urinary retention.⁴ These symptoms reflect involvement of the brain or the spinal cord. Objective neurologic deficits (e.g., motor or sensory loss) may be evident. Patients with pulmonary involvement (the “chokes”) may present with dyspnea, cyanosis, cough, frothy or bloody sputum, and central chest pain with a pleuritic component. Findings include tachypnea, tachycardia, and turbulent cardiac flow murmurs. Rarely, patients may present with cardiovascular collapse or may develop evidence of kidney or liver injury or disseminated intravascular coagulation.

Patients may present with combinations of types I and II DCS, and the extent and severity of signs and symptoms may progress over time. The onset is usually gradual and may even be delayed for many hours.^{2,9}

DIFFERENTIAL DIAGNOSIS

Diagnosing DCS, especially type I, can be difficult. Diving is a strenuous sport, and strains and sprains are as common as with other sports. It would be impractical to recompress every scuba diver who complains of headache; however, not doing so demands that the physician be precise in evaluating the patient.

The patient's dive profile should be reviewed. Decompression occurs when the dive tables are violated. In contrast, barotrauma does not relate to these tables but occurs when a patient descended deeper or ascended despite the onset of painful symptoms, or made an uncontrolled ascent without exhaling. If symptoms occurred immediately or within minutes of surfacing, barotrauma and air embolism are the most likely causes. Decompression symptoms generally develop over minutes to hours after surfacing, occasionally longer.

If the patient complains of pain in an extremity only, and the examination reveals no other involvement, a blood pressure cuff should be applied to the affected area. If symptoms are relieved when the cuff is inflated, type I DCS probably exists.

Should the physician need assistance in evaluating or referring a patient, a national reference center, the Diver's Alert Network, is available at Duke University on an around-the-clock basis at (919)684-8111.⁶

EMERGENCY DEPARTMENT EVALUATION

The history emphasizes the dive profile and any predisposing illnesses. If the patient has been diving on previous days, profiles should be obtained for the past 1 or 2 weeks. The time of onset, nature, and progression of symptoms are documented.

Regardless of the nature of the complaint, the patient requires a full physical examination. The neurologic examination includes mental status, memory, cranial nerves, sensation to pain, light touch and position, motor strength of individual muscles, deep tendon reflexes, Babinski reflex, cerebellar function, pronator drift, and tandem gait, if possible. The skin is examined for rash and edema. Any adventitious heart or lung sounds are documented, as well as the status of bowel sounds. Involved joints are examined for active and passive range of motion, effusion, and warmth or erythema. If the patient presents with altered mental status, coexistent intoxication or trauma is possible.

Applying a blood pressure cuff may be useful in confirming type I DCS (see earlier discussion). Laboratory tests are of little value in DCS, other than ruling out other causes. However, obtunded patients or those with unstable vital signs require blood gas analysis; a complete blood count; measurement of electrolytes, glucose, blood urea nitrogen, and creatinine; prothrombin time; an electrocardiogram; and a chest radiograph, at a minimum. If recompression cannot be performed promptly, a computed tomography or magnetic resonance imaging scan may identify lesions.⁸ However, because recovery is best with rapid recompression, these studies should not delay treatment.

EMERGENCY DEPARTMENT MANAGEMENT

Victims of a significant diving accident are quite ill and often require prehospital care. Such patients should have 100% oxygen by face mask and intravenous normal saline. Endotracheal intubation with cervical precautions may be required. Debate continues over the best position for transport. The Trendelenburg position may prevent potential cerebral air embolization in pulmonary barotrauma, but may worsen cerebral edema in DCS. The supine position or a few degrees of Trendelenburg are reasonable approaches. Administration of thiamine, D₅₀W, and naloxone is appropriate if the patient is obtunded. Seizures are treated with benzodiazepines.

The treatment of nitrogen toxicity is decompression to 1 atm (i.e., returning to the surface for divers) until symptoms resolve. Midazolam is preferred for the treatment of seizures, because recompression will probably be necessary to treat associated DCS, and long-acting agents may obscure the detection of oxygen toxicity secondary to recompression therapy, where 100% oxygen at increased pressure is provided for limited intervals to enhance the off-gassing of nitrogen.

Treatment of DCS is designed to reduce bubble size and to force free gas back into solution. This may be achieved by returning a diver to depth at the scene, but this approach is fraught with problems. Often, these patients are uncooperative and may vomit or have seizures. Recompression is best accomplished in a hyperbaric chamber (see [Chapter 389](#)), preferably one that allows a physician or nurse to be with the patient. Typically, the patient is recompressed to 3 to 6 atm, depending on the history and symptoms.⁷ While at these pressures, the patient breathes 100% oxygen in brief intervals. Recovery is often rapid and dramatic.

Emergency department management should be aimed at correcting treatable problems while simultaneously arranging for recompression therapy. The vital signs and neurologic status are monitored. DCS can cause third-spacing of fluid, and hydration should be aggressive, with 200 to 500 mL/h normal saline if the neurologic and cardiopulmonary status permit. In anticipation of recompression, plastic intravenous bags should be used. The cuffs of any endotracheal tube or Foley catheter used should be filled with saline, not air.

Various anticoagulating agents (e.g., aspirin, heparin, dipyridamole, and dextran polymers) have been tried without success and are not generally recommended. Intramuscular diclofenac has been used with success to relieve pain after recompression.⁵ Steroid response is variable. Because the early use of these agents has not shown any decided benefit, drug therapy can be deferred to the hyperbaric center receiving the case.

DISPOSITION

If symptoms are very mild (e.g., headache) and the history and physical examination do not immediately suggest a decompression event, the patient is observed in the emergency department or discharged home with reliable family members or friends. Delayed recompression therapy has been successful in treating minor symptoms that develop gradually if the initial examination is normal.^{9,11} Patients with significant symptoms are referred for recompression therapy. If there is doubt as to the etiology of suspicious symptoms, consultation with a hyperbaric treatment specialist is indicated. Transport to a recompression chamber may be accomplished by ambulance, low-flying helicopter, or aircraft with a fully pressurized (1 atm) cabin.

COMMON PITFALLS

- Failure to appreciate that symptoms and signs of DCS may worsen with time
- Failure to use recompression early, when it is most effective
- Failure to consider recompression as a diagnostic trial when the etiology of symptoms is in doubt
- Failure to admit patients with mild symptoms for observation
- Failure to consult a hyperbaric treatment specialist or the Diver's Alert Network

CHAPTER 391

High-Altitude Illness

David M. Richardson

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Increasing mobility and leisure time have allowed many more people to explore wilderness worlds previously experienced only by the privileged few.¹⁵ Interest in hiking, camping, rock climbing, mountain biking, alpine and cross-country skiing, and other high-altitude sports has grown dramatically over the past few decades. In the United States alone, tens of millions of athletes and tourists now seek mountainous destinations in every season of the year.¹⁴ High-speed transportation now permits travel from low to high altitudes within hours.

High-altitude medical illness, better known as *acute mountain sickness* (AMS), is a spectrum of disease ranging from subclinical effects to potentially lethal high-altitude pulmonary edema (HAPE) or high-altitude cerebral edema (HACE).¹⁶ Because barometric pressure decreases with increasing altitude, yet the fraction of inspired oxygen in air remains constant at 21%, the PaO₂ is reduced. Even a young, healthy, physically fit nonsmoker may experience PaO₂ under 60 mm Hg at 2,500 m (8,100 ft) and under 50 mm Hg at 4,500 m (14,600 ft). Symptomatic AMS is uncommon under 2,500 m but occurs in up to 25% of the population at 2,500 m, and in 75% at 4,500 m.^{8,9} Repeated attacks are common (about 20%), potentially limiting high-altitude activity and requiring prophylactic medications and a slow, controlled ascent.¹⁰

The incidence, severity, and duration of AMS are proportional to the rate and height of ascent and are modified by individual susceptibility, physical exertion, and sleeping altitude.^{6,11} Symptoms vary widely but remain consistent on repeated episodes in the same person.¹¹ AMS demonstrates no sexual preference,¹⁰ but HAPE is more common in males.¹¹ Spontaneous diuresis occurs in response to complicated fluid shifts.^{6,10} Well-being at altitude is proportional to individual diuretic response.¹³ In mild cases, symptoms abate in 3 to 7 days as acclimatization occurs.

Chronic mountain sickness, or Monge disease, may develop in some patients who do not acclimatize despite prolonged altitude exposure. It is characterized by persistent hypoxia, polycythemia (hematocrit greater than 60), and development of congestive heart failure.⁹

HAPE is a form of noncardiac pulmonary edema associated with pulmonary artery hypertension. A defect in nitric oxide synthesis may be contributory.¹⁷ It develops in 0.5% to 15.0% of persons who ascend rapidly to high altitudes and has an overall mortality of 11%. HAPE recurs in susceptible persons, thus requiring cautious reexposure.¹

HACE affects an estimated 1% of travelers to high altitude. Symptoms are due to increased intracranial pressure. While cerebral vessels dilate in response to hypoxia, the exact pathophysiology of this condition is not known.^{7,9,10,18} Recent findings indicate that the predominant underlying mechanism is vasogenic (extracellular, due to leakage of fluid and protein through the blood–brain barrier) rather than cytotoxic (intracellular, due to cellular swelling).

Hypobaric hypoxia can exacerbate preexisting cardiac or pulmonary disease.⁶ Relative contraindications to high-altitude travel include advanced age, chronic diseases, coronary artery disease, chronic obstructive pulmonary disease, pulmonary hypertension, sickle cell disease, and other diseases that compromise cardiopulmonary function.^{6,9}

Measures to prevent or reduce AMS in a person who is about to undergo rapid ascent to high altitude (particularly those with previous episodes) include cautious acclimatization and medication. A staged, gradual ascent is most effective to achieve acclimatization. Either remaining at 2,000 to 3,000 m (6,600 to 9,800 ft) for 2 to 5 days before going higher, or ascending less than 300 m (1,000 ft) per day above 2,500 m (8,200 ft) can significantly reduce symptomatology.^{11,16} Climbing high but sleeping low can also be effective in reducing the results of hypobaric hypoxia exacerbated by nighttime hypoventilation.^{6,7,13} Drinking plenty of fluids, eliminating salt intake, and limiting physical activity may restrict symptom development.^{6,10,11,13}

The carbonic anhydrase inhibitor acetazolamide causes a bicarbonate diuresis, resulting in a hyperchloremic metabolic acidosis and a compensatory respiratory alkalosis.^{7,11} Pretreatment with 250 mg every 6 to 12 hours or with 500 mg of the sustained-release formula each day, beginning 1 or 2 days before ascent and continuing at least 48 hours after ascent, mimics the acclimated state of acid–base balance.^{6,7,10,11,13,17} Some patients may not be helped, but symptoms are lessened in 30% to 50% of patients.¹¹ Side effects include paresthesias, gastrointestinal distress, somnolence, and dehydration if fluid intake is insufficient.^{11,13}

Dexamethasone, which stabilizes membranes, reduces vasogenic cerebral edema and AMS symptoms to a greater extent than acetazolamide, with fewer side effects.^{3,4,11} The dosage is 4 mg every 6 hours, starting 48 hours before ascent and continuing 48 hours after ascent.^{6,11} Combining it with acetazolamide improves efficacy over either drug alone.²⁰

CLINICAL PRESENTATION

Early symptoms of AMS are nonspecific and generally develop within 8 to 24 hours of arriving at altitude (range, 6 to 48 hours).¹¹ Headache, anorexia, nausea, vomiting, malaise, insomnia, lassitude, shortness of breath, and dyspnea on exertion make up the most common symptom complex.^{6,10,11,19} The headache is usually throbbing, bilateral, and frontal. It is worst in the morning and when supine, increases with exercise, and may be minimally responsive to aspirin or acetaminophen.¹¹ Sleep is generally poor and often exacerbates symptoms as a result of hypoventilatory hypoxia, so the patient feels worse on waking.⁶

Physical examination may reveal a dyspneic, tachypneic, tachycardic patient with peripheral or periorbital edema, and rales. Tachypnea and tachycardia serve to maximize oxygenation and oxygen delivery to tissues. Despite having edema, the patient is often dehydrated and hypovolemic, with oliguria, increased hematocrit, and hypercoagulable state.⁶ Petechiae may indicate disturbed vascular integrity, and papilledema may be present without raised intracranial pressure.¹⁰ High-altitude retinal hemorrhage is detectable as flame hemorrhages in up to 40% of AMS patients.^{6,10,11} It is usually asymptomatic and resolves without residua. Macular involvement (less than 5%) is manifest by central scotoma.^{6,10} Laboratory studies may reveal mild leukocytosis and hemoconcentration.^{6,9}

Manifestations of HAPE include worsening dyspnea, cough, hemoptysis, and cyanosis.⁶ Complications such as adult respiratory distress syndrome or infection may develop. The chest radiograph reveals a normal-sized heart and diffuse bilateral patchy infiltrates, in contrast to the typical butterfly distribution of alveolar edema.^{6,10} Arterial blood gas analysis may show hypoxia, hypocapnia, and alkalosis. Pulmonary function tests indicate decreased vital capacity and peak expiratory flow rates.¹⁶ Pulmonary hypertension with normal left atrial pressure and normal pulmonary artery wedge pressure would be expected if pulmonary artery catheterization becomes necessary.¹⁷ The electrocardiogram (ECG) most often shows only sinus tachycardia, but it may show evidence of right-sided heart strain.^{6,10}

Manifestations of HACE include increasing headache, nausea, and vomiting, accompanied by CNS deficits such as confusion, poor judgment, and ataxia.^{6,7,8,9 and 10,18} HACE can progress to coma and death if untreated and may leave neuropsychological residual even if promptly recognized and treated.¹⁰ White matter edema may be seen on computed tomography (CT) or magnetic resonance imaging of the brain.

DIFFERENTIAL DIAGNOSIS

The multiple nonspecific symptoms of early AMS may mimic viral upper respiratory infection or gastroenteritis. Poor central nervous system (CNS) function upon environmental exposure adds hypothermia, hypovolemia, and exhaustion to the differential diagnosis.⁶ Worsening pulmonary symptoms may also be due to acute exacerbations of chronic respiratory diseases such as asthma or chronic obstructive pulmonary disease.¹⁰ Other etiologies of noncardiogenic pulmonary edema should be considered (e.g., medications, neurologic disorders). Low-grade fever and leukocytosis expand the differential to more serious infections, including pneumonia and meningitis.¹⁰ The differential of CNS dysfunction also includes metabolic, psychiatric, toxic, and traumatic disorders.⁹

EMERGENCY DEPARTMENT EVALUATION

A history of recent, rapid transit to high altitude should alert the physician to the potential diagnosis of AMS. A previous history of similar episodes at altitude should immediately raise suspicion. The rapidity of ascent, altitude, activities and length of stay at altitude, the time of onset, nature and duration of symptoms, and preexisting medical conditions should be noted.

The physical examination should focus on vital signs and evaluation of CNS, cardiac, and respiratory function. A fundoscopic examination should also be performed. All patients should have an oxygen saturation measured. Laboratory evaluation of patients with constitutional symptoms of AMS should include a complete blood count, electrolytes, blood urea nitrogen, creatinine, and glucose. Those with tachypnea, hypoxia, altered mental status, or abnormal findings on cardiopulmonary examination should have arterial blood gas analysis, cardiac monitoring, an ECG, and a chest radiograph. A CT scan of the head should be performed in those with persistently abnormal mental status or severe headache.

EMERGENCY DEPARTMENT MANAGEMENT

Acetazolamide and dexamethasone are effective for treating mild-to-moderate AMS as well as preventing it.⁵ Acetazolamide relieves symptoms, improves arterial oxygenation, and prevents further impairment of pulmonary gas exchange.⁷ Multiple acetazolamide regimens are effective.² Administration of 250 mg orally every 8 hours until symptoms of AMS resolve is recommended.⁷

Dexamethasone is given in the same dose as that for prevention. Patients with dehydration should be given oral fluids. Those with severe symptoms require descent to a lower altitude. Patients with vomiting should be given antiemetics and hydrated with intravenous saline. Acetaminophen or a nonsteroidal antiinflammatory agent can be given for headache.

Lightweight, portable hyperbaric chambers (Gamow, Certec, PAC [or portable altitude chamber]) have become part of the field regimen to treat AMS. These pressurized, cylindrical, zipper body bags simulate descent to a lower altitude, the most effective treatment for altitude sickness. The patient is placed in the bag and air is pumped in. Bag pressure is maintained at a pressure of 100 mm Hg by means of a pop-off valve vent (usually 2 psi). The patient may also be placed on oxygen while in the chamber. Hyperbaric therapy with the Gamow bag is as effective as oxygen therapy for the immediate treatment of AMS.¹²

HAPE should be treated initially with oxygen and evacuation to a lower altitude.^{1,11} Sublingual and oral nifedipine (10 mg every 4 hours until improved, then 30 mg of long-acting preparation every 12 to 24 hours) given to patients with clinical and radiologic evidence of HAPE has been shown to decrease pulmonary artery pressure, improve oxygenation, and decrease subjective symptoms of AMS.^{1,11}

Nifedipine treatment offers a potential emergency measure for patients when descent or evacuation is impossible.¹¹ Nifedipine should not be used prophylactically in HAPE-susceptible subjects, however, because of potential harmful side effects, such as hypotension and consequent myocardial and cerebral ischemia and infarction.¹¹

Depending on severity, continuous positive airway pressure (CPAP or BiPAP) by mask or endotracheal intubation and mechanical ventilation with positive end-expiratory pressure may be necessary for patients with respiratory failure.^{8,14} Inhaled nitric oxide can also improve arterial oxygenation.¹⁶ Diuretics are not helpful and may be harmful in patients with underlying dehydration. If recognized early and treated aggressively, nearly all young, physically fit, otherwise healthy patients with all forms of AMS will improve quickly, often with full resolution of symptoms within 24 hours.

DISPOSITION

Young, healthy patients with mild-to-moderate AMS may be discharged with instructions not to resume ascent until after symptoms have subsided and only if preventative measures are taken. Medications should never be used to allow further ascent in light of persistent symptoms. Patients with HAPE, HACE, severe AMS, or moderate AMS and underlying cardiopulmonary or cerebrovascular disease, complications (e.g., ECG changes), or other significant medical problems should be admitted. Most such patients will require observation and treatment in an intensive care unit.

COMMON PITFALLS

- Failure to ask about altitude in patients who become ill when traveling
- Minimizing the signs and symptoms of AMS and attempting to remain at high altitude
- Treating AMS with medications to allow for further ascent or continued exposure
- Failure to descend immediately if HACE or HAPE is suspected
- Failure to use adjunctive medications and hyperbaric therapy (if available) when descent is not immediately possible
- Failure to treat severe HAPE with positive airway pressure by mask or positive end-expiratory pressure with endotracheal intubation and mechanical ventilation
- Giving medications used for the treatment of congestive heart failure or cardiogenic pulmonary edema to patients with HAPE

CHAPTER 392

Venous Air Embolism

Christopher H. Linden

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Acknowledgment](#)
[Common Pitfalls](#)
[Chapter References](#)

Venous air embolism may occur whenever the integrity of a vein is violated and its lumen is exposed to air or any other gas. The presence of a pressure gradient (i.e., ambient air pressure greater than venous blood pressure) is also required. Air may be forced into an open vein by positive external pressure, or it may be drawn into the venous system by negative intravascular pressure. Inspiration, which augments venous return and increases the pressure differential, facilitates aspiration of air into exposed central veins. However, air can passively enter any open vein above the level of the heart.

Venous air emboli of small volume (a few milliliters) are common during intravenous infusion but are clinically insignificant. Hence, they are frequently unrecognized or ignored and are rarely reported. In contrast, large air emboli are rare but quickly fatal, and they generally remain undiagnosed until autopsy. ^{14,16} Estimates of the fatal volume range from 100 to 500 mL, depending on the speed of infusion and underlying disease. Slow infusions are tolerated better than rapid ones. Emboli of intermediate size result in significant respiratory, cardiovascular, and neurologic dysfunction. Because signs and symptoms are nonspecific, knowledge of the clinical settings in which venous air embolism may occur will aid in the proper diagnosis.

Physiologically significant venous air emboli are most commonly reported after surgical procedures such as craniotomy (particularly posterior fossa surgery), sinus and neck surgery, central venous or pulmonary artery catheterization, cervical laminectomy, hemodialysis, lung and open-heart surgery, hip arthroplasty, thoracentesis, thyroidectomy, and tracheostomy. ^{4,5,14,16} The sitting (Fowler's) position and the noncollapsibility of intracranial veins account for the relatively high incidence during craniotomy. Preventing air emboli during central venous cannulation requires proper technique: using the Trendelenburg position and Valsalva maneuver, covering the catheter hub with a finger during placement, and securing the catheter and its connections with sutures or tape. ⁴

Blunt or penetrating chest trauma with concomitant airway and venous disruption may result in either insidious or acute air embolism. ⁹ The same is true for blunt and penetrating head trauma and penetrating neck trauma. ¹ With head trauma, air can enter the venous circulation via open skull fractures, basilar fractures crossing the cavernous sinus, and those involving dural venous (petrosal, sigmoid, sphenoparietal, transverse) sinuses and paranasal air (usually ethmoid) sinuses.

Serious emboli may also occur as a complication of any diagnostic or therapeutic procedure that uses air or another gas under pressure. Examples include arthrography, nasal sinus irrigation, positive-pressure ventilation, laparoscopy, presacral or retroperitoneal pneumography, pneumoencephalography, Rubin's test (vaginal insufflation), pressurized intravenous infusions, pneumourethrocytography, gas-cooled laser surgery of the uterus, and vacuum abortion with accidental reversal (i.e., pressurization) of the suction catheter. ^{3,5,14,16,17} Significant amounts of air may sometimes enter a vein during gravity infusion as a result of tubing defects, an obstructed filter, or the presence of air in a collapsible infusion bag. ⁵ Air may be rapidly aspirated into cervical or thoracic veins via central venous catheters that become disconnected, particularly when the patient assumes an upright position or inspires. ⁴ Improper ventilation of a phlebotomy collection bottle has also caused air to be forced into a vein. ⁵ Pressure-induced air embolism may occur in nonmedical settings, such as attempted criminal abortion, vaginal douching, insufflation of the vagina during cunnilingus (in pregnant women), recreational inhalation of helium or nitrous oxide from pressurized tanks, and the self-injection of air into the scrotum, urethra, or a peripheral vein (usually suicidal). ^{6,8,14,16,17}

The primary physiologic mechanism underlying clinical findings appears to be gas-bubble obstruction of the pulmonary outflow tract of the right ventricle, resulting in pulmonary vasoconstriction, pulmonary hypertension, hypoxemia, systemic hypotension, and arterial ischemia. ^{7,16,17} As usual, the heart and brain are the most susceptible organs. The whipping or churning of blood and air by ventricular contractions also results in platelet and red cell aggregation and fibrin and fat globule formation, with deposition in, and obstruction of, pulmonary arterioles. ¹¹ Secondary effects include decreased lung compliance, increased airway resistance, ventilation-perfusion mismatching, and pulmonary edema leading to additional hypoxia and hemodynamic compromise. ^{16,17} In patients with atrial or ventricular septal defects, paradoxical embolization of venous air to the left side of the heart may sometimes result in subsequent gas-bubble occlusion of the arterial circulation, with symptoms identical to those of direct arterial gas embolism (see [Chapter 388](#)). ^{6,20} Paradoxical embolization may also occur through arteriovenous anastomoses in the lung. ¹⁶

CLINICAL PRESENTATION

The severity of symptoms depends on the size of the embolus and its rate of formation. Patients with large venous air emboli that develop over a short period of time often experience sudden dyspnea or gasping, chest pain, loss of consciousness, and cardiovascular collapse. In severe cases, there may be an immediate cardiac arrest. Cyanosis, wheezing, rales, hypotension, coma, tachycardia, hemoptysis, and tachypnea are typical physical findings. Auscultation of the heart may reveal a characteristic loud churning sound or "millwheel" murmur. This coarse, continuous (systolic and diastolic), metallic or machine-like murmur is transient and heard only with large right ventricular emboli. It may be preceded or followed by tympanic, resonant, or drumlike valvular sounds, gallop rhythms, and a softer systolic murmur. Jugular venous distention may be present.

Patients with smaller emboli may complain of faintness, dizziness, shortness of breath, weakness, palpitations, and chest pain. Lesser degrees of hypotension, tachycardia, tachypnea, and central nervous system dysfunction (e.g., anxiety, confusion) may be noted on physical examination. Abnormal cardiopulmonary findings may be present. In paradoxical embolization, the patient may present with an acute stroke, myocardial infarction, or manifestations of limb or intraabdominal organ arterial insufficiency.

Hypoxia, metabolic acidosis, and an increased or decreased P_{CO₂} may be noted on arterial blood gas analysis. Thrombocytopenia is sometimes present. If continuously monitored, the end-expiratory CO₂ concentration (a reflection of the alveolar P_{CO₂}) will show an abrupt decrease. The electrocardiogram (ECG) may reveal evidence of ischemia (e.g., right ventricular ST-T wave changes), dysrhythmias, or acute cor pulmonale (e.g., right axis deviation, P pulmonale, and right bundle-branch block). Right ventricular Doppler ultrasound (usually heard best over the right third to fifth intercostal spaces) may reveal an abrupt change in heart sounds when air enters the heart. The chest radiograph may show pulmonary edema without cardiomegaly. ^{10,12} Rarely, intracardiac or pulmonary arterial air may be radiographically visualized; this confirms the diagnosis. ¹² The central venous pressure may be normal or elevated. Aspiration of air from a central venous, right atrial, right ventricular, or pulmonary artery catheter also confirms the diagnosis. ^{13,19}

DIFFERENTIAL DIAGNOSIS

Venous air embolism is most often confused with pulmonary thromboembolism and acute myocardial infarction. Without prior monitoring, the clinical setting and characteristic murmur are the primary clues to the correct etiology. In pregnant patients, amniotic fluid embolism should also be considered in the differential diagnosis. ⁸ Signs and symptoms are similar, but amniotic fluid embolism occurs almost exclusively at or about the time of delivery and is usually associated with a coagulopathy. ¹⁸

In patients with multiple trauma, conditions such as hemothorax, pneumothorax, hypovolemia, cardiac tamponade, tracheobronchial disruption, and aortic transection are more common causes of cardiovascular collapse. Fat embolism should also be considered. Hemoptysis and unexpected deterioration or arrest, especially if occurring immediately after intubation and positive-pressure ventilation in a patient with lung trauma, are clinical clues to the presence of venous air embolism. With paradoxical embolization, manifestations are usually those of arterial insufficiency, but signs and symptoms of venous air embolism may also be present.

EMERGENCY DEPARTMENT EVALUATION

Venous air embolism should be suspected in any patient who develops acute respiratory, neurologic, or cardiovascular decompensation following a diagnostic, therapeutic, or traumatic event involving air insufflation or potential venous disruption and a communication with an external or internal gaseous atmosphere. Details of the precipitant circumstances are documented, and the site of air entry is identified, if possible.

The physical examination focuses on the vital signs and the cardiovascular, neurologic, and respiratory status. Careful auscultation for abnormal heart sounds is essential.

The ancillary evaluation should include arterial blood gas measurements, cardiac monitoring, a 12-lead ECG, and a chest radiograph. In unstable patients with suspected venous air embolism, insertion of a central venous or, preferably, a right-sided heart (Swan-Ganz) catheter and aspiration of air may be diagnostic as well as therapeutic. Although not reported, findings on echocardiogram are also likely to be diagnostic. Measurement of the end-expiratory CO₂ concentration and evaluation of heart sounds by Doppler flowmeter are useful only if baseline parameters are known.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced life-support measures are instituted as necessary. Initial treatment should include prevention of further air embolization by manually sealing, if possible, the venous portal of entry and discontinuing any insufflation procedures. The patient is placed in a head-down (Trendelenburg) or head-down, left lateral (Durant) position so that the air present in the heart can be displaced from the pulmonary outflow tracts and rise toward the apex.^{2,4,14,16,17} Closed-chest cardiac massage may also be effective in forcing air out of pulmonary arteries and into smaller vessels. If vital signs remain or become stable, supportive care is all that is necessary. Small amounts of air will eventually dissolve in the blood.

All patients are given 100% oxygen to hasten the absorption of embolized air. Because air is 80% nitrogen, decreasing the partial pressure of nitrogen in the blood by giving oxygen will result in the diffusion of nitrogen from the embolus into the blood, thus decreasing the size of the air bubble.^{5,17}

In patients with profound shock or cardiac arrest, direct transthoracic aspiration of air from the heart may be lifesaving, especially in the case of a massive air embolism.^{5,14,16,17} To accomplish a right ventricular puncture, an 18-gauge, 3.5-in. or larger needle is inserted, with or without a catheter, into the fourth or fifth intercostal space at the left sternal border. It is directed perpendicularly to the chest wall. Alternatively, the needle can be inserted just to the left of the xiphoid process and directed toward the inferior tip of the left scapula. Because transthoracic aspiration may result in coronary artery or myocardial laceration and pericardial tamponade, the preferred treatment for patients with less severe hemodynamic compromise is to insert a central venous or Swan-Ganz catheter, with the tip placed at the junction of the superior vena cava and right atrium,^{2,13,19} and to aspirate the embolus. Pulmonary edema is treated with oxygen, intubation, and mechanical ventilation, as necessary.

The management of air embolism in patients with blunt or penetrating chest trauma and profound shock or cardiac arrest requires immediate thoracotomy for diagnosis, resuscitation, and treatment. Although not generally indicated for victims of cardiac arrest due to blunt trauma, thoracotomy may be lifesaving when air embolism is the underlying pathologic event. Definitive treatment usually requires hilar cross-clamping for initial control of bronchovenous communications. Selective intubation of the right or left mainstem bronchus and ventilation of the uninvolved lung can reduce the flow of air into the venous circulation, facilitate resuscitation, and obviate the need for thoracotomy in some cases.⁹ Nitrous oxide should not be used: It may diffuse into the air embolus and increase its size.^{15,17}

The management of patients with paradoxical air embolization (i.e., arterial gas embolism) is described in [Chapter 388](#). Hyperbaric oxygen therapy should be considered for patients with persistent neurologic manifestations.¹⁹

DISPOSITION

Symptomatic patients with documented or suspected venous air embolism are admitted. The level of care is based on the degree of hemodynamic and respiratory dysfunction. Depending on the circumstances, consultation with a cardiothoracic or trauma surgeon or a hyperbaric medicine specialist may be indicated. In patients who survive the acute event, the long-term outcome depends on the degree of anoxic injury and associated illnesses or trauma.

ACKNOWLEDGMENT

Francis P. Renzi contributed to previous versions of this chapter.

COMMON PITFALLS

- Failure to consider venous air embolism as a cause of acute hemodynamic decompensation
- Failure to recognize venous air embolism as a complication of head, neck, and chest trauma and of many diagnostic and therapeutic procedures
- Failure to recognize and follow measures designed to avoid iatrogenic air embolism
- Failure to place the patient in a head-down, left lateral position, and failing to give 100% oxygen
- Failure to consider concomitant arterial embolization (paradoxical embolization)

CHAPTER 393

Electrical Injuries

Peter L. Sosnow

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

There are approximately 1,000 deaths from electrocution each year in the United States. High-voltage electrical injuries occur in electrical, construction, and industrial workers, accounting for more than two-thirds of all electrocutions and serious electrical injuries. Accidental electrocution remains the second leading cause of death for these workers.¹⁵ Nonfatal, high-voltage electrical injuries that require hospitalization account for 5% of all burn unit admissions.⁹

About 30% of all electrical injuries occur in children and adolescents. Inquisitive toddlers are exposed to household current in wall sockets, electrical cords, or extension cord outlets. A child who puts the receptacle block from an ordinary extension cord into his or her mouth may create an electrical arc through saliva with a temperature approaching 3,000°C, causing a burn with enormously disfiguring potential.²⁰ This devastating injury is still not well known or appreciated by most parents.

Another group at risk is adolescent boys, who are prone to risk-taking behavior. Climbing utility poles, trespassing through transformer substations, or playing near electrical railway lines are common scenarios in which they are exposed to high-tension electrical power.¹⁷

Common electrical safety practices and appliance design have greatly reduced the risks of electrical injury in the home. Less than 1% of accidental deaths in the home are caused by electrical injury. However, dangerous practices, such as failing to ground electrical appliances properly and using electrical appliances near water, are still seen.

The severity of electrical injury is determined by the voltage, current pathway, and duration of exposure. The type of current—direct (DC), alternating (AC), or radio frequency (RF)—also determines mechanism and severity of injury.⁶

Voltage is a measure of electromotive force and is usually the only variable known when obtaining the medical history. Voltages above 1,000 V are considered high tension. Ohm's law defines *current* as voltage divided by the resistance in the path of current flow. Resistance, which is usually unknown, is the most important determinant of current and magnitude of injury.

Resistance to current flow varies for different tissues and can be ranked in order of increasing resistance as nerve, blood, muscle, viscera, skin, tendon, fat, and bone. Nerve, blood, and muscle are rich in electrolytes and have the lowest tissue resistance. Current flows easily and in higher volume through these tissues, producing the greatest damage.

The skin is the most important resistor to current flow. Typical skin resistance is about 40,000 ohms, but dry, thick, heavily calloused skin will present resistance as high as 1 million ohms. Moisture, sweat, and surface contaminants can decrease skin resistance to as low as 300 ohms. Skin resistance while immersed in water (e.g., a bathtub) is as little as 150 ohms.³

When exposed to high voltage, skin breaks down (chars and burns), which physically removes the external barrier and allows the current to have direct access to internal tissue. Likewise, the exit point of a current path undergoes skin breakdown, usually described as an “explosive” wound.

The surface area of contact, the duration of contact, and the pathway of current flow are critical in assessing the potential and magnitude for hidden internal injury. Sudden death from ventricular fibrillation is three times more likely when current flows from arm to arm than from arm to leg.

The destructive heat generated by electrical energy is inversely related to the cross-sectional area of the current path: The smaller the cross-sectional area, the greater the current density. This explains why tissue injury is much greater in fingers compared with arms, or in arms compared with the trunk, even though the same current may have traversed them for the same length of time.

AC is much more dangerous than DC. Tetanic muscle contractions are induced by the repeated stimulation of muscle fibers. Although all muscles will be affected, flexors tend to be stronger and predominate. This causes the “freezing” or “lock-on” phenomenon, which can prolong exposure and the severity of injury. AC is also much more likely to induce ventricular fibrillation and at lower energy levels than DC.⁴ The frequency of repetitive stimuli (60 cycles per second) greatly increases the likelihood of hitting the vulnerable ventricular recovery period, analogous to the well-known R-on-T phenomenon.

“Stun guns” are specialized electrical devices used by law-enforcement officials. The weapons shoot two to four electrode darts at a victim as far as 15 ft away. The darts are connected to the device by wires that deliver high-voltage (50,000 V), low-current (3 mA) pulse trains (about ten per second). These impulses induce tetanic muscular contractions and involuntary paralysis, effectively immobilizing the victim. Similar hand-held devices that utilize electrode prongs pressed directly against the skin and deliver lower voltage are also available. The overall morbidity and mortality from these devices is extremely low, especially when compared with the conventional ballistic handgun.^{8,12}

CLINICAL PRESENTATION

Victims of electrical injury may present with sudden death, cardiac dysrhythmias, external and internal tissue injuries, neurologic dysfunction, associated mechanical trauma, and various secondary complications.^{7,19} Sudden death is usually the result of ventricular fibrillation, asystole, or other fatal cardiac dysrhythmias. Sudden death may also result from direct insult to the brainstem, causing respiratory arrest.

Cardiac dysrhythmias and conduction disturbances are seen in as many as 25% of victims with electrical injury, especially patients who have had a transthoracic current pathway. These abnormalities include ventricular fibrillation, asystole, ventricular tachycardia, sinus tachycardia, atrial fibrillation, atrioventricular block, bundle-branch block, and various atrial and ventricular ectopic beats.¹⁴ Although nonspecific ST-T changes are common, true myocardial infarction is uncommon.^{2,4,5,13} This diagnosis is often confused by the fact that electrically injured skeletal muscle will produce significant elevation of CK-MB that is not of cardiac origin.¹⁴

The unpredictable course of electrical current through the body makes accurate, initial clinical assessment of internal injury extremely difficult. External signs are usually limited and deceptively minor. Entrance wounds are commonly found on the hands or upper extremities and demonstrate charring, depression, edema, and inflammatory changes. Exit wounds may be multiple and varied and may have an explosive appearance. They are commonly found at the point where the body is closest to the electrical ground (i.e., the feet) or where the loop of current flow is completed. In bathtub exposures, there may be no external burns or signs of electric current entry or exit.

Neurologic injuries are seen in some form in virtually all victims of electrical injury. Acute central nervous system manifestations include amnesia, altered mental status, irritability, depression, emotional lability, motor deficits, seizures, respiratory center depression, and coma.^{16,18} These acute changes are often transient, and excellent recovery may be seen. Peripheral nerve injuries are common and usually result from direct electrothermal injury along the path of current. Vascular injury and compartment syndrome may also contribute to peripheral nerve deficits.

Vascular and muscle damage can be extensive and severe. Coagulation necrosis and vascular thrombosis are responsible for the immediate and delayed devastation to these tissues. The net effect is an injury pattern more closely resembling a severe crush injury than a burn. Delayed rupture of injured blood vessels may be responsible for significant and catastrophic hemorrhage. Rhabdomyolysis and acute renal failure are potential complications. The mechanisms of renal insult include decreased renal perfusion from hypovolemia, along with the deposition of myoglobin and hemoglobin pigments released from massive muscle breakdown and hemolysis.¹⁰

A wide variety of skeletal fractures and dislocations may be seen from the effects of tetanic muscular contractions or from the fall often associated with an electrical injury. Long-bone fractures, shoulder dislocations, and spinal compression fractures are common.

Gastrointestinal (GI) manifestations include nausea, vomiting, abdominal pain, and ileus. Stress ulcerations (Curling ulcers) of the stomach and duodenum are common. Dysfunction of the liver, gallbladder, and pancreas is also possible. Direct electrothermal damage to viscera may produce organ necrosis or bowel perforation.

Local and systemic infections associated with burned and necrotic tissues are caused by various aerobic and anaerobic organisms, including *Staphylococcus*, *Pseudomonas*, and *Clostridium*. Overwhelming infections and sepsis are responsible for many deaths seen after initial successful resuscitation.

Electrical injury in pregnant women has been associated with fetal death and abortion. The amniotic fluid provides a rich electrolyte medium that will efficiently transmit electrical current to the fetus, creating a high risk of cardiac arrest and death.¹¹

DIFFERENTIAL DIAGNOSIS

It is important to understand and distinguish true conductive electrical injuries from burns associated with other electrothermal phenomena. Electrical flash burns result from the radiant heat produced by electrical arcs, with temperatures ranging from 3,000° to 20,000°C. These burns are usually localized to exposed surfaces and are treated in a manner similar to that for conventional thermal burns. True flame burns may also be seen as a result of ignition of clothing or other combustibles adjacent to the victim.

High-frequency electrical energy, such as that used for RF or microwave transmission, has relatively limited injury potential. RF current demonstrates the so-called skin effect, so that current flow is limited to the outermost surfaces of conductors. Accidental contact usually results in localized surface burns. True internal conductive injuries are seldom seen.

EMERGENCY DEPARTMENT EVALUATION

Victims of high-tension electrical injury should be evaluated like victims of multiple trauma. Initial assessment and stabilization of airway, breathing, circulation (the ABCs), and the cervical spine are immediate priorities. As soon as possible, supplemental oxygen, large-bore intravenous lines to initiate fluid resuscitation, and electrocardiographic (ECG) monitoring are established. A careful history is taken to determine the nature and potential severity of the electrical injury. This should include a determination of voltage, the type of current (AC or DC), the current pathway, and the duration of exposure.

Associated trauma (especially falls) must be considered as potential concurrent mechanisms of injury. A thorough, complete physical examination is mandatory to uncover potential multisystem injury. However, many important internal injuries may be missed in the emergency department evaluation. A paucity of external physical signs may belie the severity of hidden internal tissue damage.

Indications for radiographic studies are established by the history and physical examination. A 12-lead ECG should be obtained on all patients with a possible thoracic current pathway. Arterial blood gas, urinalysis, complete blood count, electrolytes, calcium, blood urea nitrogen, creatinine, cardiac enzymes, coagulation studies, and type and cross-match studies are appropriate for patients with high-voltage injuries (greater than 1,000 V). Patients with limb dysfunction or evidence of ischemia should have compartment pressure measurements, vascular assessment, and nerve function studies.

Clinical assessment of patients stunned by electrical weapons should focus on local wounding effects of the electrode darts and coexisting injuries or problems, including drug toxicity. Phencyclidine intoxication appears to be a common scenario in which this weapon may be used.¹²

EMERGENCY DEPARTMENT MANAGEMENT

Many deaths and injuries have occurred when first responders try to aid a victim of an electrical injury before the electrical hazard is safely controlled. Definitive measures to ensure safety must be taken before assistance is attempted.

Appropriate attention and priority should be given to the ABCs, including attention to and stabilization of the cervical spine. Standard advanced cardiac life-support and advanced trauma life-support protocols are used, as indicated. For victims with cardiopulmonary arrest, resuscitative measures should be maintained for extended periods, because ultimate recovery may be achieved in cases that initially appear refractory.

In patients with high-tension injuries, aggressive fluid resuscitation may be needed to treat hypovolemia and to prevent renal failure. Extensive internal tissue damage causes large intravascular fluid losses that greatly exceed the fluid replacement values usually calculated by formulas based on the percent of body surface area burned.¹⁰ Fluid requirements should instead be established to maintain brisk urine output and to prevent myoglobinuric renal failure. A urinary catheter is mandatory to monitor urine volume continuously and to detect myoglobin. Central venous or pulmonary artery pressure monitoring may be needed in patients with hemodynamic instability or those at risk for congestive heart failure. Intravenous mannitol and diuretics are appropriate adjuncts to enhance and maintain urine output. Sodium bicarbonate should be added to intravenous infusions to alkalinize the urine and prevent further myoglobin precipitation in the renal tubules. Serial monitoring of electrolytes, calcium, and arterial blood gases is necessary to detect and treat hyperkalemia, hypocalcemia, and acidosis caused by massive tissue necrosis or renal failure.

Nasogastric suction may be needed to decompress the GI tract and treat ileus. Tetanus prophylaxis must be ensured. The management of electrical surface burns is similar to that for thermal burns.

DISPOSITION

All patients with high-voltage (greater than 1,000 V) conductive injury require admission for observation and monitoring. Consultation regarding transfer to a burn center is advisable. Patients with dysrhythmias or ECG or cardiac enzyme evidence of myocardial injury should have 24 hours of continuous ECG monitoring and serial cardiac enzyme analysis.^{1,4} Admission to a telemetry unit may also be appropriate for patients with transthoracic electrical current exposure, loss of consciousness, significant burns, or other tissue damage. Myoglobinuria is another indication for hospitalization. An orthopedic or vascular surgeon should be consulted when compartment syndrome or neurovascular compromise of extremities is suspected. Children with burns to the lips or the oral cavity should have a plastic surgery consultation, no matter how benign the initial injuries appear.

Patients with low-voltage surface injuries may be discharged after appropriate evaluation, observation, and management in the emergency department. When in doubt, admission is advisable.

COMMON PITFALLS

- Failure to consider and control ongoing electrical hazards in the field, resulting in rescuer injury
- Failure to appreciate that there may be a paucity of external physical signs in patients with severe internal tissue damage
- Failure to perform cardiac monitoring and to obtain an ECG to detect dysrhythmias in patients with suspected transthoracic current pathway exposures
- Failure to provide aggressive fluid resuscitation to maintain circulatory volume and to evaluate for and treat myoglobinuria in patients with high-voltage injuries

- Failure to evaluate for compartment syndrome and neurovascular compromise in injured extremities
- Failure to appreciate that children with burns to lips from electrical appliance cords must have plastic surgical consultation to minimize scarring

CHAPTER 394

Lightning Injuries

David F. M. Brown

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Lightning injuries are the leading cause of deaths due to environmental phenomena in the United States.⁵ Although there is no central agency to collect data, estimates suggest that lightning is responsible for 75 to 300 deaths per year and up to 1,500 nonfatal injuries.^{2,4,6,8,11,12} The most common victims are people who work or perform recreational activities outside, particularly campers, joggers, farm and construction workers, golfers, and hunters.⁴ Indoor victims are likely to be using the telephone or other household appliances.⁴ The incidence of lightning injuries parallels the frequency of lightning storms; hence, most injuries occur during the summer months.^{4,5} Geographically, common areas include the Atlantic seaboard, the Southeast and Southwest, major mountain ranges, and river tidal basins.^{1,4,9,19} The case fatality rate is between 25% and 32%, and about 74% of survivors suffer permanent sequelae.⁷

Lightning is produced after warm, moist air rises within a cold high-pressure front, allowing condensation into a cloud. Air currents, ice particles, and water droplets within the cloud create a layering of ionic charges: The uppermost regions have a net positive charge, the lower regions a net negative charge.⁷ The ground beneath the cloud becomes relatively positively charged, creating a potential difference. Electrical breakdown between positively and negatively charged areas of the atmosphere causes advancement of ionic charges in a downward-branching “stepped leader” or “leader stroke” pattern propagated at one-two thousandth the speed of light. This causes a path of air to become ionized to a plasma of positive and negative ions that is a better conductor than nonionized air. As the stepped leader pattern of ion propagation nears the ground, a “pilot stroke” or “return stroke” ascends from the ground at about one-tenth the speed of light, completing a channel of ionic movement between the cloud and the ground.⁷

Because the stepped leader, which is luminous secondary to the large quantity of ionic movement, is relatively slower than the return stroke, lightning is perceived as traveling from cloud to earth. However, the main electrical discharge is usually from earth to cloud, and it appears as an instantaneous brightening of the ionized pathway (the visible lightning flash) lasting about 0.2 seconds. In rapid succession, multiple secondary leader and return strokes (between three and 40) then typically occur until the ionic potential between cloud and ground is eliminated.⁷

Thunder results from the rapid expansion of warmed air and its subsequent contraction and implosion. Practically, although not technically, lightning behaves as direct current, with an energy level of 2,000 to 2 billion V and 2,000 to 300,000 A.^{3,11} This energy is much higher than conventional electricity; however, the distinctly short duration of lightning contact (0.1 to 1.0 milliseconds) usually prohibits cutaneous penetration and commensurate deep-tissue injury.⁵ Except for direct strikes, most of the lightning current “flashes over” the outside of the victim; only occasionally does enough current leak internally to interfere with cardiac automaticity, respiratory center function, and autonomic stability.¹⁰

There are several major mechanisms of lightning injury. A direct strike occurs when the major pathway of current runs directly through the victim; this results in the highest morbidity and mortality.¹⁰ When the lightning current strikes an object in contact with the victim, the injury mechanism approximates a direct strike. With side flash, current splashes or sprays from an object through the air to the victim. Ground current, also known as step voltage or ground potential, occurs when lightning strikes the ground and spreads to involve the victim. The severity of injury due to ground current is inversely proportional to the distance from the ground strike.⁷ If ground resistance is greater than the victim's resistance, current may enter one leg and exit through the other, perhaps accounting for the higher mortality in victims exhibiting leg burns.⁷ Ground current and side-flash mechanisms often produce multiple casualties.

Associated trauma may result from myotonic extremity or neck contractions, acceleration–deceleration injuries as the victim is thrown, penetrating and blunt injuries from debris, and thermal burns exacerbated by metal jewelry or clothing fasteners or caused by ignition of clothing.

CLINICAL PRESENTATION

Because of the short duration of lightning exposure, current usually passes over the outside of the body (“flashover” phenomenon), commonly producing superficial or partial-thickness burns in a characteristic linear or arborescent pattern.^{1,2,11,18,19} Entry and exit burns and deep internal burns with resultant rhabdomyolysis and myoglobinuria are rare.^{3,8,16,19,20}

The most common cause of death in the lightning victim is cardiopulmonary arrest.^{7,8} and ^{9,13} Internal propagation of the lightning electrical potential acts as a massive direct current countershock, which depolarizes the entire myocardium and causes cardiac asystole.^{7,8,11,12} and ¹³ Due to cardiac automaticity, an organized electrical rhythm may occur, restoring spontaneous circulation.⁸ However, primary respiratory arrest due to lightning-induced paralysis of the medullary center may occur concomitantly and can outlast cardiac arrest.^{3,4,8,10,11} The critical factor in determining mortality appears to be the duration of apnea (which may also occur independently) rather than the duration of asystole.¹⁸ Without prompt and prolonged ventilatory support, any return of cardiac rhythm and circulation will rapidly deteriorate to hypoxia-induced ventricular fibrillation.^{3,7,8,19} Survivors of lightning exposure can exhibit a variety of cardiac abnormalities, with dysrhythmias and ST-T wave changes frequently reported.^{8,13,15} Acute life-threatening (and often reversible) left ventricular dysfunction or pericardial tamponade, as demonstrated by echocardiography, appears to be limited to victims of direct strikes.¹⁵

Myriad neurologic effects of lightning injury are frequently encountered. Usually, the victim falls unconscious immediately.¹⁷ In the absence of cardiopulmonary arrest, consciousness eventually returns, occasionally after a prolonged period. The next most common finding is paraplegia, occurring in up to two-thirds of seriously injured patients.^{8,17} Hemiparesis, hemiplegia, localizing sensory deficits, and autonomic dysfunction may also be found.¹⁷

Virtually all lightning-struck patients have altered mental status and anterograde amnesia; retrograde amnesia is common as well.^{7,17} When current passes through the brain, intraventricular hemorrhage, epidural and subdural hematomas, coagulation of brain parenchyma, and thrombosis of vessels can occur.^{7,17} Associated trauma may cause cervical spine fracture with resultant spinal cord injury.

The extremities may initially appear cold, mottled, pulseless, and insensitive secondary to vascular spasm and autonomic instability.^{5,7,8,11,18,19} Normal function usually returns.

Half the patients with lightning injuries have structural eye lesions.⁴ Cataracts are common and may develop in a few days or up to several years after the injury.^{3,19} Corneal lesions are also common; hyphema, iritis, vitreous hemorrhage, retinal detachment, and optic nerve injury are occasionally seen.⁵ Unreactive, dilated pupil(s) due to transient autonomic instability may occur and should not be mistaken for a sign of brain death.^{5,7,17}

Tympanic membrane rupture, the most common otologic injury, occurs in 50% of victims of lightning injury and is thought to be due to the shock wave of expanding hot air (thunder) during the strike.^{7,17} Less common findings are hemotympanum, basilar skull fracture, and various acoustic and vestibular sensorineural deficits.¹⁷

DIFFERENTIAL DIAGNOSIS

Lightning injuries have been mistakenly diagnosed as a variety of disorders. Neurologic disease processes that can mimic lightning injury include cerebrovascular accidents, seizure disorders, and craniocerebral, spinal cord, or other neurologic trauma.⁸ Cardiovascular disorders in the differential diagnosis of lightning injury

include myocardial infarction, Stokes-Adams attacks, and cardiac dysrhythmias.⁸ Also in the differential are toxic ingestions, envenomations, and physical assault. Cutaneous injuries may be misdiagnosed as electrical burns.

As in most clinical situations, the history is crucial to making the correct diagnosis. Obtaining information from bystanders is essential when the victim is incapacitated. Important points include a history of thunderstorm and outdoor occurrence of the accident. Physical findings that favor a diagnosis of lightning injury include partial or complete clothing disintegration and superficial linear, punctate, or arborescent burns. Tympanic membrane rupture is also highly suggestive.

EMERGENCY DEPARTMENT EVALUATION

The history should include the time, circumstances, and a description of events at the scene of injury. Any prehospital interventions, and their times, should be documented. Present complaints and medical history prior to presentation should also be noted.

The physical examination should focus initially on vital signs; assessment of the airway, breathing, and circulation; and evaluation for trauma and neurologic dysfunction. Serial neurovascular examinations should be performed in patients with signs of peripheral vascular insufficiency. All patients should have cardiac monitoring, an electrocardiogram (ECG), and oxygen saturation measurement. Laboratory evaluation should include a complete blood count and measurements of serum electrolytes, blood urea nitrogen, creatinine, glucose, and creatine phosphokinase. Urine should be tested for myoglobin. Patients with cardiac dysrhythmias or ischemia, respiratory arrest, or loss of consciousness should have a chest radiograph and cardiac enzyme analysis. Patients with altered mental status or neurologic deficits should also have cervical spine radiographs and a cranial computed tomography scan. Other radiographs and tests should be obtained as indicated by complaints or physical findings.

EMERGENCY DEPARTMENT MANAGEMENT

Lightning injuries may place prehospital paramedics in precarious environmental settings. Although acute medical intervention is paramount to reduce mortality,^{3,7,11} care should be taken to prevent further injury to the patient and harm to rescuers. Treatment begins with assessment and stabilization of the airway, ventilation, and circulation. Victims should be treated as trauma patients, with special attention given to cervical spine immobilization.⁵ Triage priorities, in a reversal of the usual dictum, should focus initially on victims in cardiopulmonary arrest.^{1,3,5,7,9,11,13,14} This is because virtually all victims of lightning strike who do not suffer cardiac or respiratory arrest survive.⁷ Standard advanced life-support (ACLS and ATLS) protocols should be followed. Aggressive, persistent resuscitative efforts are indicated for all victims, especially those with spontaneous cardiac rhythms and prolonged apnea or coma.^{1,5,11} Ventilatory support may be required for several hours, but even in these cases, there is potential for full recovery.^{3,11} Full support should be continued until cerebral function can be assessed.¹

All patients should initially be given supplemental oxygen, have intravenous access established, and be placed on a cardiac monitor. Intravenous fluids should be minimized to reduce any risk of cerebral edema unless hemorrhage, hypotension, or dehydration is evident or rhabdomyolysis is a concern (e.g., with deep or extensive burns or associated crush injury). Rhabdomyolysis, as indicated by myoglobinuria and elevated serum muscle enzyme levels, may necessitate fluid loading, osmotic diuresis, and urine alkalinization.²⁰ Standard burn and wound care, as well as tetanus prophylaxis, should be given, if appropriate. Patients with cardiac or neurologic abnormalities should have serial ECGs and cardiac enzyme analyses as well as routine supportive care. All patients require comprehensive and repeated physical and neurologic examinations.

DISPOSITION

Patients with cardiac or neurologic abnormalities require admission for at least 24 to 36 hours of observation and continuous cardiac monitoring. Those with associated trauma, burns, or rhabdomyolysis also may require admission for their injuries.^{1,3,13} Patients who have sustained cardiac or respiratory arrest should be admitted to an intensive care unit.

The decision to transfer a patient to another facility depends on the severity of injury and the ability of local resources to provide adequate care. If the necessary services are unavailable, the decision and the timing of transfer should be coordinated with the receiving physician at the nearest appropriate hospital. Emergency personnel with advanced life-support capability should accompany the patient.

COMMON PITFALLS

- Failure to appreciate the difference between lightning and high-voltage injuries
- Failure to give the highest priority to patients in cardiac or respiratory arrest when making triage decisions in mass casualty incidents involving lightning injury
- Misdiagnosing lightning injury as an isolated cutaneous burn or a primary neurologic or cardiovascular event
- Failure to evaluate lightning-stricken patients for associated traumatic injuries
- Misinterpreting unreactive, dilated pupils as a sign of death in patients struck by lightning
- Failure to make a prolonged effort to resuscitate patients found pulseless or apneic after a lightning strike
- Failure to appreciate the high incidence of permanent neurologic sequelae from lightning injury and to admit patients with neurologic complaints or deficits for observation

CHAPTER 395

Radiation Accidents

Irvin N. Heifetz

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency department evaluation And Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Accidental exposures to radioactive substances may occur in various settings, such as medical diagnosis and treatment, scientific research, electricity generation, military programs, and transportation of materials. Facilities using radioactive material usually have in-house experts knowledgeable about their particular products. Truckers, who yearly transport several hundred thousand shipments of radioisotopes, must carry papers specifying the exact nature of their cargo, and freight containers must be plainly labeled. Industries use the radionuclides ^{60}Co , ^{137}Cs , ^{192}Ir , and uranium isotopes. Hospitals use ^{131}I , $^{99\text{m}}\text{Tc}$, ^{67}Ga , ^{32}P , ^{133}Xe , ^{201}Tl , and ^{60}Co in various diagnostic and therapeutic modalities. Certain laboratories use ^3H , ^{14}C , ^{125}I , ^{60}Co , and ^{238}U . Many radionuclides can be found at nuclear power plants, including ^3H , ^{131}I , ^{137}Cs , ^{60}Co , ^{90}Sr , ^{144}Ce , and ^{238}Pu .

Radiation accidents are relatively rare. Since the start of the nuclear age (1944), 403 events have been reported worldwide. ¹⁶ Of the 133,617 exposed individuals, nearly 90% were victims of the accident at the Chernobyl nuclear reactor in the Ukraine in 1986. The worldwide number of persons known to have been exposed to significant levels of radiation is 2,965, nearly 75% of whom were outside of the United States. A *significant* exposure is defined by the Radiation Emergency Assistance Center/Training Site Registry as either a whole-body dose of 25 rem, a skin dose of 600 rem, or an absorbed dose of 75 rem to other tissues. Acute fatalities from such exposures have numbered 120. Twenty-nine of these occurred at Chernobyl when an incredible succession of five violations of proper operating procedure during a scheduled test at that plant resulted in two steam explosions. Radiation injuries and illness necessitated prompt hospitalization of 115 people. In addition to those who died (20 of whom had received exposures between 600 and 1,600 rem), 56 persons suffered severe skin burns.

Most accidents occur in the industrial setting, where radioactive materials are used for making precise measurements, such as the thickness of rolled products and coatings, density and concentration in liquids, moisture content, flow patterns, and degree of wear. In industrial radiography, a sealed radioactive source is used to detect metallurgic defects. Accidental exposures occur when the seal ruptures or, more commonly, when operators carelessly direct the source toward themselves or their coworkers. Most injuries are burns, usually of the hands. Although nuclear medicine laboratories (diagnostic and assay) constitute the largest number of facilities using radioactive materials, the low levels of activity and the short half-lives of the isotopes used make serious accidents unlikely. Inappropriate fear of the effects of radiation could be alleviated by improving public education on the subject. This would have a salutary influence on rational responses to these rare accidents. ¹⁰

Radiation consists of the transfer of energy from a generating source to an absorbing body via space or another medium. Nonionizing radiation, which makes up most of the electromagnetic spectrum (e.g., radio waves, microwaves, visible light), is of low frequency, long wavelength, and low linear energy transfer. Although relatively harmless, it can cause thermal damage in exposed tissues, and skin cancer may result from excessive exposure to ultraviolet waves.

Two types of widely encountered nonionizing radiation, lasers and microwaves, warrant brief discussion. Despite common use of lasers in industry (especially manufacturing and telecommunications) and medicine (diagnostic instrumentation and surgical procedures), injuries are rare. Similarly, although millions of people use microwave ovens daily, few cases of harmful effects from these sources have been documented. Prolonged direct contact of the skin with a leaking oven seal can cause a thermal burn, and ovens have occasionally been implicated in cardiac pacemaker malfunctions. The damage to human tissue from lasers is similar to that caused by an electrical burn. High-output microwave sources (industrial or medical, not domestic) may cause asymptomatic testicular damage, which could result in effects on sperm several weeks after exposure. Injuries from microwaves and lasers can be prevented by carefully adhering to manufacturers' safety guidelines.

Ionizing radiation—subsequently referred to simply as *radiation*—is emitted during the decay of unstable isotopes or radionuclides (naturally occurring or manufactured). A more stable atomic configuration results from the discharge of accelerated subatomic particles and electromagnetic waves. When the particles or waves strike another atom, displacement of an electron may cause the absorbing atom to become ionized. Tissue damage occurs when DNA and other macromolecules become ionized directly or by highly reactive free radicals of water. The amount of subcellular damage may be small enough to be readily repaired (as are most spontaneous chromosomal defects) or may lead to the death or dysfunction of the cells. Clinically observable effects will not appear for hours to years, except in the rarest case of a supralethal exposure. Destruction of dividing cells will produce signs and symptoms at a time proportional to the usual cell turnover rate in the particular tissue. Thus, effects on bone marrow, gut, and skin are seen early, but carcinogenesis appears much later.

The rate at which radionuclide disintegrations (i.e., formation of ion pairs by displacement of an orbital electron) occur is called its *activity*. One disintegration per second is called a *becquerel* (Bq). Activity was formerly measured in curies (Ci), the amount of energy emanating from 1 g of radium-226 (one Ci = 3.7×10^{10} Bq). A radionuclide with a short half-life contains more curies per unit mass than does one with a long half-life. The *roentgen* (R), which measures ionizations in air, was originally defined as the quantity of radiation producing one electrostatic unit of electrical charge in air (1.6×10^{12} ionizations). The roentgen does not readily measure all types of ionizing radiation and does not accurately reflect the radiation dose in tissue. In contrast, the *rad* (radiation absorbed dose) refers to the quantity of energy imparted to a mass of matter: one rad equals 100 ergs/g. The rad has been replaced by the *gray* (Gy) in the new *Système Internationale* (SI) nomenclature. One rad equals 0.01 Gy or one centigray (cGy), and one Gy equals 1 J/kg.

The number of ionizations per distance traveled by an ionizing particle or wave is directly proportional to the mass and charge of a particle and inversely proportional to the speed of the particle or wave. This linear energy transfer determines the relative biologic effectiveness of the source. The quality factor (QF) times the number of rad is the number of *rems* (radiation equivalents in humans or mammals). The SI unit is a *sievert* (Sv): 1 rem equals 0.01 Sv (cSv). The effective dose equivalent is derived by factoring in the relative sensitivities of various tissue and organs (0.25 for the gonads, 0.12 for bone marrow, and 0.03 for the thyroid).

Alpha and beta particles, gamma and x-rays, and neutrons all cause ionization in exposed tissue. Most commonly involved in radiation accidents are gamma rays and beta particles. Alpha particles, which may be thought of as helium nuclei (two protons bound to two neutrons), are relatively heavy (four atomic mass units) and highly charged (2^+). They have very poor penetration (about 50 μ) and are blocked by the keratin layer of skin. They do, however, produce very dense ionizations (30,000 to 100,000 ion pairs/cm³ of air).⁷ Their high linear energy transfer and relative biologic effectiveness are reflected in a QF of 20, and they are hazardous in wounds or if ingested or inhaled.¹⁴ Common sources are ^{239}Pu , ^{226}Ra , ^{212}Po , and radon and isotopes of uranium.

Beta particles are fast-moving electrons with small mass (about one-two hundredth atomic mass unit) and a negative charge. They produce no more than 200 ion pairs/cm³ of air and have a QF of 1. They can penetrate several millimeters through the skin, causing serious burns, and also create significant damage when emitted internally. ^{90}Sr , ^{137}Cs , ^{131}I , ^3H , and ^{32}P emit beta particles.

Gamma rays and x-rays are essentially the same. The former come from reactions within the nucleus, and the latter from orbital interactions. Neither has any mass or charge. They both are deeply penetrating and have QFs of 1. Because x-rays are produced when a heavy-metal target (such as tungsten) is bombarded with accelerated electrons, their energy is determined by the amount of voltage applied to the accelerator vacuum tube. Diagnostic x-ray machines use up to 150 kilovolts (kV), and x-ray therapy devices up to 300 kV at peak (kVp). ^{192}Ir , $^{99\text{m}}\text{Tc}$, ^{137}Cs , ^{131}I , ^{226}Ra , and uranium isotopes are the usual sources of gamma radiation. If these radionuclides are internalized, any alpha or beta activity will predominate over the gamma effects.

Neutrons have an atomic mass weight of 1 but are electrically neutral. They have a wide range of energies, but most are extremely penetrating, and their QFs have been estimated from less than 2 for acute effects to 20 for late effects.⁷ Free neutrons are found at nuclear power plants, particle accelerators, and weapons assembly sites.

Appreciation of the magnitude of any acute exposure to ionizing radiation is possible only by comparing it with background radiation. The estimated average annual dose of whole-body radiation to people in the United States is 200 to 250 millirems (mrem), 50% to 80% of which is from natural sources. The dose from cosmic sources (average, 28 mrem; maximum, 130 mrem) varies with elevation above sea level. The terrestrial dose (average, 26 mrem; maximum, 115 mrem) varies with the

amounts of radium, thorium, and uranium in the earth's crust at any given site.^{2c} Most of the manufactured dose is from medical diagnostic sources (78 mrem) and radiopharmaceuticals (14 mrem). Radioactive fallout and nuclear power plants contribute 4.0 mrem and 0.2 mrem, respectively.

In comparison, the radiation dose to the skin is 21 mrem for a posteroanterior chest radiograph and 682 mrem for an anteroposterior thoracic spine film. The bone marrow dose from a chest radiograph is 5 mrem; an abdominal computed tomography scan yields a dose of 500 mrem to marrow.¹ People closest to the Three Mile Island plant got an average dose of 73 mrem following the accident there. At Chernobyl, emergency personnel at the site received less than a few hundred rem, and people living within 30 km got no more than 1.5 to 20.0 rem.⁶

CLINICAL PRESENTATION

Most accidents involve local exposure of a small part of the body of one person or a few people. The skin is the organ commonly affected.¹² At doses of 300 to 600 rem, epilation and erythema are noted. Dry desquamation occurs at about 1,000 rem, and wet desquamation at about 2,000 rem. Burns from ionizing radiation often take longer (up to 2 weeks) to become clinically apparent than do thermal burns. The time to onset varies inversely with the amount of exposure. Local exposure to 1,200 rad may cause erythema, which peaks in 24 hours and fades in a few days. Above 2,000 rad, denudation, ulceration, and depletion of hair follicles and sweat glands may occur. Total body exposure to gamma rays at a dose approaching 600 rad may cause erythema in less than 24 hours. Although the initial erythema caused by ionizing radiation is painless, third-degree radiation burns are very painful, because nerve receptors generally are not damaged as they are in thermal injuries.

Whole-body exposure to more than 100 to 200 rad in a single dose may produce acute radiation syndrome (ARS).⁵ There is a very rough correlation between the nature and severity of signs and symptoms and the dose received. With optimal treatment, the LD₅₀ (dose causing death in 50% of exposed persons) at 60 days is about 450 rad; the LD₉₀ is about 700 rad.³ Classically, ARS begins with a prodromal stage characterized by nausea, vomiting, and, sometimes, diarrhea. The acuity of symptoms suggests the size of the dose: less than 2 hours, more than 400 rad; more than 2 hours, less than 200 rad; more than 6 hours, less than 50 rad. These symptoms last from a few hours to 2 days. At doses of 100 to 600 rad, a latent period of 2 to 3 weeks ensues, followed by a hematopoietic syndrome in which the rapidly dividing cells in the bone marrow are injured. The panmyelosuppressive effects seen are indistinguishable from those caused by other marrow-toxic agents. Bleeding occurs in the skin and gastrointestinal (GI) and genitourinary tracts as a result of thrombocytopenia. Destruction of granulocyte precursors renders the patient susceptible to infection. If death does not occur within 3 to 6 weeks after exposure, this syndrome resolves slowly.

In addition to the problems described, patients exposed to doses of 600 to 2,000 rad also experience a GI syndrome. Denudation of the proliferating cells of the bowel mucosal epithelium causes symptoms of greatly increased nausea, vomiting, and diarrhea. Enormous losses of fluid and plasma proteins, extreme disturbances of electrolyte balance, and enteric organism sepsis also supervene. Death of 80% to 100% of these patients can be expected within a week or so but may be delayed beyond a month.

When whole-body doses exceed 2,000 rad, minutes or hours after exposure, patients uniformly are subject to unparalleled nausea, vomiting, and diarrhea, and then tremor, ataxia, seizures, prostration, and shock. Death from this neurovascular syndrome usually occurs within 2 days; it may be immediate with 3,000 to 5,000 rad of exposure. To assist in teaching about the rare affliction that is ARS, an Internet-accessible database of case histories has been established using the framework of the World Health Organization Radiation Medical Emergency Preparedness and Assistance Network Centers.⁹

The late effects of radiation relate primarily to carcinogenesis (especially leukemia) and mutagenesis, although instances of genetic abnormalities have never been clearly documented in human studies.¹ The degree of risk is uncertain; the data are discrepant.

DIFFERENTIAL DIAGNOSIS

It is almost always clear from the history that exposure to an ionizing source has occurred. Infrequently, a patient may present with nausea and vomiting, swollen parotid glands, conjunctivitis, skin ulcerations or burns, or bone marrow depression without a readily elucidated etiology. In these instances, inquiring about possible radiation exposure would be prudent.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Because of the extreme rarity and potential calamity of an unexpected exposure, a formal plan to deal with such an event must be in place and must be well known and rehearsed.^{11,15,17} The JCAHO requires every hospital to include such a plan in its policy and procedure manual. Prudence also dictates that every regional emergency management system include radiation accidents in its disaster management protocol.^{18,19}

When notified that a radiation accident may have occurred in which many people were exposed to high levels of radiation, the physician should invoke the hospital and regional plans, following them as closely as the circumstances of the particular incident allow. The hospital's radiation safety officer, as well as the one employed at the site of the accident (or at the company whose truck has crashed, for instance), must be contacted immediately. Police and fire authorities and a public relations official should be called. The physician should communicate with the scene while the area designated in the hospital to receive patients is prepared.

It must be determined exactly what sort of accident has happened: an exposure to external radiation, contamination by radioactive matter, or possible incorporation of ionizing substances via open wounds or the GI or respiratory tracts. A history of trauma or other toxic exposures and the nature, severity, and time of onset of any symptoms should be elicited. The duration of exposure (partial or whole-body), the nature of and distance from the source, and shielding and dosimeters used, if any, all constitute important data.¹³

At the scene, rescuers should remove the patient's clothes unless he or she is in extremis; this will eliminate 80% to 90% of surface contamination and will avoid further exposure of the patient, rescuers, other caregivers, and the environment.⁴ The clothes should be quickly and carefully packaged, prominently labeled, and left at the site. Before removing the clothes, any open wounds should be covered to avoid exposing mucosal surfaces and capillary beds, which would promote absorption and incorporation. Caregivers should protect themselves against contamination by wearing gowns, gloves, masks, and shoe coverings. Patients who have been irradiated only do not become contaminated, radioactive, or dangerous to others. If the patient is stable and facilities are readily available, a very quick rinsing of obviously contaminated exposed skin may be done at this time. Any clothes and water used should be appropriately sequestered. The patient then should be totally wrapped in blankets and transported to the nearest designated hospital.

At the hospital, the victim and rescuer should remain in the ambulance until directed to the special treatment area. Ideally, this should be adjacent to the emergency department but should have a separate entrance. In hospitals without such an area, the autopsy room may suffice because it is usually distant from other patient-care areas, has drainage tables for easy collection of effluent, and often has a separate ventilation system. If the emergency department itself must be used, any noncritical patients and nonessential personnel should be directed away before radiation victims enter. The room to be used, as well as the route from the ambulance dock, should be cordoned off and labeled "Danger: Radiation." The radiation safety officer or designee should monitor with a Geiger-Müller counter all patients and personnel entering or exiting the isolated room. If possible, a buffer zone also should be established, to provide both an extra margin of separation and an area through which necessary equipment and supplies may be transferred to the treatment room.

Before any patients arrive, all pathways and floors should be smoothly covered with paper, sheets, or, optimally, ribbed plastic (waterproof and nonslippery) to help minimize environmental contamination. All switches and handles should be covered with tape. Unless the room has a separate ventilation system, the system should be shut off. The area should contain all equipment and supplies common in a room used to treat acutely ill patients, as well as extra scrub suits, gowns, gloves, plastic aprons, and shoe coverings. Large plastic bags for clothes, containers for specimens, and steel barrels for contaminated water and other items also are needed.

Also required are survey meters capable of detecting both high-range (up to 500 rem/h) and low-range (up to 20 rem/h) exposures and also common (gamma and beta) or uncommon (alpha and neutron) sources. To ensure that they are in good working condition, and to obtain instruction in their proper use, these are best acquired from the radiology department or laboratories where they are frequently used. Personnel dosimeters should also be gathered from throughout the hospital for emergency use. The best are those that provide a constant readout. They should be attached to the collars of all personnel treating the accident victims. Team members should be relieved when their badges read 5 rem, although doses up to 25 rem may be permitted under unusual circumstances, and even 75 rem in a

lifesaving effort.

If the patient's clothes were not removed at the accident scene, this should be done in the ambulance. Critical patients should be brought into the treatment room immediately. Advanced life-support measures are provided as needed. All patients are surveyed with a Geiger-Müller counter for contamination; findings should be recorded on anatomic charts. Cotton swabs should be used to sample and save contamination from the nose, ears, and mouth. Contaminated open wounds must be copiously irrigated with saline, resurveyed, irrigated with 3% hydrogen peroxide if contamination remains, and then debrided, if necessary, to prevent incorporation of radionuclides.

Once wounds have been cared for and covered with plastic, external decontamination should proceed from the area with the most debris to the area with least. Uncontaminated areas should be covered and taped. Using tepid water and mild soap or nonionic detergent, very gentle scrubbing should be done for 3 minutes with the patient lying either on a special decontamination table (similar to an autopsy table) or on a makeshift plastic trough placed on a stretcher in slight reverse Trendelenburg. Scanning for radioactivity and repeating this procedure as long as counts are decreasing should be done. Half-strength household bleach (5% sodium hypochlorite) may be used in later washes. Gentle brushing under nails and clipping of hair (not shaving, which might leave small open wounds) may be required. All fluids should be collected.

Less than 2 hours is available for possibly effective prevention of incorporation after ingestion or inhalation. Treatment of ingestions should begin with gastric lavage; whole-bowel irrigation, using a prep solution (e.g., GoLYTELY, Colyte) at 0.5 to 2.0 L/h until the rectal effluent is clear, may be beneficial. Activated charcoal is also recommended. Washings should be saved, surveyed, and disposed of by the radiation safety officer. Bronchoalveolar lavage may be helpful if radioactive dust has been inhaled, as confirmed by stained or radioactive sputum. Other methods to reduce absorption include administering Prussian blue for thallium, cesium, or rubidium, and barium sulfate or aluminum-based antacids for radium or strontium.

Isotopic dilution (competition) may be used to prevent incorporation of radionuclides that have already been absorbed. Potassium iodide (approximately 2 mg/kg) should be given orally if the thyroid dose from ^{131}I or other radioiodine exceeds 50 rad.^{2,8} If given within 1 hour of exposure, potassium iodide blocks 90% of ^{131}I uptake but only 50% at 5 hours, and little at 12 hours. To prevent recycling of radioiodine, this treatment must continue for up to 2 weeks.

Stable strontium, calcium, phosphate, zinc, and iron can be used to compete with their radioactive counterparts. Water diuresis can increase the turnover of tritium, and diuresis can also hasten the removal of radioactive sodium and potassium. Chelating agents, in standard doses, may be helpful—deferoxamine for plutonium and iron, penicillamine for cobalt and copper, and dimercaprol for mercury, arsenic, bismuth, chromium, nickel, and lead. Available only from the Department of Energy, calcium or zinc DTPA may help remove plutonium and americium as well as other transuranic and rare-earth elements. Experts should be consulted for advice (discussion follows).

All patients should have a baseline complete blood count, absolute lymphocyte count, and platelet count. These should be repeated serially for 3 days. Additional blood should be drawn and saved for chromosomal analysis of peripheral lymphocytes. Some authorities recommend taking cultures of the throat, sputum, wounds, blood, and urine so that appropriate antibiotics can be started early in a patient who may become immunosuppressed.

The prognosis of radiation injury victims is directly related to the dose received. In addition to early clinical signs, the best indicator is the total lymphocyte count after 48 hours. Counts above 1,200/ μL indicate a good prognosis; below 300, poor. The degree of chromosomal abnormalities (e.g., dicentrics and glycoporphin A locus analysis) also correlates well with prognosis.³

The Radiation Emergency Assistance Center/Training Site at Oak Ridge, Tennessee, also should be contacted for anything more than very-low-dose external irradiation to a few persons. The people there are expert in all aspects of radiation injury and treatment and are available for emergencies 24 hours a day at (423)481-1000.

DISPOSITION

Any patient judged to have been exposed to more than 100 rad should be hospitalized. Depending on the severity of illness, consultation with specialists in infectious disease, gastroenterology, hematology, pulmonary medicine, and marrow transplantation may be appropriate. Reverse isolation also may be required. If these services are unavailable in the hospital where initial treatment is given, the patient should be transferred to the closest facility so equipped.

COMMON PITFALLS

- Failure to have a plan in place for the management of radiation victims
- Failure to review and rehearse the plan with key personnel at least annually
- Failure to appreciate that there are different types of radiation and to determine which one was involved in an exposure
- Failure to have decontamination and protective equipment available
- Failure to attend to associated injuries (e.g., burns, blasts) or exposures (e.g., nonradioactive toxins)
- Letting unrealistic fear prevent the care of patients or colleagues

CHAPTER 396

Smoke Inhalation

Christopher H. Linden

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Smoke inhalation is airway or pulmonary parenchymal injury resulting from inhalation of toxic combustion products. Although the mortality from smoke inhalation in fire victims without surface burns is only 10%, this injury accounts for up to 84% of all fire-associated deaths.^{3,5,9,18} Due to advances in the treatment of shock, sepsis, and skin wounds, smoke inhalation is now the major cause of death in patients with surface burns. Most smoke inhalation fatalities are associated with residential fires.¹⁴ Many victims are clearly dead at the scene and do not enter the health-care system. Those who lack the ability to take independent escape action, such as the very young, the elderly, those with disabilities, and those impaired by alcohol or other drugs, are at greatest risk. A functioning smoke detector lowers the risk of death from smoke inhalation.

Smoke is a visible mixture of gases, vapors, fumes, liquid droplets, and solid carbon particles (dust) evolved during the combustion (the thermal degradation under conditions of high oxygen concentration) or pyrolysis (thermal degradation in an oxygen-poor environment) of organic material. Fire (a luminous gas) is not necessary for the production of smoke. In addition to fire and smoke, toxic combustion or pyrolysis products (TCPs) may include heat, invisible gases, and oxygen deprivation. Hence, pulmonary and systemic toxicity due to the smoke inhalation may occur in the absence of visible warning.

The composition of TCPs depends on the oxygen supply, rate of heating, absolute temperature, and material burned.^{6,7,12} Although fire toxicology research has identified TCPs for some materials under some conditions ([Table 396.1](#)), in actual fires, many different and often unknown materials are burned under a variety of coexisting conditions, resulting in the evolution of hundreds or thousands of different TCPs. Hence, the exact nature of TCPs in a given situation is impossible to predict, but a few generalizations can be made. Heat, carbon monoxide, carbon dioxide, dust, and oxygen deprivation are almost universally present. Fires involving plastics (e.g., acrylics, celluloids, polystyrene, polyurethane, polyvinyl chloride) burn faster and produce far more heat and smoke than those involving wood, paper, and most natural materials. Smoldering, enclosed-space fires have higher concentrations of TCPs than open, flaming ones.

Product of Combustion	Common Sources
Aldehydes	Cellulose acetate films, cotton, paper, polystyrene, polyvinyl acetate, wood
Acrolein	Acrylic carpets, acrylic, celluloid, cellulose, polyolefins
Ammonia	Nylon, nylon urethane, phenolics, urea, wood
Carbon monoxide/nitric oxide	All organic material
Chlorine/hydrochloric acid/hydrogen cyanide	Chlorinated acrylics and hydrocarbons (fire extinguishers and retardants)
Cyanide/hydrogen cyanide	Acrylonitrile, nylon, paper, polyurethane, nitrocellulose (films, resins, silk, wool)
Halogen acids and gases (HCl, HF)	Halogenated hydrocarbons, films, resins, flame retardants and extinguishers
Isocyanates	Polyurethane
Nitrogen oxides	Celluloid, cellulose nitrate fabrics, paper, petroleum products, wood
Styrene	Polystyrene
Sulfur oxides/hydrogen sulfide	Hair, hides, meat, petroleum products, rubber, wood

TABLE 396.1. Common Toxic Products of Combustion and Their Sources

The nature and severity of smoke inhalation depend on the identity, concentration, and temperature of the TCPs; the particle size of soot; the length of exposure; and the victim's respiratory rate and health status.^{4,5,6} and ⁷ Carbon monoxide (see [Chapter 323](#)) is thought to be responsible for most deaths, especially those that occur early.^{5,6} and ^{7,18} If measured immediately after exposure, elevated carboxyhemoglobin (COHb) fractions are likely to be seen in virtually all victims of smoke inhalation. However, as many as 40% of victims found dead at the scene have COHb fractions less than 50%, the fraction generally considered to be evidence of death from carbon monoxide in the forensic literature, 20% to 25% have fractions less than 30%, and up to 10% have fractions less than 10%.⁷ Cyanide poisoning (see [Chapter 331](#)) also appears to contribute to early mortality. Blood cyanide (CN) levels are elevated in up to 90% of fire victims and correlate with the COHb fraction.^{1,2,7,11,17} Potentially toxic CN levels have been noted in as many as 30% of smoke inhalation survivors and 100% of fatalities, and potentially lethal levels have been found in up to 10% of survivors and 70% of fatalities. Acrolein and hydrogen chloride reach potentially toxic levels in about 10% of fires. Methemoglobinemia has also been reported in victims of dwelling fires.¹⁰ Although the concentrations and individual toxicity of other gases are usually low, their additive or synergistic toxicity is potentially significant.⁷

TCP gases can be divided into two groups, based on their mechanism of action and site of toxicity. *Cellular asphyxiants*, such as carbon monoxide and cyanide, cause systemic toxicity without direct pulmonary effects as the consequence of hypoxia secondary to impaired oxygen delivery and use at the cellular level. *Respiratory irritants* (see [Chapter 346](#)) cause upper and lower airway and pulmonary parenchymal injury without direct systemic toxicity. Highly water-soluble gases, such as acids, ammonia, and chlorine, tend to dissolve in the moisture of upper airway surfaces, producing laryngeal and tracheal edema, ulceration, and hemorrhage. Irritant gases with lower water solubility, such as acrolein, aldehydes, isocyanates, phosphine, and oxides of nitrogen and sulfur, tend to penetrate deeper, producing tracheobronchitis or variants of the respiratory distress syndrome (e.g., pneumonitis, pulmonary edema). The location of injury also depends on the nature of the soot (see subsequent discussion). In addition, severe systemic toxicity (e.g., shock) may result in pulmonary injury, and severe respiratory tract injury may lead to systemic effects due to hypoxia.

Carbon dioxide and oxygen concentrations at a fire scene are not often sufficiently high or low, respectively, to cause direct systemic effects. However, they increase exposure to TCPs by stimulating respiration. High atmospheric temperatures contribute to inhalation injury, especially if the humidity is also high. Thermal injury is generally more immediate than that due to respiratory irritants. Inhaling air greater than 200°C can be lethal in less than 5 minutes. Inhaling hot, dry air results primarily in upper airway edema, whereas steam inhalation may cause parenchymal damage as well as upper and lower airway injury. At a given temperature, injury and mortality increase with increasing humidity because of the greater thermal capacity of water vapor.

The soot fraction of smoke consists of carbon particles and dust of varying size. The particles themselves cause little acute irritation but they adsorb various toxic gases and liquids and act as vehicles to deliver these agents to various locations in the respiratory tract. Large quantities of soot may mechanically obstruct the airways, usually at the bronchiole level. In extremely sooty situations, however, death may result from upper airway obstruction (e.g., victims of the Mount St. Helen's volcanic eruption). Particles larger than 5 µm are filtered by the nasopharynx; those 1 to 5 µm settle on tracheobronchial surfaces; those smaller than 1 µm reach the alveoli.

The dose of TCPs delivered to the airways is proportional to the minute ventilation and the duration of exposure. In addition to high ambient carbon dioxide and low oxygen levels, anxiety, confusion, physical activity, and early respiratory tract irritation stimulate respirations and thus increase TCP exposure. Impaired mobility secondary to TCP toxicity (e.g., cognitive dysfunction, respiratory distress, incoordination, weakness), visual impairment (e.g., smoke, darkness, lacrimation), and physical obstacles (e.g., slippery surfaces, structural collapse) may increase the duration of exposure. Similarly, concurrent drug or alcohol intoxication, extremes of age, and physical handicaps may impair awareness, judgment, or mobility and increase exposure time. If the cycle continues, increasing respiratory tract injury and systemic toxicity may result in complete incapacitation, culminating in death.

CLINICAL PRESENTATION

Victims of smoke inhalation may present with manifestations of respiratory tract injury, or systemic toxicity from anoxia, carbon monoxide, CN, and methemoglobinemia, or both.^{4,5,9,15,16,18,19} Respiratory tract injury may involve the upper airway, lower airway, pulmonary parenchyma, or a combination thereof. Nonspecific manifestations include cough, dyspnea, tachypnea, tachycardia, and cyanosis.

Signs of upper airway injury (eye, nose, and throat irritation) include conjunctivitis, tearing, rhinitis, pharyngitis, neck pain, dysphagia, drooling, hoarseness, and stridor. Fluorescein and slit-lamp examination of the eyes may reveal corneal burns. Examination of nasopharyngeal mucosa may reveal erythema, edema, hemorrhage, ulceration, or soot stains. Increased secretions and laryngospasm may be present. Facial burns and singed hair (head, eyebrows, or nose) are associated with a high incidence of thermal burns of the larynx and severe inhalation injury.²⁰ Direct or indirect laryngoscopy may reveal laryngeal burns or soot. A lateral soft-tissue radiograph of the neck may show laryngeal or periglottic edema. A swollen epiglottis may be seen (irritant or chemical epiglottitis). Signs and symptoms of upper airway injury are usually immediate in onset and peak within several hours of exposure.

Manifestations of lower airway injury include carbonaceous sputum production, bronchospasm (wheezing), rhonchi, chest pain (burning or tightness), and rales (due to atelectasis). Bronchoscopy may disclose tracheobronchial findings similar to those described in upper airway mucosal injury.⁵ A pseudomembranous tracheobronchitis (mucosal sloughing) has been described. Bedside pulmonary function tests (e.g., PEFr, FEV₁) may reveal decreased airflow. An increased expiratory–inspiratory ratio on flow-volume loop measurement is more sensitive than simple spirometry in detecting small changes in airway resistance. Radioisotope (xenon-133) ventilation–perfusion lung scans may show delayed washout of gas in areas of small airway destruction. A chest radiograph may be normal, particularly if obtained soon after exposure, or it may reveal bronchial wall thickening (peribronchial cuffing), subglottic tracheal edema, or atelectasis.¹³ Arterial blood gas analysis may reveal hypoxia and hypercapnia. Severe symptoms may occur immediately, particularly in those with underlying pulmonary disease. More often, symptoms are initially mild but worsen during the first 8 to 48 hours.

Pulmonary parenchymal injury causes nonspecific signs and symptoms. In contrast to localized rales from atelectasis, diffuse crackles may be heard in patients with pneumonitis or pulmonary edema. The chest radiograph may reveal patchy or diffuse infiltrates.¹³ Arterial blood gas analysis may show hypoxia and hypocapnia or hypercapnia. Hypoxia may result in secondary complications (e.g., myocardial ischemia or infarction), particularly in patients with underlying cardiovascular disease. Unventilated areas on xenon lung scanning and decreased diffusing capacity are sensitive but nonspecific findings of parenchymal injury.¹⁹ Spirometry may reveal restrictive disease due to decreased lung compliance as well as obstructive airway disease. Although pulmonary edema may sometimes develop immediately after irritant inhalation, it is usually gradual in onset and peaks 1 to 2 days (or longer) after exposure.

Bacterial pneumonia and tracheobronchitis are common complications. However, fever and leukocytosis secondary to chemically induced airway or lung inflammation may be seen in the absence of infection during the first 2 days after inhalation. Early postinhalation respiratory infections are usually due to *Staphylococcus aureus*; late infections are often caused by *Pseudomonas* and other gram-negative organisms.

Cellular asphyxia results in central nervous system (CNS) and cardiovascular depression (see [Chapter 323](#) and [Chapter 331](#)). Manifestations include agitation, confusion, coma, seizures, hypotension, and dysrhythmias. An elevated carboxyhemoglobin fraction confirms the diagnosis of smoke inhalation, but a normal carboxyhemoglobin concentration does not exclude it.

DIFFERENTIAL DIAGNOSIS

Patients with smoke inhalation may have concomitant dermal burns, traumatic injuries, and drug or alcohol intoxication and may be victims of arson, attempted murder, or attempted suicide. In patients with coma and shock, head computed tomography scanning, whole-blood CN levels, toxicology screening tests, and invasive hemodynamic measurements (e.g., central venous and pulmonary artery pressures) may be necessary to define the etiology.

EMERGENCY DEPARTMENT EVALUATION

The history includes details of exposure; symptoms, signs, and treatment before arrival; current symptoms; allergies; and previous illnesses (especially cardiac and respiratory problems). Important points in the exposure history include the nature of the burning material (natural or synthetic), length of exposure, open- versus closed-space exposure, the presence or absence of explosion, falls, jumps, other victims (injured or dead), physical injury, steam, suicide note, mask use, and the amount, color, and odor of smoke. The likelihood of inhalation injury is greater with synthetic (plastics) fires, with closed-space and steam exposures, and with exposures longer than a few minutes. Any history of altered mental status, collapse, or loss of consciousness also suggests a high risk of inhalation injury. Patients should be specifically questioned about respiratory symptoms, chest pain, alcohol and drug use, and suicidal ideation.

In firefighters, the type of oxygen mask used is important. With minimum safety apparatus, oxygen is supplied by a demand valve requiring negative (inspiratory) pressure, and smoke inhalation can occur if the mask is not perfectly tight. With continuous positive-pressure oxygen devices (e.g., the Scott airpack), smoke inhalation is impossible unless the oxygen supply, which lasts 20 to 30 minutes, depending on activity, runs out. In addition, invisible toxic gas inhalation may occur if either type of mask is removed during the clean-up or cool-down period immediately after the fire is extinguished.

After a trauma survey, the physical examination focuses on the mental status, vital signs (especially respiration), skin, eyes, nose, pharynx, and chest. Extensive burns (greater than 15% of body surface area), facial burns, singed facial hair, and soot in the airways are associated with a higher incidence of inhalation injury.²⁰ As with historical risk factors, however, their absence does not rule out significant inhalation injury.

Arterial blood gas or oxygen saturation and carboxyhemoglobin level measurement, ECG, chest radiograph, and bedside spirometry are recommended for patients symptomatic on presentation, particularly those with historical risk factors, abnormal findings on physical examination, and underlying cardiopulmonary disease. Although hypoxemia, elevated carboxyhemoglobin levels (greater than 10%), abnormal breath sounds, and atelectasis or infiltrates on the chest radiograph are diagnostic of inhalation injury, these findings are absent in most patients who later develop respiratory complications.^{3,5,18} Because carboxyhemoglobin levels decrease with increasing time since exposure (particularly if oxygen has been given), they must be measured early to detect small but significant exposures. Patients who remain symptomatic should be reevaluated after 3 or 4 hours, and sooner if symptoms worsen.

In patients with altered mental status of unclear etiology, toxicology screening tests and a quantitative ethanol level should be obtained. A whole-blood CN level is recommended in patients with coma, acidosis, shock, and high carboxyhemoglobin levels. Although not immediately useful, it may later confirm the diagnosis of CN poisoning in patients who may require empiric treatment for this condition. The methemoglobin level should also be measured in patients with refractory cyanosis.

Laryngoscopy (indirect or direct) may help identify mucosal damage in patients with mild-to-moderate upper respiratory tract symptoms, but it should not delay immediate intubation in those with severe symptoms and respiratory distress. Additional evaluation for inhalation injury (e.g., bronchoscopy, ventilation–perfusion lung scanning, flow-volume spirometry) is impractical and unnecessary for emergency department management and disposition.

EMERGENCY DEPARTMENT MANAGEMENT

Prehospital directives include prompt but safe removal of the victim from the scene of exposure; institution of basic and advanced life-support measures, as needed; and surface decontamination (e.g., clothing removal, irrigation of eyes and skin). All patients should be given supplemental oxygen. A rescuer should never enter a potentially toxic environment without adequate respiratory, eye, and skin protection.

Endotracheal intubation should be done in patients with any of the following: CNS depression (i.e., no spontaneous or coherent verbalization); respiratory distress with stridor or drooling; cyanosis or hypoxia (P_{O₂} less than 60) that does not quickly improve with maximal oxygen delivery and continuous positive airway pressure (CPAP) by mask; full-thickness burns of the face (nasolabial) or neck (circumferential); pharyngeal, laryngeal, or pulmonary edema; inability to clear secretions; or respiratory insufficiency (P_{O₂} greater than 50).^{5,6,9,16} More liberal indications for early (prophylactic) intubation include less pronounced findings that worsen despite treatment. In patients whose full-thickness face or neck burns restrict mandible or neck mobility and in those with upper airway edema, blind nasal intubation may be successful when the larynx cannot be directly visualized. In rare cases, fiberoptic endoscopic guidance, cervical escharotomy, or cricothyroidotomy may be necessary

for airway control. As always, if coexisting head or neck trauma or cervical spine injury is suspected, precautions are necessary until radiographs rule out this possibility.

Aggressive suctioning of the airway to remove mucus and inhaled debris should follow intubation. Oxygen should be humidified to prevent drying of secretions. Hypoxemia despite intubation and 100% oxygen should be treated initially with positive end-expiratory pressure (PEEP) ventilation. CPAP and PEEP may also be helpful in the prophylactic treatment of pulmonary edema. High-frequency ventilation may decrease the incidence of pneumonia and improve survival in those with severe inhalation injury. Extracorporeal membrane oxygenation procedures should be considered in patients with refractory hypoxemia. Because hyperbaric oxygen therapy requires relatively intact pulmonary function to be effective, it is unlikely to be of benefit in such patients.⁸ The efficacy of partial liquid fluorocarbon ventilation remains to be determined.

In patients without respiratory distress, stridor, or drooling, racemic epinephrine by aerosol inhalation may relieve upper airway symptoms. Bronchospasm should be treated with standard asthma medications (i.e., inhaled beta agonists). Chest physical therapy, incentive spirometry, postural drainage, and encouragement of coughing may help clear secretions and inhaled particles from the lower airway. Although corticosteroids may be useful for refractory bronchospasm, they are not recommended for pneumonitis or pulmonary edema.^{9,19} Despite theoretical benefits, corticosteroid treatment (or attempted prophylaxis) of parenchymal injury results in increased mortality from infectious complications. The administration of a single large dose of corticosteroids on initial presentation, however, may be beneficial and is unlikely to be harmful. Ibuprofen and other nonsteroidal antiinflammatory agents are of theoretical benefit in the prevention and treatment of pulmonary edema. The use of prophylactic antibiotics has not been shown to be beneficial.^{5,9}

Fever and leukocytosis persisting or developing more than 2 days after inhalation suggest infection. Although the results of sputum Gram stain and culture should ultimately guide antibiotic use, empiric coverage for both *S. aureus* and gram-negative bacteria can be started when sputum or laboratory results are not immediately available. All patients, particularly those requiring fluid resuscitation, should be reassessed frequently for deteriorating respiratory function.

Management of carbon monoxide and CN poisoning and methemoglobinemia are discussed in [Chapter 323](#), [Chapter 331](#), and [Chapter 352](#). Carbon monoxide poisoning should be treated according to the usual guidelines. It should again be noted, however, that hyperbaric oxygen therapy is unlikely to be effective in enhancing carbon monoxide elimination in patients who cannot be adequately oxygenated despite intubation and the administration of 100% oxygen. The use of the CN antidote kit in smoke inhalation victims is controversial because the induction of methemoglobinemia, which decreases the oxygen-carrying capacity of hemoglobin, could be harmful in patients with hypoxemia and elevated carbon monoxide levels.⁷ Because coma, seizures, hypotension, and acidosis suggest CN poisoning, patients with these findings (in the absence of alcohol, drugs, hypovolemia, hypoxemia, carbon monoxide poisoning, and methemoglobinemia) may be candidates for CN antidote therapy if they fail to improve with supportive care. Although giving just the thiosulfate (the portion of the antidote kit that does not induce methemoglobinemia) may be safe in patients with hypoxemia and high carboxyhemoglobin levels, the use of nitrites should be reserved for those receiving concomitant hyperbaric oxygen therapy and those in extremis.

DISPOSITION

Patients with continuing respiratory symptoms (including cough and chest tightness); altered mental status; a history of loss of consciousness; abnormal lung sounds; concurrent drug or alcohol intoxication; elevated carboxyhemoglobin levels (greater than 10%); abnormal arterial blood gas measurements, chest radiograph, or ECG; facial or nasal burns; or a history of chronic cardiopulmonary disease should be admitted (simply for observation, if active treatment is not required). Depending on the severity of clinical findings and laboratory abnormalities and the coexistence of surface burns or traumatic injuries, intensive care unit, telemetry, or floor bed admission may be appropriate. Patients with carbon monoxide poisoning may require transfer for hyperbaric oxygen therapy (see [Chapter 323](#)), and those with significant surface burns or physical injuries may require transfer to a burn or trauma center. Advanced life-support capability should be available during transfer.

Patients in good general health who are asymptomatic (on arrival or after a short period of oxygen therapy) and have a normal physical examination, arterial blood gas or oxygen saturation results (while breathing room air), ECG, chest radiograph, and carboxyhemoglobin level may be discharged, but it is generally advisable to observe these patients for at least 3 or 4 hours before making a discharge disposition. Discharged patients should be instructed to return immediately if any respiratory symptoms develop. A scheduled recheck at 24 hours may be prudent.

COMMON PITFALLS

- Failure to admit symptomatic patients, despite the absence of abnormalities on the initial physical examination, laboratory evaluation, and chest radiograph
- Failure to evaluate and treat for coexisting carbon monoxide poisoning, drug or alcohol intoxication, traumatic injuries, and psychiatric problems
- Failure to give oxygen to all patients (including those with chronic obstructive pulmonary disease)
- Failure to perform endotracheal intubation when indicated
- Failure to fluid-resuscitate patients with trauma or surface burns for fear of exacerbating inhalation injury
- Failure to recognize the potential hazards of inappropriate corticosteroid, antibiotic, and CN antidote administration

CHAPTER 397

Submersion Injuries

Gregory A. Volturo

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Drowning, responsible for over 8,000 deaths per year in the United States, is the fourth most common cause of death in adults and the third most common in children.⁵ Death rates from drowning are more than five times greater for males than for females, and nearly three times greater for Blacks than for Whites.

The highest incidence occurs between ages 10 and 19. Forty percent of victims are less than 4 years old. More than half of those who drown in swimming pools are under age 10. Swimming pools, however, account only for 10% of all reported drownings. Drownings are more likely in lakes, rivers, or oceans. Quarries, pits, ornamental pools, spas, and bathtubs also contribute to the toll.⁶ Toddlers may even become trapped in a bucket when they lean over to play with the water inside. Nonlethal incidents occur an estimated 600 times more often than their fatal counterparts.¹³ Factors that increase the likelihood of a submersion accident include alcohol and drug use, the inability to swim, seizures, hyperventilation, hypothermia, injury during diving or other water sports, and exhaustion.

Drowning is death from suffocation due to submersion in a fluid; *near-drowning* implies survival, at least temporarily, after such suffocation. Wet drowning (when fluid is aspirated) occurs in 85% to 90% of cases, and dry drowning (when fluid is not aspirated) occurs in the remainder. Dry drowning is thought to be due to laryngospasm. *Secondary drowning* is death due to respiratory failure from the respiratory distress syndrome (RDS) that occurs within 72 hours of initial resuscitation.

RDS results from an influx of proteins and fluid into the alveoli due to loss of surfactant and leaky capillary membranes and is secondary to hypoxia and acidosis. Patients with secondary drowning have subtle respiratory compromise immediately after submersion. About 15% of near-drowning victims who are conscious when admitted to the hospital die of RDS.⁵ The *immersion syndrome* is sudden death immediately following immersion in very cold water. It appears to be due to vagally mediated bradysystolic cardiac arrest, or ventricular fibrillation.²

Drowning may begin with an initial period of panic, followed by a struggle, with breath-holding. Subsequently, apnea occurs, followed by swallowing of large amounts of water, which may be vomited and aspirated. The victim ultimately loses consciousness; shortly thereafter, cardiac arrest ensues.¹⁹ More commonly, however, witnesses report that the victim was just floating on the water and became motionless or disappeared.⁷

Theoretically, in fresh-water drowning, aspirated water is hypotonic and should be rapidly absorbed across the alveolar membrane and into the intravascular space, resulting in hemodilution and hypervolemia, with lowering of serum electrolyte and protein levels. In contrast, with hyperosmolar saltwater aspiration, fluid would be expected to diffuse in the opposite direction, resulting in pulmonary edema, hypovolemia, hemoconcentration, and electrolyte abnormalities.

Although such changes may occur in those who are dead at the scene, they are of minor clinical importance in resuscitated patients, who generally have been submerged for a short period and have aspirated a relatively small volume of water (rarely greater than 3 to 4 mL/kg).^{3,5} Although pulmonary injury may occur with aspiration of as little as 2 mL/kg of water, significant changes in intravascular volume are generally not seen with less than 10 mL/kg. More than 22 mL/kg is required before electrolyte changes occur, except for incidents in water with very high solute concentrations, such as the Dead Sea.⁸

Noncardiogenic pulmonary edema may occur in both fresh-water and saltwater drowning but is less likely with aspiration of fresh water. Hypoxia and the direct effect of aspirated water combine to produce this abnormality in about 5% of near-drowning cases.¹⁴ The causes of hypoxia include diffusion abnormalities and decreased lung compliance (due to the inactivation and dilution of surfactant) and increased intrapulmonary shunting (resulting from atelectasis, bronchospasm, and obstruction of alveoli by water and debris such as vomitus or sand).⁵ Chlorine in swimming pools may have an additional deleterious effect on pulmonary tissues. Aspiration of bacteria may also result in pneumonia.

Acidosis is common and is due to both metabolic and respiratory causes (inadequate ventilation results in anaerobic metabolism with lactic acid production). The acidosis may be worse in warm-water drownings than in cold water.⁵ Generally, all patients who are acidotic on admission (pH less than 7.3) do poorly. However, profound acidosis is still compatible with full recovery.

Cardiovascular complications may develop as a result of hypoxia and acidosis. Hypothermia may also be a contributory factor. The most common findings are arterial hypotension and cardiac arrest. Ventricular fibrillation is rare, particularly in normothermic patients. The diving reflex, a vagally mediated response to cold-water immersion, consisting of apnea, bradycardia, peripheral vasoconstriction, decreased cardiac output, and increased mean arterial blood pressure, may also be responsible for some of the cardiovascular changes seen in drowning victims.²⁰ While the diving reflex has been thought to have a neuroprotective role in children, it has not been shown to be active in human adults. Hypoxic stimulation of chemoreceptors in the carotid body may result in vagally mediated bradycardia, even to the point of asystole.¹⁶

Renal failure, although uncommon, may be due to anoxia or to hemoglobin or myoglobin deposition in the renal tubules secondary to hemolysis or rhabdomyolysis.¹⁷ Hemolysis can occur in fresh-water drownings but is rare. Disseminated intravascular coagulation, also uncommon, may be caused by hypoxia, acidosis, or extensive pulmonary endothelial damage.

Severe neurologic damage occurs in 15% to 25% of near-drowning patients.¹⁷ A favorable neurologic outcome is more likely in patients receiving cardiopulmonary resuscitation (CPR) and those with hypothermia (due to its protective effect on cerebral metabolism).^{1,2,12} Neurologic injury is due to hypoxia, which is further complicated by metabolic acidosis and secondary cerebral hypoperfusion. As a result, cerebral edema develops and may lead to brainstem herniation and death. The degree of anoxic injury depends on the duration of hypoxia, the water temperature, and the patient's underlying physical condition.² From 10% to 20% of patients presenting with coma recover completely, despite initially fixed and dilated pupils.¹⁰

CLINICAL PRESENTATION

Victims of near-drowning may be awake, lethargic but arousable, combative, comatose, or in cardiac arrest on presentation. A history of coughing, choking, or vomiting may be given. In mild cases, the pulse, blood pressure, and respiratory rate may be elevated, but in patients with severe hypoxia, vital signs may be decreased or absent. Hypothermia may be present. Examination may reveal cool, clammy, pale, or cyanotic skin. Aspirated or regurgitated food, water, or other foreign material may be present in the mouth and airway. Rhonchi, rales, or wheezing may be audible on pulmonary examination. Gastric distention is common. In severe cases, decorticate or decerebrate posturing or flaccid paralysis with unreactive pupils and absent cranial nerve, brainstem, and deep tendon reflexes may be observed. Associated traumatic injuries may also be present. Victims of scuba-diving accidents may have signs and symptoms of concomitant barotrauma and decompression sickness (see [Chapter 389](#) and [Chapter 390](#)).

The electrocardiogram (ECG) may reveal evidence of ischemia, sinus tachycardia or bradycardia, or ventricular ectopy, fibrillation, or asystole. Atrial fibrillation may also occur, primarily in patients with hypothermia. Arterial blood gas analysis may reveal acidosis, hypoxia, and hypercapnia. Although leukocytosis may be present, the hematocrit is usually normal. Except for a decrease in bicarbonate, serum chemistries are usually normal on presentation. Evidence of hemolysis, infection, rhabdomyolysis, and anoxic organ damage (e.g., liver and renal failure, disseminated intravascular coagulation) may appear hours or days after the initial insult.

The chest radiograph may reveal isolated or diffuse patchy infiltrates or frank pulmonary edema. An initially normal radiograph may reveal these findings if repeated

several hours later. Pulmonary edema has been reported to develop as long as 12 hours after the submersion incident. ¹²

DIFFERENTIAL DIAGNOSIS

In patients found unresponsive in water or other fluid, the possibility of trauma (especially head and neck), drug or chemical intoxication, cardiac arrest or stroke while swimming, cerebral air embolus (in scuba divers), and attempted suicide, murder, or child abuse or neglect should be considered.

EMERGENCY DEPARTMENT EVALUATION

The history includes details such as submersion time, medium, and temperature; events surrounding the accident; level of consciousness and vital signs at the scene; and signs, symptoms, and treatment before arrival. For children who fall into pails of liquid (e.g., detergent, insecticide), or industrial workers who may be submerged in a medium other than water, the type of liquid and its potential toxicity should be ascertained. An accident near rocks, in heavy surf, or while diving, or an unwitnessed event, may suggest traumatic injury.

The physical examination is initially brief and focuses on vital signs, cardiopulmonary status, and neurologic findings. To rule out hypothermia, a rectal temperature should be taken using a low-reading thermometer or probe. Serial coma grading (using, for instance, the Glasgow Coma Scale) is helpful in monitoring progress. In all patients, an initial cardiac rhythm and chest radiograph and, subsequently, an ECG, should be obtained. Baseline laboratory evaluation should include an arterial blood gas analysis, complete blood count, platelet count, serum chemistries (electrolytes, glucose, blood urea nitrogen, creatinine), coagulation profile, and urinalysis. Seriously ill patients should also have liver function tests and calcium, magnesium, and creatine phosphokinase measurements. Cardiac enzymes should be obtained in victims who require CPR or who have dysrhythmias or ECG evidence of ischemia. A computed tomography scan of the head should be performed to evaluate for cerebral edema, trauma, and other pathology in those who are comatose.

EMERGENCY DEPARTMENT MANAGEMENT

Rapid prehospital response and early initiation of resuscitation are the most important factors influencing morbidity and mortality. Although artificial ventilation can and should be started immediately in unconscious patients, cardiac compression is impractical and ineffective while the victim is still in the water. Hence, rapid extrication is essential. It is best performed by those trained in, and equipped for, water rescue to prevent additional casualties (e.g., accidental hypothermia or submersion injury in rescuers). As soon as possible, victims should have cervical and backboard immobilization if the history or setting suggests spinal injury.

After extrication, CPR and advanced cardiac and trauma life-support measures are instituted, as necessary. The airway should be cleared of fluid and vomitus before assisted breathing is started. Except for placing the victim in a head-down position, postural drainage procedures are not recommended, because the risks (loss of airway control, aggravation of spinal and other injuries, aspiration, and interruption of CPR) outweigh the possible but unproven benefits. ^{9,14} The Heimlich maneuver may be used to clear the airway if it is obstructed with particulate matter, but it is of unproven value in removing aspirated fluid. Indiscriminate use in victims with submersion injury may result in vomiting and aspiration of gastric contents.

All victims of submersion injury should receive high-flow oxygen and endotracheal intubation if clinically indicated. Wet clothing should be removed to prevent cooling and to allow inspection of traumatic injuries. In patients who remain obtunded, cyanotic, or hypotensive despite intubation and fluid resuscitation, and in those who present with cardiac dysrhythmias, acidosis is often present, and NaHCO_3 (1 to 2 mEq/kg) should be given empirically. ¹⁷ Naloxone and 50% dextrose (or a bedside glucose determination) should also be considered in the unconscious patient.

In the emergency department, treatment of hypoxia is of utmost importance. If not intubated on the basis of clinical indications, patients with an arterial P O_2 below 60 mm Hg and a PCO_2 above 50 mm Hg, with an oxygen saturation less than 90% while receiving high-flow O_2 by mask, should be intubated. If only hypoxia is present, continuous positive airway pressure by mask (CPAP) may be useful. In intubated patients with persistent hypoxia, mechanical ventilation with positive end-expiratory pressure (PEEP) will decrease the amount of intrapulmonary shunting, reduce ventilation-perfusion mismatch, and increase the functional residual capacity, resulting in an increased PaO_2 . Its principal disadvantage is that by diminishing venous return from the head, it may result in worsening cerebral edema. ¹⁷ The use of extracorporeal membrane oxygenation or partial liquid fluorocarbon ventilation should be considered in patients unresponsive to 100% oxygen and PEEP. Because persistent hypoxia may be due to aspirated foreign material, aggressive suctioning and bronchoscopy may be necessary.

Bronchospasm can be treated with aerosolized bronchodilators and intravenous aminophylline. The administration of corticosteroids has not been shown to improve outcome and is not indicated in near-drowning. ⁷ Prophylactic antibiotics have not been proven useful in preventing infection after aspiration and are unnecessary, except when aspirated water is known to have been grossly contaminated (aspiration of sewage). ⁷

The initial therapy for hypotension is intravenous fluid replacement with an isotonic crystalloid solution. Monitoring of central venous or pulmonary artery pressures, as well as urinary output by Foley catheter, may be necessary to guide fluid resuscitation. Adequate fluid resuscitation should be achieved before vasopressors are used. Volume status must be carefully monitored so that the patient is not overloaded with fluid, which may worsen cerebral or pulmonary edema. ^{4,11,17} Severe or persistent metabolic acidosis is treated with intravenous sodium bicarbonate. ⁹

Gastric decompression by a nasogastric tube is recommended in any symptomatic near-drowning victim to prevent vomiting, aspiration, and further respiratory compromise.

Cerebral resuscitation depends primarily on rapid stabilization and correction of metabolic abnormalities. Moderate hyperventilation, elevation of the head, osmotic and loop diuretics, and muscle relaxation may be beneficial in patients with increased intracranial pressure. Pharmacologic treatment of agitation and seizures may also be necessary. ¹¹ Treatments such as therapeutic dehydration, induced hypothermia (e.g., to 30°C), barbiturate coma, and paralysis are unproved. ¹⁴

DISPOSITION

Patients who have been apneic or unconscious; those with extremes of age; those with hypoxia, dysrhythmias, ECG evidence of ischemia, or an abnormal chest radiograph; and those whose symptoms persist after emergency department evaluation and treatment should be admitted. The level of care (floor or intensive care) depends on the severity and progression of clinical and laboratory findings. Patients who are asymptomatic, or become so after 4 to 6 hours of observation, and have a normal physical examination, room-air arterial blood gas analysis, and chest radiograph may be discharged home with a responsible relative or friend. ¹⁵ They should be instructed to return immediately if any symptoms develop (e.g., cough, sneezing, dyspnea, fever).

Indications for transfer include lack of intensive care facilities and lack of a pulmonary specialist capable of performing bronchoscopy.

COMMON PITFALLS

- Failure to consider the possibility of accidental and nonaccidental trauma, cerebral air embolism, drug intoxication, hypothermia, and medical or psychiatric illness in all near-drowning victims
- Indiscriminate use of the Heimlich maneuver, which may be useful for clearing the upper airway of particulate matter but is of unproven efficacy in removing aspirated fluid
- Failure to appreciate that patients who initially appear moribund may recover completely and that, conversely, those who present with mild symptoms may later deteriorate
- Failure to observe patients with a history of near-drowning and normal findings on emergency department evaluation for at least 4 to 6 hours
- Failure to perform early evaluation and treatment of hypoxia and cerebral edema in order to prevent or minimize neurologic damage
- Failure to recognize and treat hypothermia

Airmedical care refers to the care of patients during aircraft transport. *Airmedicine* is occasionally confused with *aeromedicine*, the study of flight and altitude physiology. Although it is important to understand aeromedicine when practicing airmedicine, the two are distinct fields. The vehicle itself is only part of airmedical care; air ambulances represent sophisticated systems of care that alter previously held notions about patient referral and transport.

HISTORY

Although there is debate about when the first airmedical transport occurred, and whether the aircraft was a balloon or a fixed-wing airplane,⁷ the history of airmedicine is linked to military conflict. The helicopter was first widely and successfully used during the wars in Korea and Vietnam, where it offered advantages of access in hostile jungle terrain and rapid transport speed for short-range patient rescue.⁹ The helicopter developed significantly from an aviation perspective during the time between those two conflicts. The aircraft typically used during the Korean conflict carried the patient on externally mounted stretchers, precluding medical care in flight. During the Vietnam War, patients were usually transported inside the aircraft and received medical attention during transport. Over 100 air ambulances, performing more than 7,000 evacuations monthly by 1968, and about 900,000 total missions, were used during 11 years of operation in Vietnam.^{8,13}

Civilian application of helicopter medical care within the continental United States began as personnel experienced with military airmedical helicopter operations returned from Vietnam during the 1960s and 1970s and proposed that similar technology would be beneficial in the civilian environment, particularly for trauma victims.¹¹ Fixed-wing airmedical care systems already existed on a small scale and were used primarily to transport medical personnel to patients. During the 1970s, other countries also developed air ambulance services, some focusing on emergent patient transport, some on delivery of medical resources to remote areas, and others on rescue.

Common sense argues that patients with a survivable illness or injury will benefit from early, high-quality medical care. Early scientific analysis of clinical helicopter medical care focused on trauma, with some consideration for cardiac, pediatric, and obstetric patients. Additional focuses included appropriateness of use, estimation of need, and clinical techniques during flight.

Although a wealth of helicopter medical literature exists, rigorous appraisal has been limited by sample size, confounding variables, and lack of concurrent control groups.¹⁹ Education of referral facilities, coordination, and consultation with tertiary care hospitals before and during transport; increasing regionalization and specialization; and advances in emergency medical services (EMS) and emergency medicine have confounded efforts to separate the effects of airmedical care from other changes in medicine. There is relatively little literature evaluating fixed-wing airmedical care and even less on long-distance (“repatriation”) care during commercial airline flights.

SYSTEM DESIGN

Multiple factors influence the design of airmedical systems, the most important of which are safety and the system mission. The type of aircraft used, the medical team composition and resources, and availability are additional considerations. Search-and-rescue operations,¹⁵ for example, focus on finding and removing the victim from an endangering environment and require a design significantly different from that of interhospital patient transport programs, which focus on care in transport between relatively safe sites. Many (about 175 in the United States) full-time dedicated helicopter airmedical programs are based at or supported by hospitals and are staffed with medical professionals. Physicians, nurses, paramedics, and respiratory therapists are the most common members of the airmedical crew, with physician assistants, nurse practitioners, and other providers found in some systems.

Part-time fixed-wing airmedical programs utilize aircraft reconfigured from other uses and perform elective long-distance transfer of stable patients as their mission, using on-call nurse or paramedic crews. Some systems offer both fixed-wing and helicopter services, and an increasing number coordinate with or directly provide ground ambulance transfers as well. Few civilian airmedical systems in the United States focus on search-and-rescue operations, leaving that mission to the Coast Guard and other agencies. Many, however, perform limited search operations, and some train in regionally specific rescue, such as hover operations over water, snow, or wilderness terrain. In other countries, the rescue mission is often a component of airmedical systems, with winch lift and other rescue functions not unusual.

GENERAL AEROMEDICINE

The patient being transported by aircraft is subject to several forces not commonly encountered during hospital care: changes in altitude, noise, vibration, acceleration, and motion. With increasing altitude, oxygen tension is decreased and gas expands. The atmospheric pressure at 18,000 ft is half that at sea level. Hence, attention to oxygenation and any enclosed gas (e.g., pneumothorax, intestinal gas, middle ear, glass intravenous bottles, tube cuffs, splints) is required with any change in altitude of more than several thousand feet. The noise and vibration encountered in flight may increase stress for the patient and limit the effectiveness of routine medical procedures, such as auscultation of the chest and abdomen and palpation of the pulse.

Severe vibration may disturb fractures, trigger pacemakers and automatic internal defibrillators, reduce the accuracy of oscillographic blood pressure monitors, and limit the ability to perform manual procedures such as intravenous cannulation. Motions encountered in flight include yaw, roll, and pitch, with acceleration and deceleration in any direction also possible. Nausea, disorientation, and anxiety are not uncommon sequelae. Unfamiliar stimuli from being in atypical positions (lying backward, sitting sideways) and the strobe effect from helicopter rotors may also result in nausea and spatial disorientation. A patient who is afraid of flying may produce additional challenges for the crew.

AVIATION ISSUES

Aircraft

Factors influencing the choice of aircraft include the space and configuration of the patient care area, loading door size and arrangement, useful load, balance

flexibility, speed and climb performance, range, altitude and pressurization limits, landing zone or runway needs, and capability for Instrument Flight Rules (IFRs) in addition to Visual Flight Rules (VFRs) flight. The Federal Aviation Administration sets rules for aircraft equipment and operation in the United States, including pilot qualifications and installation of any supplemental equipment, such as patient stretchers or medical equipment. Although electronic medical equipment is often certified for hospital use, it is rarely tested in the aviation environment for interaction with navigation instruments or other aircraft electronics. Concerns regarding possible interference with medical equipment from communications devices such as cell phones are magnified in the aircraft environment, where several radio transceivers are commonly installed with antennas in close proximity to medical equipment.

Fixed-wing aircraft typically used for airmedical care are mid-sized, twin-engine propeller or jet aircraft. Most are capable of flight in poor visibility (IFR), cruise at 200 to 400 mi/h for ranges of 1,000 to 2,000 mi with useful loads of 2,000 to 7,000 lb, and can climb to altitudes of 25,000 to 30,000 ft with pressurized cabins. These characteristics make fixed-wing aircraft most useful for missions over 150 to 200 miles, in which the delay for airport transportation at either end becomes less significant. In addition, the useful load and altitude characteristics increase the margin of safety for operating these aircraft in hot or mountainous areas.

Airmedical helicopters are generally light turbine-powered, mid-sized helicopters, with the proportion of twin-engine aircraft relative to single-engine aircraft increasing steadily. Cruising speeds of 100 to 160 mi/h, with ranges of 325 to 550 miles, a useful load of 1,500 to 3,000 lb, and service ceilings of 13,000 to 20,000 ft are typical. IFR flight is possible, but the need to avoid icing conditions and to fly between or near airports capable of instrument approaches limits the usefulness of IFR for airmedical care. The Global Positioning Satellite [GPS] system has expanded airmedical IFR capabilities in some areas, but concerns regarding decreased safety with poor visibility operations continue to be validated by aircraft accidents in such weather conditions.

Landing Zones

Helicopters are generally capable of vertical takeoff and landing, but there are some limits. From the pilot's point of view, a large, level area without wires, trees, or other overhead obstructions is ideal for landings, and a tall tower with a short runway surrounded by clear airspace is best for takeoffs. Most landing and takeoff sites are compromises, with clear approach and departure from a level, 100 × 100-ft area proving adequate for most helicopter operations. Helicopter weight, wind and temperature conditions, and nearby obstructions also influence helipad locations.

Hospital helipads should be designated sites with rapid access (within minutes) to the emergency department. Some programs inspect and catalogue potential landing sites near intersections, highways, and areas of high call volume. All sites should exceed program minimum standards and should be secured by educated personnel before landing. Laws regulating helipad designation and use may vary and should also be considered.

Programs that operate in inclement weather (Instrument Meteorologic Conditions [IMC]), using IFR, require additional capabilities at landing sites, including the means to perform an instrument approach. Fixed-wing aircraft need runway or landing strip access at both the sending and receiving ends of the transport, and at least one alternative destination if flying in inclement weather. Such services and facilities are generally available only at airports and are regulated by the Federal Aviation Administration.

Weather Limits

Airmedical programs operate within weather constraints, primarily visibility (distance) and ceiling (height above ground before cloud cover). Winds aloft, temperature, dew point, and presence of icing conditions, fog, storms, and other specific conditions may also determine their ability to respond and the type of response (VFR vs. IFR, helicopter vs. fixed-wing). High temperatures reduce engine power and blade lift due to decreased air density. Because weather forecasting is not an exact science, local conditions may vary markedly from the regional forecast.

Programs must make a decision about weather conditions and their ability to respond on a call-by-call basis. Occasionally, one program may be asked to perform a mission when another has already turned down the request. The second program should be informed that the request has previously been refused and why. This allows the second airmedical program to judge whether local or regional weather conditions allow the mission to be accomplished safely. For example, there may be inclement weather between the first program and the referring facility, but the second program may have an acceptable route. This precaution is particularly true for VFR programs, as many airmedical helicopter accidents involve inadvertent entry into IMC weather and subsequent pilot disorientation.

Speed and Range

Aircraft speed, fuel capacity, and fuel consumption rate define the useful range. The ability to pick up a patient and return to base without refueling is desirable but not essential. In many cases, refueling can occur while the patient is being prepared for transport. Refueling with the patient and crew onboard is discouraged but is possible with adequate precautions. Typically, airmedical helicopters can cover a service area radius of 120 to 140 miles without refueling. Fixed-wing aircraft generally have a useful range of several hundred to a thousand miles.

MEDICAL ISSUES

Airmedical Care

Patient care during airmedical transport must take into account environmental and temporal factors. Also, the airmedical team is typically a scarce resource, and system needs must also be considered. Because the referring facility or ambulance service often requests a transfer because they are overwhelmed by patient volume or severity, the airmedical team is usually entering a stressful environment. In addition, unless the team makes frequent visits to the same referring facility, they are also entering an unfamiliar one.

The airmedical team generally begins care by placing the patient on their stretcher and attaching various monitoring devices. Intravenous lines, endotracheal and other tubes, and other equipment may be disconnected accidentally during patient movement to the stretcher and transfer to the aircraft and must be secured. Monitoring equipment must often substitute for physical assessment of the patient, given the noisy environment and limited access to the patient. Limited access also means that performing procedures such as gastric emptying, splinting, pneumothorax decompression, and patient restraint are best done before takeoff. Delays in transport resulting from flight preparation of the patient may cause conflict with the referring staff, who desire prompt evacuation, unless the unique aircraft environment is appreciated.

Once in flight, the airmedical care team must consider aeromedical influences on their medical care, as previously discussed. Treatment may be initiated or continued, radio reports given to the receiving facility, documentation begun, and triage of upcoming requests performed. These tasks are typically performed by a two-person medical crew, while the pilot attends to the aircraft. Some programs use two pilots, particularly for IFR missions, and some use one medical crew for most missions with others used for specialized care, such as neonatal or intraaortic balloon pump transports.

Choosing a Service

Choosing an airmedical service provider to transport a patient involves the same concerns as with ground ambulances: availability, location, level of care, reliability, and past performance. Receiving hospitals usually prefer to use their own program. Some third-party payors have specific transport arrangements. Referring facilities should be aware of the capabilities and limits of area airmedical programs to facilitate arrangements when the need arises.

Patient Preparation

When preparing a patient for transfer, the referring clinician should also consider likely treatments and potential complications during flight. Preparing the patient before the aircraft arrives will save the flight crew time and facilitate evacuation. Records, test results, and other documentation should also be provided.

Patient Acceptance

The referring physician must ensure that the patient is accepted by a physician who can provide care and has adequate facilities available for that care. This is both good medical practice and a requirement of the Emergency Medical Treatment and Labor Act provisions of COBRA (see [Chapter 408](#)). Some airmedical programs

have systems to arrange rapid acceptance of patients, particularly trauma and other critically ill patients referred to their own or member institutions. In other cases, acceptance by a specific physician or service may be necessary before takeoff.

Transfer of Care

After acceptance, there is a gradual transfer of responsibility from the referring to the receiving physician and facility. This responsibility transfer parallels the physical transfer of the patient and is essentially complete when the patient arrives at the receiving facility. Traditionally, the referring facility has been held legally responsible for the patient until arrival at the receiving hospital. However, this opinion was formed before the development of advanced and critical care transfer services, and airmedical staff will probably be held responsible for care provided during the transfer. Until better defined, the transition of responsibility should be mutually understood as a gradual and cooperative process. Written transfer agreements can be developed to clarify issues such as staff privileges and licensing requirements for the nurses and physicians from the airmedical program while at the referring facility or on out-of-state missions, and for the transfer of responsibility and the loan and return of patient-care equipment.

Crew Mix

The level and type of training for staff in most hospitals and ground EMS systems is well accepted, but the optimal mix of an airmedical crew remains controversial. There are supporters for physicians, nurses, paramedics, and others as airmedical crew, depending on the mission.¹⁶ The literature, although limited by sample size and confounded by program variability, suggests that physician skill and judgment are important,¹⁴ that airmedical experience is well accepted and considered a valuable educational experience by emergency medicine residents,³ and that nurses and others can perform advanced skills in programs with off-line, protocol-based medical direction.¹⁸

Physician presence arguably makes more sense as the acuity and severity of illness or injury increases and as the transport time increases. Technical ability is important, but more relevant arguments include judgment, greater medical knowledge, and ability to operate without rigid protocols and on-line medical direction. Compliance with good medical practice during transfer, as well as with federal law (see [Chapter 408](#)), also demands that the level of care must not diminish during transfer, if possible. Thus, a patient who needs the constant presence of a physician and nurse before transfer should ideally have similar care during transfer, whereas a patient whose condition is more stable and whose likely complications could be managed by protocol could be transferred by crew with a lower level of training.

Each program should consider the issue of crew mix individually after examining patient and staff data.¹⁷ Facilities requesting airmedical care should know the crew mix and capabilities of area programs, and choose the best option for their patient.

SAFETY

Patient safety includes access to medical therapy as well as vehicular transfer risks. A common misconception is that the patient must be stabilized before transfer. Patients who can be stabilized should be, but patients who need specialized definitive care may die without timely transfer, and stabilization may be impossible if such care is unavailable at the current location. Thus, it may be best not to delay the transfer because the patient is "too unstable to transfer," but instead provide *earlier* transfer because the patient is "too unstable to stay." Patient safety during transfer is a balance between the need for the transfer and the risks of that transfer.

In 1991, about 128,000 helicopter airmedical transfers occurred in the United States, with an accident rate of 3.10 per 100,000 transports, or 2.98 per 100,000 flight-hours, because each transport takes about 1 flight-hour.¹² The accident rate has decreased since the 1980s, but airmedical helicopters still crash at about three times the rate of non-EMS helicopters, and the fatality rate in those crashes is also higher. The rate of ground ambulance accidents is about ten times higher than the airmedical helicopter rate,² but the severity of injuries is lower.

Air travel, mile for mile, is safer than highway driving, but many more people are afraid to fly than to drive. Air travel generally involves less personal control, an unfamiliar environment, and greater risk of death should an accident occur. Airmedical program administrators and clinical staff should understand these perceptions and misperceptions when they educate others about their program, particularly those who resist requesting airmedical care because of unrealistic perceptions of risk.

About 90% of aircraft accidents are attributed to judgment error, usually continued flight into deteriorating weather. Airmedical helicopter accidents occur about equally during day or night; about a third occur en route, and two-thirds occur during takeoff or landing. Although a review of airmedical helicopter accidents failed to identify any other personnel causes, such as fatigue, lack of training, or drug abuse,¹⁰ pilot fatigue tends to be cited as a factor despite the findings that accidents were not clustered at the end of shifts, late at night, or in any other way likely to be associated with fatigue.

Twin-engine helicopters are often recommended, because the redundancy of systems reduces the risk of accident from engine failure. However, because few accidents overall are caused by engine failure, it is difficult to prove with statistical significance that twin-engine helicopters are safer than single-engine aircraft. Further, it is unproved that the additional cost of twin-engine aircraft is money better spent for safety than money spent on pilot training, program design and education, and other measures to improve judgment and maintenance ability.

Helicopters, perhaps more than fixed-wing aircraft, are delicate aircraft requiring frequent preventive maintenance and inspection. However, few hospital-based helicopter airmedical programs have a hanger adjacent to their helipad. Daily inspections and most routine maintenance must then be performed outdoors, often from a ladder or while balancing on small steps built into the side of the aircraft, regardless of weather or time of day, thus forcing mechanics to work in an environment unacceptable to those who service the hospital's ground vehicles. This lack of basic aviation facilities is a significant issue for the safe operation of helicopter programs at hospitals. Support for airmedical programs may be provided directly by the hospital that buys or leases aircraft and hires personnel, by a government agency that operates the program, or by a contracted aviation vendor. Regardless of the type of support, the sponsoring institution should provide adequate resources for needed maintenance, aviation facilities, pilot and mechanic training, and other aviation services necessary to operate the program safely. An understanding of aviation operations is necessary to avoid making unsafe decisions, such as skipping maintenance, hiring unqualified personnel, or taking other measures that reduce immediate costs but risk long-term problems.

A review of factors associated with occupant survival showed that interior modifications to create patient-care capability probably increase the risk of injury, due to lack of restraint systems and load-absorbing seats and addition of loose equipment and intrusions into the head-strike area.⁴ Hence, focusing on judgment training and safety-oriented interior modifications appears most likely to address the real cause of airmedical accidents and associated injuries.

COST AND CHARGES

Some argue that the true cost of operating an airmedical program should be reflected in charges for that service. However, many programs are heavily subsidized, operating under the assumption that losses will be recovered through inpatient revenue. This dichotomy creates a situation in which emergency medical services are potentially undervalued and in which the billed charges for airmedical care may vary by a factor of 10 or more for similar service. Third-party payors are understandably confused by this situation and naturally wish to pay the lowest common charge. Whether airmedical services should be subsidized or offered as a public service through taxation or other government support, and whether this undervaluing of care is damaging to emergency medicine as a specialty, remain controversial. As a system, airmedical care is less costly than similar care provided by a network of ground vehicles when critical care interfacility transport is the system's primary function.²

MEDICAL DIRECTION

Many airmedical programs use standing orders and protocols. All should have a medical director trained and knowledgeable in prehospital and airmedical care issues. The Air Medical Physician Association provides a handbook and other resources for interested physicians.¹ If written protocols vary from the treatment plan of the referring physician, the airmedical crew should be able to justify their suggested therapy, and should contact their medical director, if necessary, to discuss issues further with the referring physician. The medical director should develop and provide referring facilities with educational programs regarding the needs and capabilities of airmedical care.

FEEDBACK AND FOLLOW-UP

Because referring staff are concerned with the eventual outcome of their patients, airmedical programs should provide timely follow-up after each mission. A telephone call immediately after the mission, even if it provides little additional information, is more likely to find the referring staff still on duty and serves to answer immediate concerns. Written follow-up letters are important and can address the patient's interval status, indicate a contact person who can provide further information, or give the final diagnosis and disposition. If possible, these should go to all parties involved in the transfer, including EMS staff, emergency department or hospital physicians and nurses, and the patient's personal physician. However, because these letters are often posted in EMS headquarters or on emergency department walls, care should be taken to protect patient confidentiality. One way to do this is to draft the letter, using only the patient's age and gender and the time and circumstances of the transfer.

EQUIPMENT RETRIEVAL

Airmedical programs and referring facilities should develop a system for identifying, decontaminating, and returning equipment. Patient care may be compromised by a demand to remove splints, spinal immobilizers, intravenous pumps, pacemakers, or other equipment before flight because of a fear that it will be lost. A system that provides the referring staff with a written receipt for their equipment and a means to return it rapidly in safe and usable condition improves the relationship between care providers.

UTILIZATION REVIEW

Utilization review of airmedical care is important to establish guidelines for appropriate use and compliance with those guidelines. A statewide review process that uses objective criteria has been found to be both functional and useful in defending the utility of airmedical care, particularly to third-party payors.²⁰ Program design should include consideration of these issues when aircraft type, crew mix, equipment choice, operating area, and other choices are made that may affect use.⁵

Committee opinion based on accepted criteria may establish proper utilization but does not prove effectiveness. Studies of morbidity, mortality, specific clinical situations, effectiveness and techniques, complication rates, economics and cost per year of life saved, and other issues have been published,⁶ but the effectiveness of airmedical care remains difficult to establish without a large, well-controlled study population, due to the multitude of confounding factors involved in studying care systems.

CHAPTER 399

Disaster Planning and Management

Lucille Gans

[Disaster Planning](#)
[Disaster Management](#)
[Common Pitfalls](#)
[Chapter References](#)

Although disasters have occurred for centuries, their frequency appears to be increasing. Rising world population numbers and increasing areas of dense population, especially in potentially dangerous environments (e.g., flood plains), suggest that greater numbers of people will be affected by disasters. Despite the fact that public attention focuses on medical casualties, it is essential to consider numerous other factors when developing effective disaster plans and responses. ²⁰

Disaster may be defined as a destructive event that disrupts the normal functioning of a community. *Medical disaster* refers to a catastrophic event that results in casualties that overwhelm the health-care resources of the community involved. ² However, in addition to health and medical requirements, the basic needs of water, food, and shelter must be addressed, as well as power supplies, transportation, and communications. Refugees and displaced populations can be both the result and the cause of disasters. ⁶

Disasters may be classified as natural or human-generated. Natural disasters include earthquakes, floods, volcanic eruptions, hurricanes, tornadoes, winter storms, and other geologic and meteorologic phenomena. Human-generated or technologic disasters include explosions, chemical spills, radiation leaks, biochemical terrorism, transportation accidents, civil disturbances, and armed conflicts. Complex humanitarian emergencies generally include features of both natural and technologic disasters, such as population displacement that results from a combination of drought, famine, and political upheaval.

Disasters also may be categorized by onset and impact. For example, earthquakes and tornadoes are events that have a rapid onset, with a sudden impact on the community. In contrast, droughts and famines have a more gradual onset and generally have a prolonged impact. Numerous factors may modify the impact of a disaster on a community, including the nature of the event, time of day or year, health and age characteristics of the population affected, and the availability of resources.

Defining an event as a disaster also depends on the location in which it occurs. For example, an earthquake occurring in a sparsely populated area would not be considered a disaster if no people were injured or affected by loss of housing or essential services. In contrast, a similar quake, even one of lesser magnitude, could produce extensive losses of life and property if it occurred in a densely populated region with poor construction or limited medical resources. Similarly, a small community hospital could be overwhelmed by numbers and types of casualties that might be handled routinely by a large university hospital or metropolitan medical center.

Hospitals may further classify disasters as either internal or external. External disasters are those that do not affect the hospital infrastructure but do tax hospital resources, due to numbers of patients or types of injuries. For example, a tornado that produced numerous injuries and deaths in a community would be considered an external disaster. Internal disasters cause disruption of normal hospital function, due to injuries or deaths of hospital personnel or damage to the physical plant, as with a hospital fire, power failure, or chemical spill. ¹ Features of both internal and external disasters may be present if a natural phenomenon affects both the community and the hospital, as in the case of an earthquake causing significant destruction in both the hospital and the surrounding community.

DISASTER PLANNING

Disaster planning must address the problems posed by a variety of events, ranging in scale from mass casualty incidents (MCIs), such as motor vehicle collisions with multiple victims, to extensive flooding or earthquake damage, to civil wars. The disaster planning continuum includes advance preparations, as well as event management and recovery efforts. Those people and organizations responsible for disaster plans should consider all eventualities, from the sanitation needs of crowds at mass gatherings to evacuation procedures for buildings and geographic areas. ^{11,15}

Effective disaster planning requires identification of potential problems for the institution or community involved. Risk analysis is an essential feature of disaster planning, in which a comprehensive inventory is created for all existing and potential hazards, including location and quantity, if applicable. Hazards may include such items as chemicals used by local industry, transportation elements such as airports and railroad stations, or collections of large groups of people in areas with limited access, such as high-rise office buildings, nursing homes, or sports stadiums. Environmental and meteorologic hazards must also be considered, such as the presence of fault lines and seismic zones and the seasonal risks posed by tornadoes, hurricanes, and snowstorms.

Risk analysis should attempt to identify any groups of people at particular risk of injury or death or loss of property from each hazard. The estimated risk may be constant over time, or it may vary by time of day, season, or location relative to the community. Risk analysis necessitates the cooperation of corporate, governmental, and community groups to produce a comprehensive listing of all potential hazards. ^{12,13} It may be possible to reduce the relative risk posed by some hazards. Relocating a chemical depot further away from a school would reduce the risk that children would be exposed to hazardous materials, for example. Hazards must be identified before effective disaster responses can be planned.

Another essential feature of disaster planning is resource identification. Resources include both human and physical elements, such as organizations with specialized personnel and equipment. ^{7,18} Disaster preparedness should include assembling lists of medical and paramedical groups, public works and other civic departments, and volunteer agencies, along with phone numbers and key contact personnel for each. Hospital departments should have readily available a complete record of all personnel, including home addresses and telephone numbers, accessible 24 hours a day. Resource availability may vary with factors such as time of day and season.

Effective disaster planning must occur at all levels, from local institutions to municipal, state and federal governments, including private, volunteer, and international agencies. ³ All groups should understand their own capabilities and limitations, as well as those of the organizations with which interactions are anticipated or intended. Disaster plans should be both structured and flexible, with provisions made for plan activation and decision making by field-level managers, if indicated. ⁸

Once a plan has been devised or a strategy outlined, it should be evaluated for its effectiveness and completeness. The comprehension of people expected to implement the plan and their ability to perform duties must be assessed. In addition, more concrete concepts should be evaluated, such as availability and functioning of any equipment called for by the disaster plan. A recurring problem in disaster response is failure of communications, which may result from several conditions, including loss of infrastructure damaged by the disaster itself, as well as lack of operator familiarity, excessive demands, inadequate supplies, and lack of integration with other communications providers and technologies. Back-up communications systems, such as wireless, hardwire, and cellular telephones, may reduce the impact of disrupted standard communications, but, frequently, even advanced technology has been ineffectual during disasters. ⁹

An essential step in disaster planning and preparedness is the evaluation of the disaster response. Several methods may be used to exercise the disaster plan, the most comprehensive of which would be its full implementation in an actual disaster. However, disaster drills may also provide an excellent means of testing plans for their completeness and effectiveness. Drills may take the form of full-scale multijurisdictional exercises, using moulaged victims and requiring vast resources of supplies and personnel, or they may be limited to a small segment of the disaster response, such as drills that assess the effectiveness of communications protocols or notification procedures. The disaster plan also may be assessed by using table-top exercises, paper or mock patients, computer simulations, or seminar sessions focusing on key personnel or limited aspects of the disaster response.

Improved performance during the drill, with enhanced understanding of disaster planning and response, is more likely when drills are preceded by some notification that a drill is scheduled. The specific goal of any drill should be clearly understood in advance. If drills are to be used as training sessions as well as evaluations of preparations and response plans, personnel are more likely to make the correct or most appropriate response choices during the drill if they are prepared. Consequently, they will be more likely to take appropriate actions when faced with an unexpected disaster situation in the future. The more realistic the exercise, the more likely it is that useful information about the strengths and weaknesses of both the disaster plan and the responders will be acquired. The factor common to all

disasters is a shortage of available resources; without experiencing at least some of the stress which accompanies that situation, it is unlikely that the disaster plan and response will be taxed at a level that realistically simulates the circumstances of an actual disaster.

Essential features of all effective disaster drills are the inclusion of all parties likely to be involved in the disaster response and a critique, with debriefing, of all participants following the exercise. Regardless of the format used, the critique should consider comments from all individuals, groups, or agencies involved in the drill. Disaster planners should review all observations and comments and respond with modifications of the disaster plan, if necessary.¹⁷ Any alterations in disaster plans or response procedures must be communicated to all groups involved or affected. Periodic evaluations of disaster plans are essential to ensure that personnel have adequate familiarity with their roles in disaster situations, as well as to provide for changes in regional emergency response operations, hospital renovations and closings, and other variables.

DISASTER MANAGEMENT

The philosophy of disaster management may be summed up in the phrase, "The needs of the many outweigh the needs of the few." In other words, in a disaster situation, resources may be so limited that stringent rationing is vital to the survival of the maximum number of people. Austere conditions may be alien to responders accustomed to ample quantities of medical supplies, equipment, personnel, and time, but they are commonly encountered with any large-scale disaster. In this setting, difficult triage decisions must be made in order to ensure that all assets are used in the most efficient and pragmatic manner.¹⁹

The goal of disaster management is to provide the most appropriate intervention and assistance based on the most accurate information available in a timely manner. Disaster response includes several phases (Table 399.1) but must begin with recognition that disaster conditions exist. (Some disasters, such as hurricanes, may be preceded by a period of time, called the preimpact phase, during which advance information may be gathered about the potential effects of the disaster. The data acquired during the preimpact phase may allow prepositioning of personnel and resources in a strategic location.) Due to a lack of verifiable facts, it may be necessary, at times, to proceed on assumptions and limited data, with efforts made to tailor and modify the response as updated information becomes available. It may be helpful to consult people and organizations with experience in such varied fields as engineering, toxicology, epidemiology, geophysics, and meteorology, to name only a few, depending on the disaster or the area affected.¹⁴

ACTIVATION
Notification and initial response Scene assessment
IMPLEMENTATION
Organization of command Search and rescue Victim triage, stabilization, and transport
MITIGATION
Definitive management of scene hazards and victims
RECOVERY
Scene withdrawal Return to normal operations Debriefing

TABLE 399.1. Components of a Disaster Response

Inevitably, in the event of a disaster that produces significant or extensive morbidity and mortality, the physician on duty in the emergency department will be one of the first people called on to assume a leadership role. The existence of a hospital disaster plan provides a valuable resource, but, ideally, the emergency physician should be prepared to do more than refer to the plan when informed of the incident. The disaster response will evolve in a much more coordinated fashion if the physician understands both the hospital plan and the resources, capabilities, and disaster plans of the first responders and emergency medical services (EMS) system in the region. The physician may be required to coordinate or facilitate the hospital response and to provide direction for numerous aspects of the regional response. For example, the task of assigning personnel and resources may be delegated to the emergency physician at the regional trauma center if no adequate disaster plan exists for the local EMS system. The physician may also be consulted regarding the need for the deployment of agencies and resources from outside the affected region. Lack of familiarity with local resources and response plans may result in unnecessary and costly delays in implementing the most efficient response. In addition, emergency department staff should expect to be bombarded with requests for information on all aspects of the disaster and response, from family members, media, and government representatives and from the public at large, and be prepared to refer or respond to such questions. Early in a disaster, the emergency physician and staff will likely be expected to disseminate information about the disaster event, demonstrate expertise and leadership in the response and management efforts, and even make the initial determination that disaster conditions exist. Hospital administrators, social services, and public relations personnel can provide valuable assistance and should be notified as soon as a disaster is recognized.

In the case of damaged or destroyed health-care facilities or after a large-scale disaster, the physician may also be called on to provide medical care in unconventional settings. In the situation in which field medical care stations must be established, coordinating responses with other agencies is essential. The use of a hierarchical management system, such as the Incident Command System (ICS), to coordinate the information and resource management is essential for any large-scale disaster. It is important to remember, during the early stage of the disaster, that information available from those at the disaster area (data regarding death, injury, or damage) may not be accurate. Problems with communications are frequently the source of delays and misapplications of disaster resources. The ability of those in a region devastated by a disaster to survey the population and infrastructure may be severely curtailed by damage, such that even initial calls for help may be impossible. It is essential, therefore, that external resources of personnel and equipment be available and accessible if anticipation of potential need for them arises.¹⁶ Conversely, due to disruption of communications and transportation, it is possible for the effects of the disaster to be overestimated. In order to minimize damage and disruption, expedient decisions must be made, with future consequences of such actions considered as well. Short-term benefits and costs must be weighed against their long-term counterparts. Disasters are costly events, but judicious initial expenditures may result in substantial savings, in both monetary and humanitarian terms, over the long haul. On the other hand, excessive spending by individuals, agencies, or organizations may result in prolonged or delayed recovery from the disaster and may restrict the capability to prepare or respond when the next disaster strikes.

In the case of a disaster that causes substantial destruction of infrastructure, the response may be prolonged, requiring that long-term health-care and support services be established. Issues such as nutrition evaluation and on-going disease surveillance may require the expertise of numerous other health-care providers and agencies.¹⁰ In addition, mental health issues must also be considered for the victims and the responders, during both the emergency phase and the recovery. Posttraumatic stress disorder, major depression, generalized anxiety disorder, and substance abuse are frequently reported among disaster survivors who have experienced traumatic bereavement or severe disruption of their lives. Early access to mental health workers for evaluation and intervention reduces the incidence and severity of such reactions. In addition, Critical Incident Stress Debriefing (CISD) or a similar program is a standard component of many disaster-response agencies to reduce the mental health toll on rescuers and relief workers.^{4,5}

COMMON PITFALLS

- Failure to prepare for a disaster by identifying potential hazards in the local environment, developing contingency plans, and reviewing and correcting errors and omissions in such plans
- Failure to appreciate that disrupted communication and transportation systems frequently cause problems in assessing and responding to disasters, and that redundancy of equipment and flexibility of use of communication and transportation resources are desirable
- Failure to consider the needs of the elderly, children, and technologically dependent people, and to include such things as diapers, formula, medications, interpreters, and special transportation requirements in disaster planning and response
- Failure to appreciate that disaster responders may become casualties themselves, that they may suffer psychological effects during and after the event, and that debriefing is crucial to identify or prevent mental illness or disruptions in the personal or professional lives of disaster responders

CHAPTER 400

Informatics

Kenneth A. Williams

[Computers and Other Tools](#)
[Practical Informatics](#)
[Administrative Uses](#)
[Clinical Uses](#)
[Educational Uses](#)
[Chapter References](#)

Informatics is the study of information and its management.¹⁰ Data become information only when presented in context; information becomes knowledge only if it is understood. For example, out of context, “5.4” means little, but when associated with “potassium level,” it becomes information. When considered in light of additional information, such as a previous level of 4.3 in a patient who ran out of furosemide 2 weeks previously but continued to take potassium, knowledge has been acquired.

Problem solving involves a description of the problem, contextual analysis of objective data, the development of potential solutions, and feedback to optimize those solutions. This general plan for problem solving can be seen in traditional architectural design plans (program, site, design, evaluation), in the systems analysis approach to technology assessment (objectives and performance measures, system environment and constraints, resources, goals, management),⁵ and in many management guides (goals, objective evaluation with consequences through praise and reprimand, adjustment through review and clarification).² In medicine, examples include the problem-oriented medical record, the subjective–objective assessment plan (SOAP) progress note, and continuous quality-improvement techniques (see [Chapter 402](#)).

Perhaps the most important element of problem solving is adequate definition of the goal or problem. Careful framing of a question facilitates finding its answer; to proceed otherwise risks the collection of data without information or knowledge. Stepping back or to the side, looking at the issue from another viewpoint, waiting for the emotion of a crisis to dissipate, and searching for opportunity mingled within a crisis are techniques useful for problem definition. This sentiment is well expressed in discussions about clinical research,⁶ negotiation,⁹ and the philosophy of creative lateral thought.⁷

In emergency medicine, challenges include time constraints, reliance on the patient for information, lack of previously established rapport, and the acuity and severity of patient problems. Improved information access and management can address some of the challenges.

COMPUTERS AND OTHER TOOLS

Currently available computers use application-level software to store, manipulate, and present data with a speed and capability that easily match the needs of a typical emergency department. Personal computers with the power of some mainframes are available in many formats, with features limited only by budget. Software typically falls into categories such as utilities, spreadsheets, data bases, word processing, communications packages, programming languages, and games.

Subdivisions by complexity, approach, supplier, and other factors are possible within these categories. For example, data bases may be grouped according to how they represent data, and products then categorized as flat file (data stored as textlike files), hierarchical (data stored in indexed lists), or relational (data stored in tables of related fields) data base applications. Further, hardware and software requirements vary, and products may be classified as needing a Mac (Macintosh, by Apple Computer, Inc.), Windows (a graphical user interface environment for DOS-based personal computers, by Microsoft, Inc.), and a certain amount of hard-drive space, RAM (random access memory, the type used for rapid access while the computer is on), or other machine capabilities. Some new software focuses on linkage and integration, resulting in “groupware” packages that facilitate enterprise-wide communications, information sharing, and planning. This approach emphasizes the flow of information, giving the user a tool to analyze group interaction and process as well as the product. Additional software applications of interest to medicine include search tools to gain access to medical literature;¹⁵ encoding systems to represent medical knowledge;^{3,13} large customized data base systems that manage patient statistics, hospital utilization, budget, and other operational data for a hospital or clinic; practice management systems that perform similar functions for private or group practices; networks that link data and personnel worldwide; computer-based patient record systems; image–graphics systems; diagnostic–decision support aids;^{4,11,14} and educational tools.¹² Many examples of each of these computer applications are available and are often advertised in hospital and practice administration journals. There is little standardization of communication between these various medical software applications, despite efforts in that direction, and most emergency physicians probably do not use any of these applications on a daily basis. An excellent review of computer hardware and software applications relevant to the future of emergency medicine is available.¹

As the diversity and complexity of personal computers and their environment increase, it is important to remember that they are tools first, and the computer neophyte should only need to frame an intelligent question. Computer scientists and hobbyists can then recommend the necessary software and hardware system for answering that question. Thus, to a large extent, the desired output should drive the input and processing system.

Data collection and input techniques lag behind processing and output, and are the major obstacle to widespread clinical computing. Innovations in voice recognition, links between computer networks, digital scanning, and character recognition should overcome some of these obstacles. Meanwhile, other information management technology may be used clinically to solve many problems. Flowcharts, posters, department status boards, protocol manuals, and clinical guideline manuals are commonly used information management techniques that can serve to clarify, simplify, and standardize quality care. A medium used primarily in other areas of medicine but with great promise in emergency medicine is video, including both still and motion pictures. Documentation of general patient status; the appearance of rashes, wounds, and other lesions; and patient education are some obvious applications for video in emergency medicine.

PRACTICAL INFORMATICS

The American College of Emergency Physicians Section on Emergency Medicine Informatics has compiled a directory of computer software for emergency medicine that can generally be used on personal computers and has reviewed software applications for use in emergency medicine.⁸ The directory divides software into administrative, clinical, educational, combined, and reference categories. The advantages and challenges of applying this technology are briefly discussed next.

Administrative Uses

Billing

Billing programs range from utilities that assist with ICD coding to full-function electronic billing and accounting systems that track collection rates by physician. All are easier to use if they are electronically linked to other department systems, such as registration; otherwise, they require separate data entry.

Scheduling

Staff scheduling programs typically automate some aspects of scheduling. The more “intelligent” systems allow entry of individual preferences and account for factors such as grouping night shifts and avoiding the “third Thursday staff meeting” for those required to attend. All of the programs facilitate tracking and reporting of schedules, and most can now accommodate multiple facilities and providers. Some argue that the automated schedulers lack the intellectual finesse of a human scheduler, but many users of these programs find them quite acceptable, and all allow editing of the recommended schedule.

Tracking

Tracking programs include dispatch systems for ambulance and helicopter services, patient tracking during an emergency department visit, trauma registers, occupational injury database systems, and similar software. In addition, some tracking programs can index computer-stored patient records, allowing on-line quality

assurance, risk management, and documentation of procedural skills for credentialing purposes. Data storage and manipulation are facilitated if a relational data base format is used with standardized query language (SQL) available for data queries. Standardization and upgradability become issues if one depends on such software and there is a need to share data with others.

Clinical Uses

Calculations

Arterial blood gas interpretation, intravenous drip mix calculators, and similar utilities are available, offering both "just in time" learning for some clinical situations and standardization of care. Challenges include avoiding intellectual dependence on the program and ensuring that the program is updated as new doses or medications are added.

Communications

Electronic mail (e-mail), electronic bulletin board systems (BBS), Internet browsers, and other computer-based communications techniques have long been standard in the academic, computer, and business worlds but are just becoming common in clinical medicine. These systems typically allow grouped distribution of messages (e.g., to all residents, all staff at a certain facility, all nurses on a certain floor), easing announcements and automating their receipt confirmation. Collaborative projects, including research and committee work, can proceed rapidly and without physical travel in many cases, as all involved can share drafts, comments, and other documents electronically.

Several commercial providers offer programs that support links to other e-mail systems and also provide formatted and edited special interest groups (SIGs) similar to Internet e-mail lists. Most health-care facilities have access to the Internet, where a variety of software provide similar capabilities. Several SIGs and Internet lists focusing on EMS and emergency medicine are active, allowing prompt and broad-based discussion on a multitude of issues.

Telephones and beepers require patience; electronic communications require diligence. Because e-mail reaches the recipient only when the computer is attended to, using e-mail for essential communications requires responsible attention to the system.

Order Entry

Several software vendors produce systems that computerize the entry and reporting of orders within the hospital, including laboratory tests, imaging studies, and medications. These systems may include checking rules that prompt for more efficient and correct entry, such as prompting the user that an ordered medication appears on the patient's list of allergies, or that an ordered study was recently performed. In addition to order entry, these systems typically include a data-reporting mechanism and results reporting. These features allow the hospital to automate tracking of ordered items and correlate use with providers, services, diagnoses, or location.

Charting

Programs that produce emergency physician records have sought, fairly successfully, to avoid significant use of the keyboard on the assumption that clinicians prefer other data entry means. Voice recognition, pen-screen, touch-screen, and similar systems to speed entry of standardized information have been well developed and accepted in many departments. Integrating these systems with other computer tools has lagged somewhat, but most providers can now link their computer charting system to other department and hospital systems to allow selection of patient demographics from menus, downloading of patient charts to the billing office, and so forth. The ability to produce graphics (e.g., sketches of anatomy) and store images (e.g., digitized photos of lacerations or rashes) is also possible.

Diagnostic Support

Several commercial programs provide diagnostic support in the form of decision-making assistance. Typically, these systems require input of signs, symptoms, physical and laboratory findings, and patient demographics and then use both rule- and case-based logic to rank differential diagnoses from among an encyclopedic knowledge base. Some can suggest cost-effective next steps in evaluation or provide case simulations for educational purposes. So far, emergency medicine is a domain not well covered; the knowledge bases tend to encompass internal medicine primarily.

Drugs

Pharmaceutical references are available that provide information to guide the choice of medication and dosing. More sophisticated packages assess all medications prescribed for a specific patient for possible interactions and contraindications.

Patient Instructions

Basic packages print previously prepared sheets for common problems. The next level of sophistication includes the ability to customize the instructions for a specific patient, and the most sophisticated packages are integrated with registration and charting systems, coordinating the instructions based on demographics, diagnoses, equipment dispensed, and follow-up arranged. Patient education in the emergency department is an area ripe for improvement. Several programs can print customized discharge instructions; although lengthy, they offer some education. Formats used less often include pictorial handouts, videotapes, interactive computer programs, and simulations. Topics that are taught often, such as crutch walking, wound care, inhaler use, and oral rehydration, lend themselves to presentation by one of these formats, with staff time used to confirm understanding of key points. The ability to show patients actual crutch use on stairs, the appearance of cellulitis, or recommended foods should be more effective than oral descriptions. Challenges include developing programs, making technology available at the bedside, and achieving consensus on standard educational points.

Quality Assurance/Continuous Quality Improvement

Charting, tracking, and patient instruction systems can usually provide administrative reports summarizing use for purposes of quality assurance review. Some charting programs include prompts to remind the clinician about elements of the history or examination that may be important but are often forgotten. Some programs display the computerized chart for quality assurance review on screen, and will sort all charts on a computer disk by provider and diagnostic category. Most data base and spreadsheet programs can serve as tools for those wishing to design a personal application.

Referral

Many hospitals now offer services that match physicians seeking additional office patients with patients seeking a physician. These services typically use a data base system to match patient requirements with physician availability. Computers can also be used to provide information for follow-up by electronic transfer (typically by fax) of patient data to the referral hospital.

Registration/Triage

After billing, ADT (admission, discharge, transfer) computer systems are the most common hospital computer application. Problems include the delay often involved in finding a patient in the system, the lack of a way to identify patients positively (the sharing of insurance cards can cause problems with multiple blood types and medication allergies), and the lengthy registration process. Some facilities are promoting preregistration as an efficiency and marketing tool, with registration drives at health fairs and shopping malls. Preregistered patients have given a certain amount of medical information before their visit, with the hope that positive identification and ready access to former diagnoses, medications, and allergies, for example, will make the overall system less costly and more efficient.

Triage, originally designed as a system to avoid patient deterioration while awaiting care, has become a lengthy initial data collection process in some institutions, often creating significant waits for the triage process itself. Flexible computer-based protocols that allow the triage staff to expand or contract their time with the patient to maximize utility are available. They include standardized lists of questions, recommended laboratory studies, and other data that streamline care for the next

provider.

Records

Some health-care systems or facilities are placing patient summaries on their main computer networks, allowing rapid access to a summary of pertinent information on each patient. Accurate patient identification, accuracy of data, and confidentiality are challenges.

Educational Uses

Clinical Education

Clinician education is a continual challenge, with a staggering amount of information from diverse sources facing the clinician. Printed materials frequently are not current or are difficult to search for topic-specific information. Many abstracting services exist, with computerized data base interfaces available from the better ones. These can assist the busy clinician with generalized updates and topic reviews. Specific questions may be answered with primary searches of the medical literature. Several commercially available software packages are available that use direct modem or CD-ROM access to the National Library of Medicine's indexed MEDLINE database, and a variety of Internet resources allow access to the medical literature. As these packages become more sophisticated, they permit a shift in use from research and educational tools to clinical resources that can be used during patient visits as needed.

Several currently available CD-ROM systems have reached this level of utility and are used to access toxicology, product contents, hazardous materials, and other essential information during patient care. Challenges include learning the interface necessary to search for data adequately and the cost of searches or subscriptions. Promising technologies include natural language-processing interfaces that parse questions into search terminology and connection to the data base by the Internet, resulting in easier use and more rapid, less costly searches.

Physician education through simulations, quizzes, and other automated means is a growing area of computer use. The most sophisticated simulations use artificial intelligence programming to create an "artificial patient" whose responses do not follow a definite script but make sense to an expert in the field. Cardiac emergencies, neonatal resuscitation, and trauma care are areas where this technique holds promise, because correct physician actions are critical, but education from real cases is limited by patient volume and clinician experience.

HISTORIC PERSPECTIVE

Prior to the rapid evolution of emergency medical services (EMS) in the 1960s and 1970s, only rudimentary systems of prehospital care and patient transport existed. Although hospital-based ambulance services had been functioning in Cincinnati, Ohio, since 1865, and city services were initiated in New York in 1869, private ventures that combined transport services with another trade, such as funeral services, had the greatest market share. Such enterprises delivered prehospital care with little training, regulation, or benchmark for quality.⁹ The military advanced EMS in its care of wounded soldiers in Vietnam.¹⁴ Corpsmen and medics were trained in prehospital intervention and evacuation of the critically wounded to appropriate facilities for prompt surgical attention. The mortality of trauma patients surviving to a medical treatment facility sharply decreased.¹⁰

In 1966, the National Academy of Sciences–National Research Council, which acts as a consulting body to the government, published what has been dubbed the “white paper” of prehospital systems, “Accidental Death and Disability: The Neglected Disease of Modern Society.”¹⁰ This document summarized the inadequate delivery of emergency care, the lack of an emergency services infrastructure, and the lack of leadership in this area. It also made specific recommendations for a funded, organized, proactive, prehospital medical delivery system, launching the modern era of civilian EMS in the United States.

The “white paper,” along with others showing a rise in accidental deaths, especially on America’s highways, prompted Congress to enact the National Highway Safety Act of 1966. This act authorized spending by the newly created Department of Transportation (DOT)/National Highway Traffic Safety Administration (NHTSA) for the improvement of essential prehospital infrastructure, training of personnel, and establishment of practice guidelines. Through this legislation, states developed regional EMS systems with funding for ambulances, personnel, and communication equipment. A nationally recognized curriculum for the training of ambulance attendants (emergency medical technician or EMT-A) was established in 1971.

The success of prehospital cardiac care units in Dublin¹⁷ and of new methods of cardiopulmonary resuscitation (CPR) led EMS programs to expand their focus beyond trauma. Regional EMS demonstration projects showing favorable results led to the EMS Systems Act of 1973, which legislated further federal funding of comprehensive regional EMS systems to include money for operations, training, and research. Full-time medical directors and professional prehospital medical providers emerged.

National standards for EMT-A, EMT-I (intermediate level), and EMT-P (paramedic level) training evolved. Because some nonmedical public safety personnel were often the first to arrive at a scene with medical casualties, a first-responder curriculum was developed as well. NHTSA established such curricula, which came to be recognized as national standards.

Communications infrastructure, including 911 access, two-way radio communications, and centralized dispatch were developed, and criteria for optimal ambulance design and equipment were established. Regional EMS systems were intended to become financially independent as federal funding was phased out in favor of state discretionary funding of EMS through Preventive Health Block Grants, a product of the Omnibus Budget Reconciliation Act of 1981.⁹ The result, however, was deterioration of the movement toward national standards as regional systems yielded to state and local concerns. A multitude of systems developed independently, providing a varied range of skill levels, training, and quality of care, from one community to another. Organizations like the National Association of EMS Physicians emerged to serve as a professional body for consensus in the continuing development of EMS systems. The NHTSA has maintained its leadership role in EMS oversight at the federal level.⁵

Today, EMS systems operate in an environment of increased fiscal restraint, with an increased demand for objective proof of the efficacy of prehospital interventions. While these forces may produce more efficient systems, delivering a high quality of care, they could also erode a prehospital infrastructure that took 30 years to develop.¹³

EDUCATION

The U.S. DOT first-responder curriculum trains providers to perform basic patient assessment, manage airway obstruction, control external hemorrhage, administer cardiopulmonary resuscitation (CPR), and apply automatic external defibrillation devices. Length of training is 20 hours. The EMT-A curriculum, historically the minimum level of training required by an ambulance attendant, was revised in 1994, is now known as the basic (EMT-B) curriculum, and currently requires approximately 110 hours of training. The trainee is educated in ambulance operation, communications, documentation, scene assessment, initial patient assessment, triage, patient immobilization, basic airway maneuvers, CPR, and so on. The revised training strategy departed from the traditional diagnosis-based model to an assessment-based model and generated much national debate. Less emphasis was placed on pathophysiology and more emphasis on basic recognition of illness and execution of skills. Automatic external defibrillation was added to the curriculum. Advanced airway training was offered as well.

EMT-I and EMT-P curricula, revised in 1998, are approximately 300 hours and 1100 hours, respectively, and retain a diagnosis-based strategy for patient evaluation. The EMT-I level requires successful completion of the EMT-B curriculum as a prerequisite and includes additional training in pathophysiology, assessment skills, venous cannulation, and establishment of a patent airway. The EMT-P level includes an anatomy and physiology course, as well as the EMT-B course as prerequisites, and advanced training in pathophysiology, intravenous access, definitive airway control, and the pharmacology and administration of a variety of medications.

Despite national standards for curricula at first-responder, EMT-B, EMT-I, and EMT-P levels, states have variably adopted them in the training and certification of EMS providers in their jurisdictions. As a result, approximately forty levels of EMS providers exist nationwide.⁴ Each state adopts the curricula, in whole or in part, requires varying hours of formal education, and establishes scopes of practice presumably suited to its own needs. Although this diversity allows for the greatest flexibility to respond to local needs with local resources, it does not foster uniform standards of care and creates confusion regarding interstate reciprocity of privileges. NHTSA is currently sponsoring an EMS Education Task Force to author an EMS Education Agenda for the Future that will more explicitly define core educational content, scope of practice, and national standards for the education and certification of providers.

Specialized training programs have been established for EMTs and paramedics who function in settings where additional education is desirable. Critical care transport specialists may receive training in ventilator, invasive monitoring, and intraaortic balloon pump management. The wilderness curriculum prepares the EMT in search and rescue, environmental injuries, complications of prolonged evacuation and prehospital transport, and basic primary care in remote locations. The EMT-Tactical program prepares providers in comprehensive medical support for law enforcement teams and includes training in medical contingency planning, and in preventive medicine for the tactical team. It also includes medical support of extended operations, including primary care and recognition of performance decrement, hazardous materials (HAZMAT) safety, clinical forensics, and safe management of casualties in an austere, hostile environment. These specialized training programs

allow medical directors to fulfill their responsibility while ensuring that providers are trained to function safely and effectively in unique settings.

The training of physicians for leadership roles in EMS is also developing. Historically, any physician who had an interest and the fortitude would serve as EMS medical director. No formal training existed. Today, emergency medicine residents are provided some training in EMS systems as part of their core curriculum in postgraduate training.¹⁸ EMS experience, however, varies greatly from one training program to another. Postgraduate EMS fellowship training is now available through 1- and 2-year training programs. The 2-year programs concurrently offer a master's degree in public health, hospital administration, business, or other disciplines. Guidelines for a standard curriculum have been endorsed by the Society for Academic Emergency Medicine and the National Association of EMS Physicians.⁷ The American Board of Emergency Medicine has yet to accept EMS as a certifiable subspecialty.

STRUCTURE

Regardless of the type of EMS system, the necessity for field personnel to obtain adequate clinical exposure cannot be overemphasized. Patient outcomes improve when each medical provider achieves a threshold of patient encounters. Regionalization of EMS systems, as has occurred in the South and West, provides not only economies of scale, but also the ability to rotate personnel to ensure adequate experience, uniform patient treatment protocols, and placement of units based on patient need rather than political boundaries. In the Northeast, where each city and town often independently maintain their own EMS service, staffing requirements and overall costs are higher, and more personnel almost certainly means diluted experience and loss of skills.

Fire-Based Systems

Many fire departments (FDs), especially in the western United States, adopted EMS as part of their mission immediately after the federal legislation was enacted. Fire-based systems allowed dispatch and deployment of EMS units within a currently existing system. In most combined EMS/fire systems, EMS accounts for about three-fourths of the call load. In small cities and towns, existing personnel and facilities may be able to perform EMS duties without adding staff or infrastructure. But because firefighters are usually among the highest-paid employees, larger systems which need additional staff will incur much higher costs compared with the other EMS models.

In addition, because the FD's first priority is fire suppression, conflicts of interest may arise and lead to underresourced patient care. As the annual number of fire-suppression calls decreases and cities look more closely at the most efficient use of available resources, more FDs are becoming interested in EMS. Integration of established EMS systems with and under the direction of FDs is a politically charged topic that currently is the subject of heated debate in many cities.

In a full-service EMS system, the FD provides both treatment and transport for all patients. Advance life-support (ALS) and basic life-support (BLS) ambulances or only ALS ambulances may transport all patients. In a paramedic service-only system, the fire department provides ALS response to all, or a subset, of calls. BLS calls are referred to a private ambulance provider on the basis of either telephone triage or on-scene assessment by paramedics. ALS patients may be transported in an FD ambulance or in a private ambulance accompanied by an FD paramedic. Many FDs now provide first-responder services regardless of the source of ambulance transport, using firefighter personnel trained to respond to immediately life-threatening conditions such as cardiac arrest, respiratory distress, chest pain, and loss of consciousness.

Private Ambulance Services

Private ambulance services often bid for an exclusive contract with a governmental entity to provide EMS services, usually to a city, town, or county. The contract often stipulates that certain indirect measures of quality and performance be met, such as that all units be equipped with defibrillators, that paramedics perform a minimum number of intubations, or that certain response-time parameters be met. The community establishes regulatory control over the private service, with oversight being provided by an EMS agency or a medical director.

Private ambulance services usually provide both ALS and BLS services. To a greater extent than any of the other EMS models, private ambulances depend on efficient management of resources, such as peak-load staffing and system status management, to meet their dual demands: adequate EMS response and being a successful business. Personnel costs for the private sector are usually significantly below those for both the FD and third-service industries. The risk, however, is that the vendor could withdraw from nonlucrative markets, leaving the region or municipality searching for a means to provide uninterrupted service.

Third-Service Systems

Third service, simply defined, is an EMS system housed in a municipal department, using municipality-owned and -operated ambulances, and kept separate from police and fire services. Many medium and large cities continue to use municipal hospital-based ambulances as all or part of their EMS systems. Some third services are part of the city's Health Department, and a few are separate city agencies. This model allows for concentration on one mission—patient care—without the distraction of managing, funding, and providing other services. EMT skill maintenance is rarely a problem in these mostly urban systems. A drawback is that the third-service agency must compete with other traditionally well-supported public service agencies for budgetary funding.

Volunteer Systems

Almost three-fourths of all rural EMS providers are volunteers. The tax base cannot support a full-time professional EMS system, and the revenue to attract a private contractor does not exist. The dedication of volunteers is remarkable, as are the challenges they face in finding medical oversight, time for training, the means to maintain their skills, and the financial resources to develop and maintain their systems' infrastructure. Depending on state regulation, some volunteer services may operate without medical direction. Turnover among these providers is high. Rural systems face the same challenge of quality care as urban ones but with drastically different resources.

AMBULANCES

Type 1 ambulances have a truck frame with a box compartment for patient care. This configuration offers the greatest amount of patient care area, the highest vehicle weight, and the greatest amount of storage area. Type 1 ambulances are ideal for busy ALS systems, systems with long transport times, as well as critical care ground transport systems. The down side of such vehicles is higher acquisition costs, higher ongoing maintenance costs, and their size, which can be problematic in tight urban systems.

Type 2 ambulances are trucks with a van body. They are less expensive to acquire and operate and are the most numerous class of ambulance. They are somewhat limited in available treatment space and are small for the management of critically ill or injured patients. They are commonly held to have lesser durability than type 1 ambulances and afford the crew less protection in front-end collisions.

Type 3 ambulances have van frames and front ends, with a box patient care area. They are intermediate in acquisition and maintenance cost. They have large patient care areas and work well for the vast majority of patients. They tend to be limited in their weight restrictions. Many municipal services, particularly the smaller ones, have chosen this type of ambulance.

Type 4 ambulances are "specialty" ambulances and include air ambulances, such as helicopters. Because of their unique role and mission profile, they cannot be directly compared with other ambulance types.

Type 5 ambulances are vehicles designed to bring EMS personnel to the patient, but, in general, will not transport the patient. ALS personnel may respond with their equipment in such ambulances, meet up with a BLS team, and accompany the patient during transport in a BLS vehicle.

State laws, which can be extremely detailed, govern the configuration of each vehicle, as well as its markings. In addition, although some latitude is afforded to type 4 vehicles, each state mandates the minimum and allowable equipment and medications carried on any ambulance. Despite these regulations, there is wide variation in the equipment and medications carried on individual ambulances. This variation reflects not only the medical director's equipment (manufacturer) preferences, judgment, and vision for the service, but also those of other personnel as well as the type and geographic location of the system.

A busy urban EMS system may stock large amounts of consumable equipment to minimize “down time” to restock. Conversely, if all runs end at the base facility, lesser amounts of such items may be required. In contrast, rural EMS agencies may stock every item they may conceivably need during a prolonged transport. Variation in equipment and supplies also reflects the level of service provided. The amount of medical equipment on a BLS ambulance is much less than on an ALS vehicle.

MEDICAL OVERSIGHT

Medical oversight of out-of-hospital providers is essential to providing the best in medical care. It may take the form of direct or indirect medical control. Direct or on-line medical control refers to the immediate direction and feedback, usually by radio or telephone, that a physician provides to an EMS provider “at the point of service.” Although there is some controversy over whether such communication significantly improves the care provided,⁶ it gives EMS providers direct access to someone with a greater level of training and knowledge.

In some systems, medical control is provided by a specified physician or institution at a single base hospital. In other systems, it is decentralized, with each receiving institution acting as a base station. Medical control physicians must have an in-depth knowledge of the skills and capabilities of the EMS provider on scene and the capabilities and availability of receiving institutions in the area. They must also know applicable state and/or regional or local protocols and the medicolegal implications of situations such as refusal of treatment or transport and the care of minors, do-not-resuscitate status, and deceased patients.

Indirect or off-line medical control consists of protocol development and implementation, equipment selection, assuring adherence to clinical standards, education of EMS providers, and on-going quality improvement within the system. Such functions are generally the responsibility of the EMS medical director. Although time consuming, they are necessary to ensure that high-quality care is being delivered.

Compliance with protocols and standards of care is usually accomplished by reviewing a percentage of all EMS patient care records (charts, or “run sheets”), by reviewing individual cases that were difficult or problematic, or by reviewing the charts of selected conditions (e.g., cardiac arrests, pediatric cases, intubations, deaths, refusals of care) or individuals (e.g., new hires, those with whom there may be quality-of-care concerns, those who have just returned from a leave of absence). The initial training and continuing education of EMS providers is a key element in medical direction. The implementation of new medications, interventions, and protocols is an ongoing process. Quality improvement includes not only identifying and correcting deficiencies in current practice, but also identifying areas that, although not necessarily deficient, can be improved (response time, scene time, timely completion of charts, documentation of procedures).

COMMUNICATION

EMS communications is best viewed as a chain of events that can be described using queuing theory. The call-taker queue consists of those who dial 911. In the past, most cities and towns had their own emergency call-receiving center. Many have now been consolidated into Public Safety Answering Points (PSAPs) serving one large local jurisdiction, or multiple smaller ones. Enhanced 911 (or 911E) provides the PSAP call-taker with the physical address of the phone (street address and, in apartment buildings, the apartment number) as well as the telephone number of the caller. This information is obtained by the PSAP when the caller dials the last digit of 911, even if the caller hangs up before the call is answered. Thus, patients unable to speak, whether because of stroke, asthma, or other condition, can still receive assistance. Protocols may also allow the call-taker to ask a series of yes or no questions that mute callers can answer by pushing the appropriate button (1 or 2). In this way, the correct agency(ies) can respond. Technology is also available to approximate the location of cell phones.

EMS callers are then placed in the triage queue. Modern EMS systems use written telephone medical triage guidelines to ensure consistent and appropriate triage. More important, by asking only for information that will assist in correctly prioritizing the call, they reduce the amount of time spent questioning the patient prior to dispatch. For example, if the caller is male, over 50 years of age, and has nontraumatic chest pain, no further information is necessary for triaging the call as high priority (potential cardiac etiology). Gathering additional information and attempting to make a presumptive diagnosis is not appropriate and possibly detrimental, because it wastes time and is not relevant to the dispatch decision.

Triage protocols can reduce both type 1 and type 2 errors (overtriage and undertriage). They also protect the call-taker from the abusive retrospective review that can occur after a high-profile adverse event. Because the medical director bears responsibility for the appropriateness of these medical triage guidelines, it is strongly suggested that a nationally recognized EMS Telephone Triage product be used. Many of these products are customizable (within limits) to meet local preferences.

EMS calls are usually triaged into one of three priorities: Priority One: life-threatening; Priority Two: emergent or unknown; and Priority Three: nonemergent. These categories are designed to reflect the instability of an illness or injury and its likelihood of deteriorating in a short period of time. They are not intended to characterize whether the condition justifies the use of an ambulance or how serious it is. For instance, although a fractured hip is serious and appropriate for the use of an ambulance, it is not likely to deteriorate and therefore does not have top priority.

Once the call is prioritized, it enters the dispatch queue. The dispatcher then assigns an ambulance to respond. Assigning the closest ambulance to the call is preferred, but this process is not always straightforward. As the number of ambulances in a system increases, so does the complexity of dispatch. In larger cities, the dispatcher would have to know each street and the location of each ambulance at any given time. Most ambulances are “in service” only 15% to 40% of the time, and they may be located outside their assigned districts, making it difficult to ascertain their position without polling multiple units over the radio.

Automatic Vehicle Locator (AVL) systems can help and are increasingly being used, particularly within the private sector. Using the federal government Global Positioning Satellite (GPS) system, AVLs can locate an ambulance within a few feet, calculate the travel time to a given call, and recommend the nearest units of each appropriate type—first-responder, BLS, and ALS.

EMS demand is remarkably predictable, especially in systems with a large call volume. System Status Management (SSM) is the process of managing resources based on known patterns of calls in time and place as well as current demand. Additional ambulances are placed in service during known periods of higher demand. Available units do not remain static, but are dynamically and proactively redeployed by EMS supervisors when call volume is high in certain areas. The practice of flat staffing, in which the same number of ambulances are on duty 24 hours a day, is less efficient; patients will have to wait longer than necessary during the busier times, and resources will be wasted during slack time.

EMS radio communications primarily utilize four frequency bands: VHF-Low (40 to 60 MHz), VHF-High (140 to 170 MHz), UHF (470 to 490 MHz), and the 800 band (800 to 900+ MHz). Each has performance characteristics with strengths and weaknesses. The height of the radio antenna is usually one-fourth the wavelength. VHF, especially VHF-Low, has a wavelength a few meters long and travels a great distance, but it is unable to penetrate manufactured obstacles such as buildings. This band is commonly used by agencies similar to the Highway Patrol, covering wide distances with few artificial obstructions. It is not suitable for use in urban or suburban systems.

UHF has good penetration into manufactured objects, and its antenna is of reasonable height for portable use. The 800 band is often used because there are no available channels to be licensed on the UHF frequencies. It has excellent penetration into buildings, but the wavelength is so short that communications are essentially limited to line of sight (i.e., no over-the-horizon reception). This band is ideal for the urban environment, where one well-placed transmitter can often cover an entire city. It can also be used for a newer technique, called “trunking.”

A trunking 800 system usually consists of six to eight frequencies but has ten times that number in “virtual frequencies.” For instance, each radio may have channels 1 through 6, and each of these channels may have ten subchannels (e.g., A through J), allowing for 60 discrete channels. Each of these channels and subchannels may have restrictions on it; that is, channel 1A may be for dispatch, and all users would have the ability to listen, while channel 4B might be for medical quality assurance, and only the personnel assigned to that group would have radios with the “privileges” for channel 4B. The central computer controlling the mobile and portable radios senses which radios are tuned to which channels. When a user broadcasts on a given channel, the computer assigns an actual frequency (e.g., 800.435 MHz) and programs only the other radios tuned to this channel to go to the frequency. A similar process is used for cell phones.

Frequencies assigned by the Federal Communications Commission (FCC) for medical control, the “Med Channels,” are in the UHF band, thus allowing one radio to serve for both dispatch and hospital communication. There are ten channels in this group, eight for medical control (channels 1 through 8) and two for EMS dispatch (channels 9 and 10). Receiving hospitals may have permanently assigned med channels that allow medics to call directly, or hospitals may be part of a central

medical dispatch (C-MED) system, in which medics call C-MED and are patched into the requested hospital.

Virtually all of the radio frequencies in use for EMS are duplexed: They operate on a pair of frequencies, one to send and another to receive. This set-up allows both parties to talk at the same time, so that either the physician or the paramedic can interrupt the other if necessary. Transmissions by field personnel are weak and can only be heard directly within a few blocks. If desired, the central radio can retransmit these messages with a more powerful transmitter, using the second channel, called a “repeater.”

DISASTER PLANNING

Mass casualty incidents (MCIs; see [Chapter 399](#)) require the response of multiple different public safety and EMS agencies. They threaten to overwhelm the capacity of the out-of-hospital system as well as the medical facilities supporting them.⁸ Each EMS agency and hospital must have a plan for dealing with MCIs in their service area. The importance of having a well-understood, rehearsed, and commonly recognized plan for responding to an MCI cannot be emphasized enough. Practicing implementation of the plan provides training for all participants, prevents needless delays, and identifies areas for improvement. Agencies should have complementary plans and train together to ensure cooperation.

Risk assessment of potential MCI scenarios in a service area should be part of the plan. It involves recognizing and characterizing likely sites of an MCI, such as industrial complexes, airports, residential stock (e.g., high-rise apartments, special-needs facilities), highways and railways, and unique facilities, such as nuclear power plants.

A communications plan is essential. Often, however, it is the part of the response that fails most rapidly in an MCI. Overloaded radio channels, cell channels, and phone lines can be expected. Loss of radio towers and telephone wires may occur. The plan should identify ways to minimize the effect of these occurrences.

Mutual aid agreements with EMS, police, and fire services, as well as medical treatment facilities in contiguous service areas should be in place. The ability to assemble out-of-hospital and hospital assets beyond the affected area is often essential for a timely response to an MCI. The plan should identify the resources, personnel, transport, equipment, and facilities that can be called on.

A clearly defined incident command structure should also be in place. In some states, the highest ranking fire officer serves as overall “incident commander,” with police, EMS and other agencies functioning as subcommands under Incident Command Rules. All involved must use common nomenclature, practice, and communications protocols. There should be clear direction as to what freedom of operation prehospital providers might have without resorting to frequent on-line medical direction. Freedom of operation can be accomplished by having the medical director or designee assume EMS Command–Medical Command at the scene or via radio.

Special planning is required for HAZMAT situations, terrorist activities, weapons of mass destruction, and mass gatherings. Finally, a debriefing plan is necessary to allow for psychological recovery of involved personnel and for the planning to manage future MCIs.

FINANCING EMERGENCY MEDICAL SERVICES SYSTEMS

The expense of an EMS system is a function of personnel, administration, maintenance, training, equipment, and facilities. Other variables include the level of service provided; response-time requirements; how the cost will be apportioned among patient revenues, tax revenues, and other subsidies; the insurance coverage of the population served; and the cost of medical oversight.¹⁵

Funding of EMS systems varies greatly from system to system but can be divided into four major categories: taxes, fee-for-service billing, subscription program revenues, and special service contracts.¹⁵ Local and state tax subsidies can entirely fund an EMS system, in which care is provided as a public service. Most often, this funding comes from general tax revenues and must compete with other public programs for scarce tax dollars.

In some states, the law allows citizens to approve a dedicated tax levy for specific purposes, and voters direct funding for EMS services. Because EMS has a very positive public image, EMS systems tend to enjoy a greater degree of financial support under such a system. In other systems, tax subsidies may simply offset costs that cannot be covered by revenues from EMS billing. Subsidies are often required in small communities that lack economies of scale yet operate a full-service EMS system and in urban and rural settings. It may flow through the budget of a government agency, in the case of third service or FD, or it may be a contractual agreement between a private ambulance provider and a local government. With private contracts, most cities and towns have enjoyed almost a decade of subsidy-free EMS services, as providers have received sufficient revenue from Medicare and Medicaid reimbursement. Recent changes in reimbursement from these sources have significantly reduced the ability of private ambulances to continue subsidy-free 911 contracts.

In a service that generates its revenue from a fee-for-service plan, income is derived from emergency and nonemergency patient transports, interfacility transfers, and special-event coverage. To balance the budget, these systems must have adequate economies of scale, a population base that has the means to pay, efficient management, and effective billing. Among the billed entities are Medicare, Medicaid, private insurance companies, and individual patients.

Subscription programs are marketed to the populace by a vendor who essentially enrolls people as an “insurance policy” in case they need ambulance services. This type of system also provides service to unenrolled members but at a charge significantly greater than the enrollment fee. Some arrangements also allow the company to bill third-party payors. Special-events coverage, interfacility transport, air transport, and other contracts can provide added revenue.

RESEARCH AND INITIATIVES FOR THE FUTURE

Rising costs of health care, the increasing prevalence of managed-care organizations, demands for cost analysis and demonstrated utility of services, and the changing structure of health-care delivery will all influence EMS system development.^{11,12} EMS will undoubtedly continue to exist, as access to emergency services has come to be expected by our society. The permissive environment of EMS development and implementation of prehospital interventions without supporting data has ended.

The “chain of survival,” as described by the American Heart Association, is a good example of the success and failure of EMS research. Efforts to study the effect of interventions for cardiac arrest demonstrated the need for comparable data between systems and fostered the development of a standard for the uniform reporting of data for out-of-hospital cardiac arrest: the Utstein Style.² They also documented the effectiveness of early defibrillation in witnessed cardiac arrest. However, many interventions that are now considered standard of care (e.g., endotracheal intubation and the administration of intravenous medication) were accepted without data showing that they improved patient outcome.

Of the 5,842 scientific studies on EMS in MEDLINE since 1985, only 54 were randomized controlled trials, only one examined a major outcome, such as survival, and only one other compared the studied intervention with a placebo.¹ There is little doubt that the value of EMS systems and the services they provide will come into question in a health-care system under significant financial pressure. Emerging systems may still have a window of opportunity to study these interventions and may, in fact, be obligated to demonstrate improved patient outcome to justify the cost of implementing advanced prehospital services in their areas.

Many attempts have been made in the last 30 years to provide some standard of reporting. Most recently, a Uniform Prehospital EMS Data Conference (1993) was held, again with the hope of establishing an accepted national EMS data set.¹⁸ Uniform reporting would benefit not only research in EMS, but also system evaluation, medicolegal issues, and billing. Still left unaddressed is the linking of prehospital data with in-hospital and follow-up data, a necessary step in demonstrating the effectiveness of EMS care.

A recent assessment of state EMS systems found a lack of (1) comprehensive EMS legislation and statewide EMS plans, (2) enhanced communication systems, (3) consistent quality-assurance programs for training courses and instructors, (4) enabling legislation for trauma system development, (5) consistent and adequate funding sources, (6) priority for public information and education programs, and (7) effective data collection and evaluation systems.^{13,16} Recommendations for future development include (1) integration of health services, (2) EMS research, (3) legislation and regulation, (4) system finance, (5) human resources, (6) medical direction, (7) education systems, (8) public education, (9) prevention, (10) public access, (11) communications, (12) clinical care, (13) information systems, and (14)

evaluation.^{3,4}

It is envisioned that

Emergency medical services (EMS) of the future will be community-based health management that is fully integrated with the overall health care system. It will have the ability to identify and modify illness and injury risks, provide acute illness and injury care and follow-up, and contribute to treatment of chronic conditions and community health monitoring. This new entity will be developed from redistribution of existing health care resources and will be integrated with other health care providers and public health and public safety agencies. It will improve community health and result in more appropriate use of acute health care resources. EMS will remain the public's emergency medical safety net.^{3,4}

Through its unique position in the community as a link to health-care access, the "scope of service" of EMS systems may expand to encompass injury prevention and preventive medicine initiatives, complementing and enhancing roles currently served separately and independently by other agencies.

CHAPTER 402

Performance Improvement

Mary C. Burke

[History](#)
[Performance Improvement: The Ten-Step Approach](#)
[Chapter References](#)

An essential feature of providing high-quality medical care and good risk management in the emergency department is a well-designed and thorough performance improvement plan that scrutinizes all facets of delivering patient care. From a medicolegal perspective, the high volume, high acuity, fast pace, and lack of an established patient–physician relationship make the emergency department a high-risk area of the hospital. This, along with the complexity and diversity of the providers, patients, and ancillary services encountered in the emergency department, makes a well-designed plan an absolute necessity. In addition, the highly competitive climate of delivering health care with the highest quality and highest cost efficiency requires effective measurement of the care delivered.

HISTORY

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has required some form of quality assurance in the emergency department in order for a hospital to maintain accreditation since the 1950s. The first standards involved implicit review, such as morbidity and mortality data collection and analysis. The next generation of standards involved time-limited studies or retrospective audits. These included retrospective reviews of medical records, laboratory results, radiographs, electrocardiograms, emergency department deaths, antibiotic usage, and blood transfusions. Next came ongoing monitoring and evaluation, or “quality assurance.”¹ Its purpose was to somehow measure quality, but, more often than not, the process was nothing more than a checklist approach toward the certification process. Consequently, the task of “doing” quality assurance was viewed rather skeptically by providers of care.

The JCAHO recognized this problem and subsequently endorsed an agenda for change in 1987, which refocused standards to facilitate the implementation of an integrated program of continual quality improvement. The audit process was replaced with the new paradigm of looking at improving the entire process related to the delivery of care.³ This concept is grounded on philosophical work by numerous quality-control experts, such as Deming, Juran, Ishikawa, Crosby, and Stewhart, who introduced the concept to business with the specific goal of reducing variance, continually improving the work process, and improving the final product.⁶ The JCAHO's new approach to improving performance includes designing processes, monitoring performance through data collection, analyzing current performance, and improving sustained performance.⁴

PERFORMANCE IMPROVEMENT: THE TEN-STEP APPROACH

The JCAHO supports the use of a ten-step approach for monitoring and evaluating performance improvement ([Table 402.1](#)). This methodology serves as a guideline for providers to design and implement an effective quality-improvement plan. Virtually all aspects of care can be integrated into this ten-step process. The specifics should be adapted to the size, volume, and financial capability of the department. The ten-step process is described in detail:

1. Assign responsibility.
2. Delineate scope of care.
3. Identify important aspects of care.
4. Identify indicators.
5. Establish a means to trigger evaluation.
6. Collect and organize data.
7. Evaluate care.
8. Take actions to improve care and services.
9. Assess effectiveness of actions and ensure improvement is maintained.
10. Communicate relevant information to organization-wide quality improvement program.

TABLE 402.1. Step Process

Step 1. Assign responsibility. The department chair is responsible for designating the individuals who will oversee the development and implementation of the department performance-improvement plan. The most successful approach is to have a team of physicians and nurses working together on a combined plan.⁷ Communication, cooperation, and mutual respect are essential for success. This sets the tone for sharing responsibility, enhancing empowerment, and continually improving care.

Individuals responsible for collecting data must also be identified. They should be taught the reasoning behind the selection of data being collected; this knowledge leads to more accurate data collection. These individuals can be the department secretaries, administrative assistants, physicians, or nurses.

A clear hierarchy in the hospital performance improvement plan should also be defined, with specific reference to where the emergency department's plan fits into the overall scheme.

Step 2. Delineate scope of care. This section essentially outlines the types of clinical care that will be monitored and evaluated. The scope of care is defined by what types of services are available and provided in the department. The accreditation manual for hospitals requires that all hospitals be designated according to the scope of care provided.² Census data, such as the volume and disposition of medical, surgical, obstetric, gynecologic, pediatric, orthopedic, geriatric, and trauma patients seen in the emergency department, should be collected and reported. Hospital-specific services, such as a trauma center, burn unit, or organ transplant service, that affect emergency department care should also be mentioned.

Step 3. Identify important aspects of care. Each department should identify those aspects of care that are considered important. Generally, these are high-risk procedures, high-volume conditions, and problem-prone cases. It is virtually impossible to study all areas at all times. Consequently, each department should select aspects of care that are known or suspected to have problems. [Table 402.2](#) lists a sample of important aspects of care.

HIGH-RISK PROCEDURES

Conscious sedation
Thrombolytic therapy
Transfers

HIGH VOLUME

Tetanus status
Admissions
Completeness of medical record

PROBLEM-PRONE

Psychiatric cases (i.e., suicidal/violent patients)
Restraint use
“Left without being seen” patients

TABLE 402.2. Some Important Aspects of Care

Step 4. Identify indicators. After the important aspects of care are identified, it is then necessary to determine what variables can objectively measure that specific aspect of care. Indicators should be developed from the current literature, with specific reference to the practice of emergency medicine. A selection of examples are listed in [Table 402.3](#).⁶

TABLE 402.3. Selected Indicators

It is also suggested that department indicators coincide with hospital-wide indicators that may be used for interhospital comparisons. For example, the Maryland Hospital Quality Indicator Project⁵ uses the following data points:

- Unplanned returns to the emergency department within 72 hours of a previous visit
- The number of patients admitted to the emergency department out of the total number of returns
- Patients who remain in the emergency department more than 6 hours
- X-ray report discrepancies between an emergency department reading and a radiology reading that require a change in follow-up or treatment
- Patients who leave the emergency department before completion of treatment

State and regional variations influence the type of interhospital comparisons used. Familiarity with the indicators already being used will avoid the inefficiency of duplicate data collection.

Step 5. Establish a means to trigger evaluation. Triggers for evaluating care are occurrences or measurement thresholds that determine when a more detailed investigation of an important aspect of care must be done. Triggers can be singular or rate based. A sentinel event trigger requires evaluation every time the event occurs. One example of this type of trigger is a death in the emergency department. Complaints can also be sentinel event triggers and often indicate the need to study and improve both medical care and other areas related to patient satisfaction, such as communication, interpersonal skills, waiting times, and physical surroundings.⁸

Rate-based triggers should be determined by expert and departmental consensus as to what constitutes an acceptable and achievable goal. Such a determination will ensure better cooperation and compliance in improving an area if a single, specific problem arises. An example of this type of trigger is the average time that it takes to administer thrombolytics after a diagnostic electrocardiogram is obtained.

Step 6. Collect and organize data. For each indicator, it is essential to have a carefully designed data collection plan that identifies the following parameters:

- Data sources/data collector
- Collection methods (i.e., sampling, sampling size)
- Data to be collected
- Method of data analysis to be used to determine whether a threshold for action is reached

Step 7. Initiate evaluation. The results of all ongoing data collection and analysis should be reported back to the emergency department performance-improvement team and to the department director. This information is used to identify problems and determine whether further evaluation is necessary. This also triggers the cycle for continually improving care.

Step 8. Take actions to improve care and services. This step involves intensive work to address any problem that may have been identified. Specific actions should be initiated to improve the overall level of care provided. A specific time frame should be identified as to when a change should occur.

Step 9. Assess effectiveness of actions and ensure improvement is maintained. It is necessary to determine whether care has actually improved as a result of actions taken, and, if not, to determine what further actions need to occur. This step essentially closes the feedback loop in the performance-improvement process. It is also important to periodically monitor the same indicator to assure that quality is maintained.

Step 10. Communicate relevant information to organization-wide performance-improvement program. The results of the performance improvement effort should be forwarded to the hospital performance-improvement committee, hospital leaders, and the governing body.

Emergency departments also need to incorporate outcome monitors in the overall plan. Some of the indicators may be timeliness of surgical intervention for adult head injury, timeliness of patient transfers, and airway management for comatose trauma patients.

The final component of the complete performance-improvement plan involves thorough documentation of both patient satisfaction and patient complaints. These data should be maintained for both the clinical and nonclinical members of the department. The information can be used with the remaining quality-assessment findings to identify potential medicolegal problems.

CHAPTER 403

Triage

Anthony R. Berner

[Triage within the Emergency Department](#)
[Triage from the Emergency Department to Other Sites](#)
[Telephone Advice](#)
[Common Pitfalls](#)
[Chapter References](#)

Triage, a word derived from the French verb *trier*, meaning “to choose or sort,” was originally associated with battlefield or disaster situations. In such situations, in which casualties overwhelm the capabilities and resources of health-care systems, the triage officer must decide which patients need immediate treatment, which patients can wait for treatment, and which patients are so severely injured as to render treatment futile. Triage, in this context, is a major issue for prehospital providers of care and transport. In emergency department (ED) triage, patients are evaluated immediately on arrival, and a determination is made regarding how long they can wait for care and where they should receive this care.

The goals of ED triage are to define and classify the urgency of patients based on their complaint and presentation, to ensure their safety, to facilitate their care and flow through the ED, and to satisfy relevant legal requirements mandating “screening” examinations for all persons presenting for care. In some cases, this may include triaging patients away from the ED to other health-care sources and giving telephone advice.

TRIAGE WITHIN THE EMERGENCY DEPARTMENT

Most hospitals in the United States use registered nurses to perform triage in the ED. Despite evidence that specialized training improves performance,⁴ many report that triage nurses are not required to have special training for this role. Licensed practical nurses (LPNs), nurse practitioners, technicians, and physician assistants are also frequently employed in triage roles. Specially trained nonmedical personnel using physician-written algorithms have been shown to be highly effective, with high levels of agreement with subsequent physician review.¹⁹ Computerized algorithms have also been shown to be safe and effective adjuncts to triage.³

Triage documentation should include the chief complaint, a limited history and physical examination, vital signs, significant or relevant past medical history (e.g., immunization status), current medications, and allergies. If applicable and practical, visual acuity testing can also be performed. While excessive evaluation at the triage desk may actually prolong waiting time for sicker patients,⁷ initiating some diagnostic tests (e.g., x-rays, blood tests, urinalysis) has been shown to decrease waiting times,¹⁰ with good correlation to tests subsequently ordered by physicians.¹⁶ In some instances, initiating treatment in the triage area (e.g., administering antipyretics, oral rehydration, and topical ophthalmic anesthetics) may also facilitate ED care.

Triage classification schemes typically utilize either three or five levels of priority. ([Table 403.1](#) and [Table 403.2](#)).

EMERGENT
Complaints, vital signs, illness, or injury consistent with an acute, potentially life- or limb-threatening condition that requires immediate evaluation or treatment to prevent mortality or increased morbidity. Examples: airway obstruction, coma, uncontrolled hemorrhage, chest pain, respiratory distress, shock, multiple trauma, toxic ingestion, severely painful conditions, active labor, newborn infant, complications, dental avulsions
URGENT
Complaints, vital signs, illness, or injury consistent with an acute, potentially life- or limb-threatening condition requiring evaluation or treatment within a few hours to prevent mortality or increased morbidity. Examples: open fractures, abdominal pain, ear infections, severe headache, cat bites, moderate difficulty breathing, sore throat with dysphagia, hip or long-bone fractures
NONEMERGENT
Complaints, vital signs, illness, or injury consistent with a subacute or chronic, non-life- or limb-threatening condition that does not require evaluation or management within 24 hours to prevent increased morbidity. Examples: second degree burns, sutures removal, chronic rash, chronic joint pain, insect bites (without anaphylaxis), minor lacerations, minor isolated extremity trauma

TABLE 403.1. Triage Classification Categories: Three Levels of Priority

IMMEDIATE
Complaint or condition requiring immediate assessment and treatment; any delay represents an unacceptable risk to the life or limb of the patient. Examples: cardiac arrest, obstructed airway, shock
VERY URGENT (EMERGENCY)
Complaint or condition requiring assessment and treatment within 10 minutes. Examples: chest pain, significant hemorrhage, significant difficulty breathing, major trauma
URGENT
Complaint or condition requiring assessment and treatment within 30-60 minutes. Examples: toxic ingestion, severely painful conditions
SEMURGENT (STANDARD)
Complaint or condition requiring assessment and treatment within 1-2 hours. Examples: ear infections, abdominal pain, hip or long-bone fractures
NONURGENT
Complaint or condition requiring assessment and treatment within 2-4 hours or longer. Examples: second degree burns, sutures removal, isolated minor extremity trauma

TABLE 403.2. Triage Classification Categories: Five Levels of Priority

Generally, emergent problems include immediately life-threatening conditions, urgent problems require treatment within a fairly short time, and nonemergent problems are conditions in which delays in treatment are not expected to be detrimental. Five-level systems use additional levels primarily to further discriminate among patients with the most acute presentations (i.e., “emergent” in a three-level system). Such patients would be divided into immediate (i.e., resuscitation), very urgent, and urgent categories, with target times to evaluation and treatment of 0, 10, and 30 to 60 minutes, respectively. Such systems are used in Canada, Great Britain, Australia, and New Zealand, and include specific recommendations for acceptable waiting times in each category.⁶ Based on the triage classification, the patient can be moved immediately to the appropriate treatment area, or can be processed for patient registration.

TRIAGING FROM THE EMERGENCY DEPARTMENT TO OTHER SITES

Due to ED overcrowding and the high cost of ED care, many hospitals triage selected nonemergent patients out of the ED. In fact, in many discussions, the very term *triage* has come to mean refusal of ED services rather than prioritizing patients for care within the ED. If patients are to be refused care in the ED, they must receive an adequate screening examination as required by federal law, and there must be a practical alternative source of care. The prevailing consensus is that a screening examination constitutes a physician-directed evaluation, and treatment, if necessary, using all of the necessary resources routinely available in the hospital (see [Chapter 408](#)).

A study of more than 31,000 patients triaged from a university ED to alternative sites over a 5-year period showed no significant adverse outcomes. Patients who were refused care met strict inclusion and exclusion criteria. Follow-up data were available on only 34% of cases, but, of those, 26% had decided not to seek alternative care of any kind. Only 1% sought care at another ED.⁵ Another study, using the same guidelines, at a different hospital concluded that the guidelines may not be sensitive enough to identify all patients who need emergency care.¹⁴ Other studies have shown that high percentages of pediatric patients who were refused care

failed to keep appointments made for them by the ED.¹² All studies of patient outcome after being refused care are limited by incomplete follow-up information. It is also clear that there is significant variability among individual practitioner's assessments regarding the urgency of patients' complaints⁸ and that triage methods have not been widely standardized and statistically validated.²⁰

The Society for Academic Emergency Medicine has published an ethics statement defining refusal of ED services as ethical only if an examination has determined the lack of an emergency and assured medical stability, that alternative care is available without financial or other barriers, that the patient will be seen in a timely fashion, that the alternative site is either on campus or transportation is assured, that the patient understands and agrees to transfer, that all patients are treated equitably, and that triage criteria are based on research showing them to be safe and effective.¹⁸

Many hospitals are developing "fast-track" or "urgent care" systems in which patients with minor illness and injuries are triaged to a separate area, which may or may not be in physical proximity to the ED, for prompt service. This type of system may be particularly suitable for patients who are unlikely to require x-rays, laboratory studies, or hospital admission, all of which prolong ED waiting time.¹⁵ It is unclear whether fast-track centers within EDs actually realize the savings (either for the hospital or for society in general) for which they are intended.¹⁷

Nurse practitioners have been used to staff fast-tracks with good results, including decreased overall patient waiting times and high levels of patient satisfaction. Advanced training and physician backup are essential to a smoothly running system. Teaching hospitals have also reported good results with house officer-staffed fast-track systems, but problems can ensue when overall ED acuity is high, requiring fast-track staff to be used in other areas.

TELEPHONE ADVICE

More than 1 million telephone calls per month are made to various health information services nationwide. Studies of the types of calls made to EDs show a variety of complaints, ranging from common gastrointestinal and respiratory problems to hemorrhage and cardiopulmonary arrest. These calls are usually handled by a nurse, with or without physician backup. Because a patient cannot be examined over the telephone, the physician or nurse is limited in diagnosing or managing problems. Protocols (algorithms) for handling medical advice telephone calls have been developed and tested. Explicit training for telephone management is part of some residency programs.¹¹

Telephone advice should also be considered another form of triage. Patients who would be triaged as emergent should be advised to call an ambulance for transport to the nearest appropriate facility. Those judged to have urgent complaints or conditions should be advised to come to the ED as soon as possible, by private vehicle or public transportation, if appropriate. Alternatively, they can be advised to check with their primary care provider. If patients cannot be seen by their primary care provider in a timely manner, ED evaluation should be recommended. Patients with nonemergent conditions may be referred to their personal physician, a staff physician, or an outpatient clinic. If there is any doubt about the urgency of the complaint, patients should be advised to come to the ED immediately. Because telephone triage is based solely on reported symptoms, it is important to triage to the highest possible level based on a worst-case scenario.

Simulated calls have been used to assess the quality of advice given in response to potentially serious complaints.¹ Essential information is often not sought, and inappropriate treatment is often recommended. In general, telephone advice is often inadequate and may expose the patient to medical risk and the advice-giver to legal risk. The experience and level of training of those who give advice over the telephone do not seem to guarantee the quality of the advice. In one study, nurse practitioners managed pediatric problems over the telephone better than pediatric house officers or practicing pediatricians. Among practicing pediatricians, less experienced physicians asked more questions and spent more time on each call than their more experienced colleagues. A large British study showed that nurses managed primary care phone consults as safely as physicians.¹³

Malpractice judgments have resulted from inadequate or erroneous medical advice given over the telephone.⁹ If any medical advice is given, an assumption of duty may be presumed and the advice-giver can be held responsible for that advice, even though the advice-giver may neither have met the patient nor received any payment for services.

The American College of Emergency Physicians (ACEP) "recommends against any substantial diagnosis or treatment recommendation by telephone." Patients who have been recently discharged from the ED and have questions about their instructions are exceptions to this rule. Also, patients who need first aid information or information about accessing medical care should be obliged.² ACEP further recommends that telephone advice be given only by qualified personnel, and that the quality of advice should be maintained with explicit policies, protocols, and quality-assurance programs. Hence, secretaries should refer all calls to a nurse, preferably one trained in triage, with physician advice obtained in all but the most straightforward cases. It is also prudent to document all telephone conversations by using a logbook or patient encounter forms.

COMMON PITFALLS

- Failure to attribute presenting symptoms and signs to the most serious possible etiology, and then triage accordingly
- Failure to periodically reassess the condition of patients in the waiting room and retriage, if necessary
- Giving substantive telephone advice, especially advice to delay or avoid seeking care
- Triage to other sites without using strict guidelines, and only after an appropriate screening examination

FUNCTION OF THE LAW

The law provides behavioral rules that organize society, a way to enforce these rules, and a means to resolve disputes between parties. The legal system performs these functions with three mechanisms that differ in point of view and operation: adjudication, advocacy, and arbitration. The law has a major impact not only on the delivery of health care, but also on the management and daily operation of health-care institutions. The emergency physician should be familiar with the fact that various sources of law exist and with the general areas of law that apply to clinical practice. However, law is more often the interpretation of several potentially applicable sets of facts to a slightly unclear set of rules and cases. Rules have exceptions and special circumstances under which the law is applied differently. It is the exceptions, not the laws, that create the need for lawyers.

Sources of Law

The American legal system recognizes several sources of law, including statutory law and case law. Statutes are laws developed and codified by the elected legislative branches of federal, state, or local governments. * Case law is the accumulated body of decisions of state and federal courts. † Existing case law precedent must be followed in resolving current disputes, but variations between cases make case law more obscure and fluid than statutory law. A binding precedent in one jurisdiction may be, but does not have to be, followed by other jurisdictions. Regulations are like statutes but are promulgated by administrative agencies, generally to amplify or supplement statutes. Hence, although they are not legislated, regulations are considered administrative law. They tend to be even more fluid than case law and prone to variation with political climate. If challenged, regulations are reviewed by the courts to determine whether the regulation is within the scope and authority of the administrative body and whether it avoids abridging Constitutional rights.

CIVIL AND CRIMINAL LAW

There are two categories of legal actions—civil and criminal. Criminal proceedings arise from a charge of public offense in which a law has allegedly been broken and the aggrieved party is the government. The goal of criminal law is to punish the wrongdoer, and the punishment is usually some loss of liberty, most often incarceration or a significant monetary fine, or both. Civil disputes are actions between private parties. The goal of civil litigation is to compensate the injured or aggrieved party. Medical malpractice falls within the category of civil suits and is a tort, or a civil wrong. Torts can be either intentional, such as punching another person, or unintentional, such as hitting another person while hurrying around a corner. Within the broad category of negligence falls professional negligence, including medical malpractice. Negligence occurs when, without harmful intent or wrongdoing, one acts in a manner, either by commission of an act or omission of an act, that injures another.⁹

Most civil disputes are resolved without court trial, often with attorneys acting in an arbitration role. When it is not possible to resolve disputes privately, the courts assume that role and establish case law. Variability in case law occurs because of subtle differences in facts or laws and because there is room for human subjective interpretation in an otherwise well-defined process.

A lawyer's role is not just to interpret and argue the law, but also to understand and apply the exceptions, the special circumstances or conditions in which the general intent of the law does not apply or may be applied differently. For example, speed limits on highways may not apply to emergency vehicles during emergency operations. In many cases, the wealth of exceptions developed through case law complicates and exceeds the scope of the original law as stated, and compliance requires significant analysis and understanding of these conditions.

Malpractice

Medical malpractice is professional negligence, or medical practice falling below what is generally held to be the standard of practice for a physician with similar training in the same or similar circumstances as the physician who rendered the care in question.¹⁰ It is generally assumed that a practicing physician is required to possess the same or similar skill level as others with similar training practicing in similar circumstances, regardless of his or her specialty. It is further assumed that the physician will exercise reasonable care in the treatment of his or her patients.

The application of these assumptions to physicians practicing in emergency departments creates some confusion. In many cases, the physician providing care in an emergency department may not be trained or board certified in emergency medicine. The standard, however, remains “same or similar training in same or similar circumstances.” Therefore, physicians without emergency medicine training are not currently held to the standard of those who are trained or certified in emergency medicine when practicing in the emergency department setting. This is not to say that the standard for those certified in emergency medicine is always higher; a cardiologist moonlighting in the emergency department will probably be held to a higher standard when caring for a patient with cardiac disease than a board-certified emergency physician caring for the same patient. This situation, presumably existing because hospital credentialing criteria allow physicians without emergency medical training or certification to practice in that setting, is changing. It may reasonably be expected, based on the legal concept of detrimental reliance, that physicians practicing in emergency departments soon will be held to the standard of physicians trained and certified in that specialty. In other words, the public has a right to expect a facility offering emergency care to include access to physicians trained and competent in that specialty.

The standard-of-care definition will likely shift to require that physicians be held to the standard of a physician choosing to practice in the same setting, not to the standard of those with equal training regardless of setting. It is more logical from the patient's point of view, and as emergency physicians argue for more specialty-specific qualifications in hospital credentialing criteria, they will accelerate this shift. However, until this shift occurs, physicians practicing emergency medicine should be aware of the credentialing requirements at their facilities and comply with them meticulously. Failure to meet the credentialing requirements, or, worse, intentional misrepresentation that certain certification or training is an adequate substitute for a specified training program, may place the noncompliant physician in significant jeopardy if legal action occurs and the credentialing process is examined. In particular, self-insured hospitals may have no obligation to cover physicians who misrepresent themselves on credentialing forms. Physicians unhappy with credentialing requirements, for any of the reasons just mentioned, should work to change them rather than ignore or circumvent them.

To prevail in a malpractice, or negligence, action against a physician (defendant), the allegedly injured patient (plaintiff) must begin legal proceedings within the time period defined by the applicable statute of limitations, and prove four elements:

1. That the physician owed a duty of care to the patient
2. That the duty was not performed to the level of the generally accepted standard of care. This is known as a breach of duty.
3. That some injury occurred

4. That the breach of duty was the cause of the claimed injury

Not all bad outcomes are caused by negligent practice, just as every instance of substandard practice does not result in patient injury or legal action. Unfortunately, many patients are not informed or do not understand that a perfect outcome cannot be expected in all cases. Educating patients and their families about reasonably expected outcomes from a certain condition may help correct this misperception.

DUTY

The legal concept of a duty was created in an attempt to delineate the relationship and responsibilities between two or more parties. If one owes a duty to another, then a special relationship has been entered into—to treat another with “due care.” *Due care* is defined as ordinary reasonable care, not the best care available and not the worst. Failure to act with due care results in a breach of duty.

In general, one does not have a duty to act on behalf of another unless some special relationship exists. There is no mandate that a physician must undertake to render care to a particular patient. The relationship between physician and patient is based on contract theory in which the physician has the right to choose which patients he or she will treat.³ This means that, with a few exceptions, physicians are under no affirmative duty to render aid to a patient, even if the patient is likely to die without such aid. Should a physician not wish to enter into a treatment relationship with a patient, such limitations should be set out clearly so that they are understood and accepted by the patient. If the physician chooses to treat, payment or discussion of fees is not necessary to hold the physician liable for failing to exercise ordinary care. Even if a physician renders care gratuitously, he or she is not absolved of the duty of due care.⁵

Although at common law there is generally no right of a person to hospital admission, the freedom to choose whether to treat no longer extends to hospitals, and modifications of this general rule have been made with regard to patients who present to emergency departments.⁴ Courts have found that an emergency department physician owes a duty to all persons who present for care, and that a hospital operating an emergency department owes a duty to offer care to all persons presenting for care, including admission, if warranted. This exception to the general principle requiring a special relationship before establishment of duty has developed from the theory of detrimental reliance; patients who presented to emergency departments in the past and were denied care were found to have relied, to their significant detriment, on their belief that the hospital was offering emergency care to all who presented for such care. Thus, the duty owed by emergency physicians arises out of an exception to the general principles of duty.

STANDARD OF CARE

Where a duty exists, that duty is to treat at least to the standard of care. The plaintiff in a malpractice action must show that the treatment provided by the defendant physician did not meet the standard of care, as defined by expert testimony. An expert is a physician with the same or similar training as the defendant who testifies to what care would have been reasonably appropriate in similar circumstances.^{12,13} General practitioners are usually held to a local standard (county or state), and specialists, such as trained or certified emergency physicians, are held to a national standard.¹ As discussed, current common practice is that the standard for emergency physicians is often defined by specialists in other fields (e.g., cardiologists, orthopedists), either because that is the training of the defendant physician working in the emergency department or because the patient's problem clearly falls into that specialty in the mind of the plaintiff's attorney and the attorney is able to find a specialist willing to testify to their understanding of the standard of care. Therefore, some physicians, untrained in emergency medicine but working in emergency departments, are held to the standard of their own training rather than to emergency physician standards, and some physicians, trained in emergency medicine, are held to the standard of a specialist in whatever area encompasses the patient's problem. Both of these situations are changing. Many more trained and certified emergency physicians are making themselves available to the plaintiff's and/or defendant's bar for case analysis, expert opinions, and testimony related to the standard of emergency care. Guidelines for emergency physicians wishing to make themselves available for expert opinion work exist. Simultaneously, pressure to change hospital credentialing requirements for physicians practicing in the emergency department, increasing numbers of residency-trained emergency physicians, and other forces will probably reduce the number of physicians without emergency training or certification practicing in emergency departments. These trends, along with the development and publication of practice guidelines, should clarify the standard of care for emergency physicians.

In some circumstances, however, a higher standard of care is established by hospital policies and procedures, and these can vary significantly from facility to facility. Hospital employees must follow the policies and procedures established by the hospital.⁶ Because emergency physicians are often employed by the hospital, or are considered hospital employees, they should familiarize themselves with, and adhere to, hospital policies and procedures.

A dilemma occurs when the individual physician feels that patient care, at or perhaps above the standard, is required that would conflict with a hospital policy or procedure. Ideally, relevant policies and procedures should be developed with the input and approval of the emergency physicians involved, but if not, any legal issues should be referred to an attorney skilled in emergency medical law for opinion. Continued physician disagreement, if any, with hospital policy should be clearly documented and a course of action developed. One option is for the hospital to agree, in writing, to accept liability for any claims arising out of the disputed policy. This is referred to as an indemnity agreement, whereby the hospital agrees to indemnify the physician for the particular matter. This is clearly more confrontational than a mutually agreeable policy, but it may be a useful concept in situations in which there are impassable issues related to a particular policy.

Implicit in due care is the expectation that the physician is acting in the best interest of the patient at all times. Adhering to accepted medical practice, but in a manner that is against the best interest of a given patient, may trigger a claim of negligence. If you know or believe the standards set in your institution pose unnecessary dangers to your patients, whatever precautionary measures as are appropriate should be taken to protect the patient from harm, even if that means violating hospital policy or procedure.

INJURY

The plaintiff must also prove that an injury has been suffered to prevail in a negligence action. Regardless of how bad the care, there is no case for malpractice if there is no injury. Although, traditionally, the injury suffered had to be physical, increasingly, states are allowing recovery for infliction of emotional injuries such as emotional distress,⁸ even in the absence of physical injury. The injury may also be to a third party if it was caused by negligent treatment of the patient. For example, a patient who is discharged in an impaired state (e.g., eye patch on, narcotics given, or intoxicated) without being warned against driving and who subsequently runs over a pedestrian (third party) has a reasonable claim that the accident was foreseeable, and both the patient and pedestrian could file claims against the emergency physician.

CAUSATION

The final element of a negligence claim is causal connection between the actions of the physician and the injury. The physician's action must be the *substantia* factor in the patient's injury. No matter how bad or unexpected the patient's outcome, or how far the care rendered to the patient was below the standard, if the negligence did not cause the outcome, there is no liability for malpractice. On the other hand, the outcome from the negligent act may be separate from the overall outcome, and no matter how good the overall outcome, the negligent act may still substantially cause an injury. For example, tissue necrosis that requires skin grafting and is caused by an extravasation of dextrose intended for intravenous injection may result in disfigurement and loss of function, despite the fact that the patient recovered from the hypoglycemic episode. If the same injury occurs during futile resuscitation attempts performed on a patient who arrives in asystole, there is no causal link between the extravasation and the patient's death, assuming that the death was not caused by untreated hypoglycemia.

APPLICATION OF GENERAL PRINCIPLES

Duty

The duty of an emergency physician to care for persons is complex and may vary depending on the person's circumstances, location, and problem. It is generally accepted that the emergency physician owes a duty to persons who come to the emergency department requesting care. Patients of private physicians who come to the emergency department to be seen only by their own private physician can create a great deal of confusion for the emergency department.¹⁴ Determining who is responsible for evaluating the patient and rendering care is not easy in these situations without clear and complete policies and procedures. If not formally seen by the emergency physician, these patients are frequently not triaged, no record of their care exists, and the emergency physician on duty may not be aware of their presence in the emergency department. However, if these patients suffer a clinical deterioration while waiting, the emergency department may be liable for the patient's outcome. This is based on the theory that the emergency physician is responsible for all of the patients in the department, not just those who present for care

by the emergency physician. Hence, all persons who physically present to the emergency department must be seen by the staff, and should have a nursing evaluation if it is standard in the facility, a medical record initiated, and evaluation by the emergency physician for any potentially emergent conditions that may exist before being allowed to wait for their private physician (see [Chapter 408](#)).

This duty may also extend to those patients who initiate contact with the department by telephone or through the emergency medical system (EMS) and may include others in the hospital or on hospital grounds (e.g., patients, visitors, employees), depending on the hospital's policies regarding the scope of responsibility for the emergency physician. A record should be made of all telephone and radio patient contacts, including the subject of the call and advice given. Records should also be kept for any physician–patient encounters that occur outside the emergency department, particularly if a formal emergency department evaluation is not subsequently performed.

There are situations in which the duty owed is expanded to include other foreseeable parties. If parents, for example, are asked to participate in the care of their child, the emergency department may owe a duty of care to the parents, including a duty to protect them from injury (e.g., fainting and needlesticks) while participating in that care.⁷ If, however, the parent is not asked to participate in the patient's care but wishes to accompany the patient during the treatment, the emergency department does not owe the parent the duty of protection from fainting. Other foreseeable third parties to whom a duty is owed include bystanders who may be injured by an impaired patient within the department.

Immunity

In an attempt to encourage volunteerism in an emergency situation, many states have enacted Good Samaritan statutes, a form of immunity, to protect physicians as well as lay people from claims of malpractice if they undertake to render aid to another in an emergency. An immunity, defined as a benefit that is granted contrary to general rule, may be invoked by the emergency physician as a defense to a charge of malpractice if the circumstances of the encounter meet jurisdictional requirements. There are some typical elements of Good Samaritan statutes. The first is a class requirement that delineates the group of people to which you must belong for the immunity to apply. Many statutes provide protection for the person who arrives at the scene of an emergency, is present when the emergency occurs, or is called to the scene of the emergency and refer specifically to nurses, physicians, and EMS providers. The second element is a compensation requirement. Most immunity statutes require that the care rendered must be uncompensated. Therefore, these statutes generally do not apply to physicians whose compensated or routine job it is to provide emergency care in emergency departments, but they may apply when the emergency physician is acting outside of normal employment, such as by providing care at the scene of an automobile accident while driving home from work. There is a good faith requirement in most statutes, which means that the care rendered is done so in good faith, with the victim's best interests in mind. There is also generally a conduct requirement, stating that there be no "grossly negligent conduct." This immunity may be invoked by the emergency physician charged with malpractice if the circumstances of the event meet local requirements. Generally, compensated practice in an emergency department does not apply. An immunity does not mean that one cannot be sued (although a reasonable plaintiff would not pursue action in such circumstances), and it only offers one defense to a suit, albeit a powerful one.

Therefore, the duty of an emergency physician to care for persons is complex and may vary depending on the person's circumstances, location, and problem. It generally extends to all persons presenting physically, and probably by other means of communication, to the emergency department, and may also include others in the hospital, such as patients or visitors, employees, and persons on or near the hospital grounds, depending on hospital policy regarding the responsibilities of the emergency physician and the department. In some cases, particularly when the care given may be "volunteer" and outside the scope of typical or normal duties, there may be no duty to care, and any care given may be immune from legal action if certain tests are met.

SUMMARY

Law may be statutory, regulatory, or arise from cases. Exceptions and jurisdictional location may significantly alter findings. Medical malpractice claims arise from civil tort law, and, therefore, are not criminal in nature. The elements required to prove malpractice are duty, breach, causation, and damages. Practical application of these principles can be complex, as illustrated with the concept of duty as it applies to emergency physicians. Additional legal issues are explored in detail in subsequent chapters.

COMMON PITFALLS

- Failure to appreciate the governing laws for your jurisdiction and their exceptions
- Failure to educate patients about potential adverse outcomes as well as expected outcomes
- Failure to understand the concept of the duty to treat
- Failure to apprise oneself of hospital policies and procedures and abide by same
- Failure to consider the duty owed to third parties and society

*An act of the legislature declaring, commanding, or prohibiting something. ³

†The aggregate of reported cases as forming a body of jurisprudence. ²

‡The terms of the relationship between the physician and the patient may be general or limited. ⁸

§Evidence that hospital employees mistakenly informed parents that a dead child was alive supports a claim for emotional distress. ¹¹

Medical technology is capable of sustaining patients unable to convey their wishes about further care. Physicians may discuss such matters with patients and write orders limiting therapy, and patients may create a variety of documents, known generally as advance directives, expressing their wishes or authorizing others to make medical decisions for them in the event they become unable or not competent to voice such wishes themselves. In most cases, the patient has a serious chronic medical problem and the orders or documents are intended to limit resuscitative measures that would otherwise be initiated. These orders are often referred to as “Do Not Resuscitate” or “DNR” orders, but the term *resuscitation* is so overly vague and broad in scope as to make it meaningless without further definition. Therefore, this chapter avoids use of the word *resuscitation* as defining a specific set of medical therapies, and uses it instead to refer to the concept of efforts to restore or stabilize vital functions.

Hospitalized patients cared for by physicians who know the patients' wishes often benefit from such orders or documents limiting therapy. Problems arise when patients present to emergency departments, move from one health-care facility to another, are cared for by emergency medical services (EMS) providers, or otherwise are in a setting where their primary physician does not directly control their care and their wishes are not clearly represented in an unambiguous and verifiable fashion. It is rare that patients have a copy of the order written by their physician or their advance directive when they present to the emergency department, and even more rare that such an order or document is acceptable to the emergency physician treating the patients. For example, these documents may be vague, illegible, outdated, not legally accepted in certain states, or impossible to verify. Medical records, if present, are not likely to be current and easily verifiable as accurate or reflecting the latest wishes of patients. Further complicating the situation is the need for speed if patients are to be treated. Another difficult question is whether emergency personnel should honor a third-party (the patients' families or primary care physicians) communication (orally or through documents) regarding the patients' wishes when the directive itself is unavailable. The result is that treatment may be initiated in an effort to resuscitate the patients, even though these efforts may not be in accord with their wishes. This chapter reviews the various types of advance directives and orders limiting therapy currently in use, examines some of the issues surrounding them, and makes suggestions for emergency department care.

“DO NOT RESUSCITATE” ORDERS

One of the most pressing problems facing emergency physicians in the area of limiting patient therapy is the definition of terms. The words *do not resuscitate* (DNR) mean different things to different people. American Heart Association (AHA) standards suggest that DNR orders are appropriate for a patient who is “irreversibly, irreparably ill, whose death is imminent;....”¹⁶ By *irreversible*, it is meant that there are no known therapeutic measures that would be effective in reversing the course of the illness. *Irreparable* means the time has been reached when the course of the illness has progressed beyond the capacity of existing knowledge and technique to stem it. *Imminent death* is defined as death occurring with reasonable probability within 2 weeks of the time that the DNR order is written. Even with these definitions, problems exist. There is confusion about what is ordinarily meant by *resuscitation*, even among physicians. In one study, 90% of physicians surveyed thought that DNR meant that there be no chest compression or use of defibrillators on a patient whose heart had stopped beating; about 85% thought that DNR prohibited intubation of the airway for artificial ventilation if the patient stopped breathing; and 60% thought that DNR meant that no drugs should be used to raise the patient's blood pressure.¹³ If physicians are confused, then patients most likely are as well. What patients perceive as extraordinary measures will depend, in large part, on the orientation of their own physician.

Emergency physicians routinely perform procedures that are perceived by most patients, and some of the medical profession, as heroic and extraordinary. Therefore, the term *DNR* is too vague and broad for meaningful use. More specific instructions, such as “No CPR” or “No intubation” may be an improvement, but even more useful would be a clearer definition of *when* efforts should be made to treat the patient and the goal of those efforts, leaving the exact nature of the therapy to the treating physician. For example, documentation that a patient with chronic lung disease wants no therapy to reverse respiratory failure if respiratory arrest caused by the chronic disease is imminent, but instead prefers comfort as a goal, is clearer documentation than a vague “I do not wish any heroic or extraordinary measures” statement.

INFORMED CONSENT

Informed consent means that competent adults have the right to make decisions, after being informed about reasonable options, as to what medical care they will or will not receive, and the consequences of receiving or not receiving care.^{4,8} The right to consent to care logically leads to the right of an individual not to consent to care or to refuse care, even if this decision results in the patient's loss of life.^{2,3} Difficulties can arise, however, in emergency situations in which individuals are critically ill, incapable of receiving and processing the relevant information, or unable to convey their wishes due to a communication impairment resulting either from a chronic or acute disease process or a language barrier. In such cases, someone else (a “surrogate”) will probably be called on to make health-care decisions for the incompetent or impaired individual, and those decisions will be based either on the prior expressed wishes of the patient or on the surrogate's own judgment about what is “best” for the patient.

The evolution of health-care proxies and other means for expressing personal wishes has been prompted by advances in resuscitative and supportive medical technology, increased expression of personal beliefs, and changes in the physician–patient relationship. Hospitals are required to have mechanisms in place for patients to reach therapy-limiting decisions and to ensure that this information is available to health-care providers.⁹ The Patient Self-Determination Act of 1990 (PSDA) requires hospitals, nursing homes, home health agencies, hospices, and health maintenance organizations (HMOs) participating in the Medicare and Medicaid programs to address the subject of advance written directives with their patients. Its goal, presuming that the PSDA and other initiatives have led to an increased awareness on the part of health-care consumers about their right to guide their medical care, is to encourage people to plan ahead for their health care, although they may remain confused about the tools by which to document their wishes. It is unclear how these initiatives will impact treatment under emergency conditions.

The tools available to the patient (and to the physician) depend, in part, on the jurisdiction of the patient and the physician. Different types of directives are recognized in different states. Hence, the mobility of today's society creates a problem of legal recognition of documentation. For example, a patient who resides in Florida and has a valid living will may be vacationing in Massachusetts, where living wills are not recognized. Another problem is the issue of portability of the advance directive to unforeseen circumstances. For example, a cancer patient who made a decision in conjunction with her treating physician to forgo CPR and intubation should her heart stop beating, but who presents to the emergency room unconscious after a motor vehicle accident, presents a dilemma when a relative relates the wish for “no heroics.”

Dealing with these complex issues requires an understanding of the different ways in which patients may express their wishes and the potential impact of those wishes on patient care.

DURABLE POWER OF ATTORNEY

One form of advance directive is the Durable Power of Attorney for Healthcare. The Uniform Durable Power of Attorney Act permits a competent individual to appoint an “attorney-in-fact” (that is, a legally authorized surrogate) for health-care decisions.⁶ The surrogate may then authorize medical treatment if and when the patient becomes incompetent. The Act does not specify whether the surrogate may demand that treatment be withheld or withdrawn, especially if the treatment is arguably

beneficial or lifesaving. More than half of the states have laws that permit surrogates to make medical decisions, specifically including decisions to withdraw or withhold life support.¹⁵ Additional states have court decisions, attorney general opinions, or other statutes that interpret general power of attorney statutes to permit health-care decision making, including withdrawal or withholding of life support. Particular technical requirements for such documents may vary, making familiarity with state law crucial.

Statutes authorizing powers of attorney for health care may sometimes be interpreted as limiting the decision-making authority of the surrogate. In a Pennsylvania case, it was held that an attorney-in-fact who had been appointed pursuant to a broad but general durable power of attorney did not have the power to make critical care decisions for the patient.¹⁴ In another example, an appeals court ruled that the court-appointed guardian of a 29-year-old man in a persistent vegetative state could discontinue the man's tube feedings, but not if discontinuation of the nutrition or hydration would be likely to result in death by malnutrition or dehydration. The court also read the new statute as limiting the authority of court-appointed guardians, because guardians act with even less guidance on their wards' wishes than do surrogates appointed by the patients themselves.⁵

HEALTH-CARE PROXY INSTRUMENTS

A health-care proxy is an instrument naming another individual to make medical decisions when the patient is incompetent, often in cooperation with the patient's physician. These documents often require witnesses or legal assistance in preparation. Physician orders limiting therapy then involve the patient's attending or primary care physician in the process, with either the patient or a named surrogate collaborating with the physician to express their mutual decision through signed medical orders. Whether the emergency physician can reasonably act as an "attending physician" for the patient in this case is unclear. Problems also arise when the need to make a proxy decision arises and the proxy named some time ago has since become incompetent or died.

LIVING WILLS

Living wills are legal instruments in which patients specify their wishes without the involvement of anyone other than the person(s) who assist in drafting the instrument. In some jurisdictions, an individual may actually make certain kinds of health-care decisions that take effect at a later date, when the drafter is unable to make or communicate treatment of his or her wishes. This advance directive stands on its own, *without the involvement of a surrogate decision maker*. Nearly all states have enacted some version of a living will statute. Some also include provisions authorizing the appointment of a health-care "proxy" or surrogate. Only Massachusetts, Pennsylvania, Michigan, and Nebraska have not yet provided for living wills.

Except for a few fairly standard provisions, living will laws vary greatly from jurisdiction to jurisdiction, and familiarity with local requirements is recommended. Almost all living will statutes include three basic provisions: directive language, immunity clauses, and pregnancy clauses. In some jurisdictions, a living will is a mandatory directive, and health-care providers who fail either to follow a legally authorized living will or to transfer the patient to the care of another provider can be subject to disciplinary action by the applicable professional licensing board and other penalties. Immunity clauses are included generally to provide immunity from legal liability for health-care providers who withhold or withdraw "life-sustaining" or "life-prolonging" treatment from a "terminal" or otherwise qualified patient. Pregnancy clauses limit a female patient's right to refuse treatment statutorily if she is pregnant at the time her living will is to take effect. Typically, such provisions invalidate a living will for the entire course of a woman's pregnancy. It has been convincingly argued that pregnancy clauses may be unconstitutional, but it remains to be seen how such a statute would be interpreted by a court.

PROBLEMS WITH ADVANCE DIRECTIVES

There are a number of problems with the interpretation and implementation of advance directives. States differ on what medical conditions are covered, and the scope of a proxy's authority varies widely and is often unclear. Statutory definitions are clinically ambiguous, leaving room for the definitional problems noted earlier. The instrument may have limited applicability if state law provides that the directive only becomes operative when death is imminent, again leaving room for definitional interpretation. The types of treatment that may be foregone vary from state to state, as they do from institution to institution and from physician to physician, and this raises the question of whether advance directives are truly informed (i.e., does the patient fully understand exactly what treatment will be withheld or withdrawn under what circumstances, and with what result?).

LEGAL CONSIDERATIONS

Legal liability for wrongful death when a physician has followed a DNR order in the inpatient setting is not likely. Courts have upheld the right of the patient to make these types of decisions and the obligation of the physician to honor the patient's decision, provided that the usual principles of informed consent were followed.^{10,11} and¹² In fact, no surrogate decision maker can overcome the well-documented wishes of the patient, expressed when the patient had appropriate decisional capacity. The importance of such documentation was clearly illustrated in one case in which a patient, who was not terminally ill but had irreversible brain damage, was made DNR by her physician in consultation with her parents, who were her guardians. When the DNR order was challenged, the court found, after reasonable inquiry, that the patient's parents did not have sufficient knowledge of what the patient would have wanted, given the current set of circumstances, and, further, that the parents did not have a full appreciation of the nature of the treatment that would be denied. The court ordered that the patient not be considered DNR until there was a knowledgeable decision made by the guardians.⁷

To fit within the negligence framework, a patient claiming "wrongful life" would have to show breach of a duty owed by medical care providers to be aware of and honor the patient's previously expressed desire to forego potentially lifesaving or life-sustaining treatment, including resuscitation, and would have to demonstrate damages caused by that breach of duty. The duty, then, is owed by all medical personnel who are or should be constructively aware of the patient's wishes. A typical situation in which this duty would arise is one in which a DNR order is on the patient's chart, but resuscitation is performed by someone who is unaware of the order. While life is difficult to claim as a damage, as has been shown in failure to diagnose pregnancy cases, injury or suffering resulting from the resuscitation may be claimed as damage. One patient, who had a valid DNR order in his chart, suffered a stroke some time after being successfully resuscitated from a cardiac arrest caused by the ventricular arrhythmia for which he was being treated, and is currently suing a hospital in Ohio. The allegation is that the treatment provided for him by the hospital prevented his natural death with dignity and saddled him with thousands of dollars in unwanted expenses, and that these damages were caused by actions against his expressed wishes. Although the case was dismissed by the trial court, it was appealed by his estate and remains undecided.¹

In an attempt to avoid some of the problems that are associated with DNR orders and similar directives, some states have enacted legislation that the patient's own physician must obtain the informed consent of the patient before the patient can execute a living will, that the patient must be diagnosed as suffering from a terminal illness, and that the diagnosis must be reduced to writing and certified by an independent physician as well.¹⁶ In practice, however, the problem that the emergency physician faces in rapidly determining the validity of a variety of legal documents will not be resolved unless and until there is a readily recognizable and standard format adopted.

For civil liability to attach for following a DNR order, there would have to be evidence that the withholding or withdrawing of treatment was based on a negligent or deliberate failure to act in accordance with a duty that is owed to the patient. Note that the explicit refusal of a patient relieves the physician of any obligation to initiate the refused therapy.¹⁸ The greatest potential for liability exists where there was a misdiagnosis of a terminal condition or an unjustifiable failure to secure an informed decision regarding care from the patient or family. The likelihood for liability would seem somewhat greater for the emergency physician than for the patient's primary treating physician, because the emergency physician usually makes treatment decisions involving an unfamiliar patient in conjunction with an unfamiliar family at a highly stressful time. In cases in which criminal liability has attached surrounding resuscitation decisions, it has been for medical interventions that hastened the death of a patient, such as assisted suicide in cases of active euthanasia.

ETHICAL CONSIDERATIONS

One must, therefore, question whether patients suffering from a sudden and severe illness or injury, who are conscious and capable of understanding that their situation is grave, are competent to make immediate decisions regarding their resuscitation. It could be argued that such patients are too overwhelmed to make a well-reasoned decision about whether to forego lifesaving treatment and that it is a better policy to initiate treatment and then have the patients or surrogate decision makers make a decision about continuation of life-sustaining treatment. (As an example of this point, patients often state that, in the stress of the moment, they did not understand the details of informed consent for routine operative procedures, such as breast surgery. *) Even if there were careful prior consideration of the expected course and potential treatment by patients with terminal illnesses, and if no resuscitation were desired, intent when such patients present for emergency care at the time of decompensation is open to some amount of interpretation. Many argue that such patients, or their families, would not activate the emergency system if they did

not wish aggressive intervention.

There are ethical issues involved in transferring the responsibility for making a DNR decision from the private physician to a medical director or emergency physician who does not know the patient and who may be acting through agents such as emergency medical teams or paramedics when the private physician is unavailable. Application of these principles in the prehospital setting may lead to the announcement of the death of a patient, with the EMS providers then leaving a scene where the family members are unprepared for subsequent events. Some have suggested that this issue alone is reason for “moving death into the emergency department,”¹⁷ and that this approach may be best to muster the support and logistics needed in a society in which almost no one dies at home.

Although risk tends to be ascribed to the medical care provider whose decision to resuscitate or not to resuscitate may be challenged by families or the legal community, the risk of error is really to the patients whose lives may be terminated or prolonged in a manner that is not in accordance with their wishes. The goal of any resolution to the problem is to minimize this risk to the patients. Because any decision to withdraw life-support measures is a decision that is irreversible, the practitioner, when faced with a dilemma, must err on the side of preservation of life until all procedural safeguards can be confirmed and a well-reasoned and informed decision can be reached.

COMMON PITFALLS

- Failure to appreciate the governing laws for your jurisdiction regarding advanced directives and their implementation
- Failure to educate patients and families about treatment decisions
- Failure to understand the concept of the right to refuse care and surrogate decision making
- Failure to apprise oneself of hospital policies and procedures regarding DNR orders and advanced directives, and abide by the same

*Some states, including Pennsylvania, have passed legislation requiring that patients facing breast surgery sign a complex consent form listing alternative therapies and documenting understanding of the therapeutic options. This procedure, allegedly in response to “surprise” mastectomies performed as part of a diagnose-and-treat operation, may have improved the flow of information to some patients but has scared and confused others.

[Reporting Laws](#)
[Duty to Third Parties](#)
[Legal Liability for Disclosure of Confidential Information](#)
[Chapter References](#)

A patient's right to privacy through the confidential relationship between a physician and patient has its roots in fourth and fourteenth amendments of the U.S. Constitution. Central to all physician–patient relationships is the notion of confidentiality grounded in the words of the Hippocratic Oath. Information that is relayed to a physician in the course of patient treatment should be kept confidential to the greatest degree possible. This reliance encourages patients to freely disclose information that may be sensitive but is necessary for their care. Courts recognize that there are few matters that are as personal and of such an intimate nature as health.¹² If confidential information is going to be shared with others, it is generally held that it should be with the express consent of the patient or required by law. Unfortunately, the design and patient volume of most emergency departments makes patient confidentiality exceedingly difficult. In departments where patient beds are separated only by curtains, where histories are obtained and examinations are conducted in hallways, and where many people have access to the patient's medical information as it is written on wall boards, announced on intercoms, and displayed on computer screens, patient confidentiality is at risk. The challenge for emergency medicine is to adequately protect patient confidentiality while providing care. To do so, an understanding of the concepts behind confidentiality and their application in emergency medicine is essential.

CONFIDENTIALITY CONCEPTS

The courts take the position that one of the duties a physician owes to a patient is that of confidentiality, and a breach of this duty may give rise to a claim of negligence.¹³ Further, courts have found that part of the implied contract that exists between physician and patient includes the maintenance of a confidential relationship.^{8,16} The Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) has standards that relate to the maintenance of physician–patient confidential relationships, one of which is that the patient has the right to personal and informational privacy.

The concept of privacy, strictly speaking, refers to the “sanctity of the body” and protects one from exposure of one's body, but it is used synonymously with *confidentiality*. The terms *confidentialia* and *privilegea communications* are often used interchangeably and refer to the sanctity of patient information. The terms actually refer to two different concepts related to privacy rights. Confidential communications refer to those communications between physician and patient that the patient has a right to expect will be kept private. In contrast, privilege is a specific application of the right of privacy. A privileged communication is one protected by this right, as defined by rules of evidence created by statute. These rules enable the holder of the privilege (the patient) to prohibit the person to whom the confidential information was disclosed (the physician) from testifying to that information in court. Note that that this testimonial privilege applies only to judicial proceedings. In order to invoke the testimonial privilege, there are specific conditions that must be met:

- The person to whom the statement is made must be a physician. (The exception is information provided to the physician while other health-care providers, such as nurses, are present for the purpose of continuing to provide necessary care for the patient.)
- The second element is that a physician–patient relationship must exist at the time that the information is provided. This creates the expectation that the communication is to be held in confidence and that violation of confidences would interfere with the nature of the professional doctor–patient relationship. The information must be reasonably necessary for the treatment of the patient.

There are, however, a number of circumstances in which patient information can be disclosed, such as when the patient consents to have information shared, where the law requires disclosure of patient information, and when the patient waives the right to keep some or all of their medical information private (e.g., disclosure to insurance companies for the purposes of billing). Patient consent to disclosure, providing the patient is competent to consent, allows release of the information. As with all other types of patient consent, the physician must make some reasonable determination about the patient's understanding of the scope of the disclosure. A consent to release information must be informed and made by a competent patient and should fit within all applicable state requirements intended to be patient-protective (see [Chapter 407](#)).

In a civil commitment proceeding, the contest of a will, child custody disputes, or other actions in which the patient's physical or mental state is at issue, the physician may testify without the patient's consent. The physician may also testify about the patient without his or her consent in defending against an action brought by the patient or in actions to collect payment for services provided to the patient by the physician. In all states, there are legal requirements for reporting some communicable diseases. Most states require reporting medical conditions and incidents such as venereal disease, contagious diseases, wounds inflicted by violence or animals, poisonings, abortions, industrial accidents, child and elder abuse, and rape.

A CHRONOLOGIC APPROACH TO CONFIDENTIALITY

Prior to Arrival

Patient information not infrequently reaches the emergency department before the patient does. Emergency medical services (EMS) and prehospital care providers are required, in most areas, to provide the emergency department with a notification that usually includes medical information such as the patient's age, medical history, allergies, circumstances surrounding the current need for medical care, and current medical condition. It is easy to forget that all of the information broadcast over the EMS radio may be overheard by persons casually listening to a scanner, and some link between the patient description (address and location of the dispatched call, age and gender of the patient) and the medical event may be made. Arguably, this is a breach of patient confidentiality if it is known that radio transmissions are routinely overheard. More private means of communication, including cellular phones (still fairly easy to hear by scanner) and various scrambled or otherwise encrypted radio systems, are available. The larger issue, however, has to do not with advances in technology but with intent. There are means to intercept almost any radio transmission, given time and technology. Patient confidentiality can be better preserved by behaviors that do not unreasonably identify the patient or disclose sensitive information.

Prearrival patient information, whether it comes from EMS providers or private physicians, is often verbally transmitted or posted in a conspicuous area. Although this may make it easier for staff to communicate about expected patients, it also exposes the patient's information publicly.

During Care

Challenges to confidentiality during care in the emergency department can be grouped into either those inherent in the design of the department or those inherent in its function, including staff behavior. Several special situations require different interpretations of confidentiality.

Department Design

Typical emergency department design often dictates that patients are interviewed in rooms or areas that are occupied by more than one patient or another person who is not a care provider. Curtains have poor soundproofing qualities, and it is not unusual for two adjacent patients to overhear the details of each other's histories and then be facing one another when the curtain is pulled back to allow better observation by the department staff. Staff in emergency departments often use large display boards, intercoms, and loud voices to communicate. These techniques make confidentiality challenging. Attention to department design and staff behavior can reduce these risks without compromising patient care.

Evidentiary Testing

Blood alcohol levels, toxicology screens, tests performed as part of sexual assault examinations or in alleged abuse cases, or care of patients involved in a criminal event may involve presentation of medical fact as evidence in court, and the evidentiary nature of diagnostic testing and other findings creates a need for heightened protection of patient information. Physicians are frequently asked by law enforcement agencies to release blood and blood levels for determination of ethanol intoxication or other chemical ingestion, which may impact on the liability of the patient in a motor vehicle accident. Employers are interested in impairment by drugs, and want results of similar tests. Prosecuting attorneys need properly obtained and protected evidence to prevail in sexual assault and other criminal matters involving medical care. When patient evidence is not handled appropriately, not only is the physician-patient relationship violated, but the admissibility of the evidence in a court proceeding is threatened as well. In an Indiana case, a physician released a blood specimen taken from a patient involved in a motor vehicle accident to the police. The physician was asked to testify at the patient's trial for involuntary manslaughter regarding the drawing of the blood sample and the test results. The patient successfully appealed his conviction because of his claim that the emergency department physician's testimony was privileged and should not have been admitted into evidence. The case was sent back to the trial court for a new trial that would not include the blood alcohol evidence. ^{1,18}

Disclosure to Family Members

The general rule that information about patients should not be released without their consent also applies to family members, with several exceptions. Taking a few extra minutes to ask patients if they want family members present or informed about their care, test results, or condition affords patients a proper measure of respect and privacy. Not all patients want their families to know the details of their medical care, and most expect the opportunity to make this decision. Exceptions to this practice include situations in which patients are incompetent or minors (not emancipated). In these cases, their family should be contacted and may be an essential part of the care process. Care should be taken to confirm the identity of a "family member" with a patient before releasing details; many persons are aware that hospitals are more forthcoming with family members and may impersonate a family member in order to obtain information about a patient. If a patient is competent, this process should be rapid. Otherwise, a reasonable effort to protect the patient's confidentiality is expected.

Triage

The triage process, originally intended to prevent patient decompensation while awaiting care, has expanded in many institutions to include significant data gathering that may include confidential information. Care should be taken to avoid unnecessary breaches of confidentiality. For example, a list for patients to sign in while awaiting triage need not list the complaint; the next patient then will not be able to read about their neighbors' woes. Interviews should be as confidential as possible, without lines of people overhearing details of history. Any examination performed should be given the same measure of respect and privacy expected in other settings; patients should not be asked to significantly disrobe or otherwise expose themselves in public.

Gossip

While discussion about patients serves an educational purpose, and the occasional joke serves to relieve tension, there is no excuse for gossip that breaches patient confidentiality. Patients and others in the department may overhear discussion about other patients, which may be unavoidable within architectural and functional limits. However, they should not hear unprofessional comments or derogatory discussions about current or former patients. These events are not infrequent, and they form the basis of many patient and family complaints. The best way to prevent this from occurring is to avoid such events through common courtesy and proper manners. Reminding staff that the charting desk, break room, back hallway, elevators, and cafeteria do not provide a forum for this type of conversation may be helpful. Awareness of the frequency with which these events occur can often be heightened by patient simulation. The health-care provider should sit in a wheelchair or lie on a stretcher in typical patient care or transport areas and listen. He or she should not overhear confidential patient information.

After Care

A study reported by the Privacy Protection Commission, *Personal Privacy in an Information Society*, in 1977 noted that 51% of physicians and 70% of medical students discuss confidential patient information at social gatherings. Obviously, these disclosures can lead to significant patient embarrassment and may cause damage to the patient in the forms of loss of employment, loss of insurance, and credit denial.

In some cases, emergency access to patient medical information may be necessary by telephone or fax machine. In general, it is a good idea to limit any information provided about a patient to that required for immediate care. Hospitals must develop and implement systems for obtaining medical information by phone or by fax that provide for confirmation of the information received and for concrete identification of the information seeker's identity and reason for request. For example, such a system might include the following:

- Confirming caller identity from a list of area hospital emergency department telephone and fax numbers; even more preferable is when the caller is known to the staff receiving the request.
- Arranging for a fax machine location within a secure emergency department staff area, to prevent patient information from arriving at a public machine location, such as at the hospital switchboard or office desk
- Asking, whenever possible, for the requesting facility to send a signed patient record release form before sending a return facsimile with patient information
- Including on the facsimile cover sheet with patient records a reminder that the transmission includes confidential patient information and should be directed immediately to those caring for the patient

The Medical Record

The medical record is a complete record of a patient's history, condition, and treatment and may contain very personal information. It has been estimated that up to 75 persons may access any given medical record.³ Access to the medical record is obtained for a variety of medical and nonmedical purposes, and consent of the patient is often presumed. Some of the reasons for medical record access include third-party payor information; quality-assurance purposes; JCAHO or other accreditation or investigatory review; documentation and evidence in a legal proceeding; and medical research. The medical record may be written and stored on paper or composed on a computer and stored either on paper or in an information system. The medical record is used to chronologically document the patient's interactions with the medical system, treatment rendered, response to treatment, and plans for further care. It also serves as an important legal document. The medical record is of paramount importance when a claim of negligence, against either a physician or hospital, has been raised, or when there is some dispute surrounding the origin of the injury or illness. It may be several years from the time of the illness, injury, or treatment before a claim is litigated. The medical record is frequently the only detailed documentation of what transpired before, during, and after the patient's interaction with the provider. It is not infrequent that persons who were involved in the patient's initial illness, injury, care, or treatment may no longer be available to testify in court, but the medical record provides documentation of circumstances surrounding the event in question. A well-documented medical record will enable the physician to recall the history, treatment provided, response to the treatment, and patient outcome. Failure to keep a well-organized and confidential record may destroy the utility of the record for both medical and legal purposes; in fact, it can cause both medical and legal problems.

Entries that are made in the medical record should be made clearly, concisely, and objectively. Only information that is relevant to the care and treatment of the patient should be contained in the medical record. Subjective comments, opinions about the care given by other providers, and extraneous commentary about the patient or circumstances of the encounter are not only not needed in the record, they can form the basis of legal action. Once information is documented, the original entry should never be altered, although additional information may be added if needed, providing it is identified as an addendum and dated as such. Corrections should be made in a standard way, with a single line through the incorrect entry, insertion of the correction, the reason for the correction, the time and date of the correction, and the identity of the documenter clearly noted. Patients may be upset by incorrect information in their records (e.g., gender, age, left and right errors),

but they are generally more upset by improper corrections. The legal system is more than upset by alterations in a medical record that are made in an effort to reduce liability in a negligence action. As more emergency department records are produced on typewriters and computer printers, and are therefore more legible, they are being read by patients more often. The patient may request a copy of his or her record for many reasons, and they may be sent a copy as part of an insurance process. A concise, professional, legible, and thorough record that documents excellent emergency care should please the patient. A record that contains errors, information obtained without patient consent (e.g., "patient's co-workers contacted about his drug use and state..."), or documentation that patient information that was shared with others without consent (e.g., "patient's boss called and informed about patient's ...") may anger the patient and be the source of complaints or legal action.

Computers and Confidentiality

Computerized medical records present a special evidentiary problem for attorneys. Many state laws require that medical records be handwritten or typed and signed by a physician or other health-care provider. Some state laws require that medical records be documented in ink. Although computer-generated medical records may be printed out and may therefore satisfy the requirement of medical records, they may still need to be placed in a folder and located in a central place. Duplicative efforts like this raise additional confidentiality concerns. It is hoped that, as computerized medical record systems become more commonplace, statutes will be broadened to more readily accept computer documentation without the need for extensive paper archives. Access to computerized information can be significantly easier than access to paper records. While some argue that anyone in a white coat can stroll into most medical records departments and ask to see a particular record, computer terminals scattered throughout the institution, without attention to security, can offer much easier access to a broad range of data. Coordination with information systems staff to afford both ease of use and proper security (limiting who can access data and what data can be accessed) can improve the clinical utility of computerized records while protecting patient confidentiality.

MANDATORY DISCLOSURE

Reporting Laws

There are times when confidential patient information must be released. Most states have mandatory reporting laws for certain communicable diseases and certain suspected criminal activities. Certain agencies have the right to inspect or review records as part of their function. Accreditation bodies, third-party payors, and others may, depending on circumstances, have the right to access patient information. The emergency physician should understand the bounds of such mandatory disclosure situations as they apply locally and be prepared to both cooperate and limit that cooperation, as indicated.

Duty to Third Parties

As has been noted, obligations of the physician do not normally extend to persons other than the patient. The physician may have a duty, however, to warn third parties of significant dangers created by patients if the physician has a special relationship with either of the parties. The duty of a physician to warn some person or persons of potential dangers presented by a patient under his or her care has been interpreted by different courts to different degrees. Some courts have held that a patient confidence can be breached only when the intended victim is identifiable. Others recognize that the scope should be broadened to protection of the general public in the interest of public health. In a recent Michigan case, a physician was sued for failing to warn a family member about exposure to a highly contagious, potentially fatal disease. The question before the court was whether the physician owed a duty of care to the son (who died of meningitis) or to the mother, who was treated and released from the emergency department on antibiotics for an upper respiratory infection. Although a legitimate concern was raised regarding the confidential relationship between the patient and the physician, the court felt that the concerns were not sufficiently compelling to nullify the duty imposed on the physician.¹⁵ Courts have also upheld the requirement of the physician to warn the daughter of a patient with scarlet fever, the wife of the potential danger of infection from her husband's infected wounds, and the neighbor of a patient who had smallpox. In essence, family members are foreseeable third parties, as are neighbors and classmates. Courts have also upheld physician liability for failing to warn of psychiatric dangerousness, of potential for sudden impairment due to disease process, and of potential drug side effects.^{5,6,14,17,19,20}

Acquired Immunodeficiency Syndrome and Confidentiality

The unique characteristics of the acquired immunodeficiency syndrome (AIDS) present many ethical dilemmas for physicians. Patients who are human immunodeficiency virus (HIV)-positive, who have AIDS, or who seek counseling or testing for AIDS present special confidentiality problems for the emergency physician. Superimposed on the public health approach to confidential medical relationships is a flurry of regulatory and statutory activity regarding HIV-positive patients. Because of the way society reacts to persons with AIDS, there is heightened concern about the transmission of information relating to that condition, and some jurisdictions have legislated specific confidentiality laws related to AIDS. Regardless of the accuracy of the information released regarding patients who have AIDS, potential for liability arises. If the information provided to another is inaccurate, there is the potential for a defamation action. If information regarding patients is accurate, issues of invasion of privacy are raised. There are also issues raised by not releasing information about the HIV status of patients. If physicians know with reasonable certainty that patients are infected with HIV and are not planning to inform their sexual partners or those with whom they share needles, and the physicians fail to warn those identified third parties, liability may exist for failure to warn as well. Some states absolutely protect patients' right to confidentiality by requiring that an informed consent process be carried out before information about their HIV status can be revealed. Other states grant physicians immunity from liability if they decide to disclose due to fear of danger to identified parties. Many states have no special laws regarding patients who are HIV-positive. It is not clear where the courts will ultimately draw the line with HIV-positive patients, but it is possible that they will find that physicians have a duty to warn identified parties of real, significant, and proximate danger.

Legal Liability for Disclosure of Confidential Information

A majority of courts have upheld the right of patients to recover for unauthorized disclosure of confidential information. One theory noted by the courts is that physicians' disclosure of confidential information to third parties, without patients' consent, results in a violation of the patients' right to privacy. Physicians who violate patient confidence may also find that they are liable for damages based in tort or contract theory. Some courts have recognized a fiduciary duty on the part of physicians to maintain patient confidences.^{7,9,11} The form of the communication about patients, even to medical colleagues, is also of concern to the courts. The communications must be made in a clear and objective manner, such that patients will not be subjected to humiliation, and must be made upon appropriate request, not just in the passage of casual information. A physician who sent information about a patient and their interactions to a medical peer, which contained disparaging information about the patient, was held to have violated his duty of "loyalty" and confidentiality to his patient. The patient prevailed in an action against the physician for libel and defamation of character.^{2,4,11,13}

[Chapter References](#)

A common and problematic medicolegal issue facing emergency physicians is patient consent to, or refusal of, treatment. The theory of informed consent has developed as the result of a strong judicial deference toward the constitutionally based right of a person to individual autonomy, resulting in the fostering of rational patient decisions. The environment of the emergency department challenges the traditional rules of consent and refusal, creating a necessity for the emergency physician to be familiar with the nuances of the consent and refusal process.

TYPES OF CONSENT

It has been well established in both the legal and medical arenas that competent adults have the right to make decisions about what diagnostic or therapeutic medical treatment or medication they will or will not accept.¹¹ Treating informed patients who competently refuse care renders the physician liable for battery.¹² However, allowing a patient to refuse care when that refusal is not informed and is detrimental to their health also creates liability for the physician. Three types of consent are recognized at law: express consent, consent that is implied in fact, and consent that is implied in law. Express consent may be either oral or written: It is basically the granting of authority to render treatment. Standard hospital consent forms signed during the registration process and those for surgery or other invasive treatment are examples of express consent. Consent that is implied in fact is consent derived from the conduct of the involved parties. If, for example, patients are told that their blood pressure should be checked, and they hold out their arm, there is implied consent. The legal test is behavior such that the reasonable individual witnessing the exchange would conclude from the behavior of the parties that consent had been given. Consent that is implied in law is consent that is assumed during an emergency for emergency treatment or extension of treatment necessary to save a life or preserve health. For implied-in-law consent to be recognized, two things *must* occur simultaneously. The patient must be in actual life-threatening danger *and* the patient must be unable to give consent. One without the other will not withstand the legal test. In this situation, the law assumes that the reasonable rational patient would consent to care if able. Consent is not waived in this situation; if the physician knows that the patient would not have consented to the proposed lifesaving treatment, it should not be undertaken.

VALID CONSENT

For any type of consent to be valid, it must be informed. *Informed* means that consent is made by the patient or responsible party after the treating physician (the one performing the procedure) submits a fair and reasonable explanation of the particular procedure or treatment, including reasonably likely risks and benefits. The duty to obtain informed consent rests with the physician who is going to perform the procedure.^{3,5} There are certain elements that must be disclosed to the patient, including the nature of the patient's condition, an explanation of the proposed treatment or procedure, risks and benefits of the procedure, and alternatives to the planned procedure, including the risks of the alternative treatments.¹ In essence, the physician has a duty to disclose any substantial or material facts about a proposed procedure or treatment.¹

The legal standard is that the patient must receive all information about a proposed treatment or procedure [§] that a reasonable and prudent physician knows would be regarded as material^{1/2 1/2} by a reasonable and prudent patient. In the case of a relatively risk-free event, such as phlebotomy or physical examination, consent implied in fact is often sufficient. As the risk of the event increases, however, this form of consent is less appropriate. However, the physician, within reasonable professional judgment, is permitted to withhold certain information that would result in refusal of necessary treatment. For example, if a physician knows after discussion with family members that the patient is unreasonably terrified about a certain unlikely potential complication of therapy (e.g., diarrhea from antibiotic therapy for meningitis), this information may be withheld from the patient. This is a very difficult standard to meet when both time and treatment options may be limited and when the patient is not well known to the physician. It is imperative that the treating physician have good communication skills so that the patient is able to understand the information that the physician is trying to convey. Of equal import is the necessity of the physician to be able to understand the patient.¹⁹

COMPETENCE TO GIVE CONSENT

To make an informed decision regarding treatment options, the patient must be competent to consent. Competence for this purpose is judged more by a medical "reasonableness" standard than a legal one. Not all patients who present to the emergency department for care who are considered to be incompetent by a medical standard would be adjudicated incompetent by the courts and therefore have surrogate decision makers appointed for them. Competence in this medical sense is a very dynamic state and depends on a very complex set of factors and circumstances. Basically, the patient must be able to render a choice and understand information relevant to making this decision. This means that the patient must have the ability to appreciate the situation that he or she is in and its consequences. Further, the patient must have the ability for rational processing of the information provided. There are many factors that impact a patient's competence. Patients who are intoxicated or who are in some other way chemically impaired may not be competent. Patients who may have head injury, hypoxia, some metabolic derangement such as hypo- or hyperglycemia, or who are under severe emotional stress may not be competent. In such situations, if a true emergency exists and the patient is judged to be unable to consent, the implied-in-law consent doctrine applies.

MINORS AND CONSENT

Parents or legal guardians must, in general, consent for the care of the minor. Often, however, a minor patient seeks care in the emergency department in the absence of a parent. The emergency physician may be placed in a difficult position, caught between the risk of not evaluating and treating the patient and the risk of evaluating and treating the patient without consent. In such cases, it is advisable to evaluate and treat if delaying such could result in potential harm, to clearly document the reasoning for this, to attempt to contact the parents or guardian, and to document such attempts.

Emancipated Minors

Emancipated minors have a different legal status than that of other minors. They are able to consent for their own health care and are considered emancipated because of one or more of the following factors:

- Marital status. The minor is married, divorced, separated, or widowed.
- The nature of his or her physical condition. The patient believes that she is pregnant or he or she believes him- or herself to be suffering from or to have come into contact with any disease defined as a danger to public health, such as a sexually transmitted disease.
- Legal or financial status. The patient is either living on her or his own or is in some way financially independent.
- Is a member of the armed forces
- Is a parent

Many difficult issues are raised by this rule. For instance, if a minor believes herself to be pregnant and presents with abdominal pain, she can consent for care. If a pregnancy test is performed and is negative, what is the emergency physician to do? Are minors reliable? How can the physician be sure that the minor is in fact

emancipated?

In general, physicians who rely, in good faith, on the representations of the patient will be protected. If a patient who reasonably met the standards of emancipation on presentation is found *not* to meet the standards after some evaluation (e.g., negative pregnancy test), the physician may proceed with reasonable evaluation and treatment indicated by the patient's condition while attempts are made to better define the patient's competency.

Mature Minors

Another category of minor who may be able to consent for their own care is the mature minor. The mature minor is emotionally and intellectually mature enough to be capable of appreciating the nature of his or her illness or injury as well as the risks and benefits of proposed treatment. In some cases, a minor originally and incorrectly felt to be emancipated may meet the standards for mature minor status. Although not frequently an issue, it is important to note that no unmarried minor can give consent for abortion or sterilization, even if otherwise mature or emancipated.

Age-related competence issues do not relate solely to minors. Geriatric patients may not be able to rationally manipulate information provided to them. Emancipated minors may not be able to understand complex information regarding their own children when those children are patients.

INCOMPETENCE

There are two types of patients who are considered "mentally incompetent" for reasons other than age: those who are adjudicated and those who are unadjudicated. Patients who have been determined by the courts to be not legally competent, and therefore not capable of making sound medical treatment decisions, are adjudicated incompetent. In this case, the court will assign someone else (a "surrogate") to make health-care decisions for the individual. Usually, the court will appoint a family member, such as a parent, spouse, or offspring. Sometimes, the court appoints someone not related to the patient to make these decisions. Treatment decisions will be based either on prior express wishes of the patient (see [Chapter 405](#)) or on the surrogate's own judgment about what is "best" for the incompetent party.

Patients who, for one reason or another, are temporarily or suddenly unable to make reasonable treatment decisions for themselves are unadjudicated incompetent. Competence may be affected by medication, fatigue, stress, disease processes, and other conditions. This situation is faced frequently in the emergency department. Input from the patient's significant others is important in this situation, and efforts to speak with family, those persons with whom the patient lives, or those with whom he or she is most closely associated may be necessary to determine the patient's wishes. The theory is that these people are most likely to know what the patient would want and will be acting in the patient's best interest. Surrogates do not have constitutional standing to substitute their own judgment for that of the incompetent patient, however.⁴

Determining under what circumstances the physician can treat against the patient's will poses a medical–legal challenge. Indications that a patient may not be competent to refuse care include, but are not limited to, the following:

- Patients with mental status changes
- Patients who appear to be intoxicated or suffering from hypoxia, acidosis, or other metabolic derangement
- Patients suffering from dementia
- Patients who have suicidal or homicidal ideation or intent
- Patients who are suffering from acute organic brain syndrome

RELIGIOUS BELIEFS AND CONSENT

Religious objectors, such as Jehovah's Witnesses, pose yet another dilemma for the emergency physician. Jehovah's Witnesses may believe that acceptance of blood products will result in an irreversible denial of eternal life, and therefore render the rest of life purposeless. The refusal of blood products should not be misconstrued to mean that they are refusing other care. Competent adults have the right to refuse medical care, and the competent Jehovah's Witness who is refusing a necessary transfusion of blood products is no exception, even if that refusal leads to his or her death. ^{9,10} Appointment of a temporary medical guardian for a Jehovah's Witness is an option when there is a question about the patient's wishes. In some cases, the court has found that the interests of children may override the interests of a parent, but this is not a common finding.¹⁶

Competent adults do not have the right to impose their religious beliefs on others, including their children. States are able to intervene on behalf of children when an emergency exists and lifesaving care is being refused by parents. This is because the state has an overriding interest in protecting the welfare of its citizens, especially those who are unable to care for themselves. Courts have also reasoned that although they are unable to interfere in the religious beliefs of parents, they may interfere with actions, given just cause.¹⁸

DOCUMENTING INFORMED CONSENT

Informed consent, as outlined earlier, must be obtained by the physician who proposes to treat the patient. The way in which this consent is reasonably documented varies with the nature of the emergency and the risk of the proposed treatment. In many cases, a specific written consent form, listing the reasonable risks of the specific treatment and signed by the patient, physician, and a witness, is best, but in some cases, there is inadequate time for this process. In all cases, the consent process should be documented in the patient's record whenever a procedure or treatment is performed that would typically require informed consent if performed in the hospital.

REFUSAL OF TREATMENT AND DISCHARGE

Just as a patient must give informed consent to treatment, refusal of treatment must also be informed. In fact, the criteria for refusal are more strict than those for consent. Refusal cannot be implied either in fact or in law, because the special knowledge in the situation is held by the physician and not the patient. When a physician "suggests" a medical event (e.g., taking a blood pressure), the patient may give implied consent in fact or in law, because the physician is presumed to be the expert and is therefore in possession of special knowledge that the suggested event is proper and appropriate in the situation. The converse is not true. If a physician "suggests" an event and the patient attempts to refuse in any way, that refusal cannot be assumed to be informed. If, for example, the physician asks to take a blood pressure and the patient withdraws his or her arm instead of extending it, a reasonable observer may feel that consent had been refused, but the observer would not likely understand *why* the event was refused. Therefore, only a fully informed patient can refuse suggested treatment. This includes understanding the consequences of the refusal and failing to follow the recommended course of treatment.

Informed refusal may apply to a specific test or treatment (e.g., a rectal examination or lumbar puncture), to any further care (e.g., a patient asking to leave during care or refusing admission to the hospital), or to a portion of the physician's plan of therapy (e.g., follow-up appointments, prescribed medications, or use of seat belts). The discharge of patients from the emergency department, even if amicable and mutually acceptable, includes an informed refusal process in that the patient must understand the reasonable consequences of refusing to follow the discharge instructions.

PATIENTS WHO LEAVE THE EMERGENCY DEPARTMENT

Despite the best intentions of the emergency department staff, some patients do not follow the informed refusal process outlined for discharge from the emergency department. Traditionally, these patients fall into one of three categories, with a fourth (item 2 on the following list) added recently:

1. Those who leave before significant medical evaluation or care has occurred. This is often labeled "leaving without being seen," although this label is viewed by some as internally contradictory. A more accurate label would be "leaving before evaluation." These patients may have registered and are not found when called for bed or room assignment; some do not even register. They may be considered a group that has voluntarily withdrawn their presentation for care. Although long waiting times are a commonly cited reason for leaving, these patients often have psychiatric issues, such as difficulty with being in public places, that make care in the emergency department particularly challenging. Every effort should be made to identify patients who appear uncomfortable with the emergency department process and to offer to accommodate their care and encourage them to stay.

2. Those who leave after their insurance plan has refused to pay for care. Changes in third-party payor practices have created this new category of patients, who leave before evaluation. While many feel that this situation will be corrected by federal legislation (see [Chapter 408](#)), it is a common occurrence and is distinct from patients who anonymously leave before evaluation. Handled properly under current guidelines, these patients are informed of the availability of care (including availability of a “screening examination” as defined under COBRA) and the consequences of refusing that care. They are then giving informed refusal prior to medical evaluation and are, in effect, withdrawing their request for care. The challenge with this category of patients is to clearly distinguish between a willingness to provide care and refusal of a payor to reimburse for that care. In many facilities, that distinction is seen as too complex to explain, and efforts are focused instead on contracting with payors to provide appropriate reimbursement for different levels of service for all persons who present for care.
3. Those who leave during care without informing the staff of their intent to leave. This is often called “eloping.” These patients fall into two subgroups—competent and incompetent. The most concerning are those who are incompetent, and every effort should be made to return these patients for care. The competent patient who elopes may have not been given enough information to make an informed refusal of treatment, and if there is concern regarding further diagnosis and treatment, efforts should be made to locate the patient, relate any information necessary to ensure an informed decision, and document this exchange on the medical record. In many cases, patients elope after a particular phase of their care, such as x-rays or laboratory testing. Sometimes, this is because of a misunderstanding (“The technician said my x-rays were OK, so I thought I was supposed to go.”), and efforts should be made to ensure that patients receive clear and basic instructions to return to the emergency department after testing. In other cases, patients may be using the system for testing purposes (e.g., pregnancy testing or x-rays), and leave after a desired result is available, even if the care process is incomplete. Again, effort should be made to identify this type of patient and emphasize the importance of educated and informed discharge. Some patients elope because of anger or frustration, often due to waiting time or staff attitude. An alert staff can help identify this type of patient and offer alternatives before they elope.
4. Those who leave after announcing their intent to leave, contrary to the best advice of the staff, are commonly described as leaving AMA (against medical advice). This does not have to be an adversarial process. The informed patient is declining one recommended course of therapy; the uninformed patient needs education. The physician should then attempt to discover the reason for such refusal (often a social need, such as lack of childcare or an apartment left unlocked) and negotiate a solution or suggest (recursively, if necessary) the next best course of therapy until one is acceptable to the patient.

RESTRAINTS

There are situations in the emergency department in which patients are unable to give informed consent to treatment or refuse to do so and there is a necessity to restrain them for their own safety or the safety of the staff and other patients. Use of patient restraints, regardless of the form of the restraint, is a significant patient care intervention, and the appropriateness of such intervention must be considered carefully. Before restraints are initiated and maintained for any period of time, a physician assessment must be performed. Documentation of the intervention must contain information about the reason that the restraints are being used; some indication that the patient was not competent to refuse treatment, if that is the reason for the restraint; and the plan for reassessment of the patient. It is assumed that the patient requires restraint due to a combination of incompetence and medical necessity, but the justification for both should be clearly documented. The least restrictive safe restraint method should be employed, given the circumstances.

False imprisonment is an intentional tort whereby there is an unlawful (unjustified) restriction of a person's movement. This restriction may be either actual (e.g., the patient is physically unable to move due to wrist and ankle restraints, spinal immobilization, or administered medications) or apparent (e.g., the patient believes that he or she is unable to move because of verbal warnings, the presence of guards, or a locked room). Because this is an intentional tort, the patient need only show that there was unjustified intent to confine and does not need to show that a damage occurred, as would be required if the suit were based in negligence. Therefore, use of restraints (even those typically thought of as splints or precautions) should be accompanied by documentation justifying their use.

Restraint of a patient must also include providing adequate protection for both patient and staff. In a New York case, a patient, while restrained, was injured when another patient attempted to rape her. The degree of care owed to the patient is related to the patient's own ability to provide for his or her own safety. ¶ Staff working with patients requiring restraint should be properly trained and equipped to afford them reasonable protection from physical and other harm that may accompany the situation.

PHYSICIAN LIABILITY RELATED TO CONSENT

Expert testimony is needed to support claims of lack of informed consent and battery arising out of a medical procedure. ¹³ If the patient should claim that consent was not obtained, he or she would not need to show that the procedure was the cause of any injury, nor that the procedure was performed in a substandard manner, but only that it was performed at all and had not been consented to. In order to prevail, the physician must be able to show that the patient was informed of and understood known risks as well as those risks material to the particular patient. ^{**}

There are exceptions to the informed consent rule, however. A physician does not need to disclose to the patient those risks that are generally known to the public or those risks that are too remote to be considered actual risks and would cause the patient to refuse necessary treatment. ² In an emergency, as noted previously, the physician may render lifesaving care without obtaining consent, and the physician may not disclose some material facts if he or she believes that the disclosure poses a threat to the patient's well-being.

*A person commits the tort of battery if he or she acts with intent to cause harmful or offensive contact, and the contact occurs. ^{15,17} Even the mere touching of one person by another without consent or legal justification was a battery at common law. ¹²

†In failure-to-warn cases, the failure to disclose the alternative treatment must be the proximate cause of the patient's injury. ^{6,8}

‡The physician owes the patient a fiduciary duty of good faith and fair dealing, which gives rise to certain specific professional obligations. These obligations include not only the duty to exercise due care and skill, but also to fully inform the patient of his or her condition and to obtain the patient's informed consent to the medical treatment. ¹⁴

§The physician is not liable for not disclosing diagnostic alternatives for illness or injury as of yet undiagnosed. ¹

½½ *Materia* is defined as the significance that a reasonable person, in what the physician knows to be the patient's position, would attach to the disclosed risk. ²⁰

¶The patient was awarded \$125,000 for injuries sustained as a result of the attack. ⁷

**The determination, therefore, of what is to be disclosed is a two-tiered test. First, one must decide what the risk is based on the scientific facts (i.e., the nature of the harm and the scientific likelihood that the harm will occur). Then it must be decided whether that probability of harm is a risk that the reasonable patient would consider in deciding on a treatment.

Patient transfers are often economically motivated. In many cases, the financial motivation is remote, and is a reflection of the economic and manpower impossibility of having the best medical technology available in every community. In other cases, concern over the patient's ability to pay for services provided is the major reason for the transfer. The practice of transferring patients for the direct economic benefit of the transferring hospital has been dubbed "patient dumping," and is driven by the continuing problem of assigning financial responsibility and attendant reimbursement for the care of some patients, particularly the medically indigent and those functionally indigent due to peculiarities of health insurance coverage.

When medical care was provided as a charity by hospitals and physicians, or, more recently, when medical insurance reimbursements were adjusted to compensate for free care and bad debt, there was less of a problem. As the cost of health care rose, the burden of the medically indigent became a great strain on some hospitals, physicians, and medical insurers. Medical indigency has reached the scale at which some 15 million Americans either do not seek or do not receive health care because they cannot afford it. Medically indigent people are defined as those who lack any or adequate health-care insurance. This group includes not only those people who are uninsured because of such causes as unemployment and self-employment, but also those who are in a high-risk medical group and are therefore uninsurable.¹⁴

Currently, it is estimated that economic dumping exceeds 250,000 patient transfers annually and that approximately 15% of patients transferred in 1986 were "dumped." *Dumping*, for purposes of this chapter, refers to the transfer of unstabilized patients, the transfer of stabilized patients, or the transfer of in-house patients whose insurance has run out.¹¹ The enormous economic burden of dumping rests mainly on public hospitals, which receive the majority of the patients. The American College of Emergency Physicians (ACEP) has published guidelines for appropriate patient transfers, and continues to address the issues raised by this process.^{1,2}

The process of transfer is potentially dangerous for both patient and practitioner; the addition of economic and legal factors makes it even more risky. Hospital policy and transfer agreements, state and federal regulations and laws, professional practice standards, and other rules all have an impact on the transfer process. This chapter reviews the practice of emergency department patient transfer and proposes guidelines for improving the coordination and safety of the process.

MEDICAL AND ECONOMIC HISTORY

The increasing mobility of society, combined with an increased number of uninsured or underinsured patients, has resulted in an increased number who do not have a personal physician or an affiliation with a particular health-care institution or system and an increase in patient volumes at both emergency departments and urgent care clinics. In addition, the public has come to expect both high-quality and timely medical care, as well as complete subspecialty diagnostic and therapeutic capabilities when they present for emergency care. While basic prehospital care is all that is available in many areas, advanced life-support ambulance service is also an expectation. People want a low-cost, economically efficient health-care system, yet when faced with a personal emergency, they want the best of everything immediately.

The favored means of offering high-level care to a great number of patients—the regionalization of specialty care—currently necessitates patient transfer. Sending teams to the patient is currently common only as part of the transfer process. "Telemedicine," in which physicians receive diagnostic and therapeutic advice and even robotic surgical assistance from distant expert consultants via electronic networking, may become more common in the future, but may also result in potential liability from inaccuracies or confidentiality issues involving information transfer. The emergency physician now frequently controls prehospital care, emergency treatment, access to the hospital and advanced technologies, and patient transfer to facilities offering unique or subspecialty care, and therefore is in an important yet vulnerable position.

As individual providers, emergency physicians are often paid by either salary or fee-for-service arrangements, often with a minimum guaranteed income. Thus, there exists some direct, and certainly indirect, economic incentive to provide care for the well-insured or paying patient. Professional ethics dictate that care should be provided equally. However, at a certain point in treatment, economics may become important. Less costly alternatives are often arranged for patients who cannot afford prescribed medication, have no access to free care, or refuse admission for economic reasons.

Patients who require admission but are uninsured or have a facility-specific insurance plan may request transfer. The underinsured or uninsured patient may benefit financially from such a transfer; the truly indigent patient, who has no means of paying any medical bill, does not. The referring hospital does, however, and it may pressure the emergency physician directly or indirectly to perform such transfers. Admitting physicians may, for example, inquire about insurance coverage for legitimate reasons such as managed care contract coverage, and then encourage transfer based on economic factors. The emergency physician must always balance the risks and benefits of transfers, keeping the best interest of the patient as his or her guide.

In many areas of the country, additional economic issues are raised by managed health-care plans (MHCPs), such as health maintenance organizations (HMOs), preferred provider organizations (PPOs), and government-run health-care systems. For example, MHCPs that own or operate hospitals may enforce strict screening criteria during the triage process to prevent emergency visits by those not covered by their plan, or to prevent "unnecessary" visits by plan members. Other hospitals may have contracts with MHCPs that similarly attempt to regulate patient flow. Some institutions have capitation contracts with MHCPs, in which a fixed amount is paid on a regular basis for care of the plan's patients, giving them significant incentive to avoid unnecessary costs, sometimes by the transfer of patients, and perhaps giving significant incentive for the private physician to refer more patients to the emergency department because "the bill is already paid."

Many of the transfer issues currently faced in the emergency department are the result of other changes. The rising cost of health care has resulted in the disappearance of services that formerly were available: The intensive care unit (ICU) is full due to a nursing shortage, the only orthopedist in town moves to another state because of lower malpractice premiums, or the community hospital closes. On the other hand, advanced and expensive services that formerly were widely unavailable are now within reach via transfer and have come to be expected by the general public for problems such as cardiac disease, trauma, specialized neonatal and pediatric care, reimplantation of amputated limbs, and advanced diagnostic imaging. Emergency physicians need to be aware of the social and economic forces as well as the legal forces involved in their duty to provide care, and patients, if able, must be offered enough information to make an informed choice, and to give informed consent to a transfer if that option is proposed and is in their best interest.

DUTY TO CARE

The United States has not traditionally defined the access to health care in an emergency as a fundamental right, nor has the common law required that government provide access to health care for those people who are uninsured or underinsured.¹⁰ Until recently, it was a relatively common hospital policy that the emergency

department had no duty to care for patients who presented for care. Many hospitals did not offer emergency care for the uninsured, for those who had a personal physician in the community, or for those with particular types of insurance coverage. A two-tier health-care system, in which the rich and properly insured received better care than the poor, was developing. In parallel, specialty care hospitals became commonplace and attempted to limit access to their emergency departments to specific populations. As a result, “undesirable” patients were often denied care arbitrarily and had to seek help elsewhere or go without care. ⁴

In 1946, the Hill Burton Act required that hospitals make their services available to all persons residing in the territorial area of the hospital, among other provisions, in return for federal funds for the construction and modernization of hospitals. ⁸ Compliance was poor, as there was little enforcement of the Act's requirements and the common law no-duty rule provided no relief at law for those who were turned away. As emergency departments expanded and visits increased during the 1960s, the consequences of denying care to patients resulted in a series of legal actions that eventually compelled hospitals with emergency departments to offer care for all patients who presented, regardless of their economic, medical, insurance, or other status. Since then, courts have developed theories under which hospitals can be held liable for refusing care. ^{9,15,20}

One theory is that a duty to treat may arise when a hospital undertakes to render aid, a position that is taken in the Restatement 2nd of Torts. ¹⁸ Under this section, there is a liability for harm that attaches if the actor fails to act with reasonable care, even when the undertaking is purely gratuitous. The basis for harm to the plaintiff is that the plaintiff relied on the actor's conduct and, in doing so, either did not take the precautionary measures that he or she would have otherwise taken and/or had foregone aid from another source. In other words, if a hospital holds itself out as one that will provide care in an emergency, that fact becomes generally known to the public. ¹⁹ Patients who present for care at such an emergency department and subsequently deteriorate because therapy, once initiated, is denied or delayed on the basis of an inability to pay for it, have a legitimate claim against the hospital. ^{9,12}

Another theory successfully used by the courts to impose a duty on emergency departments to see and treat emergency patients is that of negligence. ¹⁷ Negligence is the failure to act as the prudent emergency physician would under the same or similar circumstances, resulting in some harm to the patient. Considering the presence and maintenance of an emergency department as an undertaking, negligence may be found in an emergency department's failure to properly perform that undertaking (i.e., providing aid for those who present in search of emergent medical care).

The third theory used by the courts in finding hospitals liable when they turned away emergency patients was based on reliance. Under this theory, when a hospital establishes the custom of holding itself out as being a place where one can receive emergency care, that hospital then owes a duty to those patients who rely on that custom in seeking care. ⁵ Patients who relied on this promise of care, but were harmed by that reliance because the care was denied or delayed for some reason, then had a cause of action (detrimental reliance) against the hospital.

Fourth, the issue of financial motivation in limiting, delaying, or denying care has resulted in public policy intended to coerce hospitals into providing care for all persons who present for emergency care. This argument, briefly, holds that hospitals receiving public monies (and most do, through Medicare and Medicaid reimbursement and other programs) must serve the public equally.

By the late 1970s, it became well established that hospitals with emergency departments had a duty to render, in a reasonable manner, emergency care for all patients who presented for such care, regardless of insurance, ability to pay, or other factors, unless there was good cause not to do so. The duty was not limited to public hospitals, but included private facilities and those run for profit, particularly if they accepted some public money for expenses or capital improvements. It is still unclear at exactly what point an individual becomes a patient, but that threshold is certainly crossed once any care is rendered, and it may be crossed once the patient enters the facility and requests care. One opinion that “it would shock the public conscience if a person in need of medical emergency aid would be turned down at the door of a hospital having emergency service because that person could not at that moment assure payment for the service” summarizes the situation by the 1980s. ³ Unfortunately, some hospitals were meeting the minimum requirement of seeing all patients, but then unsafely transferring those unable to pay for continued care.

On April 7, 1986, Congress passed federal antidumping legislation as a part of the Consolidated Omnibus Budget Reconciliation Act (COBRA). ¹⁷ The purpose of this legislation was to prevent a hospital from transferring unstabilized emergency patients for economic reasons. ⁴ The COBRA law applies to all emergency departments at all hospitals that receive any form of federal funding, and to all of the persons who present there for care, regardless of their age or insurance status. Although the impact of COBRA was felt throughout the country, the problem of patient dumping remained one of significant proportions. In response to this situation, amendments to COBRA, known as the Omnibus Budget Reconciliation Act (OBRA) or the Emergency Medical Treatment and Labor Act (EMTALA), went into effect on July 1, 1990. The publicity of this event served to heighten awareness of patient dumping and has resulted in significant educational efforts on behalf of hospitals and their administrations to train their nurses and physicians in the requirements of this law. Regulations went into effect late in the summer of 1994 that fully implemented the intent of the COBRA law as amended. In September 1995, regulations requiring receiving hospitals went into effect, with an immediate increase in administrative EMTALA enforcement actions as a result. In June 1998, site review guidelines for surveyors were issued, further detailing government interpretations of the law and regulations.

THE COBRA LAW IN DETAIL

Scope of Coverage

COBRA, as implemented in Regulations, applies to all persons (and to persons on whose behalf care is sought) presenting to an emergency department for care, regardless of their indigency or insurance status, and to any hospital that operates an emergency department or equivalent (e.g., labor room or mental health screening area) and receives Medicare funding. The term *transfer* is broadly defined to include any patient who does not go to the morgue or competently leave the emergency department following an informed refusal of care process. Even patients admitted to the hospital may be covered if discharged from the hospital before being stabilized. A hospital that does not have a Medicare provider agreement may be influenced by COBRA, because it is possible that this law may be used to determine the “standard of care” for patient management. A hospital is not guilty of a violation, however, if it can show that it did not depart from its normal treatment procedure for any patient with similar complaints in the emergency department. ⁷

Under the provisions of the law, patients must be offered a medical screening examination to determine whether an emergent condition (including active labor) exists. If the patient is stable (no emergent condition), then COBRA does not apply. One of the most problematic aspects of COBRA, from the perspective of the emergency department physician, is the legal definition of what are generally considered to be medical terms, such as *stability* and *medical emergency*.

Medical Screening Requirement Definitions

Presenting to the Emergency Department

Physically arriving in the department and asking for care obviously constitutes presentation, but HCFA guidelines state that any person who arrives on the premises of the hospital, seeking emergency care, should be screened. The 1994 Regulations add any presentation to the hospital's own ambulance service, if any, to the group of patients who become the responsibility of the emergency physician. ⁶ Patients who pass through the emergency department, including patients presenting for routine outpatient testing or patients presenting for direct admission after hours, must all be logged into the emergency department log. They have to be recorded, but not necessarily screened, according to HCFA enforcement patterns. These patients would not typically receive a medical screening examination unless they complained of acute problems or were observed to be in distress that was inconsistent with their scheduled presentation. Any patient who presents on the premises of the hospital must be logged and screened, if seeking care.

Obstetric patients presenting to the obstetrics department or psychiatric patients presenting to a psychiatric assessment unit, rather than the emergency department, are required to be logged and screened. HCFA interprets the term *emergency department* to cover all areas where a patient might present for primary assessment of a presenting condition on an unscheduled basis, and not just the specific area designated as an emergency department.

All patients presenting to a hospital-owned and -operated ambulance are likewise deemed to have presented to the hospital. Patients transported by non-hospital-owned ambulances are not deemed to have presented to the hospital until the ambulance has entered onto hospital-owned property. Hospital property includes all off-site locations operated under the same Medicare provider number as the hospital, under HCFA enforcement. Telephone or radio contact from outside the hospital's boundaries and not involving a hospital-owned ambulance is not deemed to be a presentation for HCFA enforcement purposes. Whether courts will follow the HCFA interpretations in civil litigation has yet to be determined, in part because few trial cases have been argued and individual cases focus on broader

issues. Several cases, however, have dealt with the issue of having “come to the hospital,” and have been consistent with the HCFA definition in their limited-fact situations.

Screening Examination

There are no specific instructions for how to do a “screening examination”; therefore, the COBRA requirement for such a screening examination creates an artificial entity. However, screening, in the epidemiologic sense, is one of the major functions of the emergency department; therefore, this type of examination is inherent in the emergency care process. According to this argument, the essence of emergency medicine is, in large measure, the recognition of signs and symptoms that may pose a risk (not recognized by the patient) of death, serious disease, or potential disability. It is this intellectual effort that distinguishes emergency medicine from other specialties.

The remainder of the practice of emergency medicine is simply treatment of the presenting or potential problem in an attempt to prevent these complications. The legal system adds credence to this argument by most often taking emergency physicians to court for failure to diagnose, rather than for errors in treatment. Therefore, according to this argument, the “screening examination” is no different from the problem-focused history and physical examination, with all indicated studies and tests, that would be performed to rule out, to a reasonable degree of medical certainty, impending death, serious disease, or potential for disability. It then follows that the screening examination should not differ from the regular evaluation performed for any patient with a similar problem.

Who Can Perform the Screening Examination

The qualifications of the person performing the screening are not specifically addressed, but the wording of COBRA amendments suggests that a physician evaluation, which is certainly a “service routinely available to the emergency department,” is required. ACEP has interpreted the medical screening requirement to mean that a qualified emergency physician will determine whether a patient is presenting with a true or potential emergency and whether the patient is likely to benefit from a transfer to another facility. This position is supported by both the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) in their accreditation manuals and most, if not all, state Boards of Registration for Nursing. The JCAHO takes the position that it is the physician who is responsible for the degree of medical treatment and evaluation of emergency department patients. Further supporting ACEP's position is the understanding that there are laws in all states that govern the practice of registered nurses and prohibit registered nurses from making medical diagnoses and discharging patients from the hospital without some higher level of certification. Others add the argument that the COBRA law specifically lists the responsible physician as one of the liable parties, and not the nurse, and that, therefore, the intent of the law was direct physician involvement in the screening examination.

It is important to note, however, that some hospitals (and MHCPs) have taken the alternative view that a nurse or other health-care provider is capable of performing a “medical screening” examination within the meaning of the law. This view is based on the theory that HCFA guidelines state that the physician has to be responsible for the screening examinations performed by nonphysicians but does not necessarily need to perform the examinations personally. In hospitals where a nurse may triage patients to other facilities and locations, some ambiguity remains. In facilities where all patients are seen by a physician, there should be little question that a physician screening examination is required. In either case, because the responsibility for the care of all of the patients who enter the department lies with the attending physician, and because it is the physician and the hospital who bear the ultimate responsibility for the patient and who are held financially liable by this Act (see later discussion), it can be argued that, at a minimum, a physician should make the decision about any patient stability for transfer or discharge, even if someone else performs the screening examination.

Where nonphysicians are utilized for medial screening functions, HCFA has been quick to cite violations in which the nonphysician was not specifically authorized as a qualified medical screening person by hospital board action, in which the services exceeded the scope of the state licensure, in which the services were not pursuant to a written protocol, and in which there were no clearly defined points at which a physician was required to be involved.

Final responsibility for the medical screening examination under HCFA Conditions of Participation in Medicare must rest with a physician, which leaves delegation of this function to nurses in the emergency department setting problematic. A 1996 Massachusetts case based on a rapid primary assessment by a registered nurse and subsequent discharge to a physician's office resulted in HCFA citations as well as an EMTALA lawsuit that produced a 1999 settlement of \$1 million.

Actions by private physicians who see their own patients in the emergency department have been cited by HCFA as violations, and the hospital and physician held responsible for the violation. The definition of what persons the hospital may be accountable for refers to employees of the hospital or any person affiliated or associated directly or indirectly with the hospital.

ADEQUACY OF MEDICAL SCREENING

The original iteration of COBRA required that the screening examination be performed within the capabilities of the emergency department. Amendments to the original act now require that all ancillaries (e.g., laboratory testing, imaging, and diagnostic services) that are available to the emergency department be considered in the patient screening process. It also includes the use of all routinely available “on-call” subspecialty physicians for consultation.

Although the Act itself does not dictate the standard for emergency medical practice, the adequacy of the medical examination is likely to be judged in two ways. One is by the normal medical malpractice and negligence standards as to what care is standard for that hospital and physician when faced with a patient presenting with the same complaint. Another is by the patient's outcome (i.e., retrospective stability), judged against the Act's definition of an emergency medical condition: a medical condition manifesting acute symptoms of sufficient severity (including severe pain) such that the absence of immediate medical attention could reasonably be expected to result in placing the health of the individual (or the unborn child of a pregnant woman) in serious jeopardy, serious impairment to bodily functions, or serious dysfunction of any bodily organ or part (or, with respect to a pregnant woman who is having contractions, there is inadequate time to effect a safe transfer to another hospital before delivery or the transfer may pose a threat to the health or safety of the woman or the unborn child). This retrospective approach, particularly when applied using the broad and subjective definition of an emergency medical condition, implies that a thorough evaluation must be performed in order to accurately assess stability, provide the most responsible patient care, and avoid potential litigation.

OBRA changed the COBRA language in two additional areas that are pertinent to the medical screening requirement. First, the definition of *active labor* was broadened to include any pregnant woman having contractions, regardless of gestational age. Second, wording was added that prohibits delaying the screening examination or subsequent treatment to “inquire about the individual's method of payment or insurance status.”

Thus, hospital contracts with MHCPs that require special approval procedures, telephone calls, or other measures that may delay care for such patients should be examined closely by legal counsel to be certain that they do not conflict with the spirit of this additional requirement. HCFA site review guidelines indicate that it is not appropriate for a hospital to request, or a managed care plan to require, prior authorization before the patient has received the medical screening examination to determine the presence or absence of an emergency medical condition or until an existing emergency medical condition has been stabilized. A hospital may request routine registration information, such as name of insurance, but may not pursue validating of that information or obtaining authorization for treatment prior to completion of the screening examination. Physicians may not alter the screening examination based on the type of insurance plan the patient has and may not refuse to screen a patient because his or her plan refused to authorize treatment or pay for screening and treatment.

Triage protocols that avoid any difference in patient care procedures for such patients would appear to be both legally prudent and medically sound. For example, contracts between the hospital and MHCP providing payment of a “screening fee” for patients retrospectively found to have nonemergent conditions and payment of mutually agreeable charges for other patients might be arranged between the hospital and MHCP, thus transferring the economic considerations to the billing office and moving money instead of patients. If any difference in procedure exists for MHCP patients, it must be clear to all that the MHCP is authorizing payment, not medical care, that the patient is being offered a screening examination, and that there is no significant economic disincentive to the patient in choosing to be examined and treated if the MHCP refuses payment authorization. If, for example, a patient is transferred or refuses care after being told that he or she will be billed for that care, the hospital and physician may be liable for damages if the patient is later found to have been unstable and can show that the reason for transfer or refusal of care was the threat of a bill for emergency services.

It is also important to note that the medical screening examination is an ongoing process rather than an isolated event. This means that there must be an ongoing monitoring of the patient's condition and that, where further diagnostic evaluation is necessary to rule out a condition that might constitute an emergency medical condition under the law, the medical screening is not yet completed and HCFA enforcement standards will deem that patient to have an emergency medical condition and unstable for EMTALA transfer purposes. The courts, however, tend to accept a physician determination of stability and not look beyond that, unless the medical

record contains clear indications to the contrary or the scope of the examination was seriously deficient in light of the presenting conditions.

Stabilizing Treatment

The necessary stabilizing treatment for emergency medical conditions and labor means that once a patient is found to be suffering from an emergency medical condition (per COBRA definition) or is in active labor, the hospital must give the patient that treatment necessary to stabilize the patient's condition, unless the patient can be transferred without danger of deterioration of his or her medical condition or unless the benefits involved with the transfer and subsequent treatment at the receiving hospital outweigh the risks. This stabilizing treatment includes delivery of the fetus and placenta in the case of active labor, and includes the provision of ancillary services, including the skills of on-call specialists. OBRA eliminates emergency physician liability if an on-call consultant refuses to see and treat a patient in a timely manner. The wording requires that, should such a situation arise, where "the on-call physician fails or refuses to appear within a reasonable period of time, and the [emergency] physician orders the transfer of the individual because the [emergency] physician determines that without the services of the on-call physician the benefits of transfer outweigh the risks of transfer, the physician authorizing the transfer shall not be subject to a penalty." In addition, the "name and address of any on-call physician..... who has refused or failed to appear within a reasonable time to provide necessary stabilizing treatment" must be included in the medical records provided to the receiving facility.

If transfer to another facility is offered and refused by the patient, this refusal should be informed and documented. This situation may arise when transfer is indicated to access stabilizing treatment. If transfer is not offered, but the patient refuses to consent to further examination and treatment for an emergent condition determined by the screening examination, this refusal should also be informed and documented. Note that this refusal provision follows the screening examination; refusal to consent to the screening examination itself may then constitute a withdrawal of the request for examination and treatment, because no determination has been made on which to base a reasonable discussion of the risks inherent in refusing the initial screening examination. Many facilities have adopted a "screening form," on which the process of such consents and refusals is documented. However, as discussed, the insertion of an additional process for a specific group of patients that delays care while determining reimbursement information may violate the law. Some have argued that the standard consent for treatment form used for other persons presenting to the emergency department covers consent for screening examinations and typically informs the patient that costs will be incurred and charges billed. It is then, according to this point of view, the responsibility of the patient and his or her third-party payor to discuss responsibility for payment. The test that is likely to be applied by the courts is whether the process used is different for any particular group of patients, whether that difference poses a potential for delayed care, and whether the care then given is standard for the presenting situation up to the point of determining whether an emergency condition exists and providing stabilizing treatment.

HCFA offices in many areas of the United States have required hospitals to remove financial consents for the initial consent documents signed prior to screening. This suggests a high risk associated with these forms and any other sign, procedure, or document that draws payment status issues to the attention of the patient prior to completion of the screening examination and stabilization.

Appropriate Transfer

The "restricting transfers until the individual is stabilized" provision means that a patient with an unstabilized emergent condition may not be transferred unless informed written request for transfer is made by the patient or responsible party, or all of the following conditions are met:

- A physician [or if not present, a qualified medical person] signs a certification that the medical benefits outweigh the risks and summarizes this argument as discussed with and consented to by the patient or responsible party.
- Treatment to minimize transfer risk is provided.
- The receiving facility has adequate capability and has accepted the patient.
- The receiving facility is provided with all pertinent records.
- The transfer is effected through qualified personnel, vehicle, and equipment.

The adequacy of the transfer arrangements will probably be judged using a standard of care test. Therefore, all the usual steps taken to arrange acceptance, send medical information, and physically transfer the patient should be met or exceeded. Reductions in level of care during transfer are problematic and should be avoided, if possible. As always, personnel accompanying the patient during transfer should also have the vehicle, equipment, training, and skill to treat all reasonably likely complications of the patient's emergency condition during the transfer. The use of hospital staff unfamiliar with emergency medicine, including the skills needed to provide care in ambulances and helicopters, should be avoided. An unstable patient, who requires the close attention of a physician and nurse while in the emergency department, probably warrants that level of care during transfer as well.

One of the primary areas in which hospitals encounter problems with the transfer regulations is in the use of private vehicles. Interhospital transfer or movement among different health system buildings generally triggers the "appropriate transfer" rules, and under these rules, a private vehicle cannot qualify as an appropriate vehicle, with appropriate medical personnel, and with life-support equipment. Hence it is a violation, unless the patient has refused ambulance transfer in writing, with the appropriate risks and benefits specifically itemized on the refusal form.

For the practitioner for whom relatively minor conditions still must be transferred for a narrow focus of care, the issue comes up as to what a patient needs to be told to justify an ambulance transfer that might not be paid for by the insurance or Medicare benefits. The answer from one regulator was to tell the patient, "This may sound stupid, but I am required by law to send you by ambulance unless you sign this refusal."

Closely associated with this situation is the use of police vehicles for transport of mental health patients, as is general practice throughout the United States. HCFA citations have been issued for use of police or private vehicles in transferring patients deemed to be a danger to themselves or others, as they are "unstable" under EMTALA standards. Although the site review guidelines indicate that stability may be achieved through the use of medications and restraint, these are not the sole criteria for stability. In addition, once there are medications administered or medical restraint orders issued, the patient is a medical patient as well and requires ambulance transfer. This definition places many hospitals in the position of following state procedures or complying with EMTALA. EMTALA specifically preempts state rules that directly conflict with its standards.

Receiving Facilities

The "nondiscrimination" requirement mandates acceptance by regional referral facilities capable of treating the patient. Although it is not specifically defined in the law, it appears that specialty referral centers are those that are able to handle medical emergencies that the sending hospital is not. Such facilities cannot refuse transfers if they have the capability to treat the patient.

Hospital-Wide Implications

Hospitals are required to have a compliance policy meeting requirements set forth by the COBRA law. Medical records, including transfer forms, are required to be maintained by the hospital for 5 years from the date of the transfer. In an effort to increase public awareness of patient rights to emergency care, hospitals are required to post signs with specific language identifying the rights of persons who present seeking care, the obligation of the hospital to provide that care, and the hospital's participation or lack thereof in the Medicaid program.

A 1999 Supreme Court decision (*Roberts v. Galin*) has specifically ruled that a case involving an inpatient who was transferred to a nursing home after 60 days of hospital care and in an allegedly unstable condition could have her EMTALA lawsuit tried, regardless of a failure to allege an intentional violation. Immediately following that decision, the United States Court of Appeals for the First Circuit (*Lopez-Soto v. Hawayek*, 1999 WL 188283) ruled that EMTALA stabilization and transfer rules apply any time a patient (or visitor or employee) on the premises of the hospital is known to have an unstable emergency medical condition as defined by EMTALA. This decision supports a prior Virginia Supreme Court ruling that EMTALA is not limited to patients presenting via the emergency department (*Smith v. Richmond Memorial*, 1992).

Enforcement Provisions

The mechanisms for enforcement under COBRA are specifically delineated within the Act itself. It is important for both physicians and hospitals to remember that that fines or termination of Medicare provider agreements can occur *even in the absence of patient injury*. The consequences of being the subject of a complaint, even if

unsubstantiated, are potentially devastating. The hospital will be subject to investigations and probably to negative publicity. It will have to spend considerable time and money preparing a defense and correcting any potential deficiencies. A negative initial determination will be difficult and costly to overturn, even if the hospital is able to do so.

A hospital that knowingly, willfully, or negligently violates COBRA can be subject to suspension or termination of its Medicare provider agreement. A physician may be terminated from Medicare for gross, flagrant, or repeated violations. The Act also provides for penalties against institutions that receive inappropriate transfers if they do not report the violations within 72 hours. Patient dumping cases are initially investigated by state agencies under contract with HFCA to determine whether there is a material concern about compliance. Once that determination is made, the information is turned over to the federal government for further action. Once a physician is found to be out of compliance with the provisions of COBRA, the state medical board will become involved. If the state medical board does not take action within 30 days, the Office of the Inspector General (OIG) will step in to make a determination of whether a penalty of up to \$50,000 is warranted. Civil monetary penalties for a violation are severe and are intended to provide a significant deterrent for those hospitals and physicians inclined to dump patients.

COBRA was not meant to supplant the medical malpractice process; it is a cause of action unto itself, and is not typically covered by physician's malpractice insurance, although most hospital insurers have defended and paid COBRA claims. Monetary compensations of up to \$5 million for personal injury resulting from patient dumping have been awarded under this law. Sanctions may come in the form of termination of the Medicare provider agreement, civil monetary penalties of up to \$50,000 per violation for both the hospital and physician, private cause of actions by the patient against the hospital for personal injury, private cause of action by the receiving facility against a transferring hospital to recover financial losses suffered as a result of an inappropriate transfer, or injunctive relief.

Prosecution of a Claim

The elements of a cause of action under COBRA¹³ that must be alleged by the plaintiff are (1) that the plaintiff presented to the defendant's emergency room or covered adjuncts such as a hospital-run ambulance service (2) with an emergency medical condition, and that the hospital either (3) did not adequately screen to determine whether an emergency condition existed, (4) discharged the patient or transferred the patient before that emergency condition was stabilized, or (5) failed to follow the statutory standards for transfer.

The standard of care in the individual emergency department to which the plaintiff presented is also important. A COBRA claim can also involve being denied care or an allegation that care provided was materially different from what other patients who present under similar circumstances would receive. It may also be established by showing that the hospital did not adhere to its own policies and procedures for evaluation of patients who present with a similar complaint. Because this cause of action was not created to supplant a medical malpractice claim, one can have both a COBRA claim as well as a medical malpractice claim arising out of the same emergency department visit.

In defending actions based on COBRA, it is important to remember that the Act is reasonably specific as to what is considered to be a violation. It requires that a medical emergency or labor be present based on a screening examination, and that the patient be transferred either without adequate stabilizing treatment or improperly. The first defense is that the patient was stable. Under this Act, a stable patient may be transferred to another institution for any reason at all (although other causes of action may be problematic if the transfer results in injury). If there is documentation that the patient received an adequate screening evaluation, and that evaluation did not reveal an emergency medical condition, then the claim may be one of medical malpractice if there is a claim of negligence, but is not an action under COBRA. The key is to determine whether the patient received a medical screening examination that was the same as would be given to anyone else who presented with the same complaint, regardless of their insurance status, and the result of that screening examination is that the patient was found to be stable. It is important to differentiate between the patient's eventual diagnosis or outcome and the result of the screening examination. It is tempting for the plaintiff to claim that the screening was inadequate if the outcome was poor, but the defense must only show that the screening met the standard examination criteria. In other words, a patient who presents with a minor ankle fracture, is felt to be stable after adequate screening and is appropriately transferred, but dies the next day from a pulmonary embolus has an unfortunate outcome, but not a COBRA claim. More problematic is the same patient who develops chronic pain in the ankle after delayed care in a receiving facility, or who has an auto accident while driving to the receiving facility because of inability to use the injured ankle.

The next ground on which to base a defense is that the patient requested the transfer or voluntarily withdrew a request for care. This has become increasingly important following the increase in the managed care population. The burden of proof is on the hospital to show that the request was withdrawn by the patient and that there was no coercion on the hospital's part involved in the patient's decision to withdraw. Documentation of offers to provide care regardless of ability to pay at the time of care, particularly efforts that may mitigate any claim that the cost of offered care was an issue, such as documented effort to assist in application for free care or the offering of reduced cost care plans where applicable, is helpful in defending a claim of economic coercion. A final defense may be that the statute of limitations for the Act has run out.

Exceptions to COBRA

1. *The patient dies before transfer or discharge.* While this outcome may raise concerns about negligence, COBRA does not apply unless the death occurred *from or during* transfer or as a result of a failure to adequately screen or stabilize. A causal relationship between the violation and the adverse outcome must still be proven for litigation purposes, although regulatory enforcement does not link violations to negative outcomes. A citation may be based on a failure of EMTALA compliance without a negative outcome. Negative outcomes, however, are considered "red flags" that stimulate more detailed review.
2. *The patient leaves against medical advice.* A patient who is offered or receives a medical screening examination and competently leaves the hospital against medical advice (AMA) has no cause of action under COBRA. However, "making" all patients who leave the department after offer of a screening examination sign an AMA form dilutes the concept of "against medical advice." The AMA process should be reserved for situations in which the physician feels there is significant medical risk if the patient leaves, not for all situations in which the physician feels at legal risk. Use of a specific form for refusal of EMTALA rights would be more appropriate in most instances. In serious cases, use of both forms would emphasize the efforts taken by the hospital or physician to attempt to provide appropriate care. Use of the AMA form routinely may have the unintended effect of shutting off insurance coverage for subsequent treatment of the same or related condition.
3. *The patient is stable.* A patient is stabilized if, after a standard medical screening examination, there is no reasonable likelihood that the patient's condition will materially deteriorate from or during the transfer. However, as discussed, stability may be open to retrospective reinterpretation in some situations.
4. *The patient requests the transfer or refuses it.* An informed patient may request or refuse transfer. While any transfer performed under these circumstances should follow good medical practice, COBRA cannot then be invoked if the patient rather than the clinician initiated the transfer. Likewise, if a patient refuses transfer when recommended, the clinician should provide the next best alternative, but cannot be held liable under COBRA for the patient's informed decision. As in informed consent, a determination of patient competency must be made. Physicians must understand, however, that getting a patient's consent to a technically incorrect action under EMTALA does not waive the violation or validate the action. Similarly, pressure to get a patient to request transfer invalidates that patient's request and can expose the hospital and physicians to EMTALA citations and fines. The patient-initiated transfer or refusal must be documented in writing and signed by the patient, if possible. If not, extensive documentation of efforts made to obtain the written request or refusal must be present in the record.

COMMON PITFALLS

- Failure to appreciate the COBRA laws and their impact on the practice of emergency medicine for both patient treatment and transfer
- Failure to educate patients and families about COBRA
- Failure to understand the relationship between the MHCPs and the emergency physician's responsibility to provide a screening examination to all patients who present for care
- Failure to apprise oneself of hospital policies and procedures regarding the COBRA laws and implementation of compliance strategy

[Chapter References](#)

Death in the emergency department is especially dramatic because of the suddenness of the loss, and because it is often traumatic and sometimes involves the young. Unexpected and untimely deaths are conspicuous because the person not only was active and visible at the time of death, but also was a significant force in the life of the survivors.¹⁸ Intervention strategies to facilitate the grieving process may help survivors avoid developing major psychiatric illness as a sequela.

Bereavement is the total normal response to loss. *Grief* denotes the intense emotions and physical symptoms associated with the loss.⁷ *Mourning* is a social expression of grief. Grief is a normal process that is usually set in motion by significant loss, such as the loss of a spouse, parent, child, or significant other. Grieving is characterized by an intensive, in-depth review of the survivor's relationship with the deceased. A grieving person reviews memories of the deceased and only gradually confronts each one with the realization that it no longer corresponds to something real. This sequence is repeated over and over. The grief response may also include physical ailments and guilt feelings, such as feeling responsible for the loss or failing to resolve personal conflicts. The grieving person gradually is reconciled to the loss and attenuates the attachment to the lost object. The psychological purposes of grieving are to break the emotional tie with the deceased person and to reinvest the attachment in living persons.

Expression of grief is determined by cultural mores.¹⁸ Some people express grief histrionically, with loud crying and sobbing, but others remain still, with little visible expression of emotion. A person displaying no overt symptoms of grief may still be deeply affected or grieving. Several responses can be perplexing and may be misinterpreted by staff.⁷ A frequent initial reaction is denial, a psychological defense that closes off perceptions of painful immediate reality. The survivor may question the physician closely for proof of the identity of the deceased or may continue to refer to the deceased as if he or she were alive.¹¹ At other times, survivors display antagonistic and angry feelings toward staff members, accusing them of being negligent or of not doing all they could have done. This anger often represents the survivors' own unconscious anger toward the deceased for abandoning them, or it may stem from guilt about unresolved conflicts with the deceased.

Medical education is deficient in the training of physicians in death notification.^{10,13} Although death in the emergency department is relatively common, physicians find this process emotionally difficult and draining. There is often no preexisting relationship between the physician and patient, and physicians may fear being blamed. They must deal with their own emotions (e.g., feelings of defeat, guilt, impotence, and incompetence) and fears of death as well as the reactions of survivors. Physicians may attempt to reduce their own stress by delaying the news, thus increasing the family's anxiety, or by rushing in unprepared and presenting the news in an awkward manner.^{1,15}

Conveying bad news compassionately and effectively requires communication skills and advanced preparation. A staff that is aware of the dynamics of grieving and the needs of survivors can facilitate the grief process, cushion the trauma of loss, and establish a basis for a healthy grief response.⁵ Issues related to death notification and the processes involved are outlined in this chapter. Similar considerations apply when delivering other types of bad news to patients, their family, and their loved ones.^{6,14} Explicit criteria should be met when declaring a person brain dead.⁸

CONTACTING SURVIVORS

The first intervention after sudden and unexpected death is contacting the survivors.¹⁰ Because there is no ongoing relationship between the emergency department staff and the survivors, the person designated to call the survivors should identify himself or herself and should establish the identity of the survivor. Talk to an adult, and try to determine whether someone is present to provide emotional or physical support.

If the family is far away, it may be necessary to inform the family over the telephone. As a rule, however, do not tell relatives of deaths over the telephone; rather, tell them that their relative is in serious condition and ask them to come to the hospital immediately.^{1,16} Information regarding the time, location, and nature of the event (illness or injury), and when and how they arrived can also be provided. Encourage the survivor to come to the hospital with a family member or close friend, allowing another person to drive. Ask them if they need directions and be prepared to provide them if needed. Having preprinted directions available is helpful in this regard. Be sure they write down this information, and have them read it back to you. Provide them with the name of the person to contact when they arrive at the hospital. If asked how the patient is doing, tell them that he or she is in critical condition, has just arrived, or is being attended by the doctor.

If the person you are trying to reach is not there, ask how to reach the person.¹⁰ If a child answers, only give information regarding the contact person. If you reach an answering machine or service, state only your name, the name of your health-care facility, the date and time of the call, the name of the person you are trying to reach, and a return telephone number that will be answered by someone who can reach you or who knows what to tell them.

MEETING SURVIVORS ON ARRIVAL

When the family arrives, a staff member, chaplain, or social worker should be available to meet them immediately. Verify the identity of the survivors, and escort them to a quiet area where they can have privacy. All emergency departments should have a dedicated family room for this purpose. This room should have comfortable seating. Tissues and a telephone with long-distance access should also be available.

If the family arrives at the same time as the patient, have someone escort them to the family room, where registrars can obtain demographic information. Contrary to tradition, however, if they wish, it is also acceptable for them to be present during the resuscitation.

INFORMING SURVIVORS OF THE LOSS

Because the physician has the most authority, he or she should never delegate the task of informing the family of the death.^{5,10,13} Further, the physician can answer the pertinent medical questions. He or she should obtain as much information as possible about the decedent and rehearse what will be said to the survivors prior to meeting them. If possible, wait for all family members to arrive before speaking to them. Have one or more staff members, such as a nurse, social worker, or chaplain, accompany you, for both your own and the family's support and to convey the message that a team was, and is, involved. This should preferably be someone who has already interacted with the family and who will be available after you leave. Make sure to clean yourself up if your clothes have been soiled. Introduce yourself and support personnel and identify by name and relationship those who are present. Sit down. Take your time and talk softly.

Nonverbal (body language) messages are important.¹⁰ The family may not remember much of what is said, but they will likely remember your demeanor. Sitting down is comforting, symbolizes that you are part of the group, and avoids the misperception of an imbalance of power. Sitting forward is engaging and connotes empathy, whereas sitting back or in a relaxed posture connotes disinterest. Sitting next to the closest relative or key survivor, or crouching down before or beside them, also connotes empathy. Address the closest relative face to face and by name. Facing them squarely shows interest. Touching the key survivor's shoulder, arm, or hand is generally welcomed as a sign of closeness, regardless of their age, gender, or ethnic background. Nodding reinforces survivors' statements and encourages them to continue speaking. In most, but not all, cultures, direct eye contact shows interest and is a sign of respect and honesty. Persistent eye contact, however, may be interpreted as controlling or threatening.

With the exception of the immediate family, ask other relatives and close friends to wait outside until the news is revealed. However, family relationships are varied, so

use judgment about whether additional family members or friends should be present when the news is revealed. If friends appear to be offering important emotional support, then, obviously, they should also be allowed to hear the news. If children are present, ask the key adult if they would prefer to have them wait outside initially. If they do, have a staff person take the children to an area with a television or toys.

Ask what family and friends already know about the incident. If they were present at the time of the decedent's demise, ask them to describe what happened. If not known, also ask them about the decedent's medical history and their health, physical condition, and level of function during the hours and days prior to death.

Briefly (in about 30 seconds) describe prehospital and emergency department events in chronologic order so that family members understand clearly what happened. Describe the course of events in simple, understandable language, avoiding medical jargon and graphic images. Be sure to validate the emergency medical services effort. To avoid confusion and be certain that the family understands that the patient is dead, use a "D" (dead, death, died) word rather than a euphemism such as "didn't make it," "gone," "passed away," or "expired." Refer to the decedent by last name and title (e.g., "Mr.") rather than "he," "she," or "your [relationship]." Do not be afraid to express your emotions and show sympathy. Tell them that you are sorry for their loss or that you are sorry to give them bad news, but do not apologize for the death itself or the care given, as this may make survivors think that the outcome could have been different if something more or different had been done.

Allow periods of silence so that the family can react to the news. Be prepared for reactions such as anger, disbelief, absolute or pathologic denial, guilt, fainting, and exacerbation of conditions such as angina. Anger may be directed toward the patient, those responsible for the death, or the medical staff. Do not argue with survivors and respond to anger without considering it a personal attack. If violence is possible (e.g., survivors are intoxicated or the decedent was a victim of an altercation and the adversarial party or parties are also in the emergency department), have security or police immediately available.

If resuscitation is in progress and survival seems unlikely, it is helpful to prepare the family for the expected outcome. Break away from the resuscitation and inform them that the patient's condition is grave and that you are doing everything possible to revive him or her.

Conveying the loss to a child is perplexing, not only for trained hospital staff, but also for family members. Encourage survivors to discuss the death with children. When adults avoid discussing death with children, they create an atmosphere of apprehension and anxiety for children, who are sensitive to evasion and family stress levels.¹ An honest discussion can be a corrective emotional experience and may help to decrease the fantasy and distortions that children have about death.¹⁶ Adult family members should not lie or distort the truth. Children carry mistaken notions about specific family deaths into adulthood, with lingering anguish and, in some cases, severe bouts of recurring depression and potential suicide.⁷ Encouraging religious interpretations is fine. Further, family members should openly discuss their own feelings with the child and should not attempt to alter the child's feelings about the loss. When the deceased is a parent, young children often require constant reassurance that the surviving parent will not disappear and will be able to maintain food, shelter, and family integrity.¹

RESPONDING TO SURVIVORS' GRIEF

Physicians can facilitate grieving by being good listeners while the survivors cry or let out their emotions.^{10,11,12} and ¹³ When survivors begin to display emotional reactions, encourage them to express their feelings and to review their last moments with the deceased. Be patient as survivors begin an obsessive review of the events leading up to the death, by repeating anecdotes from the life of the deceased and repeatedly raising the same questions regarding the circumstances of the death.¹ Again, touching or holding the survivor when appropriate will be appreciated.

When confronted with a patient expressing denial, guilt, or anger, be patient and understanding, and not defensive. Ultimately, survivors' defenses will give way to feelings of sadness and loss. Tell the family they did the right thing, even if they did not. Reassure them that everything that could have been done was done. If possibly true, tell them that the patient did not suffer. Answer questions but give only enough information to assure the family that everything reasonable was tried to resuscitate the decedent. Ask survivors if they need to use the telephone to call friends, relatives, or clergy. Offer them privacy. Tell them that you will attempt to contact the patient's physician. Have a list of clergy available for out-of-town residents. In complicated situations, enlist the aid of social services. Unless the family broaches the subjects of autopsy and organ donation, wait until later to address these issues.

PROVIDING FOR VIEWING THE BODY

Offer survivors the opportunity to view the body.¹⁰ Viewing the body facilitates the grief reaction, but if they are reluctant or unwilling to do so, do not make them feel that their decision is wrong.³ Never refer to the deceased as "the body" or "it." Instead, use the person's proper name or a personal pronoun. Warn them about the visible effects of trauma, resuscitation, and postmortem skin changes, such as cyanosis and livedo or livor mortis. Remove blood and emesis before family members see the body. Often, medical equipment must be left in place until the coroner or medical examiner completes the necessary postmortem examination, but remove unnecessary medical equipment. Describe any equipment that remains on the body and explain why it is there. Cover the body with a sheet or blanket, but leave the head and hands exposed for the family to touch, and encourage them to do this. Move the body to a private room, if possible. Let them cut off a lock of hair, if requested. Allow family to be alone with the body, unless there are legal reasons (e.g., ongoing police investigation) for not doing so. Staff should remain nearby outside of the room and should be available for support while the family is viewing the body. Most family members will leave within 15 minutes.

MAKING FINAL ARRANGEMENTS

After the family has viewed the body, it is then appropriate to have necessary documents signed.^{1,10,11} Tell them the cause of death that you will put on the death certificate and offer them the use of a telephone so that they can call a funeral home. Ask again if there are any questions. Generally, no question should remain unanswered, unless the information is unavailable. Tell them how to reach you if they have questions at a later time.

Explain the role of medical examiners and police in cases of sudden, unexpected, or violent deaths and how the decedent's belongings will be handled. If an autopsy is mandatory, explain that fact to the family. If the cause of death is unclear and the physician feels the results will be helpful, inform the family of this and ask them for permission for an elective autopsy. Tell them that an autopsy will not interfere with funeral arrangements, that no pain or suffering will result, and that no major religion absolutely prohibits autopsy. At most institutions, there is no cost to the family, but this should be confirmed.

The issue of organ and tissue donation should be broached before family members leave the hospital; in fact, most states require that this option be addressed. One might ask, "Has your family ever discussed organ or tissue donation?" or "Our hospital offers organ and tissue donation. Would you like to discuss this further with someone from the transplant program?" If the family expresses an interest, contact the appropriate agency immediately.

Performing or practicing resuscitation skills and other procedures on the newly deceased for the purposes of medical education or research should be done only after obtaining consent from the family. Surveys indicate that the public is generally accepting of such practices.²

As mentioned, have a list of clergy available for out-of-town residents, as well a list of accommodations. Also have available a preprinted list with telephone numbers and addresses of local and national support groups that you can give to survivors. Educate them about the symptoms of grief and reassure them that these symptoms are normal.¹² Depressed mood, sleep disturbance, crying, difficulty with concentration, loss of interest, anxiety, and weight loss are the most common symptoms.⁴ Provide antianxiety or hypnotic medications to survivors only if requested and only after a formal evaluation of the individual involved. Limit the supply to a few days. Arrangements should always be made for family members or friends to stay with the survivor for the next 24 to 48 hours, because suicide is a possibility, especially for a spouse who has been married for many years.^{9,16} If a survivor appears to be suicidal or homicidal, ask them about this directly, and obtain a formal psychiatric consult if they are.

Unless necessary for the medical examiner or police investigation, give survivors the decedent's personal effects and any clothing removed from the body. Advise them of the condition of clothing and place it in a paper or plastic belongings bag, not a trash bag. Inform them when everything they need to do is done and that they may leave whenever they like. The physician or a designated staff member should accompany the survivors to the door.

COMMON PITFALLS

- Making remarks such as, "Everything will be okay" or "It was God's will," which may prematurely seal off the grief response
- Failure to appreciate the importance of body language

- Failure to clearly indicate that the patient has died, by using a “D” word
- Failure to allow and encourage survivors to express their feelings
- Impeding or impairing survivors' ability to grieve, by routinely prescribing medication
- Failure to address survivors' support systems
- Failure to offer family members the option of organ and tissue donation

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of William R. Dubin who wrote the previous version of this chapter.

[Violence in the Emergency Department](#)
[Chapter References](#)

Before the 1970s, violence in the family was considered to be infrequent and was thought to result from psychopathology of the persons involved rather than being seen as a societal problem. Only in the past 15 years have data on the prevalence and outcomes of domestic violence been gathered, and it is now recognized as an endemic problem. Responses have been wide-ranging, involving advocacy, medical care, and the mental health, criminal justice, and academic communities.¹ In 1985, the Surgeon General declared domestic violence a public health problem.

The statistics on battering are alarming. On the average, ten women per day are killed by their batterers; just over half of all women murdered in the United States are killed by their male partners, and 12% of murdered males are killed by their female partners. Every 12 seconds, a woman is beaten, and 95% of the victims are women. Fifty percent of women are battered at some stage in their lives,⁶ and one-third are battered repeatedly. Battering is the most common cause of traumatic injury to females in the United States.¹⁹ Fifty percent of homeless women and children in this country are fleeing domestic violence, and about 37% of obstetric patients across class, race, and educational lines are physically abused while pregnant.¹³ In addition, the nation's police spend about one-third of their time responding to domestic violence calls. Domestic violence costs the nation \$5 billion to \$10 billion per year (estimates include health-care costs, investigative and protective services, criminal justice proceedings, and loss of productivity from work). Surprisingly, however, there are three times as many shelters for animals as for battered women.

Early studies indicated that 22% to 35% of females presenting to the emergency department (ED) with any complaint did so because of symptoms relating to partner abuse. Although it is likely that the true number is less, it is still a significant problem. Women are ten times more likely to present to the ED than to the police after they have been victimized. The emergency physician is often the first health-care provider to see the results of domestic violence and, as such, must be able to recognize and intervene on behalf of the victims.¹² In 1992, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) determined that hospitals need to develop policies and procedures to address the identification, evaluation, and treatment of victims of domestic violence and need to have evidence of a written plan to provide education for all health-care providers. However, even when such policies are in place, fewer than one in 25 cases are recognized by health-care providers.

Domestic violence, spouse abuse, partner violence, and battering all refer to the victimization of a person with whom the abuser has had an intimate or romantic relationship. The term *domestic violence* implies that all members of the household are equally likely to be perpetrators or victims. It is estimated that 10% of the elder population may be victims. Elders are also often unaware of the existence of programs that can offer aid. Many health-care providers fail to recognize elder patients at risk⁹ and may be unaware of their states' regulations concerning reporting of suspected elder abuse.⁴

All EDs should have policies and procedures addressing the care of victims of violence. Emergency physicians must be able to recognize occult cases of domestic violence and correctly interpret associated behavior. About one in five battered women presenting to physicians have sought previous medical attention for injuries. When a diagnosis of abuse is missed, treatment is likely to be inappropriate and potentially harmful. Also, failing to diagnose abuse may further the victim's sense of entrapment and thereby contribute to victimization. Clinicians must consider battering in the differential diagnosis of a number of medical complaints, particularly when treating females.⁵ Universal screening should exist for all patients.^{11,14}

GANG VIOLENCE

The increase in the number and level of violence of street gangs is partly responsible for the fact that homicide is the second leading cause of death in males aged 15 to 34 years.¹⁶ Ninety-four percent of all cities with a population greater than 100,000 have active violent street gangs. Gang membership offers a sense of belonging, protection, and status; adventure; and access to illegal monetary gains. The average age for a gang member is 15 to 21 years old.

As gang members are frequently injured, EDs need to be aware of the problems that may ensue as they treat an injured member, and also look for ways to promote violence prevention in their community.¹⁸ Prehospital providers need to be aware of gang activity in their area and work closely with local law enforcement agencies in suspected gang-related injuries.⁷

VIOLENCE IN THE EMERGENCY DEPARTMENT

Violence within the ED is a growing problem that is probably underreported. Fifty-three percent of all hospital assaults occur within the ED, and, in 1991, nine department staff members died.¹⁷ The ED lends itself to promotion of a violent environment due to the volume of sick patients, waiting times, availability of drugs, 24-hour accessibility, and potentially violent psychiatric patients awaiting medical clearance. In one study, 77% of the perpetrators were patients, and 23% were visitors, and 80% of the incidents occurred in the general treatment area or psychiatric treatment area.¹⁵

A 1993 American College of Emergency Physicians policy statement called for action by hospitals to ensure a safe environment for staff and patients alike. It addressed the provision of adequate security, coordination of hospital security with local law enforcement, the development of written protocols for violent situations in the ED, and education of staff to prevent, recognize, and deal with potentially violent situations.

CLINICAL PRESENTATION

Domestic Violence

Domestic violence cuts across all racial, ethnic, religious, educational, and socioeconomic strata. Women who are single, separated, or divorced; those between the ages of 17 and 28; those who are pregnant; those who abuse alcohol or drugs; and those whose partners abuse alcohol³ and drugs are all at increased risk. Other populations at risk include children, disabled adults, and the elderly. Persons with disabilities, both male and female, are at increased risk of abuse. Their reliance on the caregiver and their forced dependency on others for life supports heighten their risk. Abuse can occur in the home or in institutional dwellings such as group

homes, state schools, nursing homes, and hospitals.

Domestic violence may take many forms (Table 410.1).¹⁴ These behaviors can occur alone or in combination, and sporadically or chronically. In addition to physical trauma, battered women may present with a variety of other medical problems, including chronic pain syndromes, posttraumatic stress disorder, anxiety, depression, alcoholism, and other forms of substance abuse. Common presentations of battered women are listed in Table 410.2. The risk of domestic violence escalates during pregnancy, with 13% reporting abuse for the first time and 21% to 29% reporting an escalation of abuse. This may result in a variety of injuries, such as placental separation, antepartum hemorrhage, preterm labor, miscarriage, or ruptured uterus, spleen, or liver.

Physical abuse (any mechanism of injury may be used)
Verbal and emotional forms of assault, including intimidation, coercion, threats, or degradation
Withholding or denying access to money or other basic resources
Sabotaging employment, housing, or educational opportunities
Sexual assault or coercion (i.e., any type of sexual contact that is forced or coerced, including rape, incest, sexual harassment, indecent exposure, or unwanted touching)
Social isolation by denying communication with friends or relatives or making communication so difficult that the victim chooses to avoid it
Prohibiting access to needed health care
Forcing the partner to live beyond his or her means or misusing credit cards

TABLE 410.1. Examples of Domestic Violence

Injuries to the face, neck, or throat
Injuries to the chest, breast, abdomen, or genitals
Bilateral injuries
Evidence of sexual assault
Chronic pain, especially when evidence of tissue damage cannot be found
Acute pain when no external injuries are visible
Injuries during pregnancy, commonly but not exclusively to the breast and abdomen
Substantial delay between time of injury and presentation to the emergency department
Multiple injuries on various stages of healing
Extent or type of injury inconsistent with patient's explanation
Repeated use of the emergency department or primary care services
Sexually transmitted diseases, especially recurrent episodes
Psychological or somatosocial complaints
Evidence of alcohol or drug abuse
Suicidal ideation or suicide attempts
An accompanying partner (male or female) who answers or who seems overly aggressive or apologetic
Homosexuality
Pregnant patient who reports getting no prenatal care

TABLE 410.2. Common Presentations of Battered Women

Elder abuse can include physical abuse, caretaker neglect, and financial exploitation. Frequently, the caregiver of an elderly family member may be the least socially integrated adult who is unable to cope with the responsibility. Isolation is often a factor, and impairments due to age may diminish the ability of elders to defend themselves or to escape the situation. Elders may be unable to drive or use public transportation, and they may have no social network or family contact other than the batterers.

Elders often do not report abuse or neglect, either because they deny the abuse is occurring or because they fear retaliation or abandonment. Feelings of helplessness may lead an elder to believe that reporting will not improve the situation.

Gang Violence

Victims of gang violence may present with blunt or penetrating trauma.⁷ Common scenarios include walk-up or drive-by shootings, stabbings, and beatings. They may also be victims of arson and vehicular assault.

Violence in the Emergency Department

Patients may be physically violent, verbally abusive, angry, suicidal, depressed, restless, deluded, or act in a bizarre manner. They may boast of prior acts of violence, a desire to commit violence, and feelings of inability to control impulse among others. Many will manifest characteristic changes in mental attitude, posture, speech, and motor activity before displaying violent behavior. They may pace the room or hallways, clench their fists, stand against the wall, grip bed rails, and appear anxious. The tone, volume, and character of the patients' voices may indicate the potential for violence. Health-care providers may precipitate violent responses by argumentative, abrupt, or condescending attitudes or failure to provide requested services.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Domestic Violence

A history of abuse should be considered and questioned of all females presenting for emergency care.¹¹ Questioning should be carried out in confidence and with a nonjudgmental manner. A screening assessment should take place at triage if safety and privacy can be ensured. Physicians have four main areas of responsibility: to communicate their concern and validate the patient; to provide medical treatment; to review options and facilitate appropriate referrals and follow-up; and to assist in creating a safety plan.

Women who are known or suspected to be victims of domestic violence should be interviewed in private in a secure area of the ED without their partner or children present. If necessary for safety reasons, hospital security or police should be recruited. It is important to be aware of the legal requirements of reporting partner abuse in your state. If reporting is mandatory, it is important to inform the patient to prevent a perceived breach of confidentiality. Disabled patients have the legal right to be accompanied by their personal-care attendant or other supportive persons if they desire. Patients should be asked in private if they want their companion to accompany them into the treatment area, to minimize the chances that they will feel coerced into silence by an abusive companion. Lesbian partner abuse is a unique problem. The victim may not yet have come out publicly and may be reluctant to discuss the subject. It is important not to assume that it is safe for a female partner to accompany a patient to the treatment area. A history of previous trauma, chronic pain complaints, or psychological distress, which may be clues to diagnosis, should be sought from direct history or from the medical record. An interpreter should be provided, if necessary. For women, a woman trained in medical interpretation, who will honor confidentiality, is preferable to a family member. It is inappropriate to use a child as an interpreter when domestic violence is suspected.

Rather than directly asking questions about abuse relative to the presenting complaint, it may be better to focus on questions identified by the acronym SAFE:² What *Stress* do you experience in your relationships? Should I be concerned about your *Safety*? Are there situations in your relationships in which you have felt *Afraid*? Has your partner ever *Abused* you or your children? Have you ever been physically hurt or threatened by your partner? Are your *Friends and Family* aware that you have been hurt? Do you think you could tell them, and do you think they would be able to give you support? Assess the degree of social isolation. Do you have a safe place to go and the resources you (and your children) need in an *Emergency*? Do you have a plan of *Escape*? Would you like to talk to a social worker/counselor/me to develop an emergency plan?

Simply by asking the SAFE questions, the emergency physician alleviates the victim's alienation and offers her an opportunity to validate her worth, assess her safety, and become aware of community issues. Regardless of the severity of the presenting complaint or injury, the best indicator of danger is the patient's own assessment.

The frequency and severity of previous attacks are good guides to current danger. Threats are as important as the actual injury, however, and the presence of weapons in the home is an additional risk factor.¹ Battered women are most likely to be killed when they are in the act of leaving or after they have left their abuser.

State law requires health-care providers to report all rapes and sexual assaults. Cases involving the abuse or neglect of elders, minors, and certain persons with disabilities must also be reported to the appropriate government agencies. A victim may seek a temporary protective order. Patients should be encouraged to consent to specific interventions and should be given assurances of safety and confidentiality. However, no intervention should be forced on an unwilling patient. Overriding a patient's refusal violates the ethical principle of respect of patient autonomy, and, in the case of domestic violence, further disempowers the patient.

Enlisting the services of a social worker can be valuable in helping to bring victims into contact with resources such as shelters, social services, legal assistance, and support groups. If the police are not already involved, the physician can offer to call them or help the victim to do so. The patient should be told that battering is a crime and that help is available.

If the patient chooses not to seek help at the time of the ED presentation, it is important that the physician be empathic and not lay blame. Offer constructive ways to help, such as preparing an escape route should the situation at home escalate. Offer the patient information and contact numbers, which she may use later. It is important to allow the patient to remain in control. Complete medical records are important to ensure quality care for the patient and may be vital in any subsequent legal proceedings.

Gang Violence

The ED reflects the community in which it resides. If appropriate, health-care providers should be offered training in recognition of gang members, such as specific tattoos, hand shakes and mannerisms, type of clothing worn, and evidence of previous trauma. On arrival at the scene, prehospital personnel must ensure their own safety and, where necessary, await help from police before entering a hostile area. Bulletproof vests may be necessary in some communities. Where possible, the hospital should be notified that a suspected gang member is being transported and, where possible, injured members from rival gangs should be taken to different facilities.⁸

Hospital security personnel and local law enforcement need to be involved to provide security for the injured gang member, for other patients (who may be members of rival gangs), and for the health-care providers. Limiting access to the ED, body searches, and the use of metal detectors to screen patients and visitors for weapons may be necessary. The victim's injuries are cared for in the appropriate manner. Patients should be disrobed to search for concealed weapons and treated with due respect. Avoid challenging victims or other members or showing disrespect, which could result in physical confrontation.

Access to the patient should be kept to immediate family members. Other parties may be informed of the patient's condition by updates. The patient should be admitted under a "John Doe" status to prevent further injury by rival gang members during hospitalization and to help ensure the safety of health-care providers.

Violence in the Emergency Department

Many violent encounters can be prevented. The goal is to recognize, deescalate, and control the potentially violent patient before violence occurs. Patients often act out of a sense of fear and danger of their surroundings. It is important to take steps to avoid confrontation. Health-care providers should never respond to patients' threats with threats of their own. However, assaults against medical personnel should be reported to law enforcement agencies. Not doing so allows patients to think such behavior is acceptable and makes the staff feel they are not adequately protected.

The patient should be approached from the side, while observing the surroundings for possible missiles. A nonoffensive posture, with hands out front but not raised, should be employed. The care provider should be cognizant of the patient's personal space and stay two arm lengths away. It is important to acknowledge the patient's needs and ask him or her to verbalize the problems. The patient should be informed, in a low voice, that help is available and that support will be provided but that the patient must take control of his or her own behavior. Expectations should be defined, and the consequences of aggressive behavior need to be clear. Frequently, talking to the patient and making offers of food and drinks may be calming and defuse the situation.

When possible, the patient should be interviewed alone and in private, but the care provider may keep the door ajar and sit between the patient and the door. Some patients may not respond to these measures, and here a "show of force" may be needed. Prior to interviewing the patient, assemble a group of security personnel who will remain within calling distance. Frequently, this show of force may be sufficient to help disorganized patients gain control of their thoughts and behavior.

If a patient is or becomes combative or assaultive and poses a danger to self or others, physical restraints may be needed. Explain clearly to the patient what is about to happen and why. Assemble a team, preferably with five members, four to restrain the limbs and one to act as team leader. Soft restraints (e.g., leather) are used to secure each limb to the stretcher. For the particularly violent patient, the team may employ mattresses, which are used to sandwich the patient. Once the patient is on the floor, each limb is then restrained. After the patient is restrained, he or she should be searched for weapons or objects that could inflict harm, and then moved to a quiet area. The history may be difficult to obtain, and other sources, such as family members, friends, and the patient's records, should be used. A physical examination should be performed to exclude an organic cause of the patient's behavior ([Table 410.3](#)). Blood tests, including toxicology screen and a blood sugar, should be obtained. Vital signs should be checked every 15 minutes while the patient is in restraints.

Drug intoxication: PCP, LSD, cocaine, barbiturates, amphetamines, and alcohol
Trauma
Infection: AIDS, herpes encephalitis, meningitis
Metabolic: Hypoglycemia, thyroid storm, renal or liver failure, adrenal crisis, ketoacidosis, hypoxia, hypothermia, and vitamin deficiency
Neurologic: tumors, epilepsy, cerebrovascular accidents, infections

TABLE 410.3. Organic Causes of Violent Behavior

Pharmacologic intervention may be required when the patient remains disorganized and uncooperative. Haloperidol (2 to 10 mg intramuscularly or intravenously in the young and healthy and 0.5 to 2.0 mg in the elderly) is often used because of its relatively mild side effects in comparison with phenothiazines. If the patient will cooperate and take the medication orally, 10 mg every 30 minutes, to a maximum of 30 mg, may be used in healthy patients. Benzodiazepines (e.g., diazepam 5 to 10 mg, or lorazepam 2 to 4 mg, intramuscularly, intravenously, or orally) can also be used. Certain drug intoxications may require specific therapy (e.g., anticholinergic syndrome; see [Chapter 312](#)). The reason for physical or chemical restraint and measures taken to ensure the patient's comfort while in restraints should be clearly documented in the medical record.^{10,20}

DISPOSITION

Domestic Violence

The patient should be asked where she will go if she leaves the facility, and who is waiting for her outside. If necessary, she can leave through a less visible exit. She should be given a list of emergency numbers. The physician should be especially cautious if security had to be called to restrain an assailant. The option of overnight hospitalization should be discussed with the victim if she does not have an alternative safe place to go; the physician should clarify that she would be hospitalized

only for her safety, not because the physician thinks she is mentally ill.

The discharge plan should include arrangements for a safe place to stay as well as other resources for daily living, such as money, personal papers, car keys, and a change of clothing for herself and her children. Victims should be informed that local programs for battered women provide free, confidential services, and that trained advocates from these programs can provide information regarding legal rights, police and court procedures for protective orders, shelter availability, support groups, and other essential resources. There are similar services for disabled and elderly victims of domestic violence. Physicians should discuss protection against sexually transmitted diseases and pregnancy, especially for those patients who have been raped or who have experienced coercive sexual activity as part of the violence. The physician should avoid prescribing tranquilizers or other sedating psychoactive medications, which could impair the victim's ability to respond appropriately should she need to flee.

Gang Violence

Whether the patient is admitted or discharged depends on the nature and severity of injury.

Violence in the Emergency Department

Some patients may be discharged after a period of observation in the ED (e.g., those with alcohol- or drug-induced violent behavior). Some may require admission because of an underlying medical condition. Other patients may require further evaluation by mental health services and admission to psychiatric facilities. Patients without medical or psychiatric problems requiring admission who are under arrest may be discharged to the custody of law enforcement authorities.

COMMON PITFALLS

Domestic Violence

- Failure to recognize victims of domestic violence and to consider battering in the differential diagnosis of medical as well as traumatic complaints, particularly when treating females
- Asking questions in a manner that might increase the patient's perceived level of danger or sense of humiliation and blame
- Asking about domestic violence in the presence of a partner or family members
- Using a child as an interpreter
- Failure to provide appropriate safety measures for the patient while in the ED
- Failure to devise an emergency or escape plan
- Failure to provide appropriate referrals and follow-up
- Prescribing tranquilizers or other sedating psychoactive drugs

Gang Violence

- Failure to be aware of gang activity in the community and to ensure the safety of both prehospital and ED personnel
- Not searching victims adequately for concealed weapons, resulting in the potential of serious injury to health-care providers
- Failure to protect the patient by admitting them under a pseudonym
- Treating gang members with disrespect or in a confrontational manner

Violence in the Emergency Department

- Failure to assess your ED for vulnerability to attack by violent patients
- Failure to recognize the patient who is starting to escalate and who could have been calmed before the situation was out of control
- Attributing violent behavior to drug or alcohol intoxication without looking for an organic cause
- Failure to report assaults on staff to the appropriate authorities

CHAPTER 411

Acute Pain Management

Steven Rosenzweig and Daniel Mines

[Pain Assessment](#)
[Pain Management](#)
[Expediting Relief](#)
[Nonpharmacologic Therapy](#)
[Pharmacologic Therapy](#)
[Common Pitfalls](#)
[Chapter References](#)

Acute pain is the most common reason that patients seek emergency care. Patient survey studies consistently document that pain is often inadequately treated by physicians and that this problem is not limited to the emergency department.¹ Providing expert and compassionate pain relief remains one of the greatest challenges in the practice of emergency medicine.

Drugs used to treat pain act by reversing the underlying cause of pain (e.g., nitrates for angina and sumatriptan for migraine) or by suppressing the symptom (i.e., the perception of pain). This chapter focuses on drugs used to treat the symptom of acute pain. Related discussions elsewhere in this text include the chapters on conscious sedation ([Chapter 413](#)), chronic pain syndromes ([Chapter 412](#)), and poisoning with acetaminophen ([Chapter 310](#)), nonsteroidal antiinflammatory agents (NSAIDs) ([Chapter 358](#)), opioids ([Chapter 360](#)), and salicylates ([Chapter 367](#)).

PAIN ASSESSMENT

Pain is an experience that has both physical and nonphysical dimensions. Physiologically, pain is mediated by a set of neurochemical events. At the level of consciousness, it is an event of personal anguish or suffering. *The severity and quality of this suffering are highly individual; each person experiences and responds to pain in his or her own way.*

One of the most important aspects of the pain experience is the *meaning* it holds for the sufferer. Pain is often greater when its cause is perceived to be life-threatening or when it is associated with emotional trauma. Conversely, pain that is perceived to offer some secondary gain can be easier to bear.

The subjective nature of pain presents a challenge to today's medical practice, which emphasizes objective findings. It is imperative for all emergency care providers to understand that the patient need not *appear* in pain to actually *be* in pain.⁵ There exist no objective signs for accurately gauging the magnitude of a patient's pain. Indicators such as heart rate, blood pressure, respiratory pattern, facial expression, and body posture are not reliable. The presentation of pain may be obscured by the effects of medication, a cultural bias toward stoicism, or complex coping mechanisms such as joking or maintaining a facade of calm.¹ Language and cultural barriers further confound pain assessment.

Equally unreliable is an estimate of pain severity based on its etiology. Can a toothache be more painful than salpingitis? Should an ankle sprain hurt less than pleurisy? These questions cannot be answered, because suffering depends on each individual's pain threshold and sensitivity to a particular condition.

The most reliable and valid means of assessing pain severity is the patient's self-report. Clinical judgment must always be guided by the patient's own assessment.

It can be very difficult for anyone to find words to convey either the quality of pain or its severity. Descriptions lack the preferred exactness of clinical language. People resort to imagination and simile: "My back feels as if it is caught in a vise"; "my hand feels like it is on fire." Another problem is that patients and physicians use words differently. For example, a patient may use the word *sharp* to mean *severe*, whereas the physician may assume it to mean *knifelike*.

Assessing pain in children, especially infants, is even more difficult than in adults.¹⁷ The experience and expression of pain are affected by the developmental age of the child, the child's previous pain experiences, the response of the child to the medical environment, and the quality of relationship with parents or other care providers. Older children are able to describe their pain or point to pictures on a pain analogue scale. In infants and younger children, the quality of cry, facial expression, changes in vital signs, and impressions of the caretaker should all be taken into account.

Children are much less likely than adults to be given adequate analgesia for the same painful condition.²⁰ This observation has been attributed not only to the difficulties inherent to pain assessment, but also to the persistent myth that children do not experience or remember pain. As in any adult, pain in a child should be anticipated and aggressively treated.

Taking an accurate pain history, therefore, requires careful listening and clarifying. Patients can also be assisted in conveying pain intensity through descriptive scales (none—little—medium—severe—worst possible), numeric scales (rating 1 to 10), and visual analogue scales (placing a mark on a 10-cm line).

Compassion implies awareness of another's suffering, and gaining this awareness may be difficult. Physician attitudes may even interfere with pain recognition. One impediment is resistance to accepting the authority of the patient or the insight of a family member. The physician cannot be "in charge" of the assessment of pain. This situation in which the patient knows more than the doctor creates a reversal of roles that may be uncomfortable and even unacceptable for the treating physician.

Fear of creating an addiction by introducing a patient to a narcotic is generally unwarranted. Studies have shown that the short-term prescription of narcotic analgesics for acute pain syndromes is *not* associated with future dependence.¹⁶

Another impediment is fear of being manipulated into giving narcotics to patients who are feigning illness. Bear in mind that *pain* is the most common reason for drug-seeking behavior. Even a legitimate patient may feel the need to dramatize distress in order to convince the doctor of his or her need. It may indeed be impossible to know for certain whether the patient's complaint is a sham. The physician must always weigh the gain of thwarting the possible abuser against the risk of withholding relief from the person who is truly suffering.

The diagnosis of drug abuse is based on a pattern of behavior that is unlikely to be established during a single emergency department encounter. Nevertheless, a few precautions can be taken:

1. Perform a detailed history and physical, being alert to inconsistencies.
2. Attempt to confirm the patient's history by contacting the personal physician or checking medical records.
3. Communicate with colleagues about problem patients in order to corroborate impressions and develop specific treatment strategies.
4. Substitute nonnarcotic agents when indicated.
5. Write prescriptions for only small amounts of medication, or dispense one or two doses rather than actually writing a prescription.⁷

Emotional desensitization can also lead to suboptimal pain management. Emergency physicians habituate to crises and may become less attuned to the urgency of others' pain. Recurrent encounters with hostile patients, as well as physical and emotional fatigue, wear down the ability to respond compassionately. Facing our own vulnerability in the suffering of others may also lead physicians to withdraw from patients unintentionally. Compassion requires the physician to maintain an awareness of his or her own inner state in order to rise above these desensitizing factors.

Personal prejudices also interfere with empathy. Negative stereotyping and moral judgment lead to blaming the patient and undertreatment. The extreme case of withholding analgesia as a punitive measure can only be considered inhumane.

analgesic, it is widely acknowledged that an individual patient may respond to one agent and not another. ⁴

The onset of analgesia is within 1 hour for the majority of NSAIDs. For drugs with a relatively long half-life, such as diflunisal and naproxen, onset of analgesia is considerably longer but can be hastened by administration of a loading dose. Note that doses in the higher range are generally required to achieve antiinflammatory effects, which may not be seen for a few days.

For patients who cannot swallow pills, several agents are available in a liquid form (see [Table 411.1](#)). For patients who are vomiting or must remain NPO, rectal suppositories of aspirin, acetaminophen, naproxen, and indomethacin are available.

Costs of the NSAIDs vary considerably (see [Table 411.1](#)), ranging from pennies per dose of aspirin to more than a dollar per dose of newer, brand-name NSAIDs.

Ketorolac. Ketorolac tromethamine (Toradol) is the only NSAID also available for parenteral administration, either intramuscularly (i.m.) or intravenously (i.v.). It carries all the advantages and disadvantages of the other NSAIDs. Because of the drug's popularity in emergency medicine, practitioners need to be aware of its limitations. When studied in the emergency department setting, parenteral ketorolac does not provide superior analgesia to oral ibuprofen. ^{13,19} Given parenterally, ketorolac does not act any faster than many oral NSAIDs, because the drug effect is limited by time to prostaglandin inhibition, not absorption. Ketorolac is relatively expensive—a parenteral dose costs more than about ten times as much as morphine 10 mg, and 100 times as much as a full dose of ibuprofen. Repetitive dosing of ketorolac carries a higher risk of upper GI bleeding when compared with other NSAIDs. Acute renal failure has also been described. It seems reasonable to reserve parenteral ketorolac only for patients in whom the oral administration of NSAIDs should be avoided.

Selective COX-2 Inhibitors. These drugs selectively block COX-2, the form of cyclooxygenase that mediates inflammation, without affecting COX-1, the inhibition of which can produce gastric injury. In comparison, older “nonspecific” NSAIDs block both COX isoenzymes. ¹¹

Rofecoxib (Vioxx), the first COX-2 inhibitor approved by the FDA, is indicated for acute pain. Acute analgesia trials are underway with celecoxib (Celebrex), which is already approved for the treatment of rheumatoid arthritis and osteoarthritis. Both drugs appear to have an improved gastric safety profile compared with the older NSAIDs, but until more research is done, we should not assume that these drugs are without any GI toxicity. It is also not yet clear whether COX-2 inhibitors effectively treat crystal-induced arthritis, such as gout, or how quickly they produce analgesia compared with older agents. These agents are not likely to be any more effective than the older, less costly NSAIDs. Because their major advantage is their safety profile, they should be reserved for patients at high risk of NSAID side effects (discussion follows).

Advantages. The NSAIDs hold several advantages over the opioids. They do not cause respiratory depression and rarely cause mental clouding. Given their antiinflammatory properties, they treat the cause as well as the symptom of pain in conditions such as tendinitis, arthritis, or radiculitis. NSAIDs do not have abuse potential.

Adverse Effects. All NSAIDs can cause dyspepsia, the most common side effect. This can be minimized by administering the drug with food or an antacid. Less commonly, NSAIDs lead to ulcers and upper GI bleeding and perforation, complications that are seen more with chronic rather than short-term use and that may occur without warning. ⁴ NSAIDs are thus strongly contraindicated in patients with active ulcer disease, and should be given with caution to those with a history of upper GI bleeding. Other risk factors for GI complications include patient age greater than 60 years, high doses, and concurrent steroid or anticoagulant use. ¹⁰ In such high-risk patients, the chance of GI bleeding can be reduced by coadministration with a proton pump inhibitor or misoprostol, at least with long-term NSAID use. The benefit these agents offer with short courses of NSAID is less well established. Other agents that were often used for prophylaxis of NSAID-related GI complications are either ineffective (antacids, sucralfate) or marginally effective (H₂ blockers). ¹⁶ COX-2 inhibitors—without gastroprotective drugs—represent another therapeutic option in patients with risk factors for GI bleeding.

NSAIDs may also affect the kidneys, causing fluid retention and renal insufficiency, which is usually reversible. Patients at greater risk for renal complications include those with chronic renal insufficiency, congestive heart failure, and cirrhosis, as well as patients taking diuretics or angiotensin converting enzyme inhibitors. NSAIDs should generally be prescribed for no more than a few days in this patient population.

Because they interfere with platelet function, the nonselective NSAIDs predispose toward bleeding and should not be given to patients with thrombocytopenia or intrinsic clotting abnormalities. They should generally not be used in patients receiving anticoagulant therapy and in those suspected of internal bleeding, as in the case of severe headache with possible subarachnoid hemorrhage. In contrast, because the COX-2 selective NSAIDs do not inhibit platelet function, they may be used in patients with low platelet counts or in those on warfarin.

Very rarely, NSAIDs cause hypersensitivity reactions; patients who are sensitive to aspirin are at greater risk. NSAIDs are generally contraindicated during pregnancy, particularly in the third trimester.

Opioid Analgesics

Opioids are usually the first-choice drugs for the prompt relief of severe, acute pain. Unlike the NSAIDs, they have no ceiling on analgesic effect. Given intravenously, they work within minutes, and their effect can be titrated and reversed. Many patients treated with these agents, however, do not receive adequate pain relief because of physicians' misconceptions about correct dosing, route of administration, and adverse effects. ¹⁵

Dosing Considerations. In real life, the effective analgesic dose varies considerably among patients; the *correct* dose of narcotic is the dose that works. The “optimal initial dose” published in various references is only a general guideline; the “standard” 10-mg dose of parenteral morphine is inadequate analgesia for one-third of patients in severe pain. ⁹ In the initial treatment of severe pain, then, it makes sense to titrate small frequent doses to effect ([Table 411.2](#) and [Table 411.3](#)).

Drug	Route	Dosage (mg/kg/dose)
Morphine	iv.	0.1-0.2
Meperidine	iv./im.	1.0-1.5
Fentanyl	iv.	0.001-0.003
	Oral/transmucosal	0.005-0.015
Codeine	Oral	0.5-1.0 q4-6h
Acetaminophen	Oral/rectal	10-15 q4-6 h
Ibuprofen	Oral	5-10 q6-8h

For further pediatric dosing guidelines, see Appendix D.

TABLE 411.2. Pediatric Dosing Guidelines for Drugs for Pain Management

Drug	Route*	Dosage	Comments
Morphine	iv	Start 2.5 mg increments q 15 min. Risk analgesia 10-15 min. Average = 10 mg q 4h	Preferred for low agent in most situations
Fentanyl	iv	Start 2.5 mcg increments q 15 min. Risk analgesia 1-2 min. Duration 30-45 min.	Best for short procedures. No tolerance release
	iv	Not suitable for the outpatient department	
Hydroxycobalamin	iv	Start 0.1-0.2 mg increments. Risk analgesia 1-2 min. Average = 100 mg q 4h	Risk of unique CNS toxicity with repeated dosing iv route superior to oral route in these patients
Hydromorphone (Dilaudid)	iv	Start 0.2-0.3 mg increments. Risk analgesia 1-2 min. Average = 15 mg q 4h	High solubility benefits iv injection
Buprenorphine (Suboxone)	iv	Start 0.1-0.2 mg increments. Risk analgesia 1-2 min. Average = 1 mg q 4h	Most agent/antagonist May be preferred in biliary colic
	iv	Start 0.1-0.2 mg increments. Risk analgesia 1-2 min. Average = 1 mg q 4h	

Note: Monitor an appropriate vital signs (heart rate, blood pressure, respiratory rate, oxygen saturation) at 15 min intervals.
*Routes may vary by patient or other clinical circumstances. Use the iv route for patients with respiratory depression or hypotension.
†Hydromorphone is a potent emetic. Consider antiemetic prophylaxis in these patients.
‡Fentanyl is administered in many increments at regular intervals. Supplemental, bolus, and titrating iv administration should be used over 1-2
minutes with the patient awake.

TABLE 411.3. Using Guidelines for Parenteral Opioids

Once satisfactory analgesia is achieved, another common pitfall is to withhold a subsequent dose until a “standard” dosing interval has elapsed. Statements about “average duration of action” provide only a rough estimate.¹

Route of Administration. Intravenous administration of opioids is preferable to the more commonly used intramuscular route for several reasons. Absorption is more reliable, and repeated dosing is painless. It also leads to more rapid onset of analgesia; intravenous morphine begins to work within 5 minutes (peaks in 10 to 20 minutes), whereas intramuscular morphine requires 10 to 30 minutes until an effect is seen (peaks in 30 to 60 minutes).^{12,15} It is obviously easier to titrate the opioid dose using the intravenous route (Fig. 411.1). It is also important to keep in mind that the frequency and severity of several side effects, such as respiratory depression, hypotension, histamine release, and nausea and vomiting, are related to the speed of intravenous injection. They can be minimized if drugs are injected over several minutes, rather than by rapid push.

1. Initiate infusion of normal saline before administering opioids.
 2. Keep the patient in a recumbent position.
 3. Have naloxone and airway management equipment at the bedside.
 4. Avoid or adjust dose downward in patients with hypotension, COPD, or potential for airway compromise.
 5. Give **SLOWLY**, over 3–5 minutes.
 6. Titrate to pain relief.
 7. Supplement careful observation with pulse oximetry and/or apnea monitoring.
- Major risks:**
- CNS depression leading to hypoventilation or apnea
 - Hypotension

Figure 411.1. How to give intravenous opioids safely.

It is not clear which is the second best parenteral route for opioid administration. While one authority¹⁵ recommends subcutaneous (s.c.) injection as less painful than intramuscular, this benefit may be offset by an even more delayed onset of action.¹²

Opioid analgesics can be given through a number of other routes as well. The oral route is most convenient and least expensive. When both intravenous and oral routes are unavailable, alternatives include rectal suppository (morphine, hydromorphone, and oxycodone), sublingual tablet (buprenorphine), and even a nasal spray (butorphanol) and lollipops (fentanyl).

Adverse Effects. All opioid analgesics share certain side effects, although some occur more with one drug than another. A patient who has had a problem with one agent may be able to tolerate a second opioid without difficulty.

Of all the potential adverse effects, respiratory depression is the most dangerous. Using sophisticated testing, it is possible to show that therapeutic doses of most opiates cause some degree of respiratory depression in nearly all patients. Most of the time, this is not clinically important. However, patients with diminished respiratory reserve, such as those with severe chronic obstructive pulmonary disease or massive obesity, are liable to stop breathing after receiving these drugs. Even in those with normal reserve, removal of a painful stimulus, as occurs with the reduction of a dislocated joint, can precipitate respiratory depression; patients should be monitored closely after painful procedures. Except in the case of massive overdose, respiratory arrest does not occur suddenly but is heralded by a decreased respiratory rate and level of arousal.

Hypotension is the second major hazard of opioid use. Through a variety of mechanisms, opioids, particularly those given parenterally, may cause peripheral vasodilation. This seldom affects blood pressure in the supine patient, but the ambulatory patient may experience significant orthostatic hypotension. Volume-depleted individuals are at increased risk for hypotension regardless of body position. Hypotension from opioids generally resolves spontaneously within a few minutes; if necessary, intravenous fluids and possibly naloxone are effective.

Opiates occasionally trigger the release of histamine from mast cells. Because this occurs through a nonimmunologic mechanism, it is technically not an allergy. Clinical consequences include itching, urticaria, bronchospasm, and hypotension, which are not responsive to naloxone. The agents most frequently implicated in these reactions are morphine, followed by codeine and meperidine. Fentanyl has practically no potential for this complication.

Opiates commonly cause sedation and occasionally produce confusion. Therefore, patients should be warned not to drive vehicles or operate power tools when they take narcotics. Opioids present a special set of problems for head-injured patients. They may interfere with evaluation of central nervous system (CNS) function. The respiratory depressant effect of opioids is exaggerated in this group of patients, and the resultant hypoventilation may actually increase intracranial pressure, mediated by cerebral vasodilation in response to an elevated pCO₂.¹²

Opiates may cause spasm at the sphincter of Oddi and, in turn, precipitate biliary colic. Whether meperidine is less likely than morphine to do this remains unresolved. Among all opioids, the agonists–antagonists appear to have the least potential for this complication.¹⁵ Paradoxically, even though it sometimes raises biliary tract pressures, morphine is usually successful in treating pain of biliary origin.¹⁵ Nitroglycerin and glucagon, drugs that relax smooth muscle, as well as naloxone, have been used to treat opioid-induced biliary colic.^{9,15}

Opioids have other effects on the genitourinary and GI systems. They may cause urinary retention, particularly in older men with underlying prostatism. They are constipating and can sometimes cause abdominal pain or dyspepsia. Nausea and vomiting can be minimized by administering the drug to the patient in the supine position and, if necessary, with an antiemetic.⁹ GI side effects, if severe, can be reversed with naloxone.

Opioids have the potential to mask the diagnosis of serious abdominal disease. While they can be given safely to patients with abdominal pain who are under close observation, prescribing them for patients who are sent home with undiagnosed abdominal pain is potentially dangerous.

Choosing an Injectable Agent. A typical error in the use of opioids is to switch agents before the first one has been pushed to its limit, which is determined by unwanted side effects rather than an arbitrary “maximal” dose. Correct dosing is more important than the actual choice of agent.

Morphine is the traditional first-line parenteral narcotic. No other opioid is superior in relieving pain. It is also relatively inexpensive and has a relatively long duration

of action.

Despite its widespread use, meperidine (Demerol) offers few, if any, advantages over morphine. Although it is less constipating, meperidine in equianalgesic doses produces the same degree of sedation, respiratory depression, and euphoria as does morphine.⁹ With repeated dosing, meperidine has its own peculiar CNS toxicity, caused by normeperidine, an active metabolite. Findings include irritable mood, agitation, myoclonus, and seizures. CNS toxicity is more common in patients with renal insufficiency. Meperidine should not be given to patients receiving monoamine oxidase (MAO) inhibitors because of the potential for a poorly understood interaction, characterized by delirium and hyperthermia, which may be fatal.

Meperidine is recommended as a second-line analgesic for brief courses in otherwise healthy patients who have had a problem with morphine. Intramuscular or s.c. injection causes local irritation. A common mistake in the use of meperidine is to use too small a dose and too long a dosing interval.¹ [Table 411.2](#) and [Table 411.3](#) list dosing guidelines.

Fentanyl is an ideal agent for performing short, painful procedures because of its very rapid onset and limited duration of action.

Partial agonist and agonist-antagonist opioids were developed to provide analgesia with less sedation, respiratory depression, nausea, and addiction potential.⁸ Practical benefits, however, have been limited.¹⁰ Pentazocine, the only drug of this class available in an oral form, produces psychotomimetic symptoms, including disorientation, paranoia, and hallucinations, in as many as 7% of treated patients. All drugs in this class can precipitate withdrawal when they are given to patients addicted to pure opioid agonist. These drugs really offer no advantages over the strong opioid agonists, except perhaps in the management of biliary pain.

Adjuvant Agents. A number of drugs have been administered along with parenteral opioids to minimize adverse effects by reducing the amount of opioid needed to treat pain. Phenothiazines can reduce GI side effects. When they are given along with an opioid, sedative effects are increased, but analgesia is not.⁹

The antihistamine hydroxyzine (50 to 100 mg i.m. or 1 mg/kg i.m.) is often combined with opioids to potentiate analgesia. Although hydroxyzine does have additive analgesic properties, this practice poses two problems. First, it requires an intramuscular injection. Second, it may not, in fact, decrease adverse effects: Hydroxyzine itself is a mild respiratory depressant.⁶ No study has examined whether the combination of an opioid plus hydroxyzine produces respiratory depression less frequently than an equianalgesic dose of opioid alone.

Choosing an Oral Agent. [Table 411.4](#) lists dosing guidelines for a number of commonly used oral opioids. Because opioids experience a significant first-pass hepatic metabolism, a higher oral than parenteral dose is necessary to achieve the same level of analgesia.

Drug	Analgesic Equivalency ¹	Usual Starting Dose ²	Usual Interval
Morphine (MIL, Roxane) (oral)	30 mg	15-30 mg ³	3-4h
Morphine sustained-release (MS Contin, Duramorph SR)	30 mg	30 mg ⁴	8-12h
Meperidine (Demerol) ⁵	30 mg	30-100 mg	3-4h
Codeine (in Tylenol) (oral) ⁶	30 mg	30-60 mg	3-4h
Oxycodone (Oxycontin, Avia) (oral) ⁷	30 mg	1-2 mg	3-4h
Hydrocodone (in Lorcet, Lortab, Vicodin) (oral)	30 mg	5-10 mg	3-4h
Hydrocodone (Vicodin) (oral)	7.5 mg	4-8 mg	3-4h

Note: Addition of a nonopioid may allow lower dosing of opioid. In using combination products, be certain not to exceed the allowable dose of the nonopioid component.
Sub: Interval as appropriate. Individual patient may require dosing at the lower or the higher end.
Usual dosing may need to be adjusted in the elderly, patients weighing less than 50 kg, and those without or with hepatic dysfunction.
Dose equivalent to intravenous morphine 10 mg and intravenous meperidine 100 mg.
Dose of the solution as indicated.
Usual interval for chronic, severe pain.
Dependent on dosage. Usual interval with equianalgesic dosing and is not recommended for a fixed dose.
Dependent on dosage and is not recommended for use.
100 mg solution.

TABLE 411.4. Oral Opioid Dosing Information

Codeine, which has gained widespread use, perhaps because of its low abuse potential, is a relatively weak analgesic with a relatively high incidence of GI side effects. The standard 60-mg dose alone is no more effective than 650 mg of aspirin or acetaminophen.³ At higher doses, the analgesic effect does not increase significantly, but side effects do.

Oxycodone and hydrocodone are excellent oral analgesics. They can produce euphoria, and, in certain patients, this is a liability.

Meperidine and propoxyphene (Darvon) are less satisfactory oral agents. Meperidine has a short analgesic duration, produces significant euphoria, and has a unique CNS toxicity. Propoxyphene's efficacy is arguable. In some studies, it has been no more effective than placebo, but combined with aspirin or acetaminophen, it produces additional analgesia.¹² Overdose can result in seizures that are difficult to treat.

The main applications for oral morphine and hydromorphone (Dilaudid) are in cancer and sickle cell pain. Oral morphine is available as an immediate- and a sustained-release preparation.

Tramadol is an unscheduled, weak opioid agonist that also inhibits reuptake of serotonin and norepinephrine. It does not appear to produce respiratory depression or hypotension, probably because of selective opioid receptor binding. It is as effective, or less effective, than codeine or hydrocodone in combination with acetaminophen.¹⁸ Tramadol is contraindicated in patients taking an MAO inhibitor.

Combination Therapy. Rational pain management often involves combining analgesics of different classes.¹ Adding acetaminophen (or an NSAID) to an opioid often produces better analgesia than a double dose of either agent alone.³ One possible explanation for this is that the drugs work by different mechanisms. Combination therapy may permit a reduction in the opioid dose and a corresponding reduction in opioid-associated side effects.

Many formulations are commercially available that combine aspirin or acetaminophen with codeine, hydrocodone, or oxycodone. Although combination products containing codeine and hydrocodone are controlled substances, they are classified as schedule III (rather than II) and do not require duplicate or triplicate prescription paper. Therapy does not need to be restricted to these fixed-ratio products; prescribing the constituents separately may permit greater therapeutic flexibility. For very severe pain, the opioid dose can be increased without risking toxic doses of acetaminophen or aspirin. Conversely, as the pain improves, the patient can easily taper off the opioid but continue the nonnarcotic. For the outpatient treatment of severe pain, we commonly prescribe ibuprofen 2,400 mg/d in divided doses along with oxycodone 5 to 10 mg every 4 to 6 hours. An acetaminophen (120 mg) and codeine (12 mg/5 mL) elixir is available for use in children.

COMMON PITFALLS

- Relying too much on "objective" signs of pain severity and not enough on the patient's self-report
- Confusing pain avoidance behavior with drug-seeking behavior
- Withholding analgesia until a definitive diagnosis is made
- Withholding analgesia because consent for surgery or other procedure may later be necessary
- Failing to use an opioid for fear of creating addiction
- Administering opioids i.m. or s.c. when the intravenous route is superior
- Choosing a dose based on standard guidelines instead of individual patient response

CHAPTER 412

Chronic Pain Syndromes

Michael A. Turturro and Paul M. Paris

[General Evaluation](#)
[General Treatment](#)
[Diagnosis and Management of Specific Syndromes](#)
[Myofascial Pain Syndromes](#)
[Neurogenic Pain Syndromes](#)
[Common Pitfalls](#)
[Chapter References](#)

Chronic pain syndromes often challenge the emergency physician in both diagnosis and management. Some present with vague signs and symptoms and often are not definitively diagnosed on the first encounter. Treatment is often complex, requiring several regimens of varying effectiveness. Many patients have a protracted course of exacerbations and remissions, and frequently present because of inadequate pain control.

Most of the concepts that apply to acute pain management (see [Chapter 411](#)) also apply to patients with chronic pain. For example, with any type of pain, it is the patient's expectation and the emergency physician's responsibility to provide relief, and this should usually begin before a diagnosis is established. However, exacerbations of chronic pain are often due to a combination of both physical and psychological factors. Also, certain pain syndromes (e.g., neurogenic pain) may not be effectively treated by typical analgesic agents. Therefore, an understanding of both the physical and psychological pathophysiology associated with these disorders will ensure optimal treatment.

Acute pain and chronic pain differ in several ways ([Table 412.1](#)). Acute pain is generally due to actual or potential tissue damage. It typically has a rapid onset, coinciding with tissue damage, and resolves as tissue heals. Although distressing and anxiety provoking, it often can be treated effectively with proper selection and use of analgesic drugs. With chronic pain, the symptom of pain itself often becomes more of a problem than its underlying cause, altering the patient's life and frequently causing depression. Its treatment is complex and difficult. Success in treating chronic pain typically requires a multidisciplinary team approach, using various regimens of pharmacotherapy, physical therapy, and behavioral therapy.

Acute Pain	Chronic Pain
Usually due to tissue damage	Often no identifiable pathology
Is related to underlying illness	Is the problem itself
Responds to typical analgesics	May not respond to typical analgesics
Straightforward treatment	Complex treatment
Causes anxiety	Causes depression

TABLE 412.1. Differences between Acute and Chronic Pain

Chronic pain may be due to prolonged tissue destruction (e.g., cancer pain) but may also occur due to dysfunction of the central nervous system (CNS) or peripheral nervous system, and it can be exacerbated by psychological factors. The pathophysiology of chronic pain without obvious tissue pathology is unclear. Prolonged noxious sensory input from the periphery may result in self-sustaining central neural activity, possibly by reducing inhibitory input into the CNS. This may produce a "memory" effect for pain perception in the CNS.

Pain due to malignancy, although chronic in nature, may be considered sustained acute pain because it is typically associated with progressive tissue damage. Although nonnarcotic analgesics and physical therapy are often used to treat malignant pain, progressively increasing doses of opioid analgesics remain the mainstay of therapy. Despite the risk of opioid dependence, opioid analgesics should never be withheld from patients with terminal malignant pain, as pain control is the most important factor contributing to overall quality of life. Acute exacerbations of malignant pain must be treated as an emergency, with aggressive opioid analgesia. Higher doses of opioids titrated more rapidly than in opioid-naïve patients are typically needed, and this approach has been demonstrated to be safe and effective. ⁴

Behavioral and physical therapies are often used in managing chronic pain. Chronic pain commonly causes the patient to lose a sense of control over his or her environment. Allowing patients to become passively dependent on health-care practitioners and medical therapy only feeds this vicious cycle of illness and the helpless victim.

GENERAL EVALUATION

Each patient with chronic pain must also be evaluated for the development of worsening or new pathology. The physician should not assume that a patient's chronic pain exacerbation is nothing more than a worsening of an already existing disease process. For example, a patient with worsening chronic low back pain must be evaluated for new spinal cord dysfunction. Simply providing analgesics without an appropriate evaluation may result in missing serious disease.

Chronic pain patients should be considered valuable resources, because they often know the most effective therapies to treat their pain. The chronic pain patient with a true exacerbation should be treated with analgesics in the emergency department. Many of these patients require pain service referral, and communication between the emergency and pain service physicians fosters a team approach to the management of chronic pain exacerbations. For example, a contract may be developed between the patient, the pain service, and the emergency department as to when the patient will be expected to present for a pain exacerbation, the analgesic that will be used after appropriate evaluation, and the quantity of analgesics prescribed.

Typical doses of analgesics are sometimes ineffective for chronic pain syndromes, and many patients fail various modes of therapy. As a result, malingering or drug-seeking behavior may inappropriately be suspected. Patients may appear to be demanding or psychologically distressed, and may feel uncomfortable with a physician who has not been their regular caretaker. Establishing a rapport with the patient is essential, and the physician must not feel threatened by patient demands.

Drug abuse and addiction are unfortunate problems in our society, and drug abusers (whether or not they suffer from chronic pain) tend to patronize emergency departments on a frequent basis to obtain opioid analgesics. Because of this, emergency department staff members may develop a bias against all chronic pain patients. Because it may be difficult to differentiate patients with exacerbations of chronic pain from patients who are seeking drugs for abuse, many patients with real exacerbations of chronic pain are consequently labeled as drug abusers.

Drug abusers often have a history of multiple substance abuse, multiple visits for treatment of various nonspecific painful conditions, an unusual reluctance to try new therapies, or a report that their primary physician is unreachable. Because it is inappropriate and unethical to withhold analgesics from patients experiencing pain, unless the emergency physician is convinced that the patient is a drug abuser, the patient should be given the benefit of the doubt and a short course of analgesics should be prescribed. Sometimes, a known substance abuser may present with a truly painful condition. In these cases, pain should be adequately relieved in the emergency department, and judicious amounts of analgesics should be given on discharge. The use of opioid agonist-antagonists may be useful in these patients, as

they are less likely to cause euphoria. However, they should not be given to a patient physically dependent on opioids, as they may precipitate withdrawal.

True addiction, compulsive use of opioids despite signs of toxicity and inability to function due to addiction, is unusual in patients with chronic pain. However, when pain medication is withheld, such patients may learn pain avoidance or maladaptive behaviors to obtain opioids. Giving pain medication on an as-needed basis, rather than around-the-clock dosing, contributes to this phenomenon, as the patient learns to express both symptoms and maladaptive behavior to obtain the reward of receiving pain medication.

The association between depression and chronic pain is clear, but, in some patients, the painful process produces depression, and, in others, chronic pain is a manifestation of a depressive disorder. In patients with chronic pain in whom no etiologic basis can be established, the treatment is focused on the underlying depression. Depression is also known to increase opioid analgesic requirements.

GENERAL TREATMENT

The treatment of chronic pain includes the use of many modalities ([Table 412.2](#) and [Table 412.3](#)). Opioid analgesics are the most useful drugs in treating exacerbations of chronic pain. The agents used are discussed in the chapter on acute pain (see [Chapter 411](#)), but longer acting preparations, such as sustained-release morphine, oxycodone, and hydromorphone, and methadone are more appropriate for the treatment of chronic pain. These agents also avoid the risk of aspirin or acetaminophen toxicity from the nonnarcotic component of combination products, which may occur when doses sufficient to provide adequate amounts of the opioid component are taken.

Therapy	Indications
Opioid analgesics	Most causes of chronic pain; often ineffective in neurogenic pain
Antidepressants	Most causes of chronic pain
Anticonvulsants	Neurogenic pain
Transcutaneous nerve stimulation (TENS)	Low back pain, reflex sympathetic dystrophy
Local anesthetics	Phantom limb pain, neurogenic pain
Capsaicin	Neurogenic pain, arthritic pain
Behavioral therapy	Most causes of chronic pain
Physical therapy	Reflex sympathetic dystrophy, TMJ dysfunction, tension myalgia
Surgery	Refractory trigeminal neuralgia, reflex sympathetic dystrophy, phantom limb pain

TABLE 412.2. Therapies for Chronic Pain

Drug Class	Brand Name	Dosing
TRICYCLIC ANTIDEPRESSANTS		
Amitriptyline	Elavil	100 mg PO qd; up to 150 mg/d
Imipramine	Tofranil	100 mg PO qd
Nortriptyline	Pampridol	25–100 mg PO qd
Doxepin	Sinequan	25–100 mg PO qd
ANTICONVULSANTS		
Carbamazepine	Tegretol	100 mg PO qd; increase to 1000 mg PO bid or tid; max 1200 mg/d
Gabapentin	Nucyntin	100 mg PO qd; up to 3000 mg PO qd; increase on alternate days; max 3600 mg/d
SKELETAL MUSCLE RELAXANTS		
Cyclobenzaprine	Flexeril	30 mg PO tid
Cyclopemidone	Flexon	100 mg PO bid
Chlorzoxazone	Norflex	250–400 mg tid
Metaxalone	Skelaxin	800–1200 mg PO bid or tid
Metaxalone	Paraflex Forte	800 mg PO bid
Metaxalone	Metaxalone	800 mg PO bid; increase to 1200 mg PO bid
SUBSTANCE P INHIBITORS		
Capzasin	Capzasin	Apply to affected area qid

TABLE 412.3. Nonopioid Pharmacotherapy for Chronic Pain

Tramadol is an oral opioid analgesic that also has a mechanism similar to the tricyclic antidepressants (TCAs) (i.e., the inhibition of monoamine neurotransmitter reuptake). Tolerance and withdrawal symptoms appear to be absent with tramadol. However, it has been demonstrated to be less effective in the management of acute pain than other opioids¹⁴ and is associated with a high incidence of side effects. It appears to be most appropriate for adjunctive treatment of mild-to-moderate chronic pain.

TCAs are useful in treating chronic pain, both by controlling depression and by altering nociceptive responses to painful stimuli, thereby altering the cerebral process in pain perception. They are effective in pain control even if no evidence of depression exists. TCAs are effective in various chronic pain syndromes, particularly neurogenic pain, face pain syndromes, fibromyalgia, and arthritis. TCAs act synergistically with opioids in controlling chronic pain. It is likely that all TCAs are effective in treating chronic pain, but amitriptyline has been the most extensively studied. However, there is little evidence that the newer antidepressant drugs, such as the selective serotonin reuptake inhibitors (SSRIs), are useful. The recommended starting dose for all TCAs in managing chronic pain is half the antidepressant dose, which may be titrated up if necessary. Analgesic effects may not be evident for several days. Referral for follow-up is essential in patients started on TCAs in the emergency department.

Transcutaneous electrical nerve stimulation (TENS) may be effective in certain acute and chronic pain syndromes. It is used most often in chronic low back pain and reflex sympathetic dystrophy. Unfortunately, most patients note a decrease in analgesic effect over time. The “gate control” theory of pain postulates that, in the periphery, small unmyelinated C fibers transmit nociceptive information, and large myelinated A fibers transmit light touch and pressure sensations. Both of these fibers synapse at the substantia gelatinosa in the dorsal horn of the spinal cord. Stimulation of the A fibers inhibits the transmission of nociceptive C fiber stimuli into the CNS, thereby “closing the gate.” By using electricity to stimulate the A fibers preferentially, the pain stimulus entering the CNS can be controlled.

In neurogenic pain syndromes, pain originates from peripheral nerve dysfunction. Therefore, anticonvulsants play a primary role in treating most of these disorders. In addition, because substance P may be the principal mediator of neurogenic pain, an effort to inhibit substance P may be beneficial. When applied topically, capsaicin, a substance derived from red chili peppers, releases substance P from primary afferent nerve fibers; with repeated application, capsaicin depletes substance P from these nerve fibers. Consequently, capsaicin may be useful in treating the neurogenic pain of postherpetic neuralgia, reflex sympathetic dystrophy, and metabolic neuropathy, as well as other chronic pain syndromes such as psoriatic and rheumatoid arthritis. Capsaicin causes skin redness and burning. This may also contribute to its analgesic effect, as peripheral counterirritation causes pain relief by a “gate-closing” effect, as described for TENS. However, skin irritation limits the concentration that may be used, thus reducing its potential efficacy.⁹

Behavioral and physical therapy helps patients cope with chronic pain and regain a sense of self-control, thus improving overall day-to-day function. The focus with these therapies is rehabilitation, not total pain relief. However, patients must be motivated to be successful.

The most effective ways to treat these chronic pain syndromes are the multidisciplinary approaches used by pain clinics, in which combinations of the various therapies are coordinated. Thus, the emergency physician should confer with the patient's primary care or referring physician and make arrangements for follow-up before initiating or changing therapy.

DIAGNOSIS AND MANAGEMENT OF SPECIFIC SYNDROMES

Myofascial Pain Syndromes

Myofascial Pain and Fibromyalgia

Myofascial pain syndrome and fibromyalgia are conditions in which acute or chronic muscle pain, stiffness, and tenderness occur at specific anatomic sites (“trigger points”). A trigger point is an area within a taut band of skeletal muscle that, when palpated, produces referred pain in the area where the patient complains of pain (a “reference zone”). It may be activated by physical trauma, other trigger points, or psychological stress.

Fibromyalgia and myofascial pain syndrome may be considered opposites in the spectrum of a single disorder ([Table 412.4](#)). Myofascial pain tends to be localized, and the involved muscle group may twitch involuntarily. Fibromyalgia pain tends to be diffuse and is associated with systemic symptoms such as chronic fatigue, headaches, vertigo, visual disturbances, and irritable bowel syndrome. Symptoms may begin after an acute viral illness, trauma, or psychological stress.

	Myofascial Pain	Fibromyalgia
Location	Regional	Generalized
Muscular twitch	Yes	No
Systemic symptoms	No	Possible
Sleep disturbances	No	Yes
Trigger-point injection useful	Yes	Sometimes
Physical therapy useful	Yes	No
Skeletal muscle relaxants useful	No	Yes

TABLE 412.4. Myofascial Pain Syndrome Versus Fibromyalgia

Physical findings may be nonspecific, and the patient may be told that the symptoms are unexplained or psychogenic. The differential diagnosis for fibromyalgia includes other painful systemic illnesses, such as systemic lupus erythematosus, polymyalgia rheumatica, polymyositis, metabolic myopathy, hypothyroidism, chronic fatigue syndrome, and irritable bowel syndrome. Because symptoms often overlap, the diagnosis is frequently one of exclusion.

Although it has been postulated that psychological causes may underlie the pathophysiology of fibromyalgia (e.g., patients may not respond in a normal fashion to physical or psychological stress or may have a heightened perception of bodily discomfort), elevated levels of plasma substance P and decreased levels of serotonin have been demonstrated.^{12,13} Consequently, fibromyalgia patients may experience pain from stimuli that are below the painful threshold in normal patients due to neurochemical alteration of pain pathways. Complicating matters is that depression is a frequent result of fibromyalgia, and somatization disorders are more frequent in fibromyalgia patients than the general population.

The treatments of myofascial pain and fibromyalgia have certain similarities. Trigger-point injection of local anesthetics is a technique easily performed for both fibromyalgia and myofascial pain, often with rewarding results. Relief of local and referred pain and a decrease in muscle tension may be seen after injection.

Other physical techniques, such as muscle stretching, biofeedback, and exercise, are useful in myofascial pain syndrome but are of limited value in fibromyalgia. In fibromyalgia patients, analgesics usually provide only partial relief, and additional therapy with antidepressants or muscle relaxants is often needed. Cyclobenzaprine, a skeletal muscle relaxant related to the TCAs, may be particularly useful in treating fibromyalgia.² After initiating this therapy in the emergency department, follow-up care should be ensured.

Temporomandibular Dysfunction Syndrome

Temporomandibular joint (TMJ) dysfunction syndrome is increasingly common. Patients typically report facial pain and nonspecific headache, in addition to joint noise and difficulty in joint motion. Muscular and joint tenderness as well as limited TMJ range of motion may be found. The disorder is similar in many respects to both myofascial pain syndrome and fibromyalgia, and TMJ dysfunction syndrome is often referred to as a form of myofascial pain. Many patients with TMJ dysfunction also have fibromyalgia or other myofascial pain.

The etiology is unclear. Some patients may exhibit signs of TMJ dysfunction but may not have troubling symptoms. Many patients have coexistent psychiatric diagnoses, which often leads to the assumption that emotional stress plays a role in this syndrome. Many patients show a greater sensitivity to certain noxious stimuli than do pain-free controls.⁷ Patients who clench or grind their teeth secondary to stress may develop masticatory muscle hyperactivity and fatigue, which can lead to pain and altered joint mechanics.

Patients may present before definitive diagnosis with a complaint of nonspecific facial pain, or may present during a symptom exacerbation. As in other chronic pain syndromes, treatment frequently requires analgesics, antidepressants, and nonpharmacologic therapy. Physical therapy, biofeedback, and intraoral splinting help relax the afflicted muscles and reduce discomfort. Pain control with analgesics is usually necessary. Patients should be discharged on TCAs if the diagnosis is certain and should be referred to a maxillofacial specialist so that an intraoral splint can be fitted and physical therapy started.

Neurogenic Pain Syndromes

Patients with neurogenic pain syndromes ([Table 412.5](#)) commonly present when symptoms first develop. The pain in these syndromes develops from nerve malfunction, sometimes due to physical damage to the involved nerve. In certain neurogenic pain syndromes, the pain is exacerbated by other stimuli that also stimulate the same nerve, such as light touch, temperature changes, or emotional stress. This phenomenon is known as allodynia. The pain is typically described as burning in nature, and treatment is often frustrating, because both opioid and nonopioid analgesics are typically ineffective in relieving it.

Facial neuralgias	Nerve compression pain
Trigeminal	Radiculopathy
Glossopharyngeal	Entrapment neuropathy
Metabolic neuropathy	Postherpetic neuralgia
Diabetic	Reflex sympathetic dystrophy
B ₁₂	Phantom limb pain

TABLE 412.5. Neurogenic Pain Syndromes

Facial Neuralgias

Trigeminal neuralgia is a relatively common, often debilitating disorder. Typically older patients (over age 50) are affected, and women develop this disorder more

often than do men. The right side is more frequently involved, and bilaterality is rare. The second division of the fifth cranial nerve (V2) is most frequently affected. Attacks at the third division (V3) may also occur, but attacks at the first division (V1) are rare. The initial attacks are brief but severe and lancinating, often described as an “electric shock” sensation. Allodynia is prominent, and attacks may be triggered by touching the face, cold air blowing against the face, eating, shaving, or talking. Unlike other neuralgias, a sensory deficit is atypical and, if found, should alert the clinician to the possibility of nerve compression due to malignancy. As the condition progresses, the attacks become more frequent and a background ache may develop.

Glossopharyngeal neuralgia is less common and usually less severe than trigeminal neuralgia. It affects equal numbers of men and women. About 25% of cases are bilateral. Typically, a single episode of lancinating pain along the ninth cranial nerve sensory distribution (neck, throat, and ear) occurs. Atypical facial pain may occur, which is poorly localized but frequently involves the mandible. Unlike other facial pain syndromes, it is not clearly neurogenic and consequently does not respond as well as trigeminal neuralgia to anticonvulsants.³

The differential diagnosis of facial neuralgias includes cluster headaches, maxillary sinusitis, postherpetic neuralgia (especially with V1 distribution), dental pain, and TMJ dysfunction syndrome. Swallowing and chewing may trigger the pain from both facial neuralgias and TMJ dysfunction. Allodynia and the absence of TMJ tenderness suggest the former diagnosis.

The mainstay of treatment for the facial neuralgias is the administration of anticonvulsants, particularly carbamazepine.⁸ Unfortunately, patients typically present in extreme pain, and anticonvulsants usually require several days before a demonstrable effect is noticed. The recommended starting dose for carbamazepine is 100 mg qhs for 3 days, then an increase to 100 mg twice a day. The dose may need to be titrated up to 1,200 mg/d. Other drugs, such as baclofen and clonazepam, may then need to be added. Because carbamazepine may cause neutropenia, a baseline complete blood count should be obtained. Carbamazepine may cause nausea, dizziness, or somnolence, which may limit patient compliance. Follow-up with the patient's primary care physician or a neurologist should be arranged. Patients who fail medical therapy for trigeminal neuralgia often need surgical destruction of the sensory distribution of the trigeminal nerve, either by percutaneous thermocoagulation, cryosurgery, microvascular decompression, or glycerol injection.

Postherpetic Neuralgia

Postherpetic neuralgia is the most common neuropathic pain. It occurs in 10% of cases of herpes zoster, and it is more common in the elderly. It may begin during or after an attack of zoster, it typically persists for several weeks after the rash resolves, and it has no relation to the severity of the zoster attack. Burning pain occurs in the involved dermatome, which is most commonly thoracic (about 50%), V1 (about 20%), and cervical (about 20%).

Many treatments used in other neurogenic pain syndromes (e.g., diabetic neuropathy) have been recommended for the treatment of postherpetic neuralgia. However, it is difficult to determine what is truly effective because few well-designed, controlled clinical trials exist, and some cases may resolve with no treatment. The longer the condition is allowed to persist, the less likely that any one treatment will be effective.

Opioid analgesics may provide modest temporary improvement in pain, but they are typically not useful alone in the treatment of postherpetic neuralgia. Local anesthetics have been used in intravenous forms, in topical preparations such as lidocaine ointment and EMLA (prilocaine/lidocaine) cream, and in nerve blocks: All appear to provide additional short-term relief of pain due to this condition.¹⁰ Capsaicin appears to provide temporary but effective relief if used four times a day for 3 to 4 weeks. Anticonvulsants reportedly useful in treating postherpetic neuralgia include carbamazepine, phenytoin, valproic acid, and the antispastic drug baclofen. Gabapentin is a newer anticonvulsant that shows promise in treating the pain of postherpetic neuralgia in a dose titrated up to 3600 mg/d.¹¹ Antidepressants may also help relieve postherpetic neuralgia pain, but there is no clear superiority of one over another.¹⁵ In addition, there is some evidence to suggest that preemptive treatment with antidepressants during an attack of herpes zoster may reduce the prevalence of postherpetic neuralgia.¹

Acyclovir, valacyclovir, and famciclovir are useful in the treatment of an acute attack of herpes zoster, particularly in the immunosuppressed host, in decreasing viral shedding and the duration of lesions. Most evidence suggests that they also appear to have a modest effect on decreasing the incidence of postherpetic neuralgia.⁵ Although occasionally prescribed, there is also no definite evidence that steroids are useful in preventing or treating postherpetic neuralgia.¹⁶

Reflex Sympathetic Dystrophy and Causalgia

Reflex sympathetic dystrophy (RSD), also known as complex regional pain syndrome, Sudeck atrophy, shoulder–hand syndrome, and algodystrophy, is characterized by a vicious cycle of pain, disuse atrophy, and peripheral autonomic dysfunction. Patients are usually 40 to 60 years old, although children are occasionally affected. It typically occurs after major extremity trauma, but it has also been related to minor trauma, cerebrovascular accident, myocardial infarction, arthritis, infection, and local tumor infiltration. Drugs such as isoniazid, ethanol, and phenobarbital have also been implicated as causative factors. It often occurs after prolonged extremity immobilization, presumably as a result of irritation of the sympathetic ganglia.

The term *causalgia* is reserved for RSD related to a major peripheral nerve injury. After nerve damage due to an extremity injury, a positive feedback loop develops in which sympathetic efferent neurons stimulate afferent pain fibers and vice versa. Stimuli that cause sympathetic efferent outflow, such as temperature changes, often trigger this vicious cycle. Peripheral nociceptors are sensitized, and, when stimulated, they, in turn, stimulate sympathetic fibers. Thus, the cycle of pain and sympathetic overflow occurs.

The median, ulnar, and femoral nerves are most commonly affected. In patients with minor trauma, the degree of initial pain is often much greater than suggested by objective findings. The first (acute) stage occurs during the first several weeks of the disease process. Symptoms include pain, swelling, sympathetic underactivity, joint stiffness, warm skin, hypertrichosis, and edema. As the disease progresses, joint stiffness, hair loss, allodynia, sympathetic overreactivity, and muscular dystrophy occur, along with paroxysms of pain. After several months, decreased joint motion and muscle and skin atrophy occur. At this stage, the extremity appears cool, pale, shiny, and hairless. Radiographs are usually normal early in the disease and later show patchy osteopenia and erosions. The differential diagnosis includes collagen vascular disease, phlebitis, degenerative arthritis, and conversion hysteria.

Treatment is difficult, and most therapies provide only temporary relief. Medications that may be helpful include beta blockers, alpha blockers, calcium channel blockers, serotonin antagonists, capsaicin, corticosteroids, antidepressants, and anticonvulsants.⁶ As with other forms of neurogenic pain, opioids and nonsteroidal antiinflammatory agents are often ineffective. Regional blocks using guanethidine may be effective but can exacerbate the pain before it improves. Sympathetic blockade is often used but usually provides only temporary relief. Physical therapy is essential, and other nonpharmacologic therapies, such as TENS, may be used.

RSD can be prevented by avoiding prolonged immobilization in patients with extremity trauma. Recognizing the early stages and intervening before the disease progresses is important. Patients should be referred for early physical therapy.

Sympathetic blocks may provide temporary analgesia and allow for aggressive activity.

Phantom Limb Pain

Phantom limb pain is a poorly understood syndrome that occurs after extremity amputation. It, too, is difficult to treat. After amputation, phantom sensation is nearly universal, and usually resolves in less than a year. Persistent pain is thought to be related to neural damage postamputation. It has been postulated that the last impulses received by the limb before amputation may be stored in “memory,” and if these impulses are painful, the sensation may persist. Consequently, the incidence of phantom limb pain is decreased in patients given preoperative regional anesthesia. As with other chronic pain syndromes, psychological stress exacerbates the degree of pain experienced.

There are few well-designed studies that evaluate the various treatment regimens for phantom limb pain. Anticonvulsants, analgesics, and beta-blocking agents all seem to provide temporary relief. Surgical techniques such as cordotomy, stump revision, and neuroma removal have been reported, with variable degrees of success. A combination of long-term behavioral therapy and antidepressants appears to be the most useful mode of therapy.

COMMON PITFALLS

- Missing acute disease by assuming an exacerbation of chronic pain is due to preexisting disease

- Labeling chronic pain patients who have true pain as drug seekers
- Overreliance on analgesic drugs to treat neurogenic pain
- Failure to appreciate the risk of aspirin or acetaminophen toxicity when using escalating doses of combination opioid products to treat chronic pain
- Assuming the pain from fibromyalgia or TMJ dysfunction is psychogenic
- Failure to consider nonpharmacologic modalities for the treatment of chronic pain
- Failure to confer and to arrange follow-up with the patient's primary care physician or pain clinic before initiating or changing therapy

[Ketamine](#)
[Methohexital](#)
[Midazolam](#)
[Nitrous Oxide](#)
[Propofol](#)
[Chapter References](#)

Properly performed, conscious sedation of patients is an effective modality to alleviate pain and anxiety and to control unintentional and potentially harmful movement during therapeutic or diagnostic procedures such as cardioversion, incision and drainage of abscesses, chest tube thoracostomy, lumbar punctures, fracture reductions, complex suturing, and imaging studies.^{3,7,8} The advent of shorter-acting, more effective drugs (Table 413.1), the development of noninvasive monitoring devices, and well-publicized standards of care for performing conscious sedation have made it an extremely safe, practical procedure. Psychological gains for the patient, family, and staff, as well as the facilitation of testing and treatment, far outweigh the antiquated belief that sedating the patient will slow down the flow in the emergency department.

Agent	Trade Name	Route	Dosage	Duration of Action	Side Effects*
Etomidate	Amidate	iv	0.1-0.3 mg/kg	3-5 min	Hypotension, myoclonic jerking
Fentanyl	Sufentanil	iv	1-3 µg/kg	30-60 min	Tyrosyl rigidity, ptosis, vomiting, bradycardia, prostatic retention
Ketamine	Ketalar	iv	1-2 mg/kg	10-20 min	Myoclonic jerking, emergence delirium, tachycardia, hypertension, bronchospasm, emesis
		PO	6-10 mg/kg	30-45 min	
Methohexital	Brevital	iv	0.5-1 mg/kg	3-5 min	Hypotension, possible arrhythmias
		iv	10 mg/kg		
		iv	30-50 mg/kg		
Midazolam	Versed	iv	0.05-0.1 mg/kg	1-2 h	Hypotension, bradycardia
		iv	0.05-0.1 mg/kg		
		PO	0.2-0.3 mg/kg		
		iv	0.1-0.2 mg/kg		
Nitrous Oxide	Nitrospan	inhalation	50% N ₂ O / 50% O ₂ / 10% N ₂ O	Seconds to minutes	Distention of gas-filled pockets, ear pain
Propofol	Diprivan	iv	1-2 mg/kg bolus, then 1-4 mg/kg (10-100 µg/kg/min) 20-30 mg intravenous bolus	15-30 min	Hypotension, bradycardia, phlebitis

TABLE 413.1. Drugs Used for Conscious and Deep Sedation

Conscious sedation is a pharmacologically induced state of sedation that allows the patient to continue to breathe spontaneously and to maintain a patent airway and protective airway reflexes. The patient should also respond appropriately to simple commands and physical stimulation.¹ *Deep sedation* is a pharmacologically induced state in which the patient is not easily aroused but continues to breathe spontaneously, has a patent airway, and has at least partial control of the protective reflexes. The patient does not easily respond to painful or verbal stimuli.¹ Due to the nature of procedures performed in the emergency department, deep sedation is often needed to ensure an appropriate level of analgesia and immobility.

Providing sedation in the emergency department requires a team approach. The staff must be trained in monitoring techniques and educated about the dosages, routes of administration, and side effects of the drugs. Protocols delineating staffing responsibilities, monitoring guidelines, approved medications, observation periods, and discharge criteria and instructions must be addressed before implementing conscious and deep sedation in the emergency department. It is helpful to enlist the expertise and assistance of the anesthesiology department.

A patient consent form outlining the risks and benefits of the procedure should be obtained whenever time and the patient's condition allow. Patients should also have a brief general history and physical examination to ensure that they are appropriate candidates for sedation in the emergency department. In general, sedation should be reserved for patients in American Society of Anesthesia classes I to III (Table 413.2).

Class I	A healthy patient
Class II	A patient with mild systemic disease
Class III	A patient with severe systemic disease
Class IV	A patient with severe systemic disease that is a constant threat to life
Class V	An ill patient not expected to survive without an operation

TABLE 413.2. American Society of Anesthesia Physical Status Classification

MONITORING PROCEDURES

If possible, there should be a properly equipped room designated for conscious and deep sedation. All aspects of the procedure are documented, including consent, history, and physical examination, as well as condition at discharge. It is best to use a standardized departmental form that can be part of the patient's record. Oxygen, suction, intubation equipment, and the antidotes for narcotics and benzodiazepines (naloxone and flumazenil) should always be available. The room should have available a cart containing advanced life-support medications in the event of respiratory or cardiac arrest.

Most patients, especially adults, need intravenous access. This allows optimal dosing of medications and rapid access in the event of an untoward effect. The patient should have cardiac monitoring and vital signs should be monitored frequently until discharge. Continuous pulse oximetry is of paramount importance. Due to the nature of the medications used, hypoventilation, and the ensuing hypoxia, is the major cause of morbidity and mortality from conscious and deep sedation. Capnography, which monitors end-tidal carbon dioxide (PET CO₂), allows ensuing hypoxemia to be recognized by registering the rise in carbon dioxide or by triggering the apnea alarm even before the hypoxemia is clinically evident or noted by the desaturation on the pulse oximeter (see Chapter 414).

During the procedure, ventilation should be monitored by continually assessing airway patency, the depth and number of respirations, oxygen saturation, and, if available, the PETCO₂. Vital signs are obtained before sedation, then repeated and recorded every 3 to 5 minutes during the procedure. Times and dosages of all medications given are recorded. After the procedure, vital signs are recorded every 15 minutes until the patient has returned to a presedation level of consciousness.

At discharge, the physician should reevaluate the patient and document the pulmonary, cardiac, and neurologic status, as well as any pertinent findings related to the procedure.

Naloxone and flumazenil should be given only to treat hypoventilation. They are not a substitute for monitoring and should not be given simply to reverse sedation. They have shorter half-lives than the sedative agents, and the patient could revert back to a sedated state and, if left unmonitored, develop respiratory compromise.

DRUG THERAPY

The optimal drug in conscious and deep sedation would have a rapid onset and a short duration of action. It would have minimal cardiovascular and respiratory effects, predictable dosing, and a large therapeutic window. It would have both amnesic and analgesic properties. Because no single agent can do this, agents such as an amnesic drug and a local anesthetic, or an amnesic and an analgesic agent, are often used together.

The type of procedure and the patient's age, medical history prior to presentation, and acute medical condition influence the choice of agents and the route of administration. Inhalation, rectal, and oral routes have all proved to be safe and effective for sedation in procedures such as imaging studies and repairs of lacerations in children. Painful procedures, such as reductions and cardioversion, need intravenous access so that medications can be titrated to the appropriate level of sedation and analgesia; as mentioned, obtaining intravenous access also allows the use of an antagonist or resuscitative agents if untoward effects occur.

Etomidate

Etomidate is an ultrashort-acting, nonbarbiturate sedative–hypnotic with no analgesic properties. Like methohexital, it causes deep sedation, has a very rapid onset (1 minute), and has a duration of action of 3 to 5 minutes. Etomidate has minimal cardiorespiratory effects; although respiratory depression can occur, it is usually transient and associated with the use of other respiratory depressants.

The drug is given intravenously at 0.1 to 0.3 mg/kg and is currently not approved for children under age 10. Lower doses should be used when the drug is combined with analgesics.

Side effects are uncommon. Transient respiratory depression can occur. Myoclonic jerking can occur and has been mistaken for seizures; using another agent, such as fentanyl, in conjunction with etomidate may prevent or minimize the jerking. Published experience with the use and safety of etomidate in the emergency department is lacking. This agent is more expensive than alternatives.

Fentanyl

Fentanyl, a synthetic opioid, is about 1,000 times as potent as meperidine. It is short acting, with a duration of action of 30 to 45 minutes. It does not cause histamine release and has minimal cardiovascular effects. It is highly lipophilic and rapidly crosses the blood–brain barrier. Redistribution then occurs into the peripheral tissues, where it is metabolized by the liver. Like all opioids, fentanyl is reversed by naloxone. It produces respiratory depression at higher doses or when combined with other central nervous system (CNS) depressants, such as midazolam or alcohol.

Fentanyl is best given in titrated intravenous doses until the desired level of sedation and analgesia is obtained. Dosing should begin at 0.5 to 1.0 mg/kg and is slowly titrated upward every 1 to 2 minutes until the desired effect is obtained. Adequate sedation and analgesia are usually obtained with doses of 2 to 3 mg/kg when fentanyl is used alone and 1 to 2 mg/kg when other medications, such as midazolam or etomidate, are used in combination. Lower doses should be used in elderly patients and when other CNS depressants may have been previously ingested. When mild sedation is needed and venous access may be difficult, such as in small children, intramuscular injections of 2 to 3 mg/kg may suffice. Having children suck on a fentanyl lollipop until the desired effect is obtained has also proved effective in sedating small children.¹³ Due to its lack of amnesic effects, fentanyl is often combined with midazolam. Midazolam potentiates the effects of fentanyl as well as the potential for hypoxemia but does not appear to have any untoward cardiovascular effects.

Side effects of fentanyl include hypoxemia, apnea, vomiting, and pruritus. Hypotension is rare. Bradycardia may occur with high doses. Truncal rigidity and glottic spasm, which make ventilation difficult, are unique complications seen with doses above 10 mg/kg, or at lower doses if the drug is given rapidly. They can be reversed with naloxone or succinylcholine.⁶

Ketamine

Ketamine is an anesthetic that causes a dissociation between the thalamocortical and limbic systems. This, in turn, hinders the perception of visual, auditory, and painful stimuli, leaving the patient in a trance-like state.^{10,11 and 12} After absorption, ketamine is rapidly distributed and taken up by the cerebral tissue. Effects are maintained until the drug redistributes into the peripheral tissues and is metabolized by the liver.

Ketamine can be given by multiple routes. An intravenous dose of 1 to 2 mg/kg, an intramuscular dose of 2 to 6 mg/kg, a rectal dose of 5 to 15 mg/kg, an oral dose of 6 to 10 mg/kg, or an intranasal dose of 6 mg/kg provides adequate sedation and analgesia.^{10,11 and 12} Sedation is achieved within 1 minute when the drug is given intravenously, 5 minutes when given intramuscularly, and 5 to 20 minutes by other routes.

Ketamine's most common side effect is the emergence phenomenon, in which the patient wakes up hallucinating. This is more common in patients over age 10, females, and those with an underlying psychiatric disorder. It is less common with intramuscular injection and can be attenuated with benzodiazepines.

Laryngospasm and emesis are infrequent complications. Patients given ketamine may develop nystagmus, as well as muscular hypertonicity. The pharyngeal–laryngeal reflexes remain intact, although laryngospasm sometimes occurs.¹² Ketamine has minimal effects on oxygen delivery. Respiratory depression may occur with high doses or rapid intravenous infusion.¹⁰ The drug stimulates tracheobronchial and salivary secretions; this effect can be minimized by the concomitant use of an anticholinergic such as atropine. Mild-to-moderate elevations in pulse rate and blood pressure may result from ketamine's ability to block the reuptake of catecholamines, especially with intravenous infusion.¹² Elevations in intracranial and cerebrospinal fluid pressure may result from the increase in blood pressure as well as cerebral vasodilatation, resulting in increased cerebral blood flow.¹² Twitching, hypertonus, and myoclonic jerking can occur and have been mistaken for seizures. Electroencephalographic studies, however, have shown that ketamine does not cause convulsions. In fact, it has anticonvulsant properties and has successfully been used to treat refractory seizures.¹²

Ketamine is contraindicated in patients with cardiovascular disease, chronic obstructive pulmonary disease, intracranial and intraocular injuries, and increased intracranial or intraocular pressures. It is not recommended for use in patients with a history of psychiatric illness and children under 3 months of age.

Methohexital

Methohexital is an ultrashort-acting barbiturate with sedative and hypnotic effects. It produces deep sedation but provides no analgesia; at lower doses, it may actually potentiate pain perception.⁴ Methohexital produces a true unconscious state, which may be preferred for such procedures as cardioversion, chest tube insertion, or complicated reductions. It has a rapid onset of action of 30 to 60 seconds, a duration of action of 7 to 10 minutes, and a short recovery phase. Deep sedation is achieved with bolus doses of 1 to 2 mg/kg.^{2,20} Intramuscular doses of 10 mg/kg produce effects that begin in 2 to 3 minutes and last almost 1 hour. Rectal methohexital is especially efficacious in children when a motionless state is needed. A dose of 20 to 30 mg/kg induces sleep within 10 minutes and lasts for about 45 minutes. Cardiorespiratory complications rarely occur with rectal administration.⁴ Adverse reactions associated with the use of methohexital include dose-dependent respiratory depression and apnea. Oxygen desaturation is especially common when concomitant respiratory depressants are used. Hypotension is uncommon but can occur, especially in patients with hypo-olemia and sepsis. It is easily corrected by giving intravenous fluids.²⁰ Hiccups can occur, and protective reflexes may be impaired. Methohexital induces epileptiform activity by electroencephalogram in seizure patients and should be avoided in patients with epilepsy.^{14,20}

Midazolam

Midazolam is a benzodiazepine with amnesic and anxiolytic properties. At physiologic pH, the drug's open-ring structure closes, making it lipophilic and able to cross

the blood–brain barrier rapidly; there it interacts with the gamma-aminobutyric acid receptors. Midazolam has a more rapid onset and shorter duration of action than diazepam and rarely causes phlebitis. Its amnesic properties also appear to be superior to those of diazepam. It is eliminated by hepatic metabolism. Like all benzodiazepines, midazolam has no analgesic properties and must be combined with analgesics such as fentanyl or morphine, or with regional or local anesthetics, when painful procedures are performed.

The intravenous dose is 0.03 to 1.0 mg/kg, with a maximum starting dose of 4 mg. Onset of sedation is within 3 to 5 minutes, and the duration of action is about 30 to 60 minutes. With intramuscular administration, the same dose is typically used, but the onset of sedation is delayed by 15 minutes. ¹⁹

In children, oral, rectal, and intranasal routes are effective alternatives to intravenous sedation. Oral doses are 0.2 to 0.75 mg/kg, and sedation is achieved within 1 hour. Rectal administration is effective at doses of 0.3 to 0.5 mg/kg. The response by this route is variable due to the unpredictable effect of first-pass hepatic metabolism. It is not well tolerated or accepted by older children. ⁸ Intranasal administration can be used when an intravenous line is not needed or when sedation is necessary to establish one. Doses of 0.2 to 0.4 mg/kg result in sedation in about 10 to 15 minutes. ¹⁸

Lower doses should be used when analgesic agents are given concomitantly, and in elderly patients. Prolonged effects may occur in elderly patients as a result of decreased metabolic clearance and decreased first-pass metabolism.

Side effects include dose-dependent hypoventilation and hypoxemia. At high doses, midazolam blunts the central respiratory center's sensitivity to hypercapnia. ¹⁹ Apnea is rare, except when other CNS depressants, such as narcotics, are used. Hypotension can also occur with high doses.

Nitrous Oxide

Nitrous oxide is a colorless gas that, when used in combination with oxygen, provides one of the most effective and safest forms of analgesia and sedation available. It has a long history of use in dentistry, with virtually no complications. ¹⁵ The gas diffuses rapidly across membranes, providing a rapid onset and elimination. An added safety feature is that the gas is self-administered, ensuring adequate but not excessive sedation. If excessive drowsiness occurs, the patient cannot hold onto the breathing apparatus, and treatment is thus discontinued. Patients continue to maintain their protective reflexes and remain awake, but their anxiety and pain perception diminish. ¹⁵ In patients having heart attacks, nitrous oxide provides excellent pain relief and has minimal effects on the cardiovascular system. The use of analgesics and anxiolytics in combination with nitrous oxide appears to synergistically enhance the level of sedation and pain control. Potential side effects also are compounded, however, and hypoxia may become a problem, especially when narcotics are used.

Nitrous oxide is given as a 50%/50% mixture with oxygen by a demand valve mask or a mouthpiece held by the patient. In mile-high altitudes such as Denver, a 70%/30% nitrous oxide–oxygen mixture is needed to obtain adequate analgesia and to compensate for the lower partial pressure of nitrous oxide at the higher altitude. ¹⁶ Patients should be allowed to breathe the gas for several minutes before the procedure, but they should be advised not to hyperventilate or take deep breaths, as this may cause light-headedness. Providing a passive environment and using suggestions appear to enhance the effects of the drug. ^{9,16} Scavenger devices and adequate room ventilation are used to minimize the escape of the gas into the air, preventing potential acute and chronic adverse effects on the staff.

Diffusion hypoxia is a potential complication after cessation of nitrous oxide use. It may occur when nitrous oxide is used with other analgesics, but is unlikely when nitrous oxide is the only agent used. Negative pressure may result in ear pain, and even tympanic perforation may occur in children. No long-term adverse effects have been noted from this complication.

Nitrous oxide is contraindicated in patients with altered levels of consciousness, such as in head injuries and drug or alcohol intoxication. Because the gas rapidly diffuses into gas-filled pockets, it potentially can worsen conditions such as pneumothoraces, small-bowel obstructions, decompression sickness, chronic obstructive pulmonary disease, and ear effusions. ^{9,16} Finally, the gas has the potential for abuse, and every effort should be made to safeguard against its abuse.

Propofol

Propofol is a very short acting sedative–hypnotic agent, with a rapid onset of action. It is currently approved for use in adults only, but its use in children is well described in the medical literature. Propofol is given intravenously as an initial bolus, followed by a continuous infusion or by intermittent bolus injections. It is metabolized by the liver and excreted by the kidneys. It is thought to have a secondary form of metabolism, because it can be used safely in patients with liver cirrhosis and renal failure. When propofol is used as the sole agent, patients fully recover from sedation 10 to 20 minutes after the infusion is discontinued.

Propofol is often used in combination with analgesics such as fentanyl and nitrous oxide. Studies comparing propofol with midazolam found them to have equivalent amnesic properties. However, patients receiving propofol did not demonstrate the residual grogginess associated with midazolam and were discharged sooner. ^{5,15,17}

Sedation is usually achieved with a bolus of 1 to 2 mg/kg. This should be titrated with a slow push at a rate of 10 to 40 mg every 10 seconds until the sedative effects are achieved. A continuous infusion of 3 to 6 mg/kg/h (50 to 100 mg/kg/min) is then titrated to the desired level of sedation. ^{15,17} Alternatively, intermittent boluses of 25 to 50 mg can be used to maintain sedation in adults. Healthy adults may require higher doses; lower doses should be used when sedating elderly patients or when coadministering intravenous analgesics.

The major side effect noted with propofol has been transient apnea, which occurs when the bolus is infused rapidly, or when propofol is given in conjunction with opioids. Hypotension and bradycardia may also occur but are easily reversed with fluids or by terminating the infusion. Propofol may cause transient pain on injection, but this can be prevented by giving lidocaine (1 mL of a 1% solution) first.

Monitoring in the emergency department and prehospital arena is part of the initial and ongoing assessment of each patient. The goals are to recognize and quantify the degree of illness and of any change in condition. The data provided become part of the overall clinical picture, which guides initiation, titration, and changes in all aspects of care.

ELECTROCARDIOGRAPH

Although initially developed in coronary care units, bedside electrocardiograph (ECG) monitoring has become the standard of care in the emergency department for many types of patients. Obviously, any patient suspected of having acute cardiac disease or whose general illness could affect an underlying cardiac condition should be monitored. In addition, any patient whose rate, rhythm, or ECG complex could serve as an indicator of change in disease process or therapy should be monitored.

The standard lead positions from the 12-lead ECG are distal on the extremities, whereas ECG monitor leads are placed on the outer chest or shoulders and the upper abdomen. Hence, monitor leads correspond inexactly to the standard limb leads (I, II, III) and the augmented limb leads (aVR, aVL, aVF).

ECG monitoring was designed initially to determine rhythm and rate, and this continues to be its most secure use. Conduction abnormalities such as first-degree, second-degree, and third-degree blocks can be determined in many cases, as can the abnormalities of the intervals (PR, QT, QRS). ECG monitoring alone can indicate conditions such as dysrhythmias, hyperkalemia, and drug overdoses and their effects that require urgent therapy. A single-lead ECG monitor is less useful for determining the etiology of wide-complex tachycardia. ECG monitoring is not a substitute for bedside attendance by the physician or nurse, and it does not replace the 12-lead ECG. Even with multilead machines, a monitor strip should not be used to diagnose myocardial infarction, although change in a given ST segment may be an indication of ongoing ischemia.

ECG monitoring equipment is expensive. Although equipment comparison is beyond the scope of this discussion, any purchase decision should be made only after detailed equipment analysis and careful comparison shopping.

To be effective, ECG monitors require continuing upkeep and proper usage. Monitors should not have their alarms turned off. In most cases, the monitors should be hard-wired from patient rooms to a central location. Current central station computerized monitoring systems have algorithms that detect arrhythmias more accurately than do human observers. When computerized arrhythmia detection is not available, the use of additional "slave" telemetry monitors near the charting areas can be helpful.

Emergency department patients are often diaphoretic and combative, and are continuously moved around for studies, examinations, and x-rays. Artifact and wandering baseline can be minimized by proper lead attachment. Bony prominences should be avoided. The skin should be properly prepared and shaved when necessary. Poor electrical contact produces poor-quality tracings and should be minimized. The skin can be cleansed with alcohol after shaving, and a dry towel or gauze used to further prepare the site. In difficult cases, it may be necessary to use tincture of benzoin or to further tape down a lead.

A common problem is that ignored alarms trigger reams of paper printouts containing artifacts until no paper remains in the monitor. New technologies have been developed to allow cancellation of 60-cycle interference, baseline wander, and muscle and movement artifact, and computerized storage of rhythm recordings.

Once the leads are in place, a lead that adequately shows the P wave, the QRS, and the T wave should be chosen for monitoring. The gain control should be adjusted so that there is adequate QRS volume to allow sensing of the rate without undercounting or overtriggering.

To detect intermittent ischemia, the use of automated serial ECGs and continuous ST-segment monitoring is becoming more widespread. This is used both to diagnose a cardiac etiology for chest pain and to monitor patients with known coronary disease. Systems are available that monitor and save, or print, up to 12-lead ECGs. The emergency physician should not completely rely on computer detection of ST-segment changes, but should periodically review ECGs. Depending on the software, changes of less than 1 mm, for instance, may not trigger as an event, yet may be apparent to the physician.⁵

When continuous 12-lead cardiac monitoring is not being done, repetition of 12-lead ECGs is appropriate. For consistency, the stick-on patch type of chest lead sensor is best, because repeat ECGs are done with the knowledge that there is no lead placement change. Also, a review can determine that the leads are indeed in the correct interspace.

Two other techniques not in general use are signal averaging and heart rate variability monitoring. The averaging method of ECG determination uses filtering and the averaging of multiple samples to eliminate random background noise. Ventricular late potentials (signals at the end of the QRS complex or in the ST segment) are determined that identify regions of delayed conduction. These late potentials are rarely found in normal people and, when found in patients with myocardial infarction, correlate highly with the risk of ventricular dysrhythmias and ventricular tachycardia. Heart rate variability monitoring is a computer-generated measure of autonomic balance. In patients that have had a myocardial infarction, abnormal variability has correlated with a risk of sudden death. The use of late potentials and heart rate variability testing in patients with syncope of unknown etiology may be useful in determining fitness for discharge.⁶

BLOOD PRESSURE

The physicist defines *pressure* as force per unit area. Blood is a liquid (i.e., it is noncompressible), and to achieve pressure determination, a system that converts energy from one type to another must be interposed between patient and provider. Such couplings provide for *indirect* measurement (even though we frequently use the term *direct* when using intraarterial catheters), which inevitably results in imperfect representations.

Auscultation

The sphygmomanometer is the most common tool used to measure blood pressure. It uses the traditional Riva-Rocci (auscultatory) method, which consists of determining the onset (systolic pressure) and disappearance (diastolic pressure) of the Korotkoff sounds (dating back to before 1905). To maintain its sensitivity, the pressure release should occur at a rate of about 3 mm Hg per second, and the stethoscope should be placed on the skin with enough pressure to create a seal just under or slightly beyond the cuff.

Five phases of Korotkoff sounds result from turbulent flow of blood traversing the externally compressed vessel ([Table 414.1](#)). Classically, the phase 5 disappearance of tones has been used to define diastole. However, muffling values are repeatedly more consistent among different recorders, particularly in mild hypertension. Auscultatory techniques are unreliable in low-flow states, do not determine mean arterial pressure, are intermittent, and are associated with subjective variation. In aortic regurgitation or thyrotoxicosis, phase 4 persists to almost 0 mm Hg, so the transition to phase 4 is used. Many other variables impact on blood pressure measurement accuracy.⁹

Phase 1	Initial loud, clear, snapping tones
Phase 2	Continuous sequence of murmurs
Phase 3	Murmurs disappear; a less-marked tone develops
Phase 4	Muffling of the tones occurs
Phase 5	Tones disappear

TABLE 414.1. Korotkoff Sounds

The historic standard for blood pressure measurement, the mercury sphygmomanometer, is being phased out of most hospitals because of potential toxicity associated with mercury exposure should it break or leak. The standard measuring device is now the aneroid manometer. This device is portable but is far more susceptible to calibration problems, particularly when bumped, dropped, or mishandled. It must be inspected and calibrated periodically (every 1 to 6 months) against a standard.¹ The interval of inspection should be lowered until the point at which most devices are within 3 to 5 mm of standard.

In determining the appropriate cuff size, a good rule of thumb is that the bladder length is of minor clinical significance as long as at least half the arm circumference is covered by the bladder. Because most of the pressure generated by cuff inflation is concentrated on a short portion of the underlying artery, a too-narrow cuff must be blown up to a falsely high pressure, and a too-wide cuff gives a falsely low reading. The cuff width should be about 20% greater than the diameter of the arm. Standard bladder sizes relative to width and length are shown in [Table 414.2](#). If the cuff's markings indicate a correct fit, it is usually satisfactory.

Newborn arm	25 × 5.0 cm
Infant arm	5.0 × 11.9 cm
Child arm	9.4 × 21.0 cm
Adult arm	12.5 × 23.0 cm
Adult thigh	18 × 35 cm

TABLE 414.2. Standard Bladder Sizes Relative to Width and Length

Oscillation

The modern oscillometric technique (e.g., Critikon's Dinamap) is based on the detection of vascular diameter changes over the course of the cardiac cycle. Energy transmitted from the artery to the wall of a pneumatic cuff displaces and changes cuff volume. This intracuff pressure swing is electronically amplified and processed as the cuff is deflated. These oscillations peak near the mean arterial pressure.

Automated devices are convenient, but erroneous readings can occur during dysrhythmias and in low-output states, when accurate readings are critical. Complications such as vascular and nerve injury and bleeding can occur if cycled too frequently, particularly in patients with coagulopathy or those undergoing thrombolytic therapy. Users are advised to check the function of the devices frequently by ensuring that the cuff bladder completely deflates between cycles.

Doppler Ultrasound

These devices detect sound waves that reflect off moving arterial walls. They are noninvasive, highly reliable, and accurate. The detection device must be placed directly over the artery; even slight movement or malpositioning leads to erroneous results. Restless, combative, or uncooperative patients are not good candidates for this approach.

Arterial Unloading or Volume Clamping/Counterpulsation

In arterial unloading, the volume of the arterial segment beneath the cuff is held constant—its outflow is mechanically obstructed by the cuff. The pressure required to “unload” the artery during the cardiac cycle is determined. The cuff is inflated and then gradually deflated, and a small infrared light directed across a digital artery determines oscillations photoplethysmographically. Maximal oscillations occur at the mean arterial pressure, at which time the cuff pressure is automatically adjusted as it senses further oscillations. A waveform is displayed as the device adjusts upward (sensing systolic pressure) and downward (sensing diastolic pressure). The device is susceptible to hydrostatic pressure as the hand and arm are moved above or below heart level. Erroneous readings may result if the arm is moved or if the extremity is not positioned at heart level.

Arterial Tonometry

A small sensor is applied over the radial artery with sufficient pressure to cause partial flattening of the artery. Several tiny transducers are built into the device so that at least one will be optimally positioned. With careful positioning, wall tension forces are not transmitted to the sensor and only intraluminal pressure is transferred to the transducer, producing a continuous pressure curve. The device is automatically recalibrated every few minutes and requires a palpable pulse. Use is likely to be widespread in the near future.

Intraarterial Catheterization

The advantages of this technique are that it is continuous, errors are generally easily detected, it provides access to blood sampling, and reliable pressures are obtained in hypotensive states. Also, various secondary information can be inferred (sometimes only crudely) by inspecting the waveform ([Table 414.3](#)).

Heart rate
Stroke volume and cardiac output
Myocardial contractility
Resistance and compliance
Cardiac dysrhythmias

TABLE 414.3. Data That Can Be Derived from Arterial Waveform

Intraarterial approaches use saline-filled tubing that transmits the energy of the pulse wave to a transducer, which converts it to a voltage change. This change is subsequently amplified, filtered, and displayed as an arterial pressure tracing. The radial artery at the wrist is the most common site of cannulation, although, in hypotensive patients, larger arteries (e.g., femoral) may prove more accessible.

Although it is common to test for collateral circulation when cannulating the radial artery, most vascular complications related to radial artery manipulations result from embolic phenomena; therefore, the utility of such tests has been questioned.

Adding an automatic recorder to blood pressure-measuring instruments can be invaluable. A formal, exact record of such data can be placed in the patient's permanent record.

Noninvasive Measurement of Cardiac Output

The noninvasive determination of cardiac output by either or both of two new methods—impedance cardiac output¹³ and stroke distance¹²—may move to the emergency department. Impedance cardiac output determines cardiac output, with the use of electrodes placed on the neck and lower thorax, by passing a current through the patient, which is analyzed in conjunction with the patient's heart rate. Stroke distance monitoring determines blood flow by placing a Doppler ultrasound in the suprasternal notch and measuring stroke distance per cardiac contraction. Preliminary use of both of these methodologies is promising.

Central Venous Pressure Measurement

Although central venous access is often used for drug and fluid therapy, the benefit of central venous pressure (CVP) monitoring in the emergency department continues to be controversial. The CVP depends on many factors, including cardiac rhythm, intrathoracic pressure changes, tricuspid valve function, alteration in right ventricular compliance, and even the function of the lung and the left side of the heart.

A true CVP is determined by placing a catheter in the superior vena cava and measuring the height of a column of water above the presumed level of the right atrium. The right atrium is situated at the midaxillary line in a supine patient and is about 5 cm below the sternal angle in any semirecumbent position.

A noninvasive CVP determination is optimally made by measuring the height of pulsation above the sternal angle (plus 5 cm to approximate the right atrial pressure) of the column of blood in the internal jugular vein as the patient's torso is elevated. Unfortunately, this true CVP determination is often difficult to perform, and visualization of the external jugular veins or veins of the hand is substituted. These noncentral veins, however, collapse on entering the thorax and may provide a falsely high CVP determination.

Until relatively recently, invasive CVP monitoring was a standard of care in states of shock. A catheter threaded from an internal jugular vein, subclavian vein, or antecubital veins into the central circulation was used to measure pressure in the superior vena cava. It served as a measure of right atrial pressure and was thought to correlate with left ventricular end-diastolic pressure or preload. Except in young, otherwise healthy patients without acute cardiac or pulmonary dysfunction who are being evaluated for hypovolemic shock, however, the CVP is potentially misleading as an indicator of left-sided preload. Increased CVP can indicate dysfunction of the right side of the heart itself or by pericardial or pulmonary artery pressure elevation. Thus, in patients with cardiac tamponade, constrictive pericarditis, or massive pulmonary emboli, CVP is almost always elevated above 20 cm of water. Elevated pressure may also be seen in tricuspid stenosis or right atrial myxoma and superior vena cava syndrome.

In acute situations in which the physician needs to know only whether the CVP is significantly elevated, the neck veins and hand veins can be used to determine an increased CVP. In the patient with hypotension, significant elevation of the CVP can be confirmed by the presence of distended external jugular veins or the failure of the veins on the dorsum of the hand to collapse when the hand is raised 15 cm above the sternal angle (the Jacobs test). In an appropriate clinical setting, this simple method of monitoring allows the physician to determine appropriate testing and therapy.

CVP also can be measured in the inferior vena cava, or the common iliac vein, with a standard 15- to 20-cm-length femoral line. It may not give accurate measurements when abdominal conditions such as tense ascites, peritonitis, or bowel obstruction are present.

CVP trends can be more helpful than a single reading. Measurements should be repeated in the same position, using a zero-point skin mark at the level of the right atrium.

OXYGENATION

Pulse Oximetry

Measurement of oxygen saturation by the pulse oximeter (PO) has become the “fifth vital sign.” Although clinical estimation of oxygenation can be inaccurate, pulse oximetry, with some exceptions, is a valid and reliable measurement. When the oximeter is properly sensing vascular pulsation, the reading is generally accurate, even in states of low flow, hypothermia, and anemia. In profound hypoxemia, the reading is inexact but is low, not falsely near normal; when the saturation is less than 90%, the correlation with Pao_2 may be inaccurate due to shifts in the oxyhemoglobin disassociation curve.² Although the PO can be used for both oximetric (oxygen saturation) and plethysmographic (pulse or circulation) monitoring, it monitors pulse, not electrical rhythm, and is not a substitute for cardiac monitoring.

Using 660-nm (red) and 940-nm (infrared) wavelength light, the PO analyzes the pulse-added component of absorbance at the two wavelengths and produces a ratio that is empirically related to hemoglobin saturation with oxygen (Sao_2 or SpO_2). Interpretation of displayed values, using the standard oxyhemoglobin dissociation curve, allows for estimation of Pao_2 (e.g., SpO_2 of 75 = Pao_2 40 mm Hg; SpO_2 of 90 = Pao_2 of 60 mm Hg). Large changes in Pao_2 may occur before any change is noted by the PO on the long, flat portion of the oxyhemoglobin dissociation curve.

[Table 414.4](#) lists factors that may cause the PO to provide specious information; if not taken into account, these may lead to an incorrect diagnosis or management.

The major complications related to the use of the PO are a rare incidence of burns, pressure necrosis, and the potential for overly aggressive interventions in the presence of a false alarm or misleadingly low reading.

Low signal-to-noise ratio (too weak a signal or too much electrical interference)		
Probe position ("central" sites—ear, lip, tongue—may be more accurate than peripheral ones)		
Carboxy- and methemoglobin yield falsely high oxygen saturations		
Probe motion	Low perfusion states	MI
Vasoconstrictors	Electrocautery	Nail polish
Dysrhythmias (abnormal pulsations may not be detected)	Strong or flickering ambient light	

TABLE 414.4. Limitations of Pulse Oximetry

Cerebral Oximetry

In critical patients with peripheral circulatory failure, conventional PO often does not produce valid readings. A new technique, called cerebral oximetry, is being studied.⁷ The device includes a light source placed lateral to a frontal sinus on the forehead and sensors that detect light emissions that measure frontal cortex oxygen saturation. The value correlates best with mixed venous oxygen saturation and gives a measure of circulatory and oxygenating adequacy.

VENTILATION

Respiratory Rate

The respiratory system works in concert with the cardiovascular system to change the P_{O_2} and the P_{CO_2} . In the normal person at rest, diaphragmatic motion is all that is required. With obstruction or increasing respiratory needs, the abdominal muscles and the chest wall muscles are used. The anteroposterior diameter of the chest can be increased by 20% with the use of the intercostal, the sternocleidomastoid, and the anterior serrati and scaleni muscles. The use of these accessory muscles can be monitored as a measure of respiratory distress. In the respiratory center of the medulla, chemoreceptors monitor pH, an indirect measure of P_{CO_2} , because hydrogen ions do not cross the blood–brain barrier, but carbon dioxide is freely permeable. Although the overwhelming respiratory drive is an increased P_{CO_2} , peripheral O_2 oxygen receptors in the carotid and aortic bodies also signal the medulla to increase the respiratory rate in the presence of hypoxemia.

Classically, respiratory rate has been determined by counting chest wall expansions for 15 seconds and multiplying by 4, or, in more diligent observers, for 30 seconds or a minute. This is difficult to do, particularly when the patient is talking, and studies have repeatedly shown the inaccuracy of this measurement. There are mechanical methods of determining respiratory rate and pattern; there are even methods of continuous monitoring of tidal volume by electronic devices. Devices such as the impedance pneumograph, mercury-in-Silastic strain gauges, magnetometers, and respiratory inductive plethysmography may be used.

Capnometry

Carbon dioxide concentrations can be measured by a capnometer, graphically displayed as a capnogram, and recorded by a capnograph. The closer to the alveolus that one samples, the more accurately the capnogram indicates what is in the pulmonary venous blood (and thus the arterial blood). Intratracheal sampling is rare for technical reasons, but sampling from a point as close to the patient's mouth as possible, at the end of exhalation, will yield clinically useful information. In the intubated patient, sampling is best performed at the proximal end of the endotracheal tube with a T-piece.

Sampling by nasal cannula in nonintubated patients is also generally reliable. Although there are different approaches, most capnometers use infrared light, where asymmetric, polyatomic molecules such as carbon dioxide absorb specific wavelengths. The discussion here assumes that capnographic analysis is occurring close to, but not within, the trachea.

Emergency departments should generally use capnometers that can generate a waveform; otherwise, important clinical information will be lost. Those that report only the highest (end-tidal level) and lowest (inspired minimal level) carbon dioxide values are much less useful. Transcutaneous capnography may become useful in the emergency department in the future, but it currently is not recommended in adults, although it is more promising in younger children.

The capnogram can be divided into several distinct components, each of which provides valuable information ([Fig. 414.1](#)). Phase I (A to B) reflects initial expiration: The dead-space gas, virtually devoid of carbon dioxide, gives way to the sharply upstroking portion of the capnogram (phase II, B to C), which contains carbon dioxide–laden gas mixing with dead-space air. The morphology of this portion of the curve reflects the expiratory time and the evenness of ventilation. When this phase has a gradual rise, obstruction is suggested. Phase III (C to D) is the plateau of the curve: Alveolar gas is being sampled, with point D representing the end-tidal or alveolar concentration of carbon dioxide (ET_{CO_2}). The phase from points D to E represents inspiration of carbon dioxide–free gas. Unless rebreathing of exhaled carbon dioxide occurs, this should be a precipitous fall to baseline.

Figure 414.1. The component of the capnogram.

If ventilation and perfusion in the lungs are well matched, carbon dioxide readily diffuses across the capillary–alveolar membrane, and if no sampling errors are present, the ET_{CO_2} is an excellent approximation of Pa_{CO_2} . In the perfectly healthy person, there is a very small gradient; as ventilation–perfusion mismatch develops, this gradient increases.

Many conditions influence ET_{CO_2} and must be carefully considered to optimize the utility of ET_{CO_2} monitoring ([Table 414.5](#)). The ET_{CO_2} may be so suspect in many emergency department patients as to be virtually worthless. In these instances, it is better to monitor the arterial blood gas analysis.

FACTORS THAT DECREASE ET _{CO₂}	FACTORS THAT INCREASE ET _{CO₂}
Embolic phenomena (e.g., air, thrombus, fat)	Fever or increased metabolism
Cardiac arrest	Hypoventilation-CNS depression
Shock or other low perfusion states	Hypoventilation-inadequate mechanical ventilation
Chronic obstructive pulmonary disease	Hypoventilation-CNS disease
Ventilator support disconnection	Hypoventilation-neuromuscular disease
Hypothermia or decreased metabolism	
Hyperventilation	
Mechanical factors where room air is entrained	

TABLE 414.5. Clinical Scenarios Influencing ET CO₂

Capnography is valuable in assessing the proper placement of an endotracheal tube (differentiating esophageal from tracheal intubation), the adequacy of ventilation, alterations in dead space and perfusion, the rebreathing of carbon dioxide, and the effectiveness of chest compressions during cardiopulmonary resuscitation.¹⁴ However, the best overall monitor of gas exchange is auscultation of the depth, rate, and clarity of gaseous exchange and observation of the level of consciousness.

Pulmonary Function Tests

Monitoring of pulmonary airflow is becoming a standard of care. In asthmatic patients, the forced expiratory volume in 1 second (FEV₁), forced vital capacity (FVC), and peak expiratory flow rate (PEFR) have been shown to predict need for admission after treatment in the emergency department.⁴ There are many ways of determining air flow, including spirometers, pneumotachygraphs, peak flowmeters, and minipeak flowmeters, but no one device is markedly superior to the others.

Measurements should be taken with the patient in the standing position, with three or more attempts made to obtain the best value. Current recommendations include measurement of peak flow or FEV₁ on presentation, periodically during treatment, and before decision to admit or discharge. If the patient is adequately oxygenated (pulse oximeter reading greater than 90%), has a normal mental status, is receiving maximal (steroid and beta-agonist) therapy, and is improving subjectively and on pulmonary examination, arbitrary pulmonary flow assessment is not mandated. Conversely, if there is any question of admission versus discharge or response to therapy, it may be useful ([Table 414.6](#)).

Patient Status	PEFR or FEV ₁ (% of Known Best Value or of Predicted Value)
INITIAL ASSESSMENT	
Mild asthma	80%–90% predicted
Moderate asthma	50%–80% predicted
Severe asthma	<25%–50% predicted (adults)
Life-threatening asthma	<50% predicted (children)
	<25% predicted
RESPONSE TO THERAPY	
Good	≥70% predicted
Incomplete	>50% but <70% predicted
Poor	<50% but >25% predicted
Respiratory failure	<25% predicted

TABLE 414.6. Pulmonary Airflow Assessment Guidelines for Asthma Management

GASTRIC INTRAMUCOSAL pH

An innovation in the monitoring of oxygen delivery and use in critically ill patients is the measurement of gastric intramucosal pH, or gastric tonometry.⁷ A small catheter is placed into the stomach by the nasal route. Saline is used to distend a silicone balloon, which is left in contact with the gastric mucosal surface until equilibration of P_{CO₂} occurs. The P_{CO₂} value is measured and the Henderson-Hasselbach equation is used to compute the gastric intramucosal pH. This value is an indirect measure of splanchnic perfusion and oxygen extraction. A value below 7.35 suggests inadequate blood flow and oxygen delivery to the gut, serving as an indirect measure of systemic hypoperfusion.

Multiple organ system failure can be viewed as a cascade of events augmented by hypoperfusion of the gut, allowing transudation of both toxins and organisms. Thus, low values indicate the need for intensive therapy and, perhaps, for invasive hemodynamic monitoring.

Although gastric tonometry is not yet used in emergency departments, its prognostic and therapeutic implications and its minimal invasiveness may lead to its future use.

TEMPERATURE

Fever is part of an adaptive response provoked by both endogenous and exogenous mediators. The entire system is designed to defeat microbial invasion. Studies in nonhuman mammals and invertebrates have shown that artificially elevated temperature, in and of itself, reduces the morbidity and mortality of infectious diseases.

In most situations, knowing the exact temperature is unnecessary. Exceptions include hypothermia (therapy varies with the degree of hypothermia) and extreme hyperthermia (temperatures of greater than 107°F can be injurious). Generally, we need to know only whether the patient is euthermic, hypothermic, or febrile. A rectal temperature above 100.4°F (38°C) is arbitrarily defined as “fever.”

To determine the accuracy of any method of temperature measurement, values obtained should be compared with true “core” temperature. By convention, this is measured in the pulmonary artery. The esophageal temperature is a close proxy. Rectal temperatures have long been the clinical standard of measurement. They tend to be 0.51°C higher than core values. With rapid temperature changes, the temperature of stool in the rectum lags behind core temperature. Thus, in moderately to severely hypothermic patients, measurement is best accomplished with an esophageal probe.

Although, traditionally, temperatures were taken with glass, mercury-filled thermometers, current electronic devices achieve suitable accuracy and have essentially replaced them. Axillary and oral sites have been used but are much less precise. Patient and environmental factors (smoking, mouth breathing, cool or hot liquid ingestion, inability to hold the thermometer in place) may alter the oral temperature. Except in newborns, the axillary temperature has been largely discarded.

Tympanic thermometry has revolutionized temperature measurement.¹¹ The ear canal and tympanic membrane receive blood supply from the external carotid; the hypothalamus (the brain’s thermostat) receives its blood supply from the internal carotid. Thus, the common carotid artery provides both blood supplies, and, by inference, tympanic membrane temperature is another measure of core temperature. The measurement is taken by infrared sensors contained in a device that is aimed into the ear canal at the tympanic membrane. A posterior–superior tug on the pinna gives a more accurate “view” of the tympanic membrane. Most current instruments measure the core temperature and, either automatically or by a switch, add an “offset” to produce a rectal equivalent temperature. As more clinicians become familiar with the method, published studies and algorithms will use the direct reading of tympanic core temperature, and “offsets” will be discarded.

Although the evidence is conflicting, many studies have documented the accuracy of these devices in large groups of patients. Temperatures in newborns and infants

less than 3 to 6 months old should probably not be measured with ear thermometry, because the correlation with rectal temperatures in published reports is not convincing, and implications of small temperature differences in defining *fever* are more significant clinically. Extremes of ambient temperature may produce false readings. In most other groups of patients, including those with otitis media and cerumen impaction, results are acceptable.

Many clinicians have the impression, through anecdotal experience, that tympanic thermometry is not accurate. This conflict with the literature is probably based on the fact that, in many emergency departments, the initial tympanic temperature is now taken at triage, and it may be an hour or more before the clinician examines the patient. During examination, the patient may “feel warm,” or the total impression, based on presumed diagnosis, laboratory studies, and so forth, is that the patient should be febrile. If a rectal temperature is then obtained, whether normal or elevated, it is assumed to be the gold standard and correct. Remember that neither method is perfect.

We recommend, in patients over 6 months old, tympanic thermometry as the preferred method of screening. Specific clinical situations may dictate repeating the tympanic temperature or obtaining the temperature by rectum or other core site.

A new method of temperature assessment being used in operating rooms—deep-body thermometry—may become useful in the emergency department.¹⁰ This method uses a 2.5-cm disk (placed on the forehead, chest, or other location) that “nulls thermal flux” and measures “deep-body” temperatures. Preliminary work shows it to closely approximate core temperature as measured in the esophagus. Disadvantages apparent at this time include a 15-minute equilibration time and the lack of confirmatory studies.

NEUROMUSCULAR PARALYSIS

Muscle relaxants facilitate endotracheal intubation, assist in the application of controlled ventilation, and allow performance of diagnostic and therapeutic interventions. Nondepolarizing muscle relaxants (e.g., pancuronium, vecuronium, atracurium) lend themselves well to titration on the basis of both clinical observation and neuromuscular function monitoring. Various strategies are available, but train-of-four (TOF) monitoring may be the most useful technique because it is simple to perform and easy to interpret. Mechanomyography (palpation of the number and strength of evoked responses) has been the standard method, although its crudeness has led to great interest in alternative methods. Electromyography (the evoked compound action potential) reflects electrical changes in the excitable membranes of one or more muscles.

Inexpensive, portable, pocket-sized neuromuscular function monitors are available. TOF stimulation involves four electrical impulses delivered over a 2-second period; the degree of blockade can be gauged by relating the height of the fourth twitch to that of the first, or by counting the number of evoked responses present in any single train (Fig. 414.2). Generally, most procedures can be accomplished by titrating to the point at which the last two or three evoked responses are obliterated; this allows reasonable prospects for reversibility (with a combination of anticholinesterase and an anticholinergic), should the need arise. Overdosing and underdosing are thus minimized.

Figure 414.2. Train-of-four monitoring.

Double-burst stimulation has been developed to overcome some of the manual and visual difficulties associated with TOF interpretation (Fig. 414.3). In this technique, a pattern of stimulation resulting in only two evoked responses stresses the neuromuscular junction in a manner similar to that of TOF; however, double-burst stimulation appears easier to interpret. The two evoked responses are compared, rather than the first and fourth.³ Double-burst stimulation seems best suited to evaluating the degree of residual blockade rather than as a guide to drug administration.

Figure 414.3. Double-burst stimulation.

Patients should never be extubated after having received a muscle relaxant unless recovery is documented (as described previously) and adequate clinical signs of recovery are present (e.g., 5-second sustained head lift and adequate minute ventilation).

LEVEL OF CONSCIOUSNESS

Although not in widespread use, and just now beginning to find a foothold in operating rooms worldwide, the bispectral index (BIS) monitor is a signal-processing technique that allows information to be obtained on a patient's level of consciousness. An electroencephalograph-like, waveform, physiologic signal is used by a new signal-processing technique, bispectral analysis. A mathematic algorithm produces an objective measure of hypnosis. Clinical studies have shown correlation between the BIS and level of hypnosis (drug- or trauma-induced changes in level of consciousness).⁸ The device itself is approximately the size of an end-tidal carbon dioxide monitor and is applied to the patient's forehead by using special adhesive electrodes. This tool may have important applications in emergency medicine and may offer exciting opportunities for clinical intervention, monitoring, and research.

In 1985, 28.6 million U.S. citizens (12% of the population) were age 65 or over, and the elderly population is predicted to grow to 34.9 million people (22% of the U.S. population) by 2030. Elderly patients can be divided into the “young old,” a group that is best considered to be enjoying healthy retirement, and the “true old,” a group that includes the “frail elderly,” who have significant disability. Although functional capacity, not age, creates the distinction between these groups, age 65 to 80 is usually considered “young old,” and the “true old” are 80 and above. Life expectancy at age 65 is 15 years for a man and 20 years for a woman. The fastest-growing segment of the population is the 80 and above group, and, in this group, Whites and women are overrepresented. At age 65, predictors of increased longevity for men are low blood pressure, low serum glucose, not smoking, and not being obese. Continued exercise into older age is also a predictor of longevity. Emergency physicians can expect to encounter a more active and an older population in the years ahead.

Forty percent of the U.S. health-care budget is spent on the elderly. Twenty-five percent to 40% of hospital days are taken by those age 80 and above. Of all emergency department (ED) adult visits, 19.6% are by elderly patients, with 41% of these visits leading to hospitalization. The elderly also represent an ever-increasing proportion of the patients who visit EDs, and emergency physicians must understand and address the unique needs of older patients. ¹¹

Emergency physicians must change their conception of aging from a disease process to a gradual diminution of physiologic functions. The time course of functional loss is highly variable between individuals and is determined by both intrinsic and largely modifiable extrinsic factors such as smoking, diet, and exercise. The effects of diseases, environmental exposures, and stresses accumulate with age to limit the individual's functional capacity and his or her ability to maintain homeostasis. At age 30, the functional capacity of most organs exceeds by four to ten times that necessary to maintain homeostasis during life stresses. With each year over 30, there is a linear decline in the function of each organ system which is independent of other organ systems. Because of impaired functional reserve, diseases present after a lesser stress and at an earlier time. The manifestation of the disease often reflects the loss of homeostasis in the organ system with the least functional reserve rather than the effect of the disease on the organ system primarily attacked. Thus, common presentation of disease states in older patients, such as confusion, withdrawal from usual activities, falling, syncope, and weakness, results from myriad causes—from hyperthyroidism to CHF to appendicitis. The classic signs and symptoms of a disease may be absent, delayed, or altered in the elderly.

Vital signs change with age. The systolic blood pressure increases with age, and the maximal heart rate decreases (maximum expected heart rate = 230 – age). Orthostasis is common, with 50% of nursing home patients demonstrating a 20-mm Hg decline in systolic or a 10-mm Hg decline in diastolic pressure at 1 or 3 minutes after standing from a supine position. Elderly patients have difficulty maintaining thermoregulation and can have a lower baseline temperature or fail to mount a fever in response to infection. Twenty percent of elderly ED patients have an abnormal pulse oximetry reading (less than 95% oxygen saturation). An abnormal pulse oximetry reading prompted admission in 11% of patients and a change in treatment for 55% of patients in one study. ⁵

As a group, elders have tremendous physiologic heterogeneity—more than any other age group, from elder athletes to bed-ridden, terminally ill patients. Expected age-related changes may cause undue concern in the patient, families, and caregivers. Bacteriuria, premature ventricular contractions, low bone mineral density, impaired glucose tolerance, and involuntary bladder contractions are common findings in older patients. Other abnormal findings may be inappropriately accepted as part of the aging process: anemia, impotence, depression, confusion, or falling.

Changes in body mass (more fat, less water) and gradual weakening of the renal, hepatic, pulmonary, cardiac, and central nervous system (CNS) functions are expected, such that some laboratory value norms must be adjusted. Others remain the same with age ([Table 415.1](#)). The changes in medical treatment necessitated by this altered physiology are only partially understood. Because elderly patients have often been excluded from clinical trials, treating them often means extrapolating from the results of trials involving younger patients.

TABLE 415.1. Laboratory Values Affected by Age

Access to medical care and social support impacts care delivery for elders. Elderly patients often require additional time and physical space for evaluation. Access to care may be limited by factors that are not barriers for a younger population, such as narrow parking spaces and steps at an entrance. While the vast majority of elders are living independently, two-thirds of 90-year-olds need help walking. Elderly ED patients are more often acutely ill, require more diagnostic tests, and are less able to be accurately diagnosed than are younger patients. They may be misdiagnosed if a hurried, narrowly focused approach to evaluation is used. After identifying one problem and addressing it, emergency physicians may fail to recognize another problem that may be the underlying cause. In contrast to the younger patient, a single diagnosis usually does not explain all the abnormalities found in an older patient. To understand the presenting problem, deliver optimum care, and prevent future problems, the emergency evaluation must have a more comprehensive approach that includes a caregiver interview, assessment of cognitive and functional status, careful review of current and past medical problems and medications, construction of a broadened differential diagnosis, and, finally, appreciation of the resources available in the hospital and community to carry out the care plan and assure patient safety.

A systematic approach to cognitive and functional assessment should become part of routine evaluation of older patients. Using the confusion assessment method or a standard cognitive function examination, and reviewing the activities of daily living, bathing, dressing, toileting, transferring, maintaining continence, and feeding aid the physician in quantifying subtle changes in patient status. The development of delirium, or a rapid cognitive or functional decline is better appreciated by using these standard evaluation formats. The emergency physician must learn to recognize these changes as signs of potentially life-threatening illness that require investigation and hospitalization. Functional or cognitive impairment may bring the patient to the ED with failure to thrive, weakness, frequent falls, anorexia, incontinence, confusion, agitation, depression, fatigue, injury, abuse, or insomnia. A narrowly defined approach to making a rapid diagnosis may fail to identify the magnitude of the functional or cognitive impairment. Admission to the hospital or an observation area may be required to fully assess the need for treatment of an

underlying illness when patients present with acute cognitive or functional decline.

Most elderly persons live alone on low incomes and find the challenge of preparing meals a burden. Loneliness, poor dentition, and decreased ability to taste, see, and move often lead to poor nutrition. Many elderly persons do not meet minimum daily nutritional requirements. Even in nursing homes, malnutrition occurs. Any elderly patient with an unintentional weight loss of 10 or more pounds in the preceding 6 months may be suffering from malnutrition. Overweight patients may suffer from protein or vitamin deficiency. One marker of malnutrition is diminished albumin. Dizziness, syncope, depression, and mental status changes, as well as chronic joint pains, may relate to subtle nutritional deficiencies.

Patients over age 65 use an average of two to six prescribed medications and one to three nonprescribed medications. An estimated 3% to 8% of all hospital admissions for elderly patients are associated with adverse drug reactions (ADRs). Most are related to aspirin, nonsteroidal antiinflammatory agents, and cardiovascular drugs. Some medications, such as propoxyphene, long-acting benzodiazepines, and long-acting oral hypoglycemics, are contraindicated in older patients. The emergency physician must have a high index of suspicion for medication-related problems. Drug effects are often more pronounced in the elderly, and ADRs particularly related to dosing are common. ADRs and adverse drug interactions (ADIs) can also result from the emergency physician's prescriptions. A review of current medications, including nonprescribed and herbal medications, must be part of every emergency evaluation of the elderly patient before formulating a differential diagnosis, and also prior to prescribing medications. Routine application of computerized drug-interaction programs in the ED may lead to detection of drug interactions and reduce hazardous prescribing practices among elderly patients.

The elderly patient may be a poor historian due to deafness, depression, mental deterioration, or stroke. This patient may be unable to cooperate fully with the examination. The emergency physician must overcome these barriers to obtain an adequate history and examination. It is often useful to include a family member or caregiver in the evaluation. A caregiver, present in the examination room, can provide comfort to the patient, additional history, and assistance with the physical examination.

Care after discharge is critical to satisfactory emergency treatment of elderly patients. Twenty-four percent of elderly ED patients return within 3 months of the initial visit to the ED. Patients with functional problems are more likely to return. Addressing functional problems by creating more comprehensive care plans at discharge may decrease these ED returns. Home health-care services can be integral to the treatment plan. Discussion of the patient's needs with the caregiver is an essential part of emergency care, as important as a discussion with the parent of a child treated in the ED. The patient's home-care needs and resources must be assessed before discharge. Identification of elders with needs for additional outpatient care may be accomplished by asking a few simple screening questions. In many EDs, social workers, case managers, or members of a geriatric evaluation team can carry out these assessments.

Emergency physicians may be concerned about whether it is appropriate to provide care for the elderly patient who is close to death. Many elderly persons have advanced directives concerning limitations to care. Some emergency medical service systems have taken steps that allow prehospital providers to respond in accordance with these advanced directives. Concerns about providing unwanted care may lead to suboptimal investigation and treatment. The physician must not let ageism masquerade as ethics or cost effectiveness. The patient's expressed desire to forego extraordinary measures to sustain life should not limit the clinician's diligence in seeking and treating remediable illness. When thrombolytic therapy was studied in the elderly, significant reductions in mortality were realized, with less cost per life saved, in the older patients. The emergency physician should seek to determine and follow the wishes of the elderly patient who has a desire to limit care, especially when a durable power of attorney, a living will, or orders restricting resuscitation are available. However, such desires to limit care should not be misinterpreted as desires for comfort measures only. Routine emergency care includes thorough evaluation and treatment of most medical problems.

Common emergency problems relevant to the care of elderly patients and problems unique to the elderly are reviewed in the following sections.

ABUSE AND NEGLECT

Abuse and neglect of the elderly include actions or omission of actions that result in harm or threatened harm to health or welfare.¹² Although 4% of the elderly population is subject to some type of abuse or neglect each year, this entity is often unrecognized or ignored because physicians are unfamiliar with elder abuse, unsure of how to report possible abuse, or fearful of making false accusations toward caregivers. The consequences of elder abuse include not only acute injuries, but also significant long-term morbidity, functional decline, depression, and increased mortality rates.

Physical abuse is the most commonly reported form of elder abuse, yet its actual prevalence is estimated to be lower than that of other categories. This includes acts of physical violence, sexual assault, burns, and excessive physical restraint. As with child abuse, elder abuse should be considered in patients who present with single or multiple fractures, lacerations, or contusions with inconsistent mechanisms of injury.

Psychological abuse is difficult to assess in the emergency setting, as it can be subtle. Examples include verbal harassment, insults, and threats of physical harm, institutionalization, withholding care, or even homicide. Behavioral clues of severe anxiety, passivity, fear, and shame may be observed, particularly in the presence of the caregiver. Long-term abuse of this nature can lead to, and must be considered in the differential of, depression in the elderly.

Neglect may be intentional but occasionally results when a caregiver simply cannot provide adequate care. This type of abuse most commonly affects the most debilitated elderly who cannot perform basic activities of daily living. It may include withholding medications, food, clothing, glasses, dentures, hearing aids, or walkers. Deliberate misuse of medication is also categorized as neglect. Prehospital workers often discover evidence of neglectful abuse and can provide valuable information regarding living conditions.

Financial abuse includes theft and inappropriate use or withholding of money and material goods by a caregiver. This is similar to neglect, but is associated with some sort of financial or material gain on the caregiver's part at the expense of the victim.

Most elderly patients who are subject to abuse have a physical or mental impairment that renders them dependent on others for assistance. Female gender and social isolation are risk factors. Abusers are typically family members, with daughters and sons being identified most often. Forty-five percent of abusers have a history of drug or alcohol abuse, and 64% are financially dependent on the victim. Other risk factors include a family or personal history of abuse or violence, severe external stressors, forced responsibility placed on the caregiver, and severe or increasing care needs.

Physicians must report elder abuse in all states. In the majority of states with mandatory reporting laws, failure to report suspected elder abuse is a criminal offense. Elder abuse protocols similar to those for child abuse and rape should be developed and followed. They should include appropriate forms for recording information from the patient as well as the caregiver, and objective data pertaining to the physical examination and laboratory studies. Social workers and local agencies, such as the department of elderly affairs or adult protective services should be notified, and can assist in the reporting process. However, the elderly patient, if mentally competent, has the right to refuse any intervention.

ABDOMINAL CONDITIONS

Elderly patients who present with abdominal pain are a diagnostic challenge. Chronic disease and normal physiologic changes of aging contribute to the atypical and delayed presentations of abdominal disorders. Routine laboratory tests cannot be used to reliably predict which elderly patients have an acute surgical disease or which patients which should be admitted or discharged.

Nearly half of those over age 65 have gallstones,¹³ so it is not surprising that gallbladder disease is the most common cause of acute abdominal pain in the elderly. Presenting symptoms and the physical examination are often very nonspecific; less than half of geriatric patients with acute cholecystitis present with vomiting, and 25% relate no history of biliary colic. Only 30% to 55% are febrile to greater than 101°F, leukocytosis is absent in 50%, and 25% have no tenderness. Elderly patients are more likely to present with complications of cholecystitis, such as perforation, gangrenous cholecystitis, and ascending cholangitis.

Less than half of elderly patients who present with an acute complication of ulcer disease have a history of ulcers.¹⁴ Patients with underlying coronary artery disease or cerebrovascular disease who have acute upper gastrointestinal bleeding may present only with symptoms of coronary ischemia or change in mental status. Thirty percent of elderly patients with perforated ulcers have no pain.

Five percent to 10% of all cases of appendicitis occur in patients over age 60, and these patients account for half of all appendicitis deaths.¹⁵ In most cases of

appendicitis in the elderly, the appendix is perforated at surgery. Anorexia and vomiting are less common, migration of pain to the right lower quadrant is absent in up to 60%, and half of elderly patients with appendicitis have a normal white-cell count on initial presentation.

Mesenteric ischemia is truly a disease of the elderly. In its early stages, it often goes unrecognized due to the usual presentation of vague, intermittent abdominal pain and an unremarkable physical examination. The mortality rate is up to 85%. This possibility should be considered in any elderly patient with a history of vascular disease or atrial fibrillation who presents with abdominal pain.

The incidence of abdominal aortic aneurysm (AAA) increases with age and may be as high as 11% in men over the age of 65. Symptoms of abdominal, flank, back, or groin pain should raise the suspicion of an expanding or ruptured AAA. Age alone is not a contraindication to surgery; any patient with a symptomatic AAA must be evaluated for urgent surgical intervention.

CARDIAC DISEASE

More than 25% to 33% of myocardial infarctions (MIs) in all age groups are discovered only from the appearance of new changes on routine cardiograms. Thirty percent of elderly patients with cardiogram evidence of MI are asymptomatic. In studies of ambulatory monitoring of ST-segment depression, 75% of all ischemic episodes are found to be asymptomatic. Clearly, much of coronary disease is silent in elderly and other patients.

The presentation of ACSs, when not silent, become more atypical with age. In patients over age 85, atypical presentations of MI are the rule: Shortness of breath, not chest pain, is the most common presentation. The classic presentation, substernal chest pain described as a dull squeezing, is present in only 20% of patients. Abdominal or epigastric distress and fatigue or weakness are frequent complaints.³ MIs may also present as syncope, a stroke-like syndrome, or acute confusion, particularly in patients over age 75. Prodromal symptoms or anginal equivalents such as tiredness or breathlessness associated with exertion may be more helpful than acute symptoms in pointing to a cardiac origin in older patients. Elderly patients experiencing MI have a greater delay in calling 911, arriving at the ED, being examined, receiving thrombolytic therapy, and arriving at the coronary care unit (CCU). Mortality from MI is higher in the elderly. Hence, any elderly person presenting with pulmonary, cardiac, or neurologic symptoms should be quickly evaluated for myocardial ischemia with an electrocardiogram (ECG).

In elderly patients, the cardiogram is frequently abnormal, but not diagnostic.⁵ The maximal heart-rate response to stress or exercise decreases with age. Modest left ventricular hypertrophy occurs with a stiffening of the ventricular wall, reduced early diastolic ventricular filling, prolonged ventricular relaxation, and reduced endocardial perfusion. Gradual loss of the elastic characteristics of the arteries increases afterload. Baseline ECG abnormalities increase with age.² The major changes seen with age relate to degenerative changes in the heart's conduction system. The finding of a left axis deviation with left anterior hemiblock or longer PR and QRS intervals may be due to aging. First-degree atrioventricular block is present in 10% of all elderly patients and 35% of 90-year-olds. Bundle-branch block is seen in 42% of elderly patients. Hence, an elderly patient's cardiogram may be difficult to interpret without a baseline cardiogram for comparison. In the setting of recent onset of symptoms and left bundle-branch block, early comparison with a prior ECG is necessary to determine the need for thrombolytic therapy or invasive procedures.

Aggressive treatment of acute coronary syndromes (ACSs) in elderly patients is gaining acceptance in the United States. However, procedural interventions have not proved to be as effective as thrombolytic therapy. In multiple trials, thrombolytic therapy has been shown to be effective in reducing the mortality associated with MI. In trials that have included elderly patients, the benefits of thrombolytic therapy have been demonstrated in the older group. Because the elderly have a greater mortality from MI, they stand to gain significantly from treatment. Unfortunately, the elderly have been less likely to receive treatment with thrombolytic therapy. Elders benefit from CCU admission, beta blockers, angiotensin converting enzyme inhibitors, aspirin, and aggressive treatment of complications. With improved survivorship of acute MI, a growing challenge for physicians is control and treatment of congestive heart failure (CHF). Emergency visits and admissions for CHF are growing, and 80% of patients with CHF are over age 65.

When the ECG is abnormal but not diagnostic and the history suggests a possible cardiac event, it is prudent to admit the elderly patient for observation, monitoring, and further evaluation. Rapid evaluation with serial enzymatic assays and/or imaging of the heart at rest to identify myocardial damage or an ACS can be followed by provocative testing to identify underlying coronary disease. In many EDs, elderly patients at low and moderate risk for ACSs can safely complete this evaluation during an 8- to 12-hour stay for rapid evaluation and observation.

DELIRIUM AND DEMENTIA

Fifteen percent of elderly patients admitted to medical services manifest delirium, and 25% to 35% of those who are initially lucid subsequently develop delirium. Forty-one percent of demented patients are found to be delirious, and 25% of delirious patients have underlying dementia.¹⁴

Delirium is an acute, reversible global disorder of cognition affecting memory, thinking, and perception. Thoughts are incoherent and chaotic, marked by delusions, paranoia, and confabulation. Disorientation is common. Memory is poor; recent memory is more affected than is remote memory. The patient may recount hallucinations and illusions. The disorder fluctuates, and periods of clarity are often interposed. Diurnal variations and unfamiliar environmental stimuli (typified by the prehospital and ED experience) often provoke delirium. Attention is decreased, as is consciousness or responsiveness. The patient may be hypoactive, with coarse tremors and asterixis, or hyperactive, with agitation and hallucinations. Many studies have suggested that the clinical diagnosis is best made by the application of the Confusion Assessment Method (CAM) coupled with multiple observation points.

Underlying disorders such as CHF, urosepsis, pneumonia, cancer, uremia, hypokalemia, dehydration, sodium depletion, right hemispheric stroke, drug intoxication (especially anticholinergics), and myriad other pathologies must be considered in elderly patients. The diagnostic workup and treatment must be directed at the underlying disease process. Patients with acute onset or decompensation should generally be admitted. Delirium can be temporarily managed by the careful use of neuroleptics (small doses of haloperidol work well) and fluids while the emergency physician performs a thorough workup, searching for the underlying cause of this reversible condition.

Dementia is a chronic, slowly progressive loss of higher mental function. There is a gradual decrease in mental capability with normal aging. Synthesis of new information, visual motor coordination, and some nonverbal processes begin declining in the third decade. However, other cortical indices actually improve with age, such as vocabulary. Most changes in learning capabilities relate more to the presence of distinct CNS disease than to age itself. Knowing the characteristics of dementia aids in separating acute nondementia illness from dementia. Alzheimer disease is, by far, the most likely etiology of dementia.

Patients typically present with memory loss, disorientation, anomia, visual spatial deficits, apraxia, and intellectual decline. Often, the patient is brought to the ED by a concerned spouse or relative because of behavioral changes, including getting lost in familiar neighborhoods; difficulties in dressing and following simple directions; loss of interest in personal habits, family, and community affairs; and forgetfulness. The patient often denies any problems. A careful neurologic examination, focusing on cognition, and a search for underlying disease should be performed. It is important to remember that elderly patients with dementia who are being treated with psychotropic agents are three to five times more likely than younger patients to develop tardive dyskinesia.

DEPRESSION

Depressive symptoms are present in up to 27% of community-dwelling elderly; full-blown clinical depression is present in up to 15%, compared with 3% in the general population.⁴ The prevalence is higher in hospital inpatients and nursing home residents. Risk factors include female gender, widowhood or single life, stressful life events, and poor social support. While elders tend to report less depressed mood, they demonstrate a higher rate of anxiety than do younger patients, suggesting a depression-anxiety syndrome. Somatization is common and may represent the disorder itself or accentuation of symptoms of comorbidities. White men over age 60 have the highest rate of successful suicide.

There is a strong association between depression and dementia. Twenty percent of the demented are depressed, and up to 30% of spouses of demented patients suffer from depression. However, depression rarely presents as or masks an underlying dementia. The elderly tend not to offer symptoms of depression or dysphoria spontaneously, but will discuss them if asked directly. Often, the depression is associated with chronic illness, retirement, change in social status, new residence (to a nursing home, retirement village, or apartment), marital difficulties, or the death of a spouse. Symptoms may include insomnia or hypersomnia, fatigue, anhedonia, psychomotor agitation or retardation, difficulty concentrating, and violent outbursts. Some illnesses that mimic depression include hypothyroidism with myxedema,

Other hazards include poorly fitting shoes or clothes, foot disorders, and inadequate lighting. Of the subjects who have fallen, 25% report significant limitation of daily activities due to fear of future falls. This fear of falling, coupled with poor social support, not only leads to activity curtailment, but also contributes to nursing home placement in a significant number of elderly patients. Preventive strategies, addressing medications, physical conditioning, behavioral modification, and social support, have proved to significantly reduce the incidence of falls, and should be implemented whenever an elderly patient is discharged after a fall.

INFECTIONS AND SEPSIS

The “true old” or “frail elderly,” those with some degree of functional impairment, immobility, incompetence, or incontinence, are at high risk for infections and sepsis.²¹ Defense against bacterial invasion is compromised by age-related decreases in skin thickness, ciliary activity, cough reflex, gastric acid, and gut motility. Pressure sores, soft-tissue edema, and indwelling catheters provide open portals for bacterial invasion. Immune response may be improved by adequate nutrition and vitamin supplementation. Vaccination for influenza and pneumococcus is cost effective and can be undertaken in the ED.

The cardinal sign of systemic infection—fever—may be absent in up to 25% of infected elderly patients. In fact, due to loss of thermoregulation, hypothermia may occur. A rectal temperature is mandatory in any elderly emergency patient with a suspected infection. Confusion, malaise, nausea, and vomiting are common presentations of infection in the elderly.

The underlying sources of sepsis are most often respiratory (13% to 58%), urinary (15% to 34%), and intraabdominal (20%). Cellulitis, endocarditis, and meningitis are less likely but must also be considered. The bacterial causes of pneumonia, skin infection, and urinary tract infection are largely the same as in younger patients, with two exceptions: Gram-negative colonization of the oropharynx and skin is much more common, and indwelling bladder catheters are associated with urinary tract infection by antimicrobial-resistant, gram-negative bacilli such as *Klebsiella*, *Enterobacter*, and *Proteus* spp. There is growing concern with the colonization of elderly in nursing homes and hospitals with resistant bacteria. In nursing home patients sent to the ED, methicillin-resistant *Staphylococcus aureus* was present in 15% and vancomycin-resistant enterococcus in 5%. Decubiti are a predictor of colonization with multiply resistant organisms in nursing home residents presenting to the ED.

Most elderly patients with serious infections require intravenous antibiotics. There is a growing ability to provide out-patient intravenous antibiotics. New, highly effective, broad-spectrum oral antibiotics have also been developed. These developments and earlier treatment of infection in the elderly are decreasing the need for inpatient admissions for treatment of infections. Specific guidelines have been developed to determine the need for hospital admission in patients with pneumonia.

Confusion and a raised respiratory rate or upper abdominal pain are often the only prominent findings in an elderly patient with pneumonia. Fever, chest pain, and cough may be absent, and sputum production is often minimal. Confusion or rapid functional decline may be the only sign of urosepsis in the elderly. Urinary symptoms, fever, and back pain may be absent.

Asymptomatic bacteriuria is common in elderly patients and does not require treatment. Pyuria (greater than 10 white cells per milliliter of unspun urine) is sensitive but nonspecific for bacteriuria in the elderly. However, a third of patients with pyuria do not have bacteriuria. Obstruction from prostatic enlargement or uterine prolapse is a contributing factor in many elderly patients with recurrent urinary tract infections and should be discovered on physical examination during the evaluation of a patient with recurrent infections.

Pressure sores may be missed unless the patient is fully disrobed and the areas under all dressings are inspected. Decubitus ulcers require systemic antibiotics only when cellulitis, osteomyelitis, or sepsis develops. Pressure ulcers are a marker of neglect and should alert the physician to the need for improved care or the potential of abuse.

MAJOR TRAUMA

Trauma is the fifth leading cause of death in the elderly.¹⁵ Although persons age 65 and older make up 12% of the population, they account for up to 20% of trauma visits and 25.9% of fatal trauma injuries. In addition, trauma victims over age 80 suffer four times the mortality of those between ages 65 and 80. Elderly trauma victims require extended stays in the hospital, intensive care unit, and the rehabilitation facility. Individuals who survive the initial hospitalization continue to demonstrate higher mortality rates for at least 5 years when compared with uninjured cohorts. Although injury-severity scales are unreliable in predicting outcome in elderly patients, they demonstrate that mortality is increased in aged patients, compared with younger patients with similar injuries. Major causes of death among elderly trauma patients are multiple organ system failure and sepsis; mortality in younger trauma patients is determined predominantly by the extent of acute brain injury.

Diminished physiologic reserve renders elderly trauma patients susceptible to rapid demise. Hypothermia is more common in elderly trauma patients. Acute myocardial ischemia and cardiac dysfunction must be considered in hypotensive elderly trauma patients. The frailty of the heart and major vessels dictates a more aggressive search for occult injury and a more conservative policy on admitting these patients for observation and monitoring.

Two-dimensional echocardiography yields the most information in the shortest amount of time and should be used whenever cardiac injury is suspected. Structural evidence of contusion and abnormalities of wall motion can be identified, as can complications such as tamponade, rupture, and valvular defects. Atherosclerotic disease, decreased elasticity, and calcification of the aorta predispose to traumatic dissection as well as transection.

Diminished pulmonary reserve in the elderly is evidenced by reduced vital capacity and compliance, increased residual volume, and a higher prevalence of obstructive and restrictive disease. Kyphosis is present in two-thirds of geriatric patients, and chest-wall elasticity is reduced, resulting in less compliance and a propensity for multiple rib fractures. Elderly patients with suspected pulmonary contusion or multiple rib fractures should be admitted for close observation, pain control, and meticulous fluid management. Age over 65 is an indication for early ventilatory support in patients with flail chest, as mortality is significantly higher in elderly patients who have delayed intubation after manifestation of clinical signs of respiratory failure.

Elderly patients are particularly likely to develop subdural hematomas (SDHs).⁹ Brain atrophy predisposes the cerebral cortices to move within the cranium with abrupt acceleration or deceleration forces. The parasagittal bridging veins running between the brain and dura mater are short, straight veins with no tortuosity and may tear under the added stress of brain movement. These veins also become more fragile with age and tend to rupture with less acceleration or rotational force. Leakage from one or more bridging vein results in the accumulation of venous blood between the dura and arachnoid membranes. SDHs may also result from the rupture of small cortical arteries after traumatic brain injury.

With brain atrophy, more intracranial volume can be occupied by hematoma before signs of elevated intracranial pressure develop. Headache and changes in mentation are most often present, with lateralizing motor weakness evident in about 50% of cases. New-onset paresthesias, gait disturbance, aphasia, or seizures should also raise suspicion of an acute SDH. A subacute or chronic presentation of SDH is more common than acute onset in the elderly.

Age is the most significant predictor of both acute and long-term mortality among head trauma victims. Elderly patients with acute SDH and a Glasgow score below 8 have an 82% mortality rate and only a 3.6% functional recovery, compared with a 60% mortality rate and a 24% functional recovery in adults less than age 65. Minor head trauma (defined as an admission Glasgow score of 13 to 15 and only brief loss of consciousness) can also be devastating in geriatric patients. Mortality rates are higher than in younger adults (5.0% vs. 0.35%), and prolonged neuropsychiatric deficits can occur. In patients older than age 80, a 12% mortality due to minor head injury has been reported. Elderly patients are also significantly more likely to harbor an acute intracerebral lesion and to require craniotomy.

SYNCOPE, NEAR-SYNCOPE, WEAKNESS, AND DIZZINESS

Patients over age 60 who present with syncope have a 21% incidence of major morbidity or death during the 6 months after presentation, compared with a 6% incidence in patients less than age 60.⁸ An elderly patient presenting with syncope is thus at high risk and usually requires hospital admission. One study⁶ found that elderly patients with near-syncope had a 30% incidence of life-threatening etiology. Thus, near-syncope should be regarded as a high-risk event.

Cardiac causes account for 30% to 35% of syncope in elderly patients. Dysrhythmias increase in prevalence and complexity with age. Atrial fibrillation occurs in up to 8% of elderly persons. Supraventricular tachycardias are the most common cause of cardiac-induced syncope in the elderly. Although less common, bradycardic syncope occurs in elderly patients and may be part of a “brady-tachy” or “sick sinus” syndrome caused, in part, by the effects of aging and ischemia on the sinus

node. With cardiac disease resulting in ventricular dilation, the risk of ventricular dysrhythmia increases.

Other common causes of syncope and related symptoms in the elderly include vasovagal (40%), orthostatic (10% to 20%), postprandial (8%), autonomic, and cerebrovascular events. Conditions that cause syncope may be responsible for near-syncope, a feeling of weakness or dizziness. Other conditions that may present in a similar fashion are seizures, transient ischemic attacks (TIAs), depression, weakness, and vertigo. Witnessed seizures should be easily distinguished from syncope by motor activity. However, caution must be exercised before rejecting a cardiac cause of a brief seizure, because deprivation of oxygen to the brain from a cardiac cause can lead to a brief seizure. Transient focal neurologic symptoms are a hallmark of TIA. However, in the setting of a patchy cerebral circulation, focal symptoms may appear transiently from deprivation of oxygen to the brain from a cardiac cause. Vertigo should be distinguishable as a unique symptom that relates to neurologic disturbance and not confused with light-headedness that is cardiac in origin. A global symptom such as weakness requires an extensive history and evaluation to discover social, psychiatric, cardiac, hematologic, endocrine, or metabolic disorders.

Several age-related physiologic changes predispose the elderly to syncope.²¹ Baroreflexes regulating heart rate, and blood pressure may not respond to the degree that they do in the younger patient. Medications, conduction disorders, prolonged inactivity, diabetes, and mild dehydration can impair the elderly patient's ability to mount a compensatory increase in blood flow in response to upright posture or hypovolemia. As many as 50% of elderly nursing home patients will have orthostasis on standing. Baseline hypoxia develops as the alveolar-arterial oxygen difference widens with age (to 24 mm Hg at 80 years). Exposure to cigarette smoke or inhaled toxins can further widen this gradient. Hypertension and fixed atherosclerotic plaques reset the minimal blood pressure required to maintain cerebral perfusion. Anemia and cerebrovascular disease decrease cerebral blood flow, reduce oxygen content, and can bring baseline cerebral oxygen and glucose delivery close to the threshold necessary to maintain consciousness. For these reasons, elderly patients are particularly prone to syncope.

THYROID DISEASE

Thyroid disease of the elderly primarily affects women. Symptoms of hyperthyroidism, such as weight loss, fatigue, and dyspnea, can be confused with "normal aging" and be ignored. Other symptoms, including weakness, anxiety, nervousness, and palpitations, are also common complaints in elderly patients.

The presentation can be limited to one system and may reflect an enhanced sensitivity to thyroid hormone rather than markedly increased levels.⁷ Some examples of this include atrial fibrillation, often with a slow ventricular response or CHF; anorexia; and weight loss. Other presentations include bulbar myopathy (ptosis and dysphasia), with normal deep tendon reflexes (no hyperreflexia with rapid relaxation phase); agitated depression or so-called apathetic depression; and an attention deficit or emotional lability.

Patients with hypothyroidism often complain of lassitude, cold intolerance, and psychomotor slowing. Constipation affects as many as 26% of elderly men and 34% of elderly women, and may be the only clinical manifestation of early hypothyroidism. Any of these signs may be attributed to normal aging. There may be a history of thyroiditis or treated hyperthyroidism, radiation treatment to the neck for cancer, long-term lithium ingestion, or interleukin chemotherapy. The hypothyroid elderly patient may be hypothermic (less than 96°F), with hypoventilation and hypercapnia. Supraventricular or ventricular tachycardia may develop with severe hypothyroidism. Myxedema (subcutaneous glycosaminoglycans and water) of the skin, pleural, peritoneal, and pericardial cavities may be present.

Many older patients have abnormal thyroid-stimulating hormone (TSH) levels without other alterations in serum thyroid hormone levels: Subclinical hypothyroidism is present in 5% to 10%, and subclinical hyperthyroidism is present in 1% to 2%. The risks of subclinical hypothyroidism include progression to overt hypothyroidism, cardiac failure, hyperlipidemia, and neurologic neuropsychiatric symptoms. The risks of subclinical hyperthyroidism include progression to overt hyperthyroidism, dysrhythmia (especially atrial fibrillation), and osteoporosis. Elderly patients presenting to the ED with nonspecific symptoms suggestive of hyper- or hypothyroidism should be screened with a TSH level.

COMMON PITFALLS

- Failure to consider a wide differential when addressing an elderly patient's presenting problem, especially before dismissing vague and generalized complaints
- Failure to involve a family member or caregiver in all stages of the evaluation of an elderly patient, particularly in planning any treatment after discharge
- Failure to identify risk factors (such as environmental hazards and medications) that can lead to future morbidity from falls
- Failure to obtain a complete list of medications taken, including over-the-counter drugs and herbal medicines
- Failure to consider ADRs in all elderly patients and to take steps to avoid drug interactions when prescribing new medications
- Failure to appreciate that syncope in the elderly is more frequently cardiac in origin, usually requires admission, and is seldom benign
- Failure to consider infections in the elderly patient with confusing or vague complaints, even in the absence of fever or localizing signs
- Failure to provide elderly trauma patients with early ventilatory support whenever pulmonary contusion is suspected and when hypoxia is present, even if the initial chest x-ray is normal
- Failure to consider cardiac dysfunction in hypotensive elderly trauma patients
- Failure to consider bowel ischemia early in the evaluation of nonspecific abdominal pain
- Failure to consider abuse as a cause of injury in elderly patients
- Failure to consider depression and substance abuse when evaluating general symptoms such as weakness and weight loss
- Failure to recognize and treat rapid functional or cognitive decline as a sign of serious medical illness
- Failure to appreciate that suicide attempts in the elderly are always serious
- Failure to appreciate that ischemic cardiac disease in the elderly presents more often as shortness of breath or syncope than as chest pain
- Failure to respect the right of the elderly patient to participate in decision making and choose a course of therapy

Antiadrenal antibody	S	Negative at 1:10 dilution	Not applicable	Indirect immunofluorescence	
Anti-double-stranded (native) DNA	S	Negative at 1:10 dilution	Not applicable	Indirect immunofluorescence	
Antigranulocyte antibody	S	Negative	Not applicable	ELISA	
Anti-Jo-1 antibody	S	Negative	Not applicable	ELISA	
Anti-La antibody	S	Negative	Not applicable	ELISA	
Antimitochondrial antibody	S	Negative	Not applicable	Indirect immunofluorescence	
Antinuclear antibody	S	Negative at 1:40 dilution	Not applicable	Indirect immunofluorescence	
Anti-parietal-cell antibody	S	Negative at 1:20 dilution	Not applicable	Indirect immunofluorescence	
Anti-Ro antibody	S	Negative	Not applicable	ELISA	
Anti-RNP antibody	S	Negative	Not applicable	ELISA	
Anti-Scl-70 antibody	S	Negative	Not applicable	ELISA	
Anti-Smith antibody	S	Negative	Not applicable	ELISA	
Anti-smooth-muscle antibody	S	Negative at 1:20 dilution	Not applicable	Indirect immunofluorescence	
Antithyroglobulin antibody	S	Negative	Not applicable	Immunoassay	
Antithyroid antibody	S	<0.3 IU/mL	<0.3 kIU/L	Immunoassay	1
Bence Jones protein	S	None detected	Not applicable	Immuno-electrophoresis	
Qualitative	U	None detected in a 50-fold concentration	Not applicable	Immuno-electrophoresis	
Quantitative	U			Nephelometry	
Kappa		<2.5 mg/dL	<0.03 g/L		0.01
Lambda		<5.0 mg/dL	<0.05 g/L		0.01
C1-esterase-inhibitor protein	S				
Antigenic		12.4–24.5 mg/dL	0.12–0.25 g/L	Nephelometry	0.01
Functional		Present	Present	Immunodiffusion	
Complement					
C3 (adult)	S	86–184 mg/dL	0.86–1.84 g/L	Nephelometry	0.01
C4 (adult)	S	20–58 mg/dL	0.20–0.58 g/L	Nephelometry	0.01
Total complement (adult)	S	63–145 U/mL	63–145 kU/L	Immunoassay	1
Factor B	S	17–42 mg/dL	0.17–0.42 g/L	Nephelometry	0.01
Cryocrit	S	None detected	Not applicable	Manual method	
Cryoproteins	S	None detected	Not applicable	Manual method	
Cryoprotein identification	S	None detected	Not applicable	Immunodiffusion	
CSF	CSF				
Agarose electrophoresis		No banding seen in an 80-fold concentration	Not applicable	Agarose electrophoresis	
Quantitation of albumin (adult)		11.0–50.9 mg/dL	0.11–0.51 g/L	Nephelometry	0.01
Quantitation of IgG (adult)		0.0–8.0 mg/dL	0.0–0.08 g/L	Nephelometry	0.01
Haptoglobin	S	16–199 mg/dL	0.16–1.99 g/L	Nephelometry	0.01
Immunofixation	S	None detected	Not applicable	Agarose electrophoresis	
Immunoglobulin (adult)					
IgA	S	60–309 mg/dL	0.60–3.09 g/L	Nephelometry	0.01
IgE	S	10–179 IU/mL	24–430 µg/L	Immunoassay	2.4
IgG	S	614–1,295 mg/dL	6.14–12.95 g/L	Nephelometry	0.01
IgM	S	53–334 mg/dL	0.53–3.34 g/L	Nephelometry	0.01
Joint fluid crystal	JF	No crystals seen	Not applicable	Microscopy	
Joint fluid mucin	JF	Only type I mucin present	Not applicable	Manual method	
Rheumatoid factor	S, JF	<30 IU/mL	<30 kIU/L	Nephelometry	1
Serum protein electrophoresis	S	Normal pattern	Not applicable	Agarose electrophoresis	
Viscosity	S	1.4–1.8 relative viscosity units, as compared	1.4–1.8 relative viscosity units, as compared with water	Ostwald viscosimetry with water	1

Hematology and Coagulation

Analyte	Specimen	MGH Unit	SI Unit	Method or Instrument	Factor for Conversion to SI Unit
Activated protein C resistance	P	Ratio >2.0	Not applicable	Automated clotting assay	

(factor V Leiden)					
Alpha ₂ -antiplasmin	P	80%–130%	0.80–1.30	Chromogenic assay	0.01
Antiphospholipid-antibody panel					
Partial-thromboplastin time–lupus anticoagulant screen	P	Negative	Negative	Dilute phospholipid clotting assay	
Platelet-neutralization procedure	P	Negative	Negative	Clotting assay	
Anticardiolipin antibody	S				
IgG		0–15 GPL units	0–15 arbitrary units	ELISA	1
IgM		0–15 MPL units	0–15 arbitrary units	ELISA	1
Antithrombin III	P				
Immunologic		22–39 mg/dL	220–390 mg/L	Immunoassay	10
Functional		80%–130%	0.8–1.30 U/L	Chromogenic assay	0.01
Anti-Xa assay (heparin assay)	P			Chromogenic assay	
Unfractionated heparin		0.3–0.7 IU/mL	0.3–0.7 kIU/L		1
Low-molecular-weight heparin		0.5–1.0 IU/mL	0.5–1.0 kIU/L		1
Danaparoid		0.5–0.8 IU/mL	0.5–0.8 kIU/L		1
Bleeding time (adult)		2.0–9.5 min	2.0–9.5 min	Surgicutt	1
Clot retraction	WB	50%–100%/2 h	0.50–1.00/2 h	Manual method	0.01
D-Dimer	P	<0.5 µg/mL	<0.5 mg/L	Latex agglutination	1
Differential blood count	WB			Automated cell counter or manual method	
Neutrophils		45%–75%	0.45–0.75		0.01
Bands		0%–5%	0.0–0.05		0.01
Lymphocytes		16%–46%	0.16–0.46		0.01
Monocytes		4%–11%	0.04–0.11		0.01
Eosinophils		0%–8%	0.0–0.8		0.01
Basophils		0%–3%	0.0–0.03		0.01
Erythrocyte count (adult)	WB			Automated cell counter	
Male		4.50–5.30×10 ⁶ /µL	4.50–5.30×10 ¹² /L		1×10 ⁶
Female		4.10–5.10×10 ⁶ /µL	4.10–5.10×10 ¹² /L		1×10 ⁶
Erythrocyte sedimentation rate	WB			Automated erythrocyte sedimentation rate instrument	
Female		1–25 mm/h	1–25 mm/h		
Male		0–17 mm/h	0.17 mm/h		
Factor II, prothrombin	P	60%–140%	0.60–1.40	Automated clotting assay	0.01
Factor V	P	60%–140%	0.60–1.40	Automated clotting assay	0.01
Factor VII	P	60%–140%	0.60–1.40	Automated clotting assay	0.01
Factor VIII	P	50%–200%	0.50–2.00	Automated clotting assay	0.01
Factor IX	P	60%–140%	0.60–1.40	Automated clotting assay	0.01
Factor X	P	60%–140%	0.60–1.40	Automated clotting assay	0.01
Factor XI	P	60%–140%	0.60–1.40	Automated clotting assay	0.01
Factor XII	P	60%–140%	0.60–1.40	Automated clotting assay	0.01
Factor XIII screen	P	No deficiency detected	Not applicable	Urea clot dissolution	
Factor-inhibitor assay	P	<0.5 Bethesda unit	<0.5 Bethesda unit	Automated clotting assay	1
Ferritin	S			Immunoassay	1
Male		30–300 ng/mL	30–300 µg/L		
Female		10–200 ng/mL	10–200 µg/L		
Fibrin(ogen)-degradation products	P	<2.5 µg/mL	<2.5 mg/L	Latex agglutination	1
Fibrinogen	P	175–400 mg/dL	1.75–4.00 µmol/L	Automated clotting assay	0.01
Folate (folic acid)	S, P			Immunoassay	1
Normal		3.1–17.5 ng/mL	7.0–39.7 nmol/L		
Borderline deficient		2.2–3.0 ng/mL	5.0–6.8 nmol/L		
Deficient		<2.2 ng/mL	<5.0 nmol/L		
Excessive		>17.5 ng/mL	>39.7 nmol/L		
Glucose-6-phosphate dehydrogenase (erythrocyte)	WB	No gross deficiency	Not applicable	Visual fluorescence screening	
Hematocrit (adult)	WB			Automated cell counter	
Male		37.0–49.0	0.37–0.49		0.01
Female		36.0–46.0	0.36–0.46		0.01
Hemoglobin (adult)	WB			Automated cell counter	0.6206
Male		13.0–18.0 g/dL	8.1–11.2 mmol/L		
Female		12.0–16.0 g/dL	7.4–9.9 mmol/L		
Hemoglobin A ₂	WB	<3.5%	<0.04	Spectrophotometry	0.01
Hemoglobin F	WB	<0.02%	<0.0002	Spectrophotometry	0.01
Heparin-induced thrombocytopenia antibody	P	Negative	Negative	ELISA	
Iron	S	30–160 µg/dL	5.4–28.7 µmol/L	Colorimetry	0.1791
Iron-binding capacity	S	228–428 µg/dL	40.8–76.7 µmol/L	Colorimetry	0.1791
Leukocyte count (WBC)	WB	4.5–11.0×10 ³ /µL	4.5–11.0×10 ⁹ /L	Automated cell counter	1×10 ⁶
Mean corpuscular hemoglobin (MCH)	WB	25.0–35.0 pg/cell	25.0–35.0 pg/cell	Automated cell counter	1
Mean corpuscular hemoglobin concentration (MCHC)	WB	31.0–37.0 g/dL	310–370 g/L	Automated cell counter	10
Mean corpuscular volume (MCV) (adult)	WB			Automated cell counter	1
Male		78–100 µm ³	78–100 fl		
Female		78–102 µm ³	78–102 fl		
Osmotic fragility of erythrocytes	WB	Increased hemolysis as compared with normal control	Not applicable	Spectrophotometry	
Partial thromboplastin time, activated	P	22.1–34.1 s	22.1–34.1 s	Automated clotting assay	1
Plasminogen	P				
Antigen		8.4–14.0 mg/dL	84–140 mg/L	Immunoassay	10
Functional		80%–130%	0.80–1.30	Chromogenic assay	0.01
Platelet aggregation	PRP	>65% aggregation response to adenosine diphosphate, epinephrine, collagen, ristocetin, and arachidonic acid	Not applicable	Platelet aggregometry	
Platelet count	WB	150–350×10 ³ /µL	150–350×10 ⁹ /L	Automated cell counter	1×10 ⁴
Platelet, mean volume	WB	6.4–11.0 µm ³	6.4–11.0 fl	Automated cell counter	1
Prekallikrein assay	P	60%–140%	0.60–1.40	Chromogenic assay	0.01
Prekallikrein screen	P	No deficiency detected		Automated clotting assay	
Protein C	P				
Total antigen		70%–140%	0.70–1.40	Immunoassay	0.01
Functional		70%–140%	0.70–1.40	Chromogenic assay	0.01
Protein S	P				
Total antigen		70%–140%	0.70–1.40	Immunoassay	0.01
Functional		70%–140%	0.70–1.40	Automated clotting assay	0.01
Free antigen		70%–140%	0.70–1.40	Immunoassay	0.01
Prothrombin time	P	11.2–13.2 s	11.2–13.2 s	Automated clotting assay	1
Red-cell distribution width	WB	11.5%–14.5%	0.115–0.145	Automated cell counter	0.01
Reptilase time	P	16–24 s	16–24 s	Automated clotting assay	1
Reticulocyte count	WB	0.5%–2.5% red cells	0.005–0.025 red cells	Flow cytometry	0.01
Ristocetin cofactor (functional von Willebrand factor)	P				
Blood group O		75% mean of normal	0.75 mean of normal		
Blood group A		105% mean of normal	1.05 mean of normal		
Blood group B		115% mean of normal	1.15 mean of normal		
Blood group AB		125% mean of normal	1.25 mean of normal		
Sucrose hemolysis	WB	<10%	<0.1	Spectrophotometry	0.01
Thrombin time	P	16–24 s	16–24 s	Automated clotting assay	1
Total eosinophils	WB	70–440/µL	70–440×10 ⁶ /L	Automated cell counter	1×10 ³
Vitamin B ₁₂	S, P			Immunoassay	0.7378
Normal		>250 pg/mL	>184 pmol/L		
Borderline		125–250 pg/mL	92–184 pmol/L		
Deficient		<125 pg/mL	<92 pmol/L		

von Willebrand factor (vWF) antigen (factor VII:R antigen)	P			Immunoassay	
Blood group O	75% mean of normal	0.75 mean of normal			0.01
Blood group A	105% mean of normal	1.05 mean of normal			0.01
Blood group B	115% mean of normal	1.15 mean of normal			0.01
Blood group AB	125% mean of normal	1.25 mean of normal			0.01
von Willebrand factor multimers	P	Normal distribution	Normal distribution	Western blot assay	

Microbiology

Culture Specimen	Routinely Cultured for	Also Reported	Normal Flora
Throat	Group A beta-hemolytic streptococci, pyogenic groups C and G beta-hemolytic streptococci, <i>Arcanobacterium haemolyticum</i>	If a complete throat culture is requested, it will be examined for <i>Haemophilus influenzae</i> , <i>Staphylococcus aureus</i> , <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> , and yeast	Alpha-hemolytic streptococci, nonhemolytic streptococci, diphtheroids, coagulase-negative staphylococci, saprophytic neisseria
Sputum	Pneumococci, <i>H. influenzae</i> , beta-hemolytic streptococci, <i>S. aureus</i> , <i>Moraxella (Branhamella) catarrhalis</i> , pseudomonas, Enterobacteriaceae, yeast	Presence or absence of normal throat flora	Carefully collected specimens should contain few or no normal throat flora
Urine	Aerobic bacteria and yeast: abundant, >10 ⁵ colony-forming units/mL; moderate, 10 ⁴ –10 ⁵ colony-forming units/mL	Few, 10 ³ –10 ⁴ colony-forming units/mL; rare, 10 ² –10 ³ colony-forming units/mL; no growth, <10 ² colony-forming units/mL; these amounts may indicate clinically significant bacteriuria if accompanied by pyuria, clinical symptoms, or both	Carefully collected specimens should not contain mixed bacterial species (i.e., two or more of the following: lactobacilli, non-beta-hemolytic streptococci, diphtheroids, coagulase-negative staphylococci, <i>Gardnerella vaginalis</i>)
Blood	Aerobic and anaerobic bacteria, yeasts	Growth in both bottles is usually more clinically significant than growth in a single bottle	None; aerobic and anaerobic diphtheroids and coagulase-negative staphylococci are common contaminants
Cerebrospinal and other fluids	Aerobic and anaerobic bacteria; yeasts, including cryptococcus	Any organism isolated	None
Feces	Enteric pathogens: salmonella, shigella, campylobacter, plesiomonas, and acromonas when predominant	Moderate or abundant yeast or <i>S. aureus</i> ; presence or absence of normal gram-negative enteric flora; special cultures can be specifically requested for yersinia, <i>Vibrio cholerae</i> , <i>V. parahaemolyticus</i> , or hemorrhagic (O157) strains of <i>Escherichia coli</i>	Enterobacteriaceae, streptococci, pseudomonas, small numbers of staphylococci, and yeast (and anaerobes that are not cultured routinely)
Wounds	Aerobic and anaerobic bacteria, yeast		
Cervical or vaginal	Gonococci, beta-hemolytic streptococci, <i>S. aureus</i> , and <i>G. vaginalis</i> when predominant	Enteric gram-negative rods and candida, if present in large numbers	

P, plasma; S, serum; U, urine; WB, whole blood; CSF, cerebrospinal fluid; JF, joint fluid; PRP, platelet-rich plasma; ELISA, enzyme-linked immunosorbent assay; GPL, IgG phospholipid; MPL, IgM phospholipid.

Blood pressure cuff	Newborn/infant	Infant/child	Child	Child	Child	Child/adult	Adult	

Directions

1. Measure patient length with centimeter tape.
 2. Using measured length in centimeters, access appropriate equipment column.
- Alternatively, this same information can be accessed from a single measurement directly from a Broselow tape. Modified from Luten RC, Wears RL, Broselow J, et al. Length-based endotracheal tube sizing for pediatric resuscitation. *Ann Emerg Med* 1995;21:900–904.
