Ischemic strokes have traditionally been classified by clinical presentation, time course of onset, progression of deficits, accompanying symptoms, and risk factor profiles. The clinical description of the deficit identifies the extent and location of the stroke and allows accurate communication regarding patient status. The time course and progression of symptoms suggest certain etiologies; for example, prolonged, “stuttering” deficits indicate a thrombotic phenomenon, while an abrupt onset of the maximal deficit suggests an embolic event. Associated symptoms reveal other causes of neurologic deficits (e.g., a seizure preceding a Todd's paralysis or a migraine headache preceding an ischemic stroke of vascular origin). Consideration of cerebrovascular risk factors helps to classify the stroke as lacunar, embolic, thrombotic, extracranial, or intracranial.

Pathologically, ischemic strokes are divided into *blanca* and *hemorrhagic* infarcts. A bland infarct is a pale region, caused by an occluding thrombus, with red blood cells found only at the periphery. Hemorrhagic infarcts are thought to occur after fragmentation of an occluding embolus and show large numbers of red blood cells in the infarcted area secondary to reperfusion of the injured arterial bed. This is consistent with data indicating a higher frequency of hemorrhagic transformation among cardioembolic strokes. The absolute level and rate of change of arterial blood pressure also plays an important role in this “hemorrhagic transformation.” The timing of hemorrhagic transformation is variable, occurring hours to weeks after symptom onset. The clinical effects are also variable, ranging from asymptomatic to catastrophic. Hemorrhagic transformation should be considered in any patient who experiences an abrupt decrease in neurologic function after a stroke.

CLINICAL PRESENTATION

Anterior Cerebral Artery Syndrome

Patients with infarction in the territory of the anterior cerebral artery present with hemiparesis involving the leg more than the face or arm. Urinary incontinence and primitive reflexes (grasp and suck) are often present. The patient may perseverate with speech or motor movements and respond slowly to questions. If both anterior cerebral arteries originate from a common trunk, a bilateral parasagittal infarct may occur, with paraplegia and speechlessness (anarthria).

Middle Cerebral Artery Syndrome

Infarction in the distribution of the middle cerebral artery is the most common of the stroke syndromes. Patients with infarcts of the middle cerebral artery present with weakness of the face and arm greater than that of the leg, often with corresponding cortical sensory loss. The presence of aphasia localizes the lesion to the dominant hemisphere. Inattention, extinction on double simultaneous sensory or visual testing, neglect, or constructional or dressing apraxia indicates nondominant hemisphere involvement. Homonymous hemianopia and conjugate eye deviation toward the side of the infarct may also be found. All of these findings are present in the patient with a proximal trunk occlusion and variably present when branches of the middle cerebral artery are involved.

Posterior Cerebral Artery Syndrome

Infarcts in this territory present with homonymous hemianopia secondary to visual cortex involvement. The patient is often unaware of the deficit until formally tested. Motor involvement is minimal, but sensory loss, including both light touch and pinprick, may be severe. There is no aphasia or disruption of nondominant hemisphere functions. Small branches of the posterior cerebral artery anastomose with branches of the anterior and middle cerebral arteries in border zones between the arterial distributions. These areas are at risk for *watershed infarcts* during periods of decreased blood flow.

Vertebrobasilar Artery Syndrome

The classic sign of brainstem stroke is the presence of crossed symptoms: ipsilateral cranial nerve palsy and contralateral hemiplegia. One of the most common strokes in this region is due to occlusion of the vertebral or posterior inferior cerebellar artery, resulting in the *lateral medullary (Wallenberg) syndrome*. Patients may present with ipsilateral facial pain (described as a sharp or stabbing sensation to the face or eye), vertigo, headache, limb ataxia, Horner syndrome, and weakness of the soft palate, with dysphagia and dysphonia. Contralateral symptoms include loss of pinprick and temperature sensation in the arm and leg. Other brainstem syndromes may result in deafness, nausea, vomiting, vertigo, and diplopia.

Cerebellar Infarction

A subset of posterior circulation strokes are those that involve the cerebellum. The most common initial symptom is the sudden inability to walk or stand. This may be followed by complaints of headache, nausea, vomiting, central vertigo, and, possibly, a stiff neck. Cranial nerve findings may also be present. Although the initial CT scan is often unremarkable, one-third of patients develop significant posterior fossa edema. In this confined space, edema produces pressure on the brainstem, causing a decrease in the level of consciousness, typically after a stable period of 6 to 12 hours. Pathologic respiratory patterns and pupillary dilation are late findings, indicating impending herniation. Recognition of cerebellar infarction is critical, and frequent neurologic assessment imperative. Repeat CT scanning or MRI is indicated for patients with a declining level of consciousness. Surgical decompression or the use of diuretics and corticosteroids to prevent edema may be lifesaving.

Lacunar Syndromes

Lacunar infarcts cause several distinct stroke syndromes. Lacunes are found almost exclusively in the basal ganglia, internal capsule, thalamus, and brainstem and are associated with hypertensive arteriopathy. Approximately 20% of patients with lacunar infarctions have had a prior TIA, and the onset of symptoms is often surprisingly gradual (over 36 hours in up to 30% of patients). Deficits often improve with time, and treatment is aimed at control of hypertension after the acute episode resolves. An evaluation for embolic sources should also be undertaken. Lacunar strokes are classified by clinical presentation.

The most frequent lacunar syndrome, *pure motor stroke*, causes paresis or plegia of the face, arm, and leg. It is easily diagnosed when the deficit involves all three areas equally, but may also present as a partial deficit. The location of the lacune may be in the internal capsule or pons. Cortical sensory deficits are notably absent.

Pure sensory stroke is the result of infarction of the ventral posterior nuclei of the thalamus and results in sensory loss in the face, arm, and leg. The patient may also complain of paresthesias involving the affected side. There is no hemiplegia or other cortical signs.

Patients with *clumsy hand–dysarthria syndrome* present with slurred speech and weakness and ataxia of the upper limb. Facial weakness may also be present. The syndrome is most commonly associated with lesions of the anterior limb and genu of the internal capsule and typically has a good functional outcome.

DIFFERENTIAL DIAGNOSIS

[Table 203.1](#) lists conditions that may mimic ischemic stroke and is divided into structural and nonstructural diseases. CT scanning is used initially to evaluate these possibilities and to rule out structural causes of neurologic deficits.

A nonenhanced CT scan of the head should be obtained in all patients to identify intracranial hemorrhage and to rule out other causes for neurologic deficits. An ischemic stroke does not become hypodense for 6 to 72 hours after vessel occlusion and is often not visible on initial CT evaluation. If CT scanning is unavailable, the patient should be stabilized and transferred as rapidly as possible to a facility with CT capability.

MRI, carotid ultrasonography, echocardiography, and angiography have limited roles in the acute evaluation of most patients with ischemic stroke and are utilized in selected cases after hospital admission. An exception is the patient with a possible vertebrobasilar or carotid artery dissection. These patients should be considered for emergent ultrasound, angiography, or MR angiogram (MRA), because dissection is commonly treated with anticoagulation.

Advances in the evaluation of acute ischemic stroke continue. As MRI becomes faster and more available, it may become the diagnostic test of choice, allowing earlier assessment of the size of infarction and measurement of tissue perfusion and metabolism. Xenon CT now allows identification of regional cerebral blood flow. Transcranial Doppler can noninvasively identify occlusion of the middle cerebral artery. These may prove useful in the future in selecting patients for thrombolytic therapy.

EMERGENCY DEPARTMENT MANAGEMENT

The goal of acute stroke management in appropriate patients who present within 3 hours of symptom onset is the reversal of clinical deficits by reestablishing cerebral blood flow with intravenous thrombolytic agents. In patients presenting beyond 3 hours, there is no intervention that has proven effective in reducing infarct size; the objective of treatment is to limit infarct progression and recurrence. Current approaches to preventing or minimizing infarct progression include maintenance of adequate cardiac output to preserve cerebral blood flow, regulation of core temperature, and control of the blood glucose level. Strategies to prevent infarct recurrence focus on anticoagulation and antiplatelet therapy.

Thrombolytic Therapy

Current recommendations by the American Heart Association and American Academy of Neurology support the use of recombinant tissue plasminogen activator (r-TPA) in carefully selected patients when the diagnosis has been established by physicians with expertise in stroke and the cranial CT has been interpreted by a qualified individual. These recommendations followed Food and Drug Administration approval for use of r-TPA in acute ischemic stroke and are based primarily on the results of the NIH/NINDS Stroke Study, Parts I and II. These trials found that stroke patients treated with r-TPA were at least 30% more likely to have minimal or no disability 3 months after the event, compared with those who received placebo (absolute increase in favorable outcome, 11% to 13%). Though treated patients had a symptomatic hemorrhage rate of 6.4% (vs. 0.6% for placebo), there was no significant difference in mortality at 3 months (17% r-TPA, 21% placebo).¹⁷ Post-hoc analyses do not support withholding therapy from any patient on the basis of suspected stroke subtype, age, clinical deficit, or CT findings of early ischemic changes.

Concern has been raised regarding the fact that only the NINDS trials have shown benefit, while four other trials (ASK, MAST-E, MAST-I, and ECASS) found either no benefit or they found potential harm. It should be noted that there were many fundamental differences between the NINDS trials and the other studies, which make direct comparison problematic. These differences include thrombolytic agent used, dose, time-to-treatment, blood pressure management, and number of protocol violations. Two subsequent trials (ECASS II and ATLANTIS) specifically evaluated the use of intravenous r-TPA beyond 3 hours and found no benefit.

Other concerns address the reproducibility of the results in the community setting. Ten postapproval studies involving more than 500 r-TPA-treated patients have all found results similar to those of the NINDS trials. One of these studies involved patients treated by emergency physicians at hospitals using standardized treatment protocols.²¹

The development of treatment guidelines for stroke may improve patient selection and speed the delivery of thrombolytics to appropriate patients. The National Institutes of Health recommends that stroke patients undergo evaluation by a physician within 10 minutes of emergency department arrival, CT within 25 minutes, and CT interpretation by 45 minutes. Total “door-to-needle” time for patients meeting appropriate inclusion criteria, and no exclusion criteria, should not exceed 60 minutes.

Table 203.3 outlines inclusion and exclusion criteria for the use of r-TPA in acute stroke. Eligible patients should be treated with 0.9 mg/kg of r-TPA (maximum dose, 90 mg), with 10% given as a bolus over 1 to 2 minutes, and the remainder given over 60 minutes via infusion pump. Table 203.4 presents pre- and posttreatment blood pressure control guidelines. An algorithm for the management of suspected intracranial hemorrhage secondary to thrombolytic therapy is shown in Fig. 203.1.

TABLE 203.3. TPA in Ischemic Stroke: Inclusion and Exclusion Criteria^{1,17,18,20}

Pre-treatment
A. Monitor blood pressure (BP) every 15 minutes.
B. If systolic BP is > 185 mm Hg or diastolic BP is > 110, the BP may be treated with one to two 10- to 20-mg doses of labetalol given i.v. push within 1 hour and/or nitroglycerin push.
C. If these measures do not reduce the BP below 185/110 and keep it down, the patient should not be treated with TPA.
Post-treatment
A. If systolic BP is 160 to 230 mm Hg or if diastolic BP is 95 to 120 on two or more readings 5 to 10 minutes apart:
1. Give labetalol 10 mg i.v. over 1 to 2 minutes. The dose may be repeated or doubled every 10 to 30 minutes, up to 150 mg.
2. Monitor BP every 15 minutes during labetalol treatment and observe for development of hypotension.
B. If systolic BP is > 230 mm Hg or if diastolic BP is in the range of 121 to 140 mm Hg for two or more readings 5 to 10 minutes apart:
1. Give labetalol 10 mg i.v. over 1 to 2 minutes. The dose may be repeated or doubled every 10 to 30 minutes, up to 150 mg.
2. Monitor BP every 15 minutes during labetalol treatment and observe for development of hypotension.
3. If unsatisfactory response, infuse sodium nitroprusside (0.5 to 1.0 µg/kg/min). Continuous arterial monitoring is advised if sodium nitroprusside is used.
C. If diastolic BP is > 140 mm Hg for two or more readings 5 to 10 minutes apart:
1. Infuse sodium nitroprusside (0.5 to 1.0 µg/kg/min).
2. Continuous arterial monitoring is advised if sodium nitroprusside is used.

TABLE 203.4. Blood Pressure Management in Acute Stroke¹⁸

mechanisms. Neuronal protective agents are aimed at attenuating the biochemical cascade of events leading to cellular death after hypoxic insult. Drugs presently under investigation include excitatory neurotransmitter antagonists and inhibitors of local inflammatory responses. The use of a glycoprotein IIb/IIIa platelet inhibitor in acute stroke was found to be safe in a phase II dose escalation trial and may offer the potential for use alone or in combination with thrombolytic therapy. New thrombolytic agents with higher clot specificity are undergoing testing. A trial of the antifibrinolytic agent Ancrod recently reported positive outcomes when used in stroke patients treated within 3 hours.^{8a,22} A trial on the delivery of intraarterial prourokinase also reported improved outcomes in patients with proximal middle cerebral artery occlusions in patients treated out to 6 hours.^{8a}

DISPOSITION

Factors influencing disposition in the patient with ischemic stroke include infarct location, time of symptom onset, infarct size, stroke etiology, concurrent medical conditions, and social resources available to the patient. The vast majority of stroke patients are admitted to the hospital, often to a specialized unit or floor skilled in the care of patients with neurologic deficits. Cardiac monitoring should be arranged for those with potential dysrhythmias either as an etiology or as a consequence of the infarct.

Patients with minor, completed strokes are potential candidates for evaluation in an emergency department clinical decision unit. Predefined protocols for neurologic consultation, subsequent neurologic and vascular imaging, and initiation of therapy to prevent recurrent stroke in this setting speed patient care and reduce length of hospital stay.

Patients treated with r-TPA and those with impaired gag or swallowing reflexes or mental status changes should be admitted to the intensive care unit. Intensive care unit admission is also indicated for patients with cerebellar strokes and should be considered for patients with large hemispheric strokes who are at risk for the development of cerebral edema 24 to 48 hours after the event.

Stroke patients are often cared for in the inpatient setting without neurologic consultation. Neurologic consultation in the emergency department is indicated when the diagnosis is unclear or when further evaluation is required (e.g., arterial dissection, migrainous infarct, unusual hematologic conditions). Because anticoagulation is controversial, it is reasonable to consult a neurologist before initiating heparin, particularly in the patient with a progressing deficit. Patients with cerebellar infarction should have neurosurgical consultation, because decompressive craniectomy may be lifesaving in selected patients.

COMMON PITFALLS

- Failure to identify, evaluate, refer, and/or treat stroke patients who are eligible for thrombolytic therapy
- Failure to perform a complete history and physical examination, particularly in uncooperative elderly patients. The history and physical examination are the basis for determining the extent of a stroke and its etiology.
- Failure to consider unusual etiologies of stroke, such as arterial dissection and emboli in younger patients with new neurologic deficits
- Misdiagnosis of cerebellar stroke as alcohol or drug intoxication, labyrinthitis, benign positional vertigo, or severe gastroenteritis, and failure to obtain neurosurgical consultation
- Failure to optimize cardiac output and to treat temperature elevations in the emergency department
- Managing blood pressure too aggressively. Reduction of blood pressure may reduce cerebral blood flow and cause extension of an ischemic stroke.

HEMORRHAGIC CEREBROVASCULAR DISEASE

Intracerebral hemorrhage (ICH), defined as hemorrhage directly into the brain parenchyma, affects 10% to 15% of all stroke patients. Major risk factors for intracranial hemorrhage include advancing age, hypertension, and race. Blacks have a higher incidence of ICH than do Whites; Asians have an even higher incidence. Other risk factors include cigarette smoking and alcohol use.

The most common site for ICH is the putamen, which accounts for 35% to 50% of all hemorrhages. Next in frequency are the subcortical white matter (30%), the cerebellum (16%), the thalamus (10% to 15%), and the pons (5% to 12%).¹³ Pathologically, these are areas of the brain supplied by small arteries that are 50 to 200 μm in size.

CLINICAL PRESENTATION

The onset of ICH is usually heralded by a sudden headache, vomiting, and neurologic deficit. The majority of patients exhibit a decreased level of consciousness due to elevated intracranial pressure (ICP). ICH often occurs during activity and only rarely has its onset during sleep. In one-third of cases, clinical deficits are maximal at onset. In the remaining two-thirds, the symptoms follow a steadily progressive course over the first 30 minutes. Coma is a poor prognostic sign and is associated with larger hemorrhages and ventricular extension. Headache and vomiting are typically absent in ischemic strokes and thus are of help in identifying patients with ICH. Early seizures are uncommon in ICH involving the putamen, thalamus, and pons but may be present in up to one-third of patients with subcortical white matter ("lobar") hemorrhages. Hypertension is noted in over 90% of patients with ICH.

The clinical deficits are related to the location and size of the hemorrhage. Putaminal hemorrhages cause a dense contralateral hemiplegia with sensory loss and homonymous hemianopia. The eyes show conjugate deviation away from the paralyzed side, which may be overcome with caloric testing or doll's-eye reflex testing. Thalamic hemorrhages cause similar motor and sensory findings but may also cause conjugate downward gaze with pinpoint, unresponsive pupils. Deficits from a lobar hemorrhage depend on the size and location of the hemorrhage. Pontine hemorrhage typically causes a severe occipital headache, followed rapidly by a decreased level of consciousness; coma is present in 80% of patients. Patients may become hyperthermic and may have severe neurologic deficits. These include quadriplegia, loss of corneal reflexes, and pinpoint pupils with absent horizontal eye movements on caloric or doll's-eye reflex testing. Cerebellar hemorrhage causes extremity and truncal ataxia and an inability to walk. These symptoms are commonly accompanied by vomiting, dysequilibrium, and headache. An ipsilateral gaze palsy may also be present. Patients with cerebellar hemorrhage may initially appear stable but can deteriorate rapidly to coma and death.

DIFFERENTIAL DIAGNOSIS

The presence of intracerebral blood on head CT should not automatically be ascribed to a hypertensive hemorrhage. Various nonhypertensive causes of ICH include arteriovenous malformation, berry aneurysm, sympathomimetic drug use, intracranial tumor, anticoagulant and thrombolytic agent use, hematologic disorders (e.g., leukemia, thrombotic thrombocytopenic purpura, hemophilia), cerebral vasculitis, and mycotic aneurysm.

EMERGENCY DEPARTMENT EVALUATION

The evaluation of patients with suspected ICH is similar to that for ischemic stroke. However, patients with ICH may exhibit rapid neurologic deterioration and a decreased level of consciousness, necessitating acute airway intervention. Vital signs should be monitored closely, and frequent neurologic assessments are required. Laboratory data should be obtained to help identify possible contributing causes, such as coagulopathy, thrombocytopenia, or platelet dysfunction. Toxicologic screening is indicated for patients with atypical presentations and for younger patients without a history of hypertension. Cardiac monitoring is essential, because dysrhythmias are common from either increased sympathetic discharge or impending tonsillar or uncus herniation.

The CT scan typically shows high attenuation in the area of hemorrhage. There is usually a "ring" of low attenuation surrounding the hemorrhage because of edema of the adjacent tissue. Angiography and/or MRI/MRA should be considered when an aneurysm, arteriovenous malformation, or central nervous system tumor is strongly suspected.

EMERGENCY DEPARTMENT MANAGEMENT

The goals of emergency care for ICH are rapid diagnosis, management of the airway, control of ICP, and early neurosurgical consultation. Oxygen should be administered to all patients. Intubation is indicated for airway protection or hyperventilation to reduce ICP. Rapid-sequence intubation with paralytic agents may be

necessary to obtain adequate CT images in a combative patient.

Management of hypertension in the patient with ICH is directed at managing the competing interests of decreasing ongoing hemorrhage against overreduction of cerebral perfusion pressure. Current recommendations⁴ are to initiate treatment for systolic pressures greater than or equal to 180 mm Hg or diastolic pressures greater than or equal to 105 mm Hg and to maintain a mean arterial pressure below 130 mm Hg in persons with a history of hypertension. In patients with an ICP monitor, cerebral perfusion pressure (mean arterial pressure – ICP) should be kept above 70 mm Hg. Useful antihypertensive agents in the setting of ICH include nitroprusside, esmolol, and labetalol.

ICP control is important in the patient with ICH. Acute elevations in ICP, as manifested by decreasing level of consciousness and neurologic deterioration due to mass effect, are initially managed with elevation of the head (30 degrees), osmotherapy, and hyperventilation. Although there is no universally accepted standard therapy for the management of ICH, current recommendations support the use of a stepwise approach⁴ beginning with mannitol (20% solution; 0.25 to 0.5 g/kg every 4 hours) in patients with progressively increasing ICP values or clinical deterioration. Furosemide (10 mg every 2 to 8 hours) may be administered simultaneously with osmotherapy.

Reduction of the pCO₂ to 30 to 35 mm Hg lowers ICP by 25% to 30% in most patients, though peak ICP reduction may be delayed up to 30 minutes after the pCO₂ is changed. Because hypocarbia causes cerebral vasoconstriction, overaggressive reduction in pCO₂ may reduce cerebral blood flow below critical values; this should thus be avoided.

In general, ICP monitoring is indicated in patients with a Glasgow Coma Scale score of less than 9 and in those whose condition is thought to be deteriorating due to increases in ICP. Other patients may warrant ICP monitors, however, particularly those with intraventricular hemorrhage.

Neurosurgical consultation should be obtained early, and, if unavailable, the patient should be stabilized and transferred. The indications for hematoma evacuation depend on many factors, including patient age, hemorrhage location, and surgical accessibility. Patients who present initially with coma or loss of brainstem function generally do not benefit from surgical evacuation, whereas those who experience progressive deterioration after a lobar hemorrhage are often operated on. In patients with cerebellar hemorrhage, surgery is recommended for all hematomas exceeding 3 cm in diameter. All patients with ICH should be admitted to a neurosurgical intensive care unit for close observation and monitoring.

COMMON PITFALLS

- Failure to diagnose cerebellar hemorrhage. Patients may be misdiagnosed with acute viral syndrome, labyrinthitis, or intoxication. Surgical intervention may be lifesaving.
- Delay in transport. Patients with ICH require early neurosurgical consultation and should be transported to an appropriate facility if immediate neurosurgical attention is not otherwise available.

Peripheral neuropathies are confusing entities for both neurologists and nonneurologists. The types and etiologies of peripheral neuropathy are numerous, and the pathophysiology is not well understood in many cases. Nevertheless, only 15% to 30% of patients undergoing intensive evaluation fail to have a diagnosis made. ^{2,5}

The peripheral nervous system begins within the spinal canal with the spinal nerve roots and extends outward to include all distal nerve tissue. When faced with disorders of this system, emergency physicians should examine the chronicity, pattern, and symmetry of symptoms to establish a working differential diagnosis. ^{1,2,5} In general, peripheral neuropathies can be divided into several basic categories: polyneuropathy, plexopathy, radiculopathy, and mononeuropathy.

POLYNEUROPATHY

Polyneuropathy results from the simultaneous dysfunction of multiple peripheral nerves. Symptoms include diffuse motor or sensory loss or both, with variable autonomic nervous system dysfunction.

Acute Polyneuropathy

CLINICAL PRESENTATION

Polyneuropathies that develop over several days to 2 weeks are considered acute. Of these, Guillain-Barré syndrome (GBS), also known as acute inflammatory demyelinating polyradiculoneuropathy, is the most common. ^{7,9,15,17} GBS is a worldwide, nonseasonal, acute polyneuropathy that affects all ages, with a yearly incidence of 0.6 to 2.4 cases per 100,000 population. ¹⁷ Men are affected slightly more than women by a ratio of 1.25 to 1.5:1. ^{7,9,15,17} The exact etiology is unclear, but pathologic examination reveals inflammation and segmental demyelination as the primary defect in 85% of cases, while primary axonal degeneration occurs in 15% of cases. ⁹

Classically, patients experience a prodromal event such as upper respiratory tract infection, gastroenteritis (especially due to *Campylobacter jejuni*, which is the most commonly identified pathogen associated with GBS ^{9,10}), surgery, vaccination, or infection with agents such as *Mycoplasma*, the herpesviruses, and the human immunodeficiency virus (HIV). This is followed in 1 to 3 weeks by the onset of a symmetric ascending motor paralysis that progresses to its peak over 10 to 14 days. Motor weakness is both proximal and distal, with legs being involved prior to the arms and trunk. Additional findings include hyporeflexia or areflexia within 1 week of symptom onset, distal paresthesias and numbness, minimal sensory losses, cranial nerve palsies, and autonomic dysfunction. Bowel and bladder disturbances are uncommon (15%) and brief in duration. ¹ Patients are afebrile and mental status is unaffected. It is not unusual for patients to present with low-back, hip, and thigh pain that is confused with disc disease or lumbar strain.

Several atypical presentations or variants of GBS are described. In pure motor GBS, there are no sensory losses or paresthesias. ^{9,18} Pure sensory GBS involves ascending sensory loss and areflexia without motor weakness. ^{15,18} The Miller Fisher variant of GBS consists of ophthalmoplegia, ataxia, and areflexia. ^{9,15,18} A regional variant, pharyngeal-cervical-brachial GBS, presents with motor weakness limited to the neck, pharynx, shoulders, upper arms, and diaphragm; in the paraparetic GBS variant, motor weakness is limited to the legs. ¹⁸ In the pure pandysautonomia variant, autonomic dysfunction and areflexia occur without motor or sensory loss. ^{15,18}

The various presentations and variants of GBS make diagnosis difficult. However, marked or persistent asymmetry of weakness, lack of facial and respiratory muscle weakness in a patient with generalized paralysis, prolonged incontinence, a sharp sensory level, or fever strongly suggests another diagnosis. ^{1,17}

DIFFERENTIAL DIAGNOSIS

Poliomyelitis

In the United States, nearly all cases of polio are related to the use of the live attenuated oral vaccine. Patients with polio first develop an acute viral illness with fever, headache, meningeal signs, and muscle pain and tenderness. These symptoms are present 1 to 2 days before weakness develops. Polio paralysis is more proximal than distal; legs are involved more than arms; and, classically, involvement is asymmetric. Sensory loss is extremely rare, and its presence should raise the suspicion of other diagnoses, especially GBS. The most serious complication of polio is respiratory muscle paralysis. Progression of paralysis abates when patients become afebrile. ¹²

Tick Paralysis

Tick paralysis typically affects children in the spring and summer months. Symptoms, which are nearly identical to those of GBS, result from a toxin that is present in the saliva of ticks (usually *Dermacentor*) that have been attached to the human host for a period of 5 to 7 days. The diagnosis is made when the offending tick is located, and treatment consists of removal of the tick and supportive care. Symptoms begin to improve within hours of removal, and generally resolve completely within 2 to 3 days. One tick species found only in Australia, *Ixodes holocyclus*, is associated with paralysis that can progress despite tick removal. For this species, a hyperimmune serum has been developed.^{8,12}

Botulism

Exposure to botulinum toxin, which inhibits the release of acetylcholine at neuromuscular junctions, results from the ingestion of improperly canned foods or raw honey or, rarely, from cutaneous infection with *Clostridium botulinum*. Initial symptoms begin hours to several days after exposure and include nausea, vomiting, and dry mouth in patients who have ingested the toxin. Neurologic symptoms begin with cranial nerve palsies with prominent ocular findings, followed by symmetric, descending motor weakness. Sensation and mental status are not affected. Fever is absent. Treatment consists of antitoxin therapy (available through the Centers for Disease Control [CDC]) and supportive care, including respiratory support as necessary.¹²

Acute Intermittent Porphyria

In this disorder, stimulation of an enzymatically deficient heme synthesis pathway results in the buildup of neurotoxic precursors. Acute attacks classically begin with severe abdominal pain, which is followed by tachycardia, hypertension, and mental status changes. Seizures may occur. A sensorimotor polyneuropathy that can be symmetric or asymmetric, and ascending or descending, may develop and can progress to respiratory failure and death. Treatment consists of intravenous glucose and hematin to shut down the defective pathway, beta blockers to control hypertension, and supportive care.^{1,3,5}

Heavy Metals

Most neuropathies due to heavy-metal poisoning are subacute or chronic. Acute presentations are associated with thallium exposure and massive arsenic exposure. Thallium ingestion produces abdominal pain, vomiting, and diarrhea, followed by painful paresthesias and the rapid onset of diffuse motor weakness. Differentiation from GBS is often made 1 to 2 weeks after the onset of symptoms, when thallium-induced alopecia becomes apparent. Acute arsenic polyneuropathy, which is also clinically similar to GBS, begins 8 to 20 days after a large exposure and is associated with gastrointestinal symptoms, renal failure, hepatic failure, and mental status changes.¹

Diphtheria

Diphtheria begins as a pharyngeal infection caused by an exotoxin-producing *Corynebacterium diphtheriae*. Subsequent toxicity, both cardiac and neurologic, correlates with the severity of the pharyngeal disease. Paralysis of local pharyngeal muscles, followed by cranial nerve palsies, occurs in the first or second week of infection. Cardiac toxicity begins 1 to 2 weeks after the onset of illness. The polyneuropathy, which is mainly motor, does not develop until 5 to 8 weeks after onset. Weakness may begin in all extremities simultaneously, or it may first appear in proximal muscles and then spread distally. Occasionally, the primary site of infection is a skin wound, in which case sensorimotor changes are first noted near the infected wound. Treatment of diphtheria involves use of antitoxin within the first 48 hours of infection. Treatment of the neuropathy consists of supportive care.¹²

Others

Acute polyneuropathy may also be a complication of collagen vascular disease, uremia and dialysis, malignancy, critical illness, nutritional deficiencies, infectious agents, or a host of toxins and drugs. Myasthenia gravis, transverse myelitis, lumbar disc disease, spinal cord compression, and acute myopathy are other neuromuscular disorders that can present with weakness that must be differentiated from GBS. Weakness produced by metabolic disorders such as acute hypophosphatemia, hypermagnesemia, hyperkalemia, hypokalemia, and periodic paralysis may mimic GBS. Finally, hysteria and malingering should also be considered.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Patients presenting with the acute onset of weakness warrant rapid assessment of airway, ventilatory capacity, and cardiovascular status. Following stabilization, history and physical examination, including a detailed neurologic examination, are the principal methods of emergency department diagnosis of GBS. The emergency physician should obtain a complete blood count, serum electrolytes, calcium, magnesium, phosphate, glucose, blood urea nitrogen, creatinine, erythrocyte sedimentation rate, chest radiograph, and electrocardiogram on all patients.

Additional studies may be needed to rule out other causes of acute weakness; they include antinuclear antibodies, rheumatoid factor, thyroid function tests, liver function tests, creatinine phosphokinase, serum and urine protein electrophoresis, cryoglobulins, vitamin B12, heavy-metal screens, urinary porphobilinogens, and serologic tests for HIV, Lyme disease, and Epstein-Barr virus (EBV).^{2,3,4} and ^{5,13,15} Some of these studies might be obtained by the emergency physician if clinical evaluation raises the suspicion of a specific disease process. Otherwise, additional testing should be left to the consulting neurologist following characterization of the neuropathy by nerve conduction studies and electromyography.

Patients suspected of having GBS should undergo lumbar puncture, even though cerebrospinal fluid changes may be delayed 1 to 2 weeks after the onset of symptoms. The characteristic findings are normal pressure and albuminocytologic dissociation (elevated protein level with fewer than 10 mononuclear cells/ μ L). An increased cell count should raise the suspicion for HIV or Lyme disease as the precipitating event.^{3,13,15,17}

Baseline measurements of pulmonary function are important, because 25% to 33% of patients with GBS eventually require mechanical ventilation.^{10,15} Forced vital capacity (FVC) or inspiratory force (IF) should be tested in the emergency department. The hospital respiratory therapist may be able to provide the appropriate portable devices if they are not available in the department. A quick bedside test is to have the patient take a deep inspiration and then count as long as possible; the ability to count to 25 correlates with an FVC of 2 L, and a count to only 10 with an FVC of 1 L.¹⁵ FVC of less than 12 to 15 mL/kg or an IF of less than 20 cm H₂O are indications of impending respiratory failure and the need to initiate mechanical ventilation.^{3,7,15} Patients who remain in the emergency department for several hours should have serial pulmonary function testing. Bulbar muscle strength should also be followed, as intubation may be required to maintain a patent airway and prevent aspiration. Frequent vital signs and continuous cardiac monitoring are essential to identify autonomic dysfunction. Blood pressure fluctuations should be treated, as needed, with fluids and short-acting agents.

DISPOSITION

Every patient with an acute polyneuropathy should be evaluated by a neurologist. Admission to the hospital for further diagnostic studies and continued monitoring of vital signs and respiratory status is required. Whether an intensive care unit is necessary for all patients is controversial. Clearly, any patient with significant respiratory impairment (e.g., FVC less than 20 mL/kg,^{7,17} IF less than 25 cm H₂O,⁷ difficulty swallowing, etc.) or autonomic instability should be admitted to an intensive care unit. For all others, the decision depends on the adequacy of monitoring in other settings. Patients with severe or rapidly progressive GBS benefit from early plasma exchange or immune globulin therapy; therefore, these patients should be transferred to a facility capable of providing such therapies.^{1,7,17}

COMMON PITFALLS

- Mistaking the low back pain of GBS for disc disease or back strain
- Failing to admit patients with minimal, but suggestive, symptomatology
- Monitoring inadequately for respiratory and autonomic dysfunction

- Ascribing the symmetric weakness of GBS or other acute polyneuropathies to a psychiatric disorder
- Failure to recognize variant presentations of GBS

Subacute Polyneuropathy

Polyneuropathy that develops over a period of several weeks to months is said to be subacute; however, the distinction between subacute and acute polyneuropathy is not always clear. For example, while half of patients with GBS present with symptoms that develop over 10 to 14 days, in the other half, symptoms progress over 3 to 4 weeks.^{3,5} Subacute polyneuropathies may be symmetric or asymmetric. Symmetric disease generally begins with distal sensorimotor losses and tends to produce marked sensory impairment. Asymmetric neuropathies are frequently the result of neuronal ischemia; nerves are randomly affected, producing patchy sensorimotor losses.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of *symmetric* subacute polyneuropathy includes GBS, chronic inflammatory demyelinating polyneuropathy, diabetes mellitus, collagen vascular and autoimmune diseases, nutritional deficiencies, uremia, amyloidosis, heavy-metal intoxication, industrial solvents (e.g., glue sniffing), a multitude of toxins and medications, Lyme disease, and HIV infection.

The etiologies of *asymmetric* disease include diabetes mellitus (e.g., diabetic amyotrophy), collagen vascular and other autoimmune diseases, peripheral vascular disease, sarcoidosis, neoplastic disease, paraproteinemia, leprosy, Lyme disease, HIV infection, and idiopathic disease.

Other diseases that produce subacute weakness and may be confused with subacute polyneuropathy are myasthenia gravis, amyotrophic lateral sclerosis, Parkinson disease, and depression.

EMERGENCY DEPARTMENT EVALUATION, MANAGEMENT, AND DISPOSITION

History and physical examination are the principal methods of evaluation. Key historic elements to elicit are a history of neuromuscular or systemic disease, medications (prescription and nonprescription), and potential infectious or toxic exposure. Laboratory studies should include complete blood count, serum electrolytes, calcium, magnesium, phosphate, glucose, blood urea nitrogen, creatinine, and a screening chest radiograph. As with acute neuropathies, further studies should be obtained only if a specific etiology is suspected following evaluation of the patient.⁴

Most patients with subacute polyneuropathy may be referred to their primary care physician for outpatient evaluation and referral to a neurologist. If a medication is suspected as the etiology, it should be discontinued or changed after consultation with the primary care physician. Short-term follow-up should be arranged.

COMMON PITFALL

Assuming that subacute polyneuropathy is secondary to a chronic medical condition, thus overlooking potentially treatable causes

Chronic Polyneuropathy

Chronic polyneuropathy develops over months to years. Patients generally have marked sensory changes, but motor losses are prominent as well. Muscle wasting and foot deformities are clinical clues to a chronic neuropathy. The differential diagnosis is vast; it includes both acquired conditions and numerous hereditary disorders. Adults presenting for primary evaluation of a peripheral neuropathy that, by history and examination, appears to be chronic should be referred to their primary care physicians.

Plexopathy and Radiculopathy

CLINICAL PRESENTATION

A plexopathy is a disorder that affects the brachial or lumbosacral plexus. Symptoms include pain and mixed motor and sensory deficits in a pattern that cannot be attributed to individual peripheral nerves or nerve roots.

Acute or subacute plexopathies are associated with local trauma (e.g., shoulder dislocation), compression (e.g., retroperitoneal hematoma or abdominal aortic aneurysm), vascular disease (usually due to diabetes or collagen vascular disease), or infection (e.g., Lyme disease), or they may be idiopathic.¹⁶ Chronic plexopathy is associated with infections, vascular disease, collagen vascular disease, tumor, infiltrative processes, and radiation therapy.

Idiopathic lumbosacral plexopathy is rare,^{5,16} but acute idiopathic brachial plexopathy is well described. It is seen most commonly in men in the third or fourth decade of life,¹¹ and there appears to be some association with recent viral illnesses and immunizations.^{5,11} Symptoms begin with the sudden onset of severe shoulder pain that may extend into the neck and upper arm. Less commonly, the lower plexus cords may be affected, producing symptoms in the forearm and hand. Within days to weeks, motor weakness and sensory loss develop, usually coinciding with resolution of pain.^{5,11,16} About 90% of patients recover good neurologic function by 3 years.¹¹

In contrast to plexopathy, a radiculopathy affects spinal nerve roots. Symptoms include pain and sensorimotor deficits in a pattern consistent with the involved nerve root (e.g., lancinating pain along the L-5 nerve root dermatome). Frequently, several adjacent roots are affected, making differentiation from a plexopathy or multiple mononeuropathies clinically impossible. The etiologies of radiculopathy include all those of a plexopathy, as well as specific spinal canal or cord disorders such as herniated disc, spinal stenosis, and epidural tumor, abscess, hematoma, granuloma, and infection.^{1,6}

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of brachial plexopathy and lumbosacral plexopathy includes polyneuropathy, multiple mononeuropathies, and spinal cord and root disorders. Brachial plexopathy can easily be confused with C-5 root compression, and lumbosacral plexopathy with L-4 compression.⁶ The pain of idiopathic brachial plexopathy tends to resolve as motor symptoms develop, unlike the persistent pain of C-5 root compression.⁶ In addition, C-5 root pain increases with neck movement, coughing, and sneezing, while brachial plexopathy pain increases with shoulder movement.⁵ Pain from both lumbosacral plexopathy and L-4 root compression is persistent. Iliopsoas weakness is common in lumbosacral plexopathy but is not seen with L-4 root lesions.

Thoracic outlet syndrome (TOS) can mimic brachial plexopathy by producing pain and weakness in the arm. Provocative maneuvers suggestive of TOS include loss of the radial pulse and onset of symptoms when the patient inhales deeply and the shoulder is hyperabducted and externally rotated with the head turned to the unaffected side (Wright's maneuver) or the neck is extended with the head rotated to the affected side (Adson's test).¹⁴ Other local joint or tendon disorders, muscular disorders, and amyotrophic lateral sclerosis may also mimic plexopathy, but can usually be differentiated by their lack of sensory abnormalities.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The history and physical examination, including a detailed neurologic examination, are essential in management decisions. In patients with chronic symptoms, minimal immediate diagnostic workup is necessary. A chest and neck radiograph or lumbosacral films are reasonable screening tools for such patients.

Acute symptomatology, on the other hand, requires an aggressive approach. Patients with symptoms of *acute brachial plexopathy* should have cervical spine, chest, and shoulder radiographs.^{5,11} Laboratory studies such as complete blood cell count, serum electrolytes, glucose, blood urea nitrogen, creatinine, and sedimentation

rate may be considered if the history or physical examination suggests infection, diabetes, or collagen vascular disease.

Acute lumbosacral plexopathy generally occurs secondary to another disease process. A complete blood cell count, serum electrolytes, glucose, blood urea nitrogen, creatinine, erythrocyte sedimentation rate, and lumbosacral films are appropriate. An abdominal ultrasound or computed tomography is indicated if an aortic aneurysm or other retroperitoneal pathology (e.g., bleed, tumor) is suspected. A determination of postvoid residual urine volume will aid in defining the extent of the neurologic deficit.

The approach to an *acute radiculopathy* is dictated by the history and physical examination. An evaluation consistent with an acute herniated disc and no objective neurologic deficits may require only conservative management with analgesia, muscle relaxants, limited activity, and close follow-up. Most other etiologies require an aggressive evaluation, including blood testing, a determination of postvoid residual urine volume, and spinal imaging.

DISPOSITION

Acute symptoms resulting from plexopathies are often difficult to distinguish from root and spinal cord disorders.^{5,6} Therefore, both generally require urgent neurosurgical consultation. Spinal computed tomography, magnetic resonance imaging, or myelography may be required to determine the correct diagnosis, and hospital admission to complete such testing is recommended. Outpatient follow-up is appropriate for patients with chronic symptoms.

COMMON PITFALLS

- Attribution of symptoms to mononeuropathy, and thereby failing to proceed with the appropriate diagnostic evaluation required for plexopathies and radiculopathies
- Failure to consider potentially catastrophic etiologies for acute plexopathies (e.g., abdominal aneurysm)
- Failure to consider potentially catastrophic etiologies for acute radiculopathies (e.g., spinal epidural abscess or acute cord compression)

Mononeuropathy

CLINICAL PRESENTATION

Mononeuropathies produce variable symptoms of pain and sensorimotor loss in the distribution of a single peripheral nerve. The actual neuronal injury may be classified as neuropraxia (a “stunned” nerve with an intact, but nonconducting axon), axonotmesis (damaged axon in an intact nerve trunk), or neurotmesis (disrupted nerve trunk).^{11,14} The speed and degree of neurologic recovery are related to the type of injury present.

Nerve compression and entrapment are the most frequently encountered etiologies for mononeuropathies in the emergency department. Entrapment syndromes (e.g., carpal tunnel syndrome) have been associated with pregnancy, rheumatoid arthritis, osteoarthritis, gout, hypothyroidism, acromegaly, amyloidosis, multiple myeloma, collagen vascular disease, local tumors, and repetitive activity.^{1,5} Other causes of mononeuropathies are trauma (mechanical, electrical, or thermal), collagen vascular disease, diabetes mellitus, vascular disease, infection, granulomatous disease, infiltrative disorders, neoplasia, radiation therapy, and primary nerve tumors.

A unique form of mononeuropathy is mononeuritis multiplex. This entity involves the simultaneous or near-simultaneous dysfunction of two or more peripheral nerves. It may result from multiple pressure palsies, infections (e.g., leprosy, Lyme disease, HIV infection), infiltrative or neoplastic disease, vascular disease, or collagen vascular disease.⁵ The abrupt onset of mononeuritis multiplex in patients with a collagen vascular disease or other vasculitis is of specific concern, as it generally indicates an acute necrotizing vasculitis that requires aggressive treatment.¹

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a mononeuropathy includes radiculopathy, plexopathy, polyneuropathy, local joint or muscular disorders, hysteria, and malingering.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The evaluation of mononeuropathies should focus on identification of a specific etiology. Once the nature of the deficit and its mode of onset are reviewed, the history should elicit any traumatic injury, occupational factors (e.g., repetitive activity), or symptoms suggestive of diabetes or collagen vascular disease. The physical examination should include a detailed neurologic examination to determine whether the deficits fit the distribution of a single peripheral nerve. An excellent summary of peripheral nerve dermatomes can be found in Appendix A in *Disorders of Peripheral Nerves*, by Schaumburg et al.¹⁹ Evidence of systemic disease, trauma, and possible entrapment sites should be sought.

Complete blood cell count, electrolytes, blood glucose, erythrocyte sedimentation rate, antinuclear antibody testing, thyroid function tests, and serum protein electrophoresis are indicated only if a systemic disorder is suspected. Radiographs may be helpful in cases associated with trauma or when bone abnormalities are a possible cause of entrapment.

DISPOSITION

Most patients with a mononeuropathy can be discharged, with a splint, to outpatient follow-up. Identified etiologies, such as diabetes or repetitive activities, should be addressed, and patients in whom the etiology is unclear should be referred to their primary care physician or a neurologist for further testing, which may include nerve conduction studies and electromyography. Posttraumatic mononeuropathy should be evaluated urgently by a plastic surgeon, orthopedic surgeon, or neurosurgeon, although expectant management is generally the preferred approach to care.

Admission to the hospital is indicated for acute mononeuropathy multiplex in patients with known or suspected collagen vascular disease or vasculitis. As previously mentioned, this disorder usually indicates an acute necrotizing vasculitis, which requires aggressive steroid and/or other immunosuppressive therapy.¹

COMMON PITFALLS

- Failure to differentiate a mononeuropathy from a polyneuropathy, plexopathy, or radiculopathy
- Failure to detect systemic signs of collagen vascular disease or other vasculitis disorder in patients with mononeuropathy multiplex

[Chapter References](#)

Weakness is a commonly encountered symptom in patients presenting for emergency medical care, but only rarely is it due to a primary disorder of muscle or neuromuscular transmission. These primary disorders are not only uncommon, but also often subtle and variable in presentation and, therefore, easy to misdiagnose. Because these disorders may be serious and potentially life-threatening, they should always be included in the differential diagnosis of true weakness.

Once considered, the most important way to diagnose these neuromuscular disorders is an appropriately focused history and physical examination. Emergency physicians must also be knowledgeable about the diagnostic tests commonly used to help identify these disorders. ¹¹

Many neuromuscular disorders can present as rapidly progressive, generalized weakness that has the potential to cause life-threatening ventilatory compromise. When faced with a severely weak patient, the emergency physician must know how to intervene safely and rapidly while simultaneously considering the differential diagnosis and possible acute precipitants.

MYOPATHIES

Primary muscle disease presents with muscular weakness as the predominant symptom. Weakness is generally proximal and symmetric in distribution. Deep tendon reflexes are preserved, and there are no sensory complaints, distinguishing the myopathies from acute inflammatory polyneuropathy (Guillain-Barré syndrome). Myopathic weakness is not marked by diurnal variation and usually spares the extraocular, facial, and bulbar muscles (distinguishing the myopathies from myasthenia gravis and other disorders of the neuromuscular junction). Pain may occasionally be present (e.g., tenderness in polymyositis, or the pain and swelling infrequently seen in acute rhabdomyolysis). Although myopathic disease characteristically is of gradual onset with a slow progression of symptoms, several disorders can present with rapidly progressive, generalized weakness, and are thus of particular concern to emergency physicians. An overview of the spectrum of myopathic disorders is given in [Table 205.1](#).

HEREDITARY
Muscular dystrophies Metabolic myopathies Periodic paralysis
INFLAMMATORY
Idiopathic (polymyositis, dermatomyositis) Other connective tissue disorders Infectious (toxoplasmosis, leishmaniasis, Lyme disease, viral infections)
ENDOCRINE/METABOLIC
Endocrine (hypothyroid, adrenal, parathyroid, pituitary) Electrolyte abnormality (sodium, potassium, calcium, magnesium, phosphate)
DRUG-INDUCED
Myopathies (statins, calcium, corticosteroids, chloroquine, colchicine, levamisole, colchicine, zidovudine, others) Rhabdomyolysis (alcohol, opiates, barbiturates, cocaine, phencyclidine, amphetamines, others) Malignant hyperthermia (general anesthetics, depolarizing muscle relaxants) Neuroleptic malignant syndrome (neuroleptics)
OTHER
Trauma, ischemia, surgery

TABLE 205.1. Classification of Myopathies

The hereditary myopathies include the various forms of muscular dystrophy as well as the metabolic myopathies and periodic paralysis. The *muscular dystrophies* are characterized by the insidious onset of muscle weakness, with progressive deterioration over time. The types are differentiated by mode of inheritance, age at onset, rate of progression, and the selectivity of muscle involvement. ⁸ Diagnosis is made on the basis of family history, clinical features, and the results of creatine phosphokinase determination, electromyography, and muscle biopsy. The muscular dystrophies should be included in the differential diagnosis of chronic and subacute progressive weakness. It is also important to remember that the muscular dystrophies are associated with an increased frequency of cardiac failure, arrhythmias, pneumonia, and respiratory failure, as well as an increased susceptibility to anesthetic-induced malignant hyperthermia. Thus, the threshold for instituting close monitoring of cardiopulmonary function should be lower in patients with these disorders.

Metabolic myopathies are disorders of glucose or lipid utilization and energy production in skeletal muscle. The best known is muscle phosphorylase deficiency (McArdle disorder). Primarily affecting males, it occurs in the late teens and is characterized by painful muscle cramps, stiffness, and weakness after intense exercise, resulting from an enzymatic block in the glycolytic pathway and subsequent depletion of high-energy phosphate stores. Overexertion in these patients may lead to rhabdomyolysis and myoglobinuria. The disorder is diagnosed by a careful history and confirmed by a forearm ischemic exercise test and muscle biopsy. Treatment involves dietary measures and exercise limitation. This disorder should be considered in patients presenting with a history of intense postexercise muscle pain.

The several types of *periodic paralysis* (hypokalemic, thyrotoxic, hyperkalemic, and normokalemic) are caused by defects in muscle membrane permeability to sodium and potassium. Although rare, these are disorders that the emergency physician should be familiar with so that an appropriate history can be elicited, a diagnosis made, and correct therapy initiated. Although these episodic disorders usually spare the respiratory muscles, respiratory arrest has been reported and is always a danger in the profoundly weak patient.

In hypokalemic periodic paralysis, attacks characteristically begin in adolescence and recurrences are usually more than a month apart. Attacks last from hours to days and are triggered by sleep, exertion, high carbohydrate intake, cold, and stress. Symmetric weakness of the proximal limb muscles is noted. The diagnosis is based on patient history and serum potassium determination (usually 2.5 to 3.5 mEq/L during attacks). If attacks are infrequent, provocative testing with glucose and insulin infusion may be needed (performed in a controlled setting by a neurologist). Acute therapy is with potassium chloride (10 mEq/h intravenously or 40 to 60 mEq PO, repeated in 1 hour if needed). Acetazolamide prophylaxis and avoidance of high-carbohydrate meals are useful in chronic management.

Thyrotoxic periodic paralysis is a variant of hypokalemic periodic paralysis and occurs most frequently in young Asian and Hispanic males, often with only minimal clinical evidence of hyperthyroidism. The weakness can be mild to severe, primarily affects the lower extremities, and tends to occur at night or in the early morning. Therapy consists of the cautious administration of oral or intravenous potassium (rebound hyperkalemia is common) and control of the hyperthyroid state. ^{12,13}

In the less common, hyperkalemic form of period paralysis, attacks typically begin in the first decade of life, occur more frequently, and are of shorter duration (usually less than 2 hours). They may be precipitated by exercise, cold exposure, fasting, or potassium ingestion. During an attack, the serum potassium is usually greater than 5 mEq/L, although the level may remain normal (normokalemic periodic paralysis is a clinically indistinct variant of the hyperkalemic form). The brief attacks seldom require emergency treatment. If necessary, acute attacks may be treated with oral glucose, with inhalation of nebulized beta-adrenergic agents, or with

glucose and insulin (1 ampule D₅₀W with 5 U regular insulin). To prevent attacks, a thiazide diuretic may be used, along with avoidance of known precipitants.

Diagnosis is the challenge of these uncommon episodic illnesses for the emergency physician. Brief recurrent attacks of limb weakness should not be attributed to psychiatric causes without considering periodic paralysis. Similar previous episodes should be identified, and serum potassium and thyroxine levels should be measured. Other causes of hypokalemia and hyperkalemia should be considered as well.

Polymyositis, an inflammatory disorder of skeletal muscle, is the most common primary myopathy to affect adults but is nonetheless a rare disease (annual incidence of one per 100,000).¹ Muscle damage is caused by cell- and antibody-mediated autoimmune attack, but the ultimate etiology is unknown. Dermatomyositis, a common variant, is polymyositis with characteristic skin changes. Approximately 20% of patients with polymyositis or dermatomyositis have an associated connective tissue disease such as scleroderma, lupus, or rheumatoid arthritis.

The disease begins with the gradual onset of symmetric weakness of the proximal extremities that progresses over weeks to months, classically ascending from the lower to the upper extremities and finally involving the neck and pharyngeal muscles. Rarely, the disease presents in a fulminant form with severe generalized weakness, respiratory insufficiency, and rhabdomyolysis.

Characteristically, the patient notes difficulty in performing everyday activities such as rising from a chair, climbing stairs, or reaching overhead. Muscle pain and tenderness are occasionally noted. The facial and extraocular muscles are not involved.

The diagnosis of inflammatory myositis may be made by a combination of proximal muscle weakness, elevated muscle enzymes (creatine phosphokinase and aldolase), characteristic electromyogram, magnetic resonance imaging, and muscle biopsy. Autoantibodies may be positive. The erythrocyte sedimentation rate is often normal or only mildly elevated and is not a reliable indicator of disease severity.¹

Long-term treatment of polymyositis is with corticosteroids; a cytotoxic drug such as azathioprine is occasionally used as well. Although relapse can occur, most patients with idiopathic polymyositis or dermatomyositis improve with therapy, and up to 50% can eventually discontinue corticosteroid treatment. For severe weakness, high-dose intravenous immunoglobulin can be helpful.⁶ Plasma exchange has not proven effective.

EMERGENCY DEPARTMENT EVALUATION AND DIFFERENTIAL DIAGNOSIS

After initial attention to ventilatory status, evaluation of the patient presenting with the acute or subacute development of muscular weakness should focus on the history: the time course of the illness, progression of symptoms (including whether the weakness is periodic, fluctuating, or progressive), precipitating factors, associated pain or stiffness, any sensory complaints, and whether there is any associated fever, rash, arthralgia, or other symptoms. Information should be elicited about family history, any underlying illnesses, medication use, and exposure to home-canned or other contaminated food.

On physical examination, the patient should be tested for the ability to perform simple tasks (e.g., lifting arms above head, ability to make a tight fist, rising from a chair, rising on the toes), and the distribution of muscle involvement should be determined (including whether the extraocular, facial, or bulbar musculature is involved). Pathologic fatigue of muscles may be elicited by having the patient sustain an upward gaze, count loudly, or hold the arms horizontally. The muscles should be inspected for size and irritability and palpated for tenderness. The neurologic examination must include an evaluation of pupillary size and reactivity, sensory function, and deep tendon reflexes. Evidence should be sought for any potential precipitating illness; when appropriate, an adherent tick should be carefully sought. Using the history and physical examination, it is generally possible to exclude upper and lower motor neuron disease, myelopathy, and peripheral neuropathy from the differential diagnosis.

Elements of the diagnostic evaluation may include a complete blood cell count; determination of glucose, electrolyte, blood urea nitrogen, creatinine, creatine phosphokinase, calcium, magnesium, and phosphorus levels; sedimentation rate; electrocardiogram; chest radiograph; arterial blood gas analysis; and bedside spirometry. Additional studies may be necessary in the course of evaluation after referral to an internist or neurologist.

The differential diagnosis of subacute or chronically progressive weakness includes polymyositis (progressive, proximal limb weakness; sparing of extraocular muscles; elevated creatine phosphokinase); the muscular dystrophies (distinguished by family history, progression of symptoms over years, and selective pattern of muscle involvement); myasthenia gravis (almost always presenting with early involvement of extraocular and facial muscles and confirmed by a response to a short-acting anticholinesterase and characteristic results on repetitive nerve stimulation testing); polymyalgia rheumatica (proximal muscle pain and stiffness without true weakness, elevated erythrocyte sedimentation rate); and drug-induced myopathy. Thyroid or other endocrine myopathy can also present as proximal muscle weakness, as can severe hypokalemia, hypophosphatemia, or hypermagnesemia. Chronic alcohol abuse can produce a syndrome of proximal muscle wasting and weakness, often with coexistent evidence of alcoholic peripheral neuropathy. Finally, infectious etiologies of myositis or myopathy should be sought.

The differential diagnosis of acutely developing weakness includes myasthenia gravis; inflammatory polyneuropathy (Guillain-Barré syndrome); neurotoxin exposure (e.g., botulism, tick paralysis, organophosphate poisoning); severe electrolyte abnormality; drug- and alcohol-induced myopathy; periodic paralysis; and (rarely) polymyositis.

EMERGENCY DEPARTMENT MANAGEMENT

In patients with neuromuscular disease presenting with *severe and rapidly progressing weakness*, the crisis is usually precipitated by an intercurrent illness, most commonly a respiratory tract infection. These patients often present with ventilatory compromise, ineffective cough, and difficulty handling secretions. Decompensation to respiratory failure can be rapid. Immediate attention should be directed to oxygenation and ventilatory status. Serial physical examination, arterial blood gas determination, and spirometry are essential, and endotracheal intubation should be performed at the earliest sign of difficulty. Normal levels of pCO₂ and pO₂ are often maintained nearly to the point of profound respiratory failure and respiratory arrest.

The need for intubation and mechanical ventilation is best guided by serial measurement of vital capacity. A declining vital capacity or a vital capacity less than 15 mL/kg is an indication for urgent intubation. Testing of maximum inspiratory (PI_{max}) and expiratory (PE_{max}) pressures is also helpful in quantitating respiratory muscle weakness (PI_{max} less than 20 cm H₂O and PE_{max} less than 40 cm H₂O are correlated with inadequate ventilation and ineffective cough, respectively). Patients with severe weakness should be ventilated, at least initially, in the controlled mode.

Attention to hemodynamic stability is the next priority, with continuous electrocardiographic monitoring and evaluation of fluid needs. Creatine phosphokinase determination and urinalysis are mandatory to identify acute rhabdomyolysis. Patients with severe weakness require admission to an intensive care setting for supportive care, monitoring of cardiorespiratory status, treatment of any underlying illness, and further diagnostic evaluation.

In patients with *slowly progressive neuromuscular weakness*, the first priority is, likewise, to ensure cardiorespiratory stability. After appropriate diagnostic testing, these patients may require hospital admission for clinical observation, identification and treatment of any underlying illness, and further evaluation. Admission is indicated if there is any concern about the patient's respiratory reserve, if the degree of pharyngeal muscle weakness suggests a risk of aspiration, if rhabdomyolysis is suggested by creatine phosphokinase determination and urinalysis, or if the patient cannot function satisfactorily at home. The decision to manage the problem on an outpatient basis must be made after consultation with the primary care physician, internist, or neurologist, and on the condition that follow-up can be reliably arranged.

DISORDERS OF NEUROMUSCULAR TRANSMISSION

Myasthenia Gravis

Understanding disorders of the neuromuscular junction ([Table 205.2](#)) is of special importance for emergency physicians, because patients with these disorders may present with critical neuromuscular dysfunction requiring rapid diagnostic evaluation and specific management. The emergency physician must also be aware of the

commonly used medications that can cause precipitous worsening of muscle strength in these patients.

AUTOIMMUNE
Myasthenia gravis, Eaton-Lambert syndrome
TOXIN INDUCED
Botulism, tick paralysis, envenomation (coral snakes, black widow spiders), paralytic shellfish poisoning
DRUG INDUCED
Aminoglycosides, procainamide, penicillamine, phenytoin, chloroquine, psychotropic drugs, others
POISONING
Organophosphates, carbamates

TABLE 205.2. Disorders of Neuromuscular Transmission

Myasthenia gravis, the most common disorder of the neuromuscular junction, is an autoimmune disorder in which antibodies are directed against the acetylcholine receptor, reducing the number of available receptors and impairing neuromuscular transmission.⁷ In the majority of patients, the disease is associated with an abnormality of the thymus gland, either thymoma or thymitis. The thymus appears to be the site where B cells are sensitized to the acetylcholine receptor, initiating the disease process. The disease can occur at all ages but is most common in women in their mid-20s. The peak incidence for men is in the sixth or seventh decade.

The hallmark of myasthenia gravis is pathologic fatigue, owing to the loss of the generous physiologic reserve that normally supports transmission across the neuromuscular junction. Muscle weakness worsens with sustained activity and improves with rest; patients commonly report worsening of symptoms as the day progresses.

Myasthenia gravis is a disease of insidious onset, developing over a period of weeks to months. The muscle weakness occurs at first in transient attacks, at times precipitated by infection, stress, or pregnancy. The extraocular muscles are most commonly affected, and the most typical presentation is one of recurring episodes of diplopia and ptosis that are often noticed later in the day. There may also be weakness of eye closure, weakness of the muscles of facial expression, or difficulty chewing; transient dysarthria and dysphagia are common. Patients may also have involvement of the proximal limb and truncal and respiratory muscles and note difficulty climbing stairs or combing their hair.

The disease is extremely variable in its clinical presentation and may affect diverse muscle groups in an asymmetric, unpredictable manner, fluctuating in intensity over time. Spontaneous remissions and relapses are common, and the ultimate progression of the disease is highly variable. Respiratory crisis requiring mechanical ventilation occurs in up to 20% of patients.⁹

Immunosuppressive therapy for myasthenia, which is quite successful in controlling the disease, is responsible for a significant proportion of long-term morbidity and mortality. Fortunately, a large percentage of patients show marked improvement with treatment and can often be weaned off immunosuppressive agents. With proper management, mortality for the disease itself, previously as high as 30%, is now less than 5%.⁷

EMERGENCY DEPARTMENT EVALUATION AND DIFFERENTIAL DIAGNOSIS

For the patient presenting with a history of episodic weakness and fatigue involving extraocular, facial, and/or bulbar musculature, the evaluation should focus on obtaining a careful history, ruling out an underlying precipitating illness, demonstrating pathologic fatigue on physical examination, and developing a differential diagnosis.

On physical examination, provocative maneuvers to demonstrate weakness after repetitive or sustained muscle activity can assist in suggesting the diagnosis of myasthenia (e.g., ptosis or diplopia provoked by prolonged upward gaze, dysarthria or dysphonia with loud counting, inability to hold a tongue blade tightly in clenched teeth, or fatigue on holding the arms abducted or with repeated deep knee bends). Physical examination should also carefully assess pupillary response, sensation, and deep tendon reflexes, which should all be normal in the patient with myasthenia gravis. Underlying or precipitating illness should be carefully sought. The examination should also focus on the status and reserve of the respiratory system, especially on the adequacy of the resting tidal volume and the ability to manage secretions.

Patients with localized or mild symptoms suggestive of myasthenia gravis are usually referred to a neurologist for confirmatory testing. Testing includes an anticholinesterase test, in which the short-acting agent edrophonium is given intravenously while observing the patient for resolution of weakness in an affected muscle group. A repetitive nerve stimulation test is more definitive and is recommended as the next step in diagnosis. In myasthenia, a decrement in the amplitude of the muscle action potential is noted when the motor nerve is repetitively stimulated at 3 cycles per second. Further evaluation includes an assay for circulating antiacetylcholine receptor antibodies (found in 90% of patients with generalized disease), computed tomography scanning of the thymus, thyroid function tests, and serologic screening for the presence of other autoimmune diseases.

The differential diagnosis includes drug-induced myasthenia, botulism, tick paralysis, organophosphate poisoning, Eaton-Lambert myasthenic syndrome, inflammatory polyneuropathy (Guillain-Barré syndrome), a primary or secondary myopathy, other causes of oculomotor palsy (diabetes, multiple sclerosis, aneurysm), and neurasthenia. History, physical examination, and simple laboratory data should enable the clinician to readily distinguish among these entities. However, myasthenia gravis (like periodic paralysis and multiple sclerosis) can easily be misdiagnosed as a psychiatric problem (depression, anxiety, or a somatoform disorder). One should be extremely wary of making a diagnosis of a psychiatric or functional illness in a patient complaining of weakness, without carefully considering the possibility of one of these diagnoses.

EMERGENCY DEPARTMENT MANAGEMENT

Unrecognized airway and ventilatory problems remain the greatest danger in myasthenia gravis. If there is any concern about progression of the disease from whatever cause, neurologic consultation and monitoring of the patient in an intensive care unit is warranted. Underlying respiratory tract infection or other precipitant should be identified and treated aggressively. Early antibiotic therapy is of utmost importance in the treatment of an associated infectious illness.

Management should focus on the patient's respiratory status and ability to handle secretions. The picture may be complicated by poor oral intake and, occasionally, by drug-induced muscarinic side effects such as bronchorrhea and bronchospasm. Arterial blood gas analysis and bedside spirometry should be performed. One should be aware that respiratory failure can develop insidiously and that it may occur despite normal arterial blood gases and apparently good peripheral motor strength. The deterioration to respiratory arrest can be precipitous. Endotracheal intubation should be performed at the earliest suggestion of respiratory compromise, which is best detected by serial measurements of vital capacity, inspiratory and expiratory force, and the patient's ability to clear secretions.

Respiratory infections are common precipitants of myasthenic crisis and must be diagnosed and treated aggressively. Electrolyte abnormalities that may be exacerbating the clinical picture should likewise be identified. Prominent muscarinic side effects from cholinergic overmedication (e.g., bradycardia, abdominal cramping, bronchorrhea) may be treated with atropine. All medications should be withdrawn, any underlying illness treated, and volume status and caloric intake normalized if possible. Improvement is often relatively rapid, and the patient is commonly restarted on anticholinesterase medication within 48 hours. For patients who do not respond to the aforementioned measures, plasmapheresis is, as a rule, rapidly effective and has dramatically reduced morbidity from respiratory failure. Muscle strength typically recovers within 5 days after the initiation of plasmapheresis or plasma exchange.⁵ Intravenous immunoglobulin has also proven useful and has the advantage of not requiring specialized equipment.¹⁵ High-dose corticosteroids are also commonly administered to patients in crisis.

Long-term treatment of myasthenia gravis involves several different modalities. Anticholinesterase agents, which potentiate the action of acetylcholine at the

postsynaptic membrane, are the drugs of first choice in treatment. Although they provide symptomatic relief, improvement is usually incomplete, and they do not influence the progression of the disease. Pyridostigmine, at an initial dose of 60 mg three times a day, is the agent most commonly chosen. An experienced neurologist should initiate and monitor anticholinesterase therapy in myasthenia gravis. The medication dose is adjusted cautiously while clinical signs are monitored; the edrophonium test may be repeated to help gauge therapy. Muscarinic side effects can be troublesome, but more serious is the development of a depolarizing neuromuscular block secondary to overmedication, the so-called cholinergic crisis.

Thymectomy leads to improvement in most patients and is increasingly recommended for patients with generalized myasthenia gravis and persistent symptoms.¹⁹

Corticosteroids produce favorable results in over 80% of patients but, because of side effects, are usually reserved for patients with inadequate response to anticholinesterase therapy and thymectomy. Corticosteroids reduce antiacetylcholine receptor antibody levels and probably have additional direct effects on the neuromuscular junction. They may initially aggravate muscle weakness, however, so it is generally recommended that therapy be initiated with low doses and in-hospital observation. Azathioprine or cyclosporine can be used as supplemental agents or in patients unable to tolerate corticosteroid therapy.

A patient with known myasthenia gravis who presents with severe weakness may be suffering from either a rapid worsening of the disease (“myasthenic crisis”) or a depolarizing neuromuscular block as a result of cholinergic overmedication (“cholinergic crisis”). Myasthenic crisis is the much more common of the two and may be precipitated by poor compliance with medication, drug interaction, underlying infection, or other stress.^{2,17} The patient with cholinergic crisis is more likely to present with symptoms of cholinergic overactivity, including miosis, sweating, salivation, and gastrointestinal distress (muscarinic effects), as well as muscular cramps and fasciculations (nicotinic effects). However, the presentation of a patient with progressive weakness who has been treated with increasing doses of anticholinesterase medication may be confusing, even to the most experienced clinician. In practice, the distinction between myasthenic crisis and cholinergic crisis is of little clinical relevance to the emergency physician, because the management approach is the same. Attempting to distinguish myasthenic from cholinergic crisis with an edrophonium test in the severely weak patient is both unreliable and hazardous.

The emergency physician must be aware that a number of medications can impair neuromuscular transmission and exacerbate weakness in patients with myasthenic gravis (Table 205.3). These drugs include aminoglycoside antibiotics, certain cardiovascular drugs, phenothiazines, and anticonvulsants.^{14,20} These drugs act either by preventing release of acetylcholine from the presynaptic membrane or by binding to the postsynaptic membrane, producing a curare-like effect. Benzodiazepines and potent analgesics such as morphine and meperidine can also aggravate weakness in myasthenics. All of these agents should be avoided whenever possible in the management of patients with myasthenia; when required, they must be used cautiously and with careful monitoring. Acute intercurrent medical and surgical problems in patients with myasthenia gravis should always be managed in consultation with a neurologist.

ANTIBIOTICS	HORMONAL AGENTS
Aminoglycosides, tetracycline, fluoroquinolones, clindamycin, sulfonamides, erythromycin, ampicillin, chloroquine	Corticosteroids
ANTICONVULSANTS	PSYCHOTROPICS
Phenytoin, phenobarbital	Phenothiazines, lithium
CARDIOVASCULAR	ANALGESICS/SEDATIVES
β-blockers, calcium-channel blockers, lidocaine, quinidine, procainamide, diuretics	Morphine, meperidine, benzodiazepines, antihistamines

TABLE 205.3. Common Drugs Capable of Impairing Neuromuscular Transmission or Exacerbating Weakness in Patients with Myasthenia Gravis

Other Disorders of Neuromuscular Transmission

Several other disorders of neuromuscular transmission should enter into the differential diagnosis of muscular weakness. The *Eaton-Lambert syndrome* is a very rare syndrome of weakness and fatigability caused by a defect in the release of acetylcholine from the presynaptic membrane of the neuromuscular junction. It is usually a paraneoplastic condition, associated particularly with small-cell carcinoma of the lung. Clinically, there is weakness of the proximal limb muscles, hyporeflexia, dry mouth, and impotence. The extraocular and facial muscles are usually spared. When the motor nerve is stimulated at high frequency during electromyographic testing, an incremental response of the muscle action potential is observed, the opposite of what occurs in myasthenia gravis. Treatment includes anticholinesterase agents, immunosuppressants, plasmapheresis, and therapy for the underlying tumor.¹⁸

Botulism is caused by a neurotoxin produced by the anaerobic organism *Clostridium botulinum*. Botulinum toxin, considered to be the most powerful poison known (0.1 μg of toxin A can be lethal in humans), binds irreversibly to the presynaptic membrane, blocking calcium-mediated release of acetylcholine, and thus interfering with neuromuscular and cholinergic autonomic transmission.⁴ The principal source of the toxin is inadequately prepared food; home-canned products are most often incriminated. Infantile botulism is an insidious form of the disease in which viable bacilli are ingested and survive in the infant's intestine, where toxin is then elaborated. Infants with this disease are often seen by a physician several times before the diagnosis is considered.

Wound botulism is a rare entity (most recent cases occurring in injection drug abusers) in which the clostridial organisms grow and produce toxin in injured, devitalized tissue.⁴ The responsible wound is often surprisingly benign in appearance.

Botulism may vary from a mild illness to a fulminant, fatal one. Prodromal symptoms of nausea, vomiting, diarrhea, and a dry, painful throat develop hours to days after ingestion of contaminated food. Neurologic symptoms are usually noted within 72 hours of ingestion and include anticholinergic effects (dry eyes, dry mouth, dilated pupils, ileus, and urinary retention) and fluctuating but rapidly progressive weakness, with early involvement of the extraocular and bulbar muscles (with ptosis, diplopia, dysphagia, and dysphonia as common early symptoms). The disease then progresses over several days to involve all the muscles of the trunk and extremities. Respiratory compromise can develop rapidly as the symmetric paralysis descends. There are usually no cognitive or sensory abnormalities; deep tendon reflexes are normal to decreased.^{10,16}

The diagnosis of botulism must be made primarily on clinical evidence (acute onset of gastrointestinal, autonomic, and cranial nerve dysfunction), aided by epidemiologic, laboratory, and electrophysiologic findings. If the disease is suspected, state health authorities and the Centers for Disease Control and Prevention should be contacted for assistance in performing assays for the toxin, for release of botulinum antitoxin, and for the initiation of appropriate control measures. A blood sample should be sent for toxin assay, and specimens of food, gastric contents, and stool should be sent for toxin assay and culture. Wounds can also be cultured and assayed for toxin.

Because only one-third of patients with food-borne botulism have detectable toxin in the blood, confirmation, in most cases, depends on demonstration of botulinum toxin in stool or leftover food.¹⁴ However, laboratory confirmation, even when successful, is often delayed. The edrophonium test is often helpful in distinguishing botulism from myasthenia gravis, but a positive test is occasionally seen with botulism. Findings on repetitive nerve stimulation are similar to those in patients with the Eaton-Lambert syndrome.

Treatment consists of efforts to eliminate the toxin, provision of respiratory and other supportive care, and early use of trivalent botulinum antitoxin. Precipitous respiratory failure is the primary cause of death, and serial measurements of vital capacity and inspiratory and expiratory force are thus essential. Approximately one-third of patients require mechanical ventilation, often for several weeks or more. The current mortality rate for food-borne botulism in the United States is about 10%.¹⁶ Recovery is characteristically very slow, with weakness and autonomic symptoms often persisting for months. Infantile botulism, once diagnosed, is usually a self-limited disease that does not require antitoxin or antibiotics. In wound botulism, wound debridement and high-dose penicillin are indicated.

Tick paralysis is an ascending flaccid paralysis caused by a neurotoxin elaborated by an engorged tick that has been adherent to the human host for several days. The toxin blocks release of acetylcholine at the neuromuscular junction and also impairs conduction in peripheral motor nerves. In the United States, the disease

occurs primarily in children during the late spring and summer in the Rocky Mountain and northwestern regions and is caused by a female wood tick (*Dermacentor andersoni*) or common dog tick (*Dermacentor variabilis*). The presenting symptom is an ascending, symmetric paralysis that progresses over 1 to 2 days to involve the extraocular and bulbar muscles. If the cause is unrecognized, respiratory paralysis can follow. Ataxia may be an early finding. Patients are alert and afebrile. Sensory changes are rarely noted, and deep tendon reflexes are markedly decreased.

The differential diagnosis of this acutely developing disorder includes Guillain-Barré syndrome, poliomyelitis, diphtheritic polyneuropathy, botulism, myasthenia gravis, and transverse myelitis. Any patient presenting with an afebrile ascending paralysis requires a careful physical examination to detect an adherent tick, often found on the scalp. After removal of the tick, neurologic recovery occurs within 24 to 48 hours. Unrecognized, the disease has proved fatal in 10% of patients. ³

The venom of the *black widow spider* causes uncontrolled release, and eventually depletion, of acetylcholine from presynaptic terminals; that of the elapid and hydrophid *snakes* causes a nondepolarizing, postsynaptic, neuromuscular block; and the neurotoxin elaborated by dinoflagellates in *paralytic shellfish poisoning* decreases sodium-channel permeability in nerves, leading to weakness, paresthesias, and ataxia.

The same drugs that can exacerbate myasthenia gravis can also produce varying degrees of neuromuscular blockade and weakness in patients without underlying neurologic disease (see [Table 205.3](#)). Because there is normally ample reserve supporting neuromuscular transmission, a noticeable clinical effect is generally restricted to elderly patients, patients with associated electrolyte abnormalities, those with muscle weakness due to another condition, and those with high serum drug levels secondary to overdose or impaired elimination. These drugs act either presynaptically or postsynaptically and produce symptoms that resemble naturally occurring myasthenia gravis. Treatment includes discontinuing the offending agent and providing supportive care. Calcium gluconate or an anticholinesterase can be used acutely to reverse severe symptoms.

COMMON PITFALLS

- Attributing a history of episodic weakness to psychiatric disorder without considering the possibility of a neurologic disease (e.g., periodic paralysis, myasthenia gravis, or multiple sclerosis)
- Failure to take a careful, focused history in a patient presenting with a possible neurologic complaint. Misdiagnosis is common if historic information is overlooked.
- Failure to rule out electrolyte abnormalities in evaluating the weak patient
- Failure to perform a thorough search for an underlying precipitating illness in a patient with myopathy or myasthenia gravis who presents with an exacerbation
- Attempting an edrophonium test or other pharmacologic maneuvers in the acute management of myasthenic patients presenting in crisis. Acute treatment initially involves attention to airway and ventilatory status (with a low threshold for endotracheal intubation), treatment of any underlying illness, withdrawal of medications, and volume replacement. Management decisions should be made in consultation with a neurologist.
- Prescribing medications that may exacerbate weakness in myasthenia gravis. Emergency physicians must be aware of drugs that can impair neuromuscular function. Treatment decisions should be made in consultation with a neurologist.

- [Common Pitfalls](#)
- [Chapter References](#)

Seizures account for an estimated 1% to 2% of emergency department visits. Two to 4 million Americans have epilepsy, a condition of recurrent unprovoked seizures. A much larger number of people have seizures provoked by an underlying pathologic process.

Seizures result from any of a variety of pathologic processes that provoke excessive and disorderly neuronal discharge in the cerebral cortex. The manifestations of a seizure reflect the area of the brain in which neurons are discharging. Seizure discharges may be focal or may be generalized throughout the cerebral cortex. Consequently, the clinical spectrum of seizures includes focal or generalized motor activity, altered mental status, sensory or psychic experiences, or autonomic disturbances.

Ictus refers to the period during which a seizure occurs. An aura, or “warning,” represents the beginning of a partial seizure, which can remain focal or can spread into a generalized event; a corollary is that patients with a primary generalized seizure disorder do not have an aura. The period after a seizure but before the patient returns to baseline is called the postictal period.

Status epilepticus is the condition in which seizures last more than 30 minutes or in which there are recurrent seizures without a return to baseline mental status between events. There are a projected 126,000 to 195,000 cases of status epilepticus each year in the United States, with an overall mortality of 22%. There is a bimodal distribution of cases, with the highest incidence occurring in the first year of life and after the age of 60. Over one-half of patients presenting to the emergency department in status epilepticus have no prior seizure history.

The classification of seizures ([Table 206.1](#)) is based on the behavioral and electrophysiologic features of the event rather than on specific pathophysiologic mechanisms or anatomic localization. Seizures can be broadly divided into primary generalized seizures and partial seizures (also called focal seizures). *Primary generalized seizures* do not have an inciting focus, but begin bilaterally in both hemispheres of the cerebral cortex. *Partial seizures* begin in a localized area of the brain; they may remain focal but can also spread to incorporate both hemispheres, in which case, the seizure is termed *secondary generalized*.

I. PARTIAL SEIZURES
A. Simple Partial
1. Motor
2. Somatosensory
3. Autonomic
4. Psychic
B. Complex Partial
C. Secondary Generalized
II. GENERALIZED SEIZURES
A. Nonconvulsive (absence)
B. Convulsive
1. Tonic-clonic
2. Clonic
3. Tonic
4. Myoclonic
5. Atonic
III. STATUS EPILEPTICUS
A. Convulsive generalized
B. Convulsive focal
C. Nonconvulsive

TABLE 206.1. Classification of Seizures

Primary generalized seizures are broadly classified further as convulsive or nonconvulsive. All primary generalized seizures, except myoclonic seizures, are associated with an altered level of consciousness. Thus, it is not possible to have a bilateral tonic-clonic event with preservation of mental status, and this criterion can be helpful at times in distinguishing neurogenic seizures from psychogenic seizures

Absence seizures are primary generalized events characterized by an alteration in mental status without significant motor activity. They are more frequent in the young, usually beginning between the ages of 5 and 10 years, and are infrequent after the mid-teens. The average duration is 10 seconds, and there is rarely a postictal period.

Partial seizures are subdivided according to associated impairment of consciousness. Simple partial seizures have no impairment of consciousness and are categorized according to clinical presentation (see [Table 206.1](#)). Partial seizures that are associated with an impairment of consciousness are termed *complex partial seizures*.

Aside from the seizure activity itself, seizures may have harmful secondary consequences. A transient impairment of consciousness may result in a fall or a motor vehicle accident. The convulsive movements of a seizure may result in injury from direct trauma to head, trunk, or limbs. There are also metabolic consequences. There is typically a period of transient apnea and hypoxia, the duration of which varies with the duration of seizure activity. There is an increase in blood pressure, serum lactate and serum glucose levels, and white blood cell (WBC) count (but with no increase in bands). Body temperature is frequently elevated.¹⁴ Acidosis due to elevated lactate occurs within 60 seconds of a convulsive event and normalizes within 1 hour after ictus.¹² A transient cerebrospinal fluid pleocytosis of up to 20 WBC/ μ L has been reported to occur in 2% to 23% of seizure patients ([Table 206.2](#)).

PHYSIOLOGIC
Hyperthermia
Acidosis
Hypoglycemia/hyperglycemia
Hyposia
Acidosis
Leukocytosis
Cerebrospinal fluid pleocytosis
SYSTEMIC
Central nervous system edema
Pulmonary edema
Hypertension followed by hypotension
Dysrhythmias
Rhabdomyolysis
Disseminated intravascular coagulation
Fractures/dislocations

TABLE 206.2. Physiologic and Systemic Consequences of Convulsive Seizures

If the seizure lasts more than 30 minutes, the body's homeostatic regulating mechanisms begin to deteriorate; blood pressure begins to decrease, and the blood pH and lactate level can normalize if the patient's respiratory status is not compromised. It is hypothesized that even if systemic factors such as acidosis and hypoxia are controlled, prolonged status epilepticus results in neuronal damage secondary to the release of neurotoxic excitatory amino acids and influx of calcium into cells.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

A number of conditions can be confused with seizure disorders, among them syncope, arrhythmia, migraine, vertigo, sleep disorders, decerebrate posturing, drug reactions, tetanus, strychnine poisoning, and psychogenic events. A detailed history and physical can usually differentiate among these.

Syncope can be associated with occasional twitching movements that can be misdiagnosed as a seizure. Tonic-clonic movements, tongue biting, and postictal amnesia have not been commonly described in convulsive syncope. When put in the context of when and where the event occurred, length of event, and type of movements, convulsive syncope can usually be fairly reliably differentiated from seizure.

Migraine with an aura can be confused with nonconvulsive seizures. This is compounded by the finding that many migraine patients have abnormal electroencephalograms (EEGs). Basilar migraine can result in loss of consciousness, making the differentiation even more difficult.

Other entities that have been confused with seizures include narcolepsy, hyperventilation syndrome, hypoglycemia, and dystonic reactions. Of note, tonic, clonic, and tonic-clonic seizures are associated with altered consciousness, while dystonic reactions are not.

Psychogenic seizures, also referred to as pseudoseizures, are functional events with a clinical presentation mimicking neurogenic seizures, yet with no corresponding alteration in EEG activity. These events are often conversion reactions and not under the patient's conscious control. It is estimated that 20% of patients followed in epilepsy clinics are misdiagnosed and actually have psychogenic seizures.⁶

Psychogenic seizures often last longer than neurogenic events, frequently for more than 5 minutes. There usually is not a postictal period; patients can often recall events during the seizure, have not been incontinent, and do not incur physical injury. However, it must be stressed that exceptions to all of the aforementioned are commonly found, including incontinence and prolonged postictal periods. Psychogenic seizures are classically manifested by forward-thrusting pelvic movements and head-turning from side to side.⁶

Several maneuvers and tests are useful in diagnosing psychogenic seizures. These patients often avoid or resist noxious stimuli. They may display gaze aversion and look away from an examiner, regardless of position. On laboratory testing, psychogenic seizure patients do not have a metabolic acidosis, which is nearly universal with generalized convulsive seizures, and there is not a postictal increase in serum prolactin levels.

Seizures may be the result of acute or progressive neurologic insults or systemic stressors, and the evaluation of the patient with seizures must always look for these potentially reversible or treatable causes (Table 206.3). The two most commonly identified etiologic antecedents to seizures are neurologic injury from birth (8%) and cerebrovascular disease (11%).⁷ Other identified etiologies of secondary seizures include trauma (5.5%), neoplasm (4%), degenerative disease (3.5%), and infection (2.5%).

TABLE 206.3. Etiology of Seizures

Metabolic and toxin-related etiologies must always be considered in the differential diagnosis. Hypoglycemia is the most common metabolic cause of seizures; hyponatremia, hypocalcemia, and hypomagnesemia are much less common.¹⁸ Interestingly, the metabolic encephalopathies, such as nonketotic hyperglycemia and uremia, can cause both focal and generalized seizures. Alcohol is the toxin most commonly associated with seizures, followed by tricyclic antidepressants, cocaine, amphetamines, antihistamines, theophylline, and isoniazid. Drug withdrawal, including noncompliance with anticonvulsant medications in patients with a known seizure disorder, is a leading cause of recurrent seizures.¹⁴

Acute central nervous system (CNS) infections are responsible for 4% to 12% of acute isolated seizures and up to 28% of cases of refractory status epilepticus.

A number of physiologic and psychological stressors can activate seizure disorders. These stressors include fatigue, sleep deprivation, hyperventilation, photic stimulation, emotional stress, and menstruation. In rare cases, seizures can be triggered by colors, objects, music, and voices. Pregnancy can also result in the onset of a seizure disorder, separate from eclamptic seizures.

EMERGENCY DEPARTMENT EVALUATION

The evaluation of the patient who has had a seizure should begin with a careful history that includes a description of the event and an indication of the frequency, pattern, and duration of recent or previous seizures. A history of incontinence, loss of consciousness, and self-injury during the event should be elicited. It should be determined whether there was an aura or a postictal period. Every attempt should be made to interview observers and to obtain a clear description of the seizure to avoid misdiagnosing nonseizure events.

The circumstances preceding a seizure must be elucidated. Inciting factors such as medication noncompliance, infection, pregnancy, sleep deprivation, alcohol use, or other drug or medication use should be identified. A history of head trauma, headaches, diabetes, cancer, cerebrovascular disease, electrolyte imbalances, or infections can prove vital to making a diagnosis.

The physical examination begins with the vital signs, which can provide important red flags of underlying pathology. Signs of trauma should be sought, and a careful neurologic examination performed. Both unilateral and bilateral pupillary dilatation as a result of seizure has been reported. A focal deficit can represent a metabolic derangement such as hypoglycemia, an old lesion, new intracranial pathology, or a Todd paralysis secondary to the seizure. Todd paralysis can be manifested as either a motor or a sensory deficit. Although it typically resolves within hours of seizure, neuroimaging is usually necessary to differentiate a Todd paralysis from other causes of acute focal neurologic dysfunction.

Note should be made of the patient's mental status before and after a seizure. Postictal confusion is common, but almost always resolves over a few hours. Other causes of altered mental status must be strongly considered in patients whose mental status remains impaired, or when family or friends note an abnormally long postictal phase or unusual behavior manifestations. It is estimated that approximately 15% of patients treated for convulsive status epilepticus continue to be in nonconvulsive status after their motor activity is controlled; this unrecognized status may be a factor in the high mortality associated with status epilepticus and suggests the need for EEG monitoring in the "postictal" period.⁶ Causes of altered mental status in patients who have had a seizure are listed in [Table 206.4](#).

Postictal state
Persistent nonconvulsive seizures
Metabolic abnormality
Hyperosmolar state
Central nervous system infection
Central nervous system vascular event
Drug effect
Psychiatric dysfunction

TABLE 206.4. Causes of Altered Mental Status in Patients Who Have Had a Seizure

Patients are often brought to the emergency department after having had an episode of loss of consciousness of unknown cause. The differential diagnosis in these difficult cases includes seizures, and there are clues that can suggest that a seizure occurred. Postictal patients often have hyperreflexia, upgoing toes, evidence of incontinence, or a tongue laceration. Laboratory testing in postictal patients often demonstrates a metabolic acidosis or an elevated serum creatine phosphokinase level. These findings can be helpful and should be sought, but, unfortunately, they are time and patient dependent and their absence does not rule out the possibility that a seizure occurred.

The details of the history and physical examination should dictate the urgency and course of any further emergency department evaluation. Of all laboratory tests, serum glucose determination followed by a serum sodium determination has been found to be the most valuable in diagnosing an unsuspected etiology of seizure.^{1,15} The decision to measure other electrolytes, creatinine, blood urea nitrogen, calcium, and magnesium is based on the individual patient assessment; generally, these tests are of limited value in patients with no underlying medical problems who have returned to baseline. An arterial blood gas analysis is indicated when hypoxia or an underlying acidosis is suspected. A pregnancy test should be obtained in all women of childbearing age.¹ Serum anticonvulsant levels should be checked in patients with epilepsy who have had a seizure and in patients for whom a history cannot be obtained ([Table 206.5](#)).

Drug	Trade Name	Route	Seizure Type	Loading Dose (mg/kg)	Daily Dose for Adults (mg)	Therapeutic Range (µg/mL)
Phenytoin	Dilantin	PO, IV	F, GC	20	300-400	10-20

TABLE 206.5. Drugs Used in the Treatment of Epilepsy

Alcohol is by far the most common drug of abuse associated with seizures, followed by cocaine. Serum alcohol and theophylline levels and urine drug-screening tests should be ordered based on clinical suspicion. It is worth remembering that patients with epilepsy can have other medical problems (e.g., depression), so other possibilities (e.g., tricyclic overdose) should not be overlooked.

Patients who have had a seizure but who are not immunocompromised and who do not have an abnormal mental status, fever, or meningeal signs do not require a lumbar puncture as part of their emergency department evaluation.⁵ However, seizures, especially status epilepticus seizures, are associated with hyperthermia, leukocytosis, and altered mental status, thus often forcing consideration of meningitis. It is also important to note that, as mentioned previously, seizures can cause cerebrospinal fluid pleocytosis, further confusing the issue occasionally. Antibiotics, once started, must be continued until cerebrospinal fluid culture results are available.

Computed tomographic (CT) scanning of the head should be performed in the emergency department when an acute intracranial event, such as subdural or subarachnoid hemorrhage, is suspected. Patients with a history of acute trauma or malignancy, or with an abnormal neurologic examination, are most likely to have an abnormal imaging study.

All patients who have had a first-time seizure need an imaging study, but not necessarily an emergent CT scan obtained in the emergency department. If the patient has a normal mental status and neurologic examination and is judged to be reliable for follow-up, it is reasonable, after consultation with a neurologist, to arrange for outpatient magnetic resonance imaging (MRI). MRI is superior to CT scanning in identifying structural epileptogenic abnormalities.²

EEG monitoring is not a standard practice in the emergency department, yet there are clear indications for its use on an emergent basis. Any patient with altered mental status in whom nonconvulsive status epilepticus is suspected requires an emergent EEG. An emergent EEG is also indicated in patients with refractory status epilepticus who have been managed with paralysis or barbiturate coma.

Additional laboratory and radiographic testing may be indicated to identify underlying complicating factors, such as cardiac dysrhythmia, urinary tract infection, sepsis, or pulmonary disease.

EMERGENCY DEPARTMENT MANAGEMENT

Most seizures are self-limited and do not require immediate intervention. If the patient is seen during the seizure, the focus should be on protecting the patient from injury. Airway patency should be ensured, but objects should not be inserted into the patient's mouth. Patients who have experienced a seizure once are at risk for recurrent seizure episodes, so proper precautions should be taken to keep the guard rails on stretchers up and to prevent the patient from ambulating unaccompanied.

First-Time Seizures

Patients who have had a single, unprovoked seizure have about a 35% risk of recurrence within the next 5 years; the risk of recurrences increases to approximately 75% after two or three seizures.¹¹ When a cause of the seizure is identified, management is based on the underlying pathology. When no cause can be identified, a

risk–benefit analysis regarding initiation of antiepileptic therapy must be performed. There are significant psychosocial consequences of a diagnosis of epilepsy, as well as potential dangers from the chronic use of antiepileptic medications. Thus, one must be cautious when labeling patients as epileptic and instituting treatment from the emergency department.

Intravenous phenytoin or fosphenytoin loading, 20 mg/kg, can be accomplished quickly and leads to therapeutic blood levels within 1 hour of the infusion's completion. Intravenous phenytoin loading can be associated with local infusion site irritation, hypotension, confusion, and ataxia; consequently, infusions should not be run faster than 50 mg/min in adults. Fosphenytoin is a water-soluble disodium phosphate ester of phenytoin, which does not need a propylene glycol vehicle and has a more physiologic pH than does phenytoin. It has fewer side effects than phenytoin, though rapid infusion can still cause hypotension, ataxia, and confusion. Fosphenytoin can be given safely by the intramuscular route, with 100% bioavailability and therapeutic serum levels within 1 hour of a loading dose. ⁷ Oral phenytoin loading is another option; it results in unpredictable absorption, however, with only 60% of patients being therapeutic at 12 hours after a 1-g dose. A daily maintenance dose of 300 mg can be given at bedtime, although, in some patients, divided dosing can provide better seizure control by minimizing variations in the blood level.

Recurrence of Seizures in Patients with Known Seizure Disorder

Noncompliance with anticonvulsant medication is, by far, the most common cause of seizure recurrence in a patient with a known seizure disorder. A patient who has been on phenytoin, but has a subtherapeutic level, should be given supplemental intravenous phenytoin or fosphenytoin to reestablish serum levels in the therapeutic range. Intramuscular fosphenytoin is another option and eliminates the need for infusion pumps and cardiac monitoring. The patient can then be discharged with instructions to resume oral dosing within 12 hours. Likewise, patients with subtherapeutic valproic acid levels can be supplemented with intravenous valproic acid administered over 1 hour at a rate no faster than 20 mg/min, and discharged on their oral regimen.

Patients managed on carbamazepine who have a seizure due to noncompliance present more of a management problem, because this drug cannot be loaded orally or intravenously. In these cases, if the patient can tolerate phenytoin, consideration should be given to loading the patient with phenytoin and continuing on this drug until therapeutic levels of carbamazepine are achieved.

Patients who have seizures despite therapeutic anticonvulsant levels must be evaluated carefully for precipitating factors such as infection, new anatomic lesions, or new medications. Decisions to increase the drug dose should be made only after communication with the patient's primary care physician. A second anticonvulsant should be added to the patient's regimen only when seizures are refractory to monotherapy and there are clinical signs of toxicity.

The evaluation of pregnant patients with new-onset seizures should follow the same principle as in other patients. However, if no etiology is identified, anticonvulsants should be withheld and the patient referred for close follow-up. Eclampsia is an additional consideration in patients at more than 20 weeks' gestation.

Noncompliance and sleep deprivation are the two most common causes of seizure recurrence in pregnant patients with epilepsy. ⁴ Active seizures should be treated pharmacologically just as in the nonpregnant patient, because the risks to the fetus of hypoxia and acidosis are greater than the potential teratogenicity of anticonvulsant medications. Phenytoin and phenobarbital have similar teratogenic profiles; carbamazepine is probably the safest of the anticonvulsants to use in pregnancy. Beyond 24 weeks' gestation, fetal monitoring should be provided during and after a seizure.

Alcohol-Related Seizures

Alcohol-related seizures deserve special mention, because alcohol use is frequently involved in patients presenting to emergency departments with seizures. Alcohol-withdrawal seizures classically occur 6 to 48 hours after a significant reduction in the serum alcohol level, but they have also been associated with rising blood ethanol levels in some patients.

Alcohol-related seizures are temporally associated with alcohol use but are not necessarily solely the result of the alcohol. Alcoholics are susceptible to cerebrovascular insults, trauma, metabolic disorders, and infections, and are thus at increased risk for seizures.

Management of the alcoholic who has had a seizure focuses on determining whether the event was a withdrawal seizure or due to another etiology. Patients with a first-time alcohol-related seizure should be evaluated fully in the same manner as any other patient.

The diagnosis of alcohol-withdrawal seizures is based on the history, and the clinician must always consider the possibility that another etiology is responsible. Benzodiazepines alone are sufficient to prevent successive withdrawal seizures in the acute setting, but there is no good evidence to support the use of phenytoin either acutely or chronically in the management of alcohol-withdrawal seizures. Patients who have had one alcohol-withdrawal seizure and have been observed to remain seizure-free and at baseline mental status for 6 hours, with no evidence of withdrawal, can be discharged if a suitable environment is available. ³

Psychogenic Seizures

Psychogenic seizures should be suspected in patients who are refractory to anticonvulsants and whose clinical presentation is atypical. The diagnosis is suspected particularly when a convulsing patient does not have a metabolic acidosis, and it can be confirmed, when possible, by demonstrating that the clinical convulsion is not accompanied by an abnormal EEG. Management of psychogenic seizures is dependent on making the correct diagnosis; although this sounds obvious, the anxiety associated with evaluating a convulsing patient often leads to the initiation of pharmacologic interventions before an adequate assessment can be performed. ⁸ The key to management is avoiding iatrogenic harm by aggressive pharmacologic interventions or supportive measures such as intubation. Long-term management usually involves a comprehensive evaluation in an epilepsy monitoring unit, with a coordinated approach involving both an epileptologist and a psychiatrist.

Status Epilepticus

The management of convulsive status epilepticus involves simultaneous maintenance of the patient's airway, breathing, and circulation; diagnostic testing; and pharmacologic intervention (Fig. 206.1). Status epilepticus tends to occur more frequently in patients with an underlying neurologic insult, either old or new, and refractory status epilepticus almost always indicates the presence of an underlying CNS disorder. Morbidity and mortality in status epilepticus is related to the etiology, duration, and systemic consequences of the event.

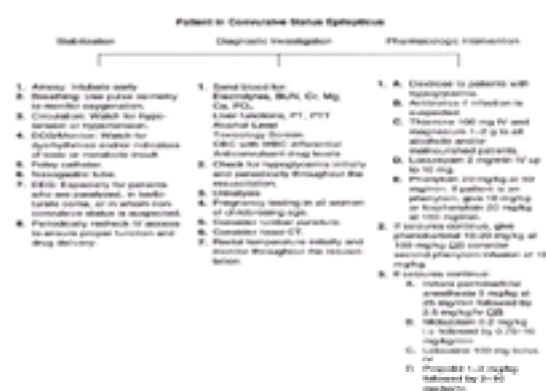

Figure 206.1. Approach to patient in status epilepticus. (Modified from Jagoda A, Riggio S. Refractory convulsive status epilepticus. *Ann Emerg Med* 1993;22:1343.)

Airway support should be aggressive, and continuous pulse oximetry should be employed. Patients should be intubated at any sign of hypoxia or loss of protective gag reflex. Intravenous access should be secured using a non–dextrose-containing solution, because phenytoin precipitates if it is inadvertently administered with dextrose (dextrose will not precipitate fosphenytoin); fluids should be run at keep-open rates unless the patient is hypotensive, because status epilepticus can be

associated with both cerebral and pulmonary edema.¹⁹

The blood glucose level should be checked immediately by bedside testing. Consideration should be given to sending blood for determination of electrolytes, magnesium, phosphate, calcium, liver and renal function, hematocrit, WBC count, platelet count, anticonvulsant levels, and drug screen, including alcohol. The urine should be checked for evidence of rhabdomyolysis, and a pregnancy test should be sent on all women of childbearing age.

Patients in status epilepticus should be placed on a cardiac monitor, and an electrocardiogram should be done. A nasogastric tube should be placed to prevent gastric distention, and a Foley catheter should be placed to help monitor volume status. A head CT scan should be done at some point in all patients. Consideration should be given to performing a lumbar puncture.

The pharmacologic management of status epilepticus begins while the patient is being stabilized and diagnostic testing performed. Hypoglycemia is treated immediately with thiamine and dextrose. Antibiotics should be given very early in the management of any patient in whom meningitis or sepsis is suspected.

The benzodiazepines diazepam and lorazepam are considered the first-line drugs in the management of status epilepticus. Lorazepam (2 mg/min, up to 10 mg) or diazepam (5 mg/min, up to 20 mg) will stop seizures in the majority of cases. Both drugs are efficacious, but lorazepam is preferred because its anticonvulsant action lasts up to 12 hours, compared with 20 minutes for diazepam. Consequently, if lorazepam terminates the seizure activity, no additional anticonvulsant needs to be immediately given; a long-lasting anticonvulsant such as phenytoin must be added when diazepam is used, because, otherwise, the patient is at high risk of seizure recurrence.¹³

When seizures persist despite a full loading dose of a benzodiazepine, phenytoin or fosphenytoin is added at a rate of 50 mg/min or 150 mg/min, respectively. Status epilepticus that does not terminate at this point is usually the result of some significant underlying CNS lesion. If seizures persist, the current recommendation is to give additional phenytoin, up to a total dose of 30 mg/kg.¹³

If seizures persist after the phenytoin infusion, phenobarbital (20 mg/kg) should be given intravenously at a rate of 100 mg/min. Because respiratory depression is all but inevitable at that point, intubation is likely to be necessary, if it has not already been performed.

Patients who continue to seize despite the aforementioned interventions should be put into pentobarbital coma by giving 5 mg/kg at 25 mg/min, followed by 2.5 mg/kg/h as an infusion. Besides requiring ventilatory support, these patients are at significant risk for hypotension, and therefore require hemodynamic monitoring. Hypotension should be treated with fluids and vasopressors as needed. EEG monitoring should be instituted to evaluate for continued seizure activity.¹³

Many other drugs have been tried in the management of refractory status epilepticus, but no controlled trials support their use.⁹ These include continuous infusions of benzodiazepines, propofol, intravenous lidocaine, and rectal chloral hydrate.^{13,15} Current recommendations would support use of these drugs only if it is not possible to administer pentobarbital anesthesia.

Nonconvulsive Status Epilepticus

Nonconvulsive status epilepticus presents as altered mental status ranging from a mild behavioral alteration noticeable only to family or friends to frank coma.^{10,16} Other manifestations may include speech arrest, cognitive deficits, delusions, paranoia, hallucinations, or psychosis. Because, by definition, there is rarely a significant motor component, the diagnosis is often missed, and there are many case reports of these patients initially being diagnosed with a psychiatric illness. Nonconvulsive status epilepticus has been reported in every age group, can be the initial presentation of a seizure disorder, and has been reported to last as long as 8 weeks.

The diagnosis should be suspected in patients with a seizure history who present with a prolonged postictal period or an unusual behavior pattern. It should also be considered in patients without a seizure history who present with altered mental status of undetermined etiology. The diagnosis is made by electroencephalography. Treatment is the same as for convulsive status epilepticus, beginning with lorazepam, 2 mg/min, until the EEG normalizes or a total of 10 mg is administered. This should be followed by phenytoin loading, although it is questionable whether phenytoin is effective in absence status.¹⁷

DISPOSITION

The disposition of patients who have had a seizure depends on the etiology of the event and, often, on the socioeconomic environment to which the patient will return. Of prime importance is communication with the primary care provider who will be responsible for following up on the patient's diagnostic tests and medications.

Hospital admission should be considered when the cause of a seizure is unclear, when seizure recurrence has not been controlled, when the seizure is secondary to a treatable underlying illness, or when there is concern that the patient will not receive timely outpatient evaluation. All patients who have been in status epilepticus should be admitted, usually to an intensive care setting.

COMMON PITFALLS

- Failure to maintain and protect the airway during the management of status epilepticus
- Failure to check a Dextrostick in patients with seizures or refractory status epilepticus
- Infusion of phenytoin with a dextrose solution
- Failure to perform a complete secondary survey in postictal patients
- Assumption that altered mental status is due to a postictal state and failure to consider other possible etiologies
- Confusion of decerebrate posturing for a tonic seizure
- Failure to obtain a pregnancy test in women of childbearing age
- Failure to make a reasonable effort to obtain witnesses' accounts of a seizure
- Failure to recognize a psychogenic seizure as a nonneurologic event
- Failure to advise a patient who has had a seizure not to drive or operate dangerous equipment
- Increasing a patient's anticonvulsant medication dose without obtaining a proper history for precipitating stressors or medication compliance
- Failure to communicate with the primary care provider

[Patients with Known Multiple Sclerosis](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Multiple sclerosis (MS) is a disease of the central nervous system (CNS) in which the myelin sheath that surrounds axons is damaged as a result of an inflammatory process. The scattered areas of demyelination in the brain and spinal cord are known as plaques. Axons are relatively spared, although there is recent evidence that substantial axonal damage can occur, especially in the later phases of the disease. MS is believed to be immunologically mediated and to occur in genetically susceptible individuals.

Clinically, MS is characterized by neurologic symptoms and signs that are attributable to lesions in the different locations and that appear at different times over the patient's course. It is primarily a disease of young adults, the majority of patients reporting their first symptoms between 20 and 45 years of age. The incidence is approximately two to ten cases per 100,000 people per year.⁹ Women are affected 1.8 times as often as men, and Whites twice as often as Blacks. Apart from trauma, MS is the most significant cause of neurologic disability afflicting young adults,¹⁸ with major consequences for patients, families, and society.

The course of MS is variable and relatively unpredictable. It is characterized by exacerbations of acute or subacute onset that last for days to months. Exacerbations are more commonly manifested by the reappearance of previous signs and symptoms than by the development of new ones. Recovery between exacerbations may be incomplete, however. *Relapsing, remitting disease* refers to a situation in which the clinical course between exacerbations is stable. In general, a pattern of intermittent exacerbations is more frequent in the earlier stages of the disease, while progressive deterioration, with or without superimposed exacerbations, is more common in the later stages (secondary progressive course). A small percentage of patients experience disease progression from the onset, with or without superimposed exacerbations (progressive relapsing and primary progressive disease).¹¹

CLINICAL PRESENTATION

New Patient with Acute Focal Neurologic Deficit

The diagnosis of MS neither can nor should be definitively made in the emergency department (ED). First, most diagnostic frameworks incorporate elements of a clinical picture that changes over time; this is unavailable to the emergency physician seeing the patient at only one point in time. Second, diagnostic test results that enhance the confidence of a clinical diagnosis of MS are often not immediately available in the ED. Third, the diagnosis of MS imposes a significant psychological burden on the patient and should not be made without a substantial degree of certainty.

Symptoms of MS generally develop over hours or days, but may sometimes occur with the suddenness usually characteristic of strokes. Negative signs or symptoms (e.g., loss of vision, strength, or sensation) are due to slowed or blocked conduction in axons that undergo demyelination. The demyelinating process can also result in the generation of ectopic impulses, as well as abnormal transmission of impulses between neighboring nerve fibers. These phenomena are the basis for the generation of "positive" symptoms, such as Lhermitte's sign, an electric shock-like, tingling, or vibrating sensation in the torso or extremities that is produced by flexion of the neck. Despite the fact that demyelination can occur anywhere within the CNS, MS lesions have a predilection for certain sites, resulting in a relatively limited distribution of initial symptoms.¹⁵

The possible clinical manifestations of MS are extremely varied and may take the form of virtually any neurologic symptom. While no symptoms or neurologic findings are pathognomonic, some are characteristic and may heighten the clinician's diagnostic suspicions ([Table 207.1](#)). The majority of patients present with one or more of these signs and symptoms.

Optic neuritis
Diplopia and oculomotor dysfunction
Weakness: monoparesis, paraparesis
Paresthesias and numbness
Incoordination, unsteady gait, abnormal balance
Vertigo
Bladder, bowel dysfunction
Tremor

TABLE 207.1. Common Initial Symptoms of Multiple Sclerosis

Decreased visual acuity and symptoms related to oculomotor dysfunction (e.g., diplopia) are among the most common initial presenting symptoms of MS. Optic neuritis characteristically presents with monocular blurred vision (bilateral in 30%), and, often, retroorbital pain or headache and alteration of color vision.¹⁵ The optic disc may appear normal or swollen, blurred or hyperemic. An afferent pupillary defect (Marcus Gunn pupil), consisting of diminished response to a direct light stimulus and a normal consensual response to a light stimulus in the opposite eye, may be noted. Optic nerve involvement may remain as an isolated manifestation, but roughly half of these patients are diagnosed with MS within 15 to 20 years.^{16,17} Neuromyelitis optica or Devic disease, an uncommon disorder, consists of optic neuritis and transverse myelitis.

Nystagmus and diplopia occur commonly in patients with MS. The finding of internuclear ophthalmoplegia, especially in a young adult, is very suggestive. This form of dysconjugate gaze, referable to the medial longitudinal fasciculus of the brainstem, involves limited adduction of one eye and nystagmus in the abducting eye on lateral gaze.

Paresthesias and dysesthesias are characteristically bilateral and ascending but may affect both hands or one side of the body. Motor weakness may occur as paraparesis, hemiparesis, or monoparesis and is generally accompanied by signs of upper motor neuron dysfunction (e.g., hyperreflexia and positive Babinski sign). Transverse myelitis can be the initial neurologic event; symptoms include ascending weakness and numbness below the level of the lesion.

Transient attacks of paroxysmal dysarthria and ataxia are also suggestive of demyelinating disease when they occur in a young person without vascular risk factors.

Patients with Known Multiple Sclerosis

In most cases, the natural history of MS is characterized by episodes of neurologic dysfunction alternating with periods of stabilization or remission of symptoms.

Common signs and symptoms of chronic disease are listed in [Table 207.2](#). Patients with known MS may present to the ED because of an exacerbation of previous deficits, because of the development of new deficits, or because of medical complications of the disease.

Problem	Drugs Used in Treatment ^{17,18}
Weakness, monoparesis, paraparesis, hemiparesis, quadriplegia	Corticosteroids, potassium channel blockers (i.e., 4-aminopyridine, 3,3'-diaminopyridine)
Spasticity	Baclofen (oral or intrathecal), tizanidine, gabapentin, baclofen
Paresthesia	Amiriguine, carbamazepine, gabapentin, corticosteroids if disabling
Bladder dysfunction	Depends on type of impairment
Optic atrophy, blurred vision, central scotomata	Interferon β (intramuscular) for acute optic neuritis
Internuclear ophthalmoplegia, diplopia	Corticosteroids
Loss of balance, incoordination, ataxia, tremor	Cannabidiol for tremor; corticosteroids for balance
Cognitive changes	Serotonin reuptake inhibitors
Depression	
Sexual dysfunction	
Fatigue	Amantadine, CNS stimulants, fluoxetine
Vertigo	Meclozine, promethazine, diazepam, acetazolamide
Paroxysmal symptoms (aching, burning, twitching, Lhermitte's sign)	Carbamazepine, phenytoin, tricyclic antidepressants, low-dose antiepileptics, gabapentin
Pseudotumor cerebri	Acetazolamide, furosemide, acetaminophen

TABLE 207.2. Common Chronic Problems of Multiple Sclerosis

Factors that have been cited as having an association with the occurrence of MS exacerbations are infection (including minor respiratory infections), emotional stress, spinal anesthesia, heat exposure, and the postpartum period. Pregnancy itself has not been associated with an increase in the frequency of attacks.¹⁰

Common secondary complications in patients with MS are pneumonia, infections of the urinary tract, septicemia, respiratory failure, pulmonary embolism, bladder and renal calculi, and pressure ulcers of the skin.¹⁵ Elevated body temperature, occurring as a result of infection or because of exposure to heat, can be associated with a transient increase in neurologic symptoms. Fever-related exacerbations that include dysphagia can result in aspiration pneumonia.

Fatigue is a common complaint of patients with MS. It typically increases with exercise, heat exposure, or as the day progresses. This pattern of fatigue is distinct from that associated with depression, which is more likely to be present earlier in the day or to be constant.¹² Spasticity, a manifestation of upper motor neuron disease, is characterized by increased muscle tone, hyperreflexia, decreased mobility, painful muscle spasms, and weakness. There is conflicting evidence as to whether seizures occur more frequently in MS patients than in the general population. When seizures occur, they should not be attributed to MS until other causes have been ruled out. Similarly, aphasia and dementia should prompt a search for alternate causes.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of an acute focal neurologic deficit is broad and includes the intracranial and spinal cord processes listed in [Table 207.3](#). Some of the more common diseases capable of causing multifocal CNS lesions disseminated over time are systemic lupus erythematosus, Lyme disease, sarcoidosis, and CNS vasculitis. Because MS is a disease that is confined to the CNS, patients generally lack the rheumatologic and constitutional symptoms and laboratory abnormalities that are present in many of these other disease states. Spinal cord compression by mass lesions or hematomas must be considered in the patient who presents with symptoms referable to the spinal cord. The differential diagnosis of transverse myelitis includes both infectious (e.g., herpes simplex) and postinfectious causes.

BLEEDING (SPONTANEOUS OR TRAUMATIC)
Subdural Hematoma
Intracerebral Hemorrhage
Epidural Hematoma
Subarachnoid Hemorrhage
INFECTIOUS
Adenovirus
Brain
Epidermal
Subdural
Intracerebral/Intraventricular

NEURODEGENERATIVE
Alzheimer's Disease
Creutzfeldt-Jakob Disease
Prion Disease
Psychogenic Pseudotumor Cerebri

TABLE 207.3. Differential Diagnosis of Acute Focal Neurologic Deficit

EMERGENCY DEPARTMENT EVALUATION

When faced with a patient with one or more focal neurologic deficits in whom MS is suspected, one of the emergency physician's major tasks is the exclusion of other more treatable disease entities. The definitive diagnosis of MS is most appropriately left to the neurologist in the non-ED setting. MS remains primarily a clinical diagnosis, requiring the demonstration of focal neurologic signs and symptoms scattered over time and space. Just as no neurologic findings are pathognomonic for MS, no laboratory test is universally diagnostic. Imaging studies of the brain and spinal cord, cerebrospinal fluid (CSF) examination, and evoked potentials are the major adjuncts used to increase one's confidence in the clinically suspected diagnosis.

Magnetic resonance imaging (MRI) is superior in sensitivity to contrast-enhanced computed tomography (CT) for evaluation of the lesions of MS. A negative MRI does not, however, have sufficient sensitivity or negative predictive value to rule out the diagnosis.¹⁴ MRI is well suited for the diagnostic workup of patients suspected of having MS and for monitoring the course of the disease and its response to therapy. The number, size, and distinctive location of areas of increased signal found on MRI help distinguish MS from other neurologic diseases. Multiple white matter and periventricular lesions are characteristic, and lesions are commonly seen in the brainstem and cerebellum as well. Signal enhancement with gadolinium is characteristic of the disruption of the blood-brain barrier that occurs with active inflammatory lesions.

Newer and faster MRI techniques show promise of achieving even greater sensitivity for the lesions of MS. Findings on MRI are common in patients with optic neuritis, even when there is no other clinical evidence of MS, and MRI has been demonstrated to have prognostic value in predicting conversion from isolated syndromes, such as optic neuritis, myelitis, and internuclear ophthalmoplegia, to MS.^{24,15} MRI is also useful in identifying alternate diagnoses, such as intracranial neoplasm, vascular abnormalities, and spinal cord lesions.

Examination of the CSF can help to confirm the diagnosis. Useful findings are the presence of myelin basic protein (indicative of rapid myelin degradation); an elevated level of immunoglobulin G (IgG), out of proportion to that in serum; and the presence of oligoclonal immunoglobulin bands on protein electrophoresis. Other common CSF findings include elevated total protein and a modestly increased mononuclear cell count (less than 50 cells/ μ L). In addition, CSF analysis permits the exclusion of infection as the cause of symptoms.

Evoked potentials (EPs) are electrodiagnostic studies that measure the electrical potentials (voltages) that are evoked in response to the application of brief sensory stimuli. De-myelination causes abnormal axonal conduction that can be picked up on EP testing as abnormal potentials. This modality falls into the domain of the neurologist and is not part of the ED evaluation.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment of acute exacerbations of MS is most appropriately undertaken in consultation with a neurologist. Immunosuppression with corticotropin (ACTH) or

cortico-steroids, traditionally a mainstay of therapy for relapses in patients with known disease, is predicated on the presumed immune basis for the disease. High-dose intravenous bolus methylprednisolone is superior to placebo in decreasing the recovery time with MS relapses.^{5,13} Critical analysis of the benefit of corticosteroids in shortening the duration of relapse, preventing relapse, and modifying long-term disease progression is ongoing.⁶

Preliminary studies comparing different steroid regimens (e.g., intravenous vs. oral) have failed to demonstrate a clear advantage of one over the other.¹ An exception is the use of corticosteroids in the treatment of optic neuritis. A reduction in the rate of development of MS has been demonstrated at 2 years for short-term treatment with intravenous methylprednisolone followed by prednisone, but not for prednisone alone.² Intravenous methylprednisolone has also shown short-term benefit in improving visual acuity, but this benefit diminishes over time. Prednisone has not demonstrated this same benefit and is actually associated with an increased risk of new episodes of optic neuritis compared with placebo.³ New modalities for the treatment of relapses, based on the known pathophysiology of the myelin plaque, are currently in clinical trials.

Prevention of the exacerbations associated with MS and alteration of the progression of neurologic disability are currently the focus of extensive research. Therapeutic interventions aimed at limiting demyelination, enhancing remyelination, and improving conduction in demyelinated fibers are being investigated. Interferon beta-1b, interferon beta-1a, and copolymer 1 have shown significant promise and are the first drugs to have been demonstrated to alter the course of relapsing disease. Beta-interferons have been shown to decrease clinical relapse rate and the severity of exacerbations, and to result in a lower lesion burden on MRI.^{7,8} Copolymer 1 has been shown to reduce relapse rate and improve disability status.⁹ Administration of these drugs falls under the domain of the neurologist.

In the patient with known disease who presents with fever, sources of infection should be sought and treated aggressively. Patients with bladder dysfunction are particularly susceptible to urinary tract infection; decubitus ulcers and pneumonia are other common sources of infection that should be considered. In any event, antipyretics should be administered. An elevated temperature that is related solely to heat exposure should be treated by active cooling measures.

DISPOSITION

The new patient with clinically suspected MS may warrant hospital admission to complete the diagnostic workup, to exclude other causes of signs and symptoms, and to undergo aggressive treatment of debilitating symptoms. For the patient with known MS, determination of the need for hospitalization depends on the general medical condition as well as the neurologic status. Patients may also require hospitalization for medical complications of MS (e.g., infection), for the administration of aggressive treatment of neurologic symptoms, and for the supportive care necessary because of disability during disease exacerbations.

COMMON PITFALLS

- Failure to identify and treat other disease entities in the patient with known or suspected MS
- Failure to consider the possibility of intercurrent medical illnesses, especially those that commonly affect the chronically ill neurologic patient (e.g., urinary tract infection, pneumonia, decubitus ulcers)
- Failure to consider MS in the young patient presenting with focal neurologic signs and symptoms. The presenting symptoms of MS can be vague and transient, and can seem bizarre. A psychogenic etiology remains a diagnosis of exclusion.
- Failure to realize that rheumatologic or constitutional symptoms or abnormal laboratory values should call the diagnosis of MS into question

CHAPTER 208 Parkinsonism

Brendan R. Furlong

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Parkinsonism, or Parkinson syndrome, is a group of progressive degenerative central nervous system disorders characterized by cardinal motor signs of bradydyskinesia, tremor, rigidity, and postural instability. Idiopathic Parkinson disease (PD) is the most common cause of parkinsonism and accounts for 80% of cases. Secondary parkinsonism, from a host of disparate causes, constitutes the remaining 20% ([Table 208.1](#)).

Parkinson disease (PD)
Neurodegenerative processes
Multiple system atrophy (MSA)
Progressive supranuclear palsy (PSP)
Corticobasal degeneration (CBD)
Drugs—phenothiazines, butyrophenones, anticonvulsants
Toxins—Methylphenyl tetrahydropyridine (MPTP), carbon monoxide, manganese
Trauma
Malignancy—lymphoma, glioma
Arteriosclerotic parkinsonism
Infections—epidemic encephalitis, von Economo's encephalitis

TABLE 208.1. Causes of Parkinsonism

The incidence of parkinsonism and PD is approximately 20 per 100,000 and increases with age.^{8,10} There does not appear to be a genetic predisposition for PD when the disease begins after age 50, although there may be one for early-onset disease.¹⁰ There is no gender difference, but PD appears to be more common in Whites than in other groups.¹¹ The survival rate for appropriately treated PD approximates that of the general population, whereas that of secondary parkinsonism is markedly less and the clinical course more complicated.⁶

Although the precise cause and pathophysiology of PD is not known, profound localized depletion of the neurotransmitter dopamine in the substantia nigra is the biochemical marker for the disease.^{2,9} The mainstay of therapy for PD is neurotransmitter replacement in the form of levodopa. Infections (von Economo's pandemic of encephalitis lethargica), toxins (the designer drug methylphenyl tetrahydropyridine [MPTP]), and medications (phenothiazines) are known causes of secondary parkinsonism (see [Table 208.1](#)).

In practice, the diagnosis of parkinsonism and PD is made on clinical grounds, but the ultimate diagnosis still rests with neuropathologic confirmation at autopsy.³ The various secondary parkinsonian syndromes show etiology-specific pathologic changes in the extrapyramidal system and the cortex of the brain. PD has distinct cellular degeneration of the substantia nigra with characteristic Lewy bodies.⁴ Precisely how the neurochemical and pathologic changes in parkinsonism result in dysfunction of the regulation of tone and motor activity is not completely understood.⁶

CLINICAL PRESENTATION

Patients can present to the emergency department (ED) with complaints referable to undiagnosed parkinsonism or with complications of previously diagnosed illness. Although emergent interventions are rarely needed for the disease itself, because effective symptomatic treatment is available and there is the possibility of preventing disease progression, it is desirable to make the diagnosis as early as possible.

The clinical manifestations of parkinsonism develop insidiously and gradually. Motor deficiencies are usually asymmetric. Rigidity may be present on flexion and extension of the extremities and neck, and “cogwheel” rigidity on passive extension of the elbow or circumduction of the wrist may be noted. Early on, ambulation is generally slow; short or shuffling steps (*march à petits pas*), instability, and falls occur later. The classic tremor of PD is a 3- to 6-Hz distal resting tremor that increases in periods of anxiety and disappears during sleep or voluntary motor activity. Monotonous speech and decreased speech volume are other early features, and there is eventual development of drooling, dysphagia, and masked facies. Sensory findings are generally absent. The Mini-Mental State Examination is usually normal early in the disease. Depression may occur. The presence of early dementia and psychosis (unrelated to medicines), autonomic dysfunction (orthostasis), cerebellar findings, and supranuclear gaze palsy suggest one of the secondary causes of parkinsonism.^{3,6}

In patients with known PD, complications of therapy or a worsening of symptoms while on therapy is often the reason for presentation to the ED. The so-called on-off phenomenon, sudden wide fluctuations in motor function, ranging in severity from dyskinesia to freezing, can be particularly troubling to patients. “Wearing off,” or loss of therapeutic effect, should prompt a reassessment of the medication regime and also confirmation that secondary parkinsonism has not been erroneously diagnosed as PD. Orthostasis, nausea, vomiting, and acute psychosis can be caused by various dopaminergic and anticholinergic agents. Differentiating disease progression from medication inadequacy or excess can be difficult, but is an important part of ED management.

Other complications related to general motor disability (e.g., traumatic injuries due to falls) are significant reasons for ED presentation. In addition, many older patients, the cohort most affected by parkinsonism, have multiple medical conditions that can be more difficult to manage in the setting of progressive parkinsonism.

DIFFERENTIAL DIAGNOSIS

The primary entities in the differential diagnosis of parkinsonism are idiopathic PD and secondary parkinsonism. To help distinguish PD from other causes of parkinsonism on a clinical basis, Gelb et al.³ have suggested specific diagnostic criteria for PD: bradykinesia, rigidity, and the asymmetric onset of resting tremor, all of which must have a substantial and sustained response to levodopa or dopamine agonist therapy. The presence of postural instability, freezing phenomena, hallucinations, dementia, severe dysautonomia, or supranuclear gaze palsy within the first 3 years of disease presentation suggests a secondary form of parkinsonism.³ PD has a gradually progressive course; rapid progression strongly suggests another form of parkinsonism.³

EMERGENCY DEPARTMENT EVALUATION

The ED evaluation of a patient with clinical symptoms suggestive of parkinsonism consists primarily of a history and physical examination. For patients with new symptoms, clinical assessment is aimed at identifying parkinsonism and then differentiating between the secondary parkinsonian syndromes and PD.

For patients previously diagnosed with parkinsonism, evaluation should focus on progression of disease, complications of medical treatment, and concomitant medical conditions.

EMERGENCY DEPARTMENT MANAGEMENT

Strategies for the management of parkinsonism in the ED should be coordinated with the physician who will treat the patient for the long term.

For patients who are *newly diagnosec* with PD, treatment includes agents to alleviate disabling symptoms, as well as agents that are potentially neuroprotective. [Table 208.2](#) outlines treatment options. The centrally acting dopamine agonist levodopa is the mainstay of symptomatic treatment. It is desirable to use the minimum amount of levodopa necessary to control symptoms, because the metabolism of levodopa is thought to contribute to an excess of oxyradicals in the substantia nigra, leading to further cell degeneration. Levodopa's peripheral side effects (nausea, vomiting, and orthostasis) are thus limited as well. ⁹ Carbidopa blocks the peripheral metabolism of levo- dopa, allowing lower doses of levodopa to be effective centrally. For this reason, the levodopa–carbidopa combination drug, Sinemet, has become a mainstay of treatment. The dopamine agonists bromocriptine and pergolide are often used as adjuvant therapy and help reduce the dose of levodopa required while themselves serving as neuroprotective agents. The monoamine oxidase (MAO) B inhibitor selegiline is utilized primarily as a neuroprotective agent, but may also have some symptomatic benefit. The anticholinergic drug benztropine is prescribed selectively for patients with tremor predominance. Surgical options are generally used only in those with severe disease refractory to medical management.

MECHANISM
Dopamine Precursor Centrally increases the pathologically deficient dopamine, which is able to cross the blood-brain barrier; improves symptoms; most often used in combination with carbidopa Side effects: dyskinesia, psychosis, nausea/vomiting, postural hypotension
Peripheral Dopamine-decarboxylase Inhibitor Carbidopa: peripheral dopamine decarboxylase inhibitor; decreases peripheral breakdown of levodopa, allowing lower dose therapy Side effects: may exacerbate central dopaminergic side effects when levodopa dose not adjusted accordingly
Dopamine Agonist Nonergoline dopamine agonist used in adjunct to levodopa decreases the dopamine requirement (thus allowing lower dose levodopa therapy); also appears to decrease dyskinesias and "on-off" side effects Side effects: hyperemesis, nausea, vomiting, constipation, fatigue, hallucinations Ergoline dopamine agonist used in adjunct to levodopa; also used to treat as monoamine; particularly early in young-onset PD Side effects: hyperemesis, nausea, vomiting, constipation, confusion, hallucinations, dyskinesia, dystonia
MAO-B Inhibitor Selegiline: MAO-B inhibitor thought to reduce the peroxide produced as MAO-B metabolizes dopamine; may also have some therapeutic effect Side effects: sleep disturbance, psychosis, agitation, confusion, dyskinesia
Anticholinergic Drug Benztropine: central muscarinic blocker; useful in treating the tremor of PD Side effects: typical anticholinergic symptoms and signs
MECHANISM
Electrical deep-brain stimulation Reduction of pathologic Neural cell transplantation

TABLE 208.2. Management of Parkinson Disease

For patients with *known* PD, ED management is directed at recognizing the inadequacy or excess of the medication regimen and adjusting dosages accordingly. The “on–off” phenomenon is thought to be due to fluctuations in drug concentrations. Changing doses and/or dosing intervals and adding other antiparkinsonism agents may be necessary. A sustained-release levodopa–carbidopa combination appears to reduce the total levodopa requirement, as well as variations in drug concentration.¹ Medication excess may cause acute psychiatric and cognitive side effects, such as psychosis, hallucinations, delusions, agitation, and confusion. This may require a decrease in dopaminergic and anticholinergic medications and the initiation of clozapine. ⁹ The peripheral side effects of excessive dopamine (nausea, vomiting, and orthostasis) are treated by reducing levodopa doses. Optimizing the balance of various agents can be difficult and should be coordinated with the patient's primary physician.

The management of the parkinsonian syndromes other than PD is generally less effective. Parkinsonism due to prescription medications may improve with cessation of the implicated agent, but parkinsonism associated with prior MPTP use is not reversible. Symptoms of neurodegenerative parkinsonism can be managed with the same agents as used for those of PD, but there tends not to be a sustained response to therapy.

For all parkinsonian syndromes, injuries from falls, infections (e.g., aspiration pneumonia), and concomitant medical conditions should be evaluated and managed as with other patients, keeping in mind the limitations imposed by the patient's chronic level of functioning.

DISPOSITION

Whether the diagnosis of parkinsonism is made in the ED or the patient is being seen for complications of therapy or progression of symptoms, the patient's primary care physician or neurologist should be consulted. This assures continuity of care, which is essential to optimize the management of this chronic condition. Rarely is admission to the hospital or transfer to a tertiary care center indicated for parkinsonism itself. Complications such as sepsis or injuries from falls are more likely to be indications for inpatient management.

COMMON PITFALLS

- The diagnosis of parkinsonism may be missed in patients with vague complaints of dizziness, unsteadiness, or inability to walk, unless the signs are specifically sought on careful neurologic examination
- The complex medical regimens for PD require precise modifications to maximize clinical benefit while minimizing side effects

While MH occurs by a peripheral reaction, NMS and SS are centrally mediated. Although the complex role of neurotransmitters in heat regulation is not clearly understood, dopamine is involved. The extrapyramidal system, which maintains equilibrium and muscle tone, involves the activity of a number of neurotransmitters, including dopamine, serotonin, acetylcholine, and GABA.

CLINICAL PRESENTATION

NMS presents with altered mental status, autonomic instability, hyperpyrexia, and muscular rigidity, which develop rapidly over 1 to 3 days. Not every patient presents with all signs, although hyperpyrexia and altered mental status are nearly always present. Diagnostic criteria for NMS are presented in [Table 209.4](#). Temperature in excess of 41°C has been reported. Muscular rigidity of the thorax may impair breathing. Autonomic dysfunction may cause severe variations of both blood pressure and pulse. Some patients may develop seizures, trismus, opisthotonos, and positive Babinski's signs.

Patient taking neuroleptic with Fever Muscle rigidity ↑ CPK Or two of the above, plus four of the following: Tachycardia Abnormal blood pressure Tachypnea Altered mental status Diaphoresis Leukocytosis

TABLE 209.4. Diagnostic Criteria for Neuroleptic Malignant Syndrome

MH can occur at any interval after initiation of anesthetics. Masseter muscle spasm is generally noted initially, and then generalized muscle rigidity leads rapidly to hyperpyrexia. Some patients develop recurrent symptoms 48 hours after the initial episode.

SS was first described in 1955 but, most notably, was likely the cause of death in the Libby Zion case.¹ It involves an alteration in mental status, autonomic dysfunction, and increased neuromuscular activity, the latter causing a rise in temperature. Diagnostic criteria for SS are presented in [Table 209.5](#). Mental status changes may be manifested as agitation, confusion, drowsiness, coma, and/or seizures. Autonomic dysfunction may produce nausea, salivation, tachycardia, diaphoresis, diarrhea, hyperthermia, hypertension, and mydriasis.

The addition or increase in dosage of a serotonergic agent Plus three of the following: Agitation Mental status changes Diaphoresis Diarrhea Myoclonus Fever Tremor Hyperreflexia Incoordination No neuroleptic has been involved.

TABLE 209.5. Diagnostic Criteria for Serotonin Syndrome

Reported neuromuscular findings can include ankle clonus, hyperreflexia, rigidity, tremor, ataxia, head twitching, mutism, bilateral Babinski's, and myoclonus. Many of the findings are similar to those of NMS, but mydriasis is seen with SS and lead-pipe rigidity with NMS. Symptoms can be seen within 15 minutes and can last for up to 6 hours. The duration of symptoms in other cases is dependent on drug half-life, but, in severe cases, symptoms can persist for up to 6 weeks.

Because all three syndromes share similar presentations, with severe muscle contraction and hyperpyrexia, they share common complications of rhabdomyolysis, myoglobinemia, and intravascular hemolysis. Patients may also develop pulmonary embolism, cardiovascular collapse, myocardial infarction, and acute respiratory failure. The brain is particularly sensitive to heat. Temperatures above 42°C cause central nervous system (CNS) damage, initially to the more sensitive cerebellum and eventually to the cerebral cortex, brainstem, and spinal cord.

DIFFERENTIAL DIAGNOSIS

Infectious etiologies, particularly meningitis, are generally the primary consideration in the differential diagnosis. Many authors suggest initial empiric CNS coverage in all patients suspected of having NMS.

In fever, the hypothalamic "set point" is altered so that the body seeks to stay at an elevated temperature. Fever appears to be mediated by prostaglandins and can be reduced by the use of prostaglandin inhibitors. Such medications have no effect on environmental hyperthermia or drug-induced hyperthermia.

Drugs may increase basal heat production by increasing metabolism, stimulating beta receptors, impairing sweating, or uncoupling oxidative phosphorylation (e.g., salicylates). All three syndromes increase metabolism. In addition, neuroleptic medications may impede sweating through anticholinergic mechanisms.

Lethal catatonia is a disorder similar to these syndromes, and occurs in patients with psychiatric disorders (primarily schizophrenia) who are not taking antipsychotic medications. The pathogenesis is unknown, although dopamine antagonism or depletion appears to underlie the disorder.⁸ Patients initially develop mood swings, anorexia, and insomnia, followed by muscular rigidity, severe agitation, and psychosis. Autonomic instability (labile blood pressure and pulse and severe hyperthermia) is also seen.

Finally, patients can develop catatonia with profound muscular rigidity and continued hyperthermia. Patients with lethal catatonia are at risk for similar complications, including acute renal failure, rhabdomyolysis, acute respiratory failure, and disseminated intravascular coagulation. Management is directed at reducing temperature and preventing renal failure and rhabdomyolysis. Bromocriptine, amantadine, and dantrolene have been used, but with variable response. Benzodiazepines have also been useful. Electroconvulsive therapy given early in the course of lethal catatonia is reported to be particularly effective.¹²

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

As in all patients, attention to the ABCs takes priority. All should receive high-flow oxygen and have at least two intravenous (i.v.) sites established. Rapid cooling should be initiated by the use of fans and cool-water spray.

Renal failure may be prevented or lessened by saline diuresis (up to 150 mL/h) accompanied by an osmotic agent (e.g., mannitol) or a diuretic (e.g., furosemide).

Rhabdomyolysis can be prevented or lessened by sodium bicarbonate by increasing urinary pH. In theory, sodium bicarbonate will inhibit the formation of ferrihemate, a nephrotoxin. Hyperkalemia may accompany extensive rhabdomyolysis and can be treated by calcium gluconate, insulin and glucose, or exchange resins.

Monitoring of cardiac rhythm and core temperature is essential. Electrolyte abnormalities, including hypocalcemia, hyperkalemia, and hyperphosphatemia, are common, as is leukocytosis, with or without a left shift. Liver damage from hyperthermia is reflected in elevated transaminases and alkaline phosphatase. A computed tomography scan should be performed to rule out a cerebral bleed, and a lumbar puncture may need to be performed to rule out bacterial meningitis.

With the increasing emergency department use of succinylcholine for rapid-sequence intubation, emergency physicians need to be aware of the early signs of MH. Masseter muscle contraction or any developing muscular rigidity should lead to immediate treatment, which is outlined in [Table 209.6](#). Agents safe for use in patients with MH include vecuronium, pancuronium, etomidate, propofol, opiates, barbiturates, benzodiazepines, and ester-based local anesthetics such as lidocaine. Dantrolene, the mainstay of treatment, is a muscle relaxant that decreases the release of calcium by the sarcoplasmic reticulum. The dosage is 0.8 to 3.0 mg/kg i.v. q6h, up to a maximum of 10 mg/kg/d.

Discontinue precipitating agent.
Administer dantrolene 2 mg/kg i.v., up to 10 mg/kg/d.
Infuse saline with sodium bicarbonate to maintain urinary output.
Monitor systemic pH to prevent alkalosis.
Cool patient with cooling blanket, ice packs, or evaporation.
Monitor for electrolyte imbalance and cardiac dysrhythmias.
Avoid the use of calcium antagonists or digoxin.

TABLE 209.6. Treatment of Malignant Hyperthermia

Specific treatment for NMS is not well established. Neuroleptic agents should be discontinued. Dantrolene appears to be most useful in patients with prominent muscle contraction. Bromocriptine mesylate, a dopamine agonist, is widely used alone or in combination with dantrolene; the dosage is 2.5 to 7.5 mg orally q8h. Bromocriptine is most useful when hyperthermia is not accompanied by dramatic muscle rigidity. Amantadine, another dopamine agonist, also has been used with some success. Levodopa and carbidopa-levodopa are useful in many patients, particularly those in whom NMS is associated with the recent withdrawal of these medications.

Treatment of SS consists of discontinuing the offending medication and providing supportive care. Benzodiazepines have been useful in decreasing hyperactivity, as has chlorpromazine, though with somewhat variable efficacy. Cyproheptadine (4 mg/h) or methysergide (2 mg b.i.d.) has been reported to decrease the symptoms of SS.⁹

DISPOSITION

All patients with these syndromes require inpatient treatment, generally in the intensive care unit, with consultation with a psychiatrist (for NMS, SS) or anesthesiologist (for MH). Mortality has fallen dramatically in all three syndromes with increased recognition and early aggressive treatment.

COMMON PITFALLS

- Very high temperatures (in excess of 42°C) are rarely due to bacterial or viral infection; thus, more unusual causes of hyperthermia should be considered. Nonetheless, patients with NMS, SS, or MH should undergo evaluation for infection, generally including lumbar puncture.
- Patients receiving succinylcholine as a component of rapid-sequence intubation are at potential risk of MH. Periodic evaluation for masseter spasm may alert the physician to developing MH.
- Patients with severe hyperthermia (greater than 41°C) require immediate cooling, regardless of the underlying etiology. Antipyretics are not effective for environmental hyperthermia or in drug-induced syndromes such as MH, SS, or NMS. Hyperthermic individuals should be monitored for signs of rhabdomyolysis, renal failure, or other end-organ damage.
- Patients receiving serotonin agonists should not receive other serotonin-active drugs, including such commonly prescribed medications as meperidine and dextromethorphan.

CHAPTER 210 Bleeding Disorders

Kathleen C. Hubbell

[Pathophysiology](#)
[Emergency Department Evaluation](#)
[Laboratory Tests](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Emergency physicians encounter bleeding on a daily basis: Bleeding lacerations, epistaxis, bruising, hematuria, gastrointestinal (GI) bleeding, and blunt and penetrating trauma are common complaints in the emergency department. Most of these patients have normal clotting function and are bleeding because of a local lesion. Their bleeding can be controlled by pressure, packing, suturing, or other local therapy aimed at the specific lesion, and bleeding does not recur if the lesion is properly treated.

On the other hand, a patient with a bleeding disorder may bleed spontaneously as well as after trauma, and treatment of the local lesion may not control the bleeding or prevent its recurrence. The disorder may be congenital or acquired, and may involve one or more components of the body's complex coagulation system.

PATHOPHYSIOLOGY

Hemostasis is normally maintained by the balanced functioning of four elements: the blood vessel wall, the platelets, the clotting factors ([Table 210.1](#)) and inhibitors, and the fibrinolytic system. Altered function of any of these components may lead to bleeding or thrombosis.

Factor	Common Name	Concentration Required
I	Fibrinogen	100 mg/dL
II	Prothrombin	30%–40%
III	Tissue thromboplastin	—
IV	Calcium	—
V	Labile factor, proaccelerin	30%–40%
VII	Proconvertin	30%–40%
VIII	Antihemophilic globulin	30%–40%
IX	Christmas factor	30%–40%
X	Stuart–Prower factor	30%–40%
XI	Plasma thromboplastin antecedent	20%
XII	Hageman factor	None
XIII	Fibrin-stabilizing factor	1%
Prekallikrein	Fletcher factor	None
High-molecular-weight kininogen	Williams–Fitzgerald–Flouquet factor	None

Adapted from White GC, Marder VJ, Colman RW, et al. Approach to the bleeding patient. In: Colman RW, Hirsh E, Marder VJ, et al, eds. Hemostasis and Thrombosis: Basic Principles and Clinical Practice, 3rd ed. Philadelphia: JB Lippincott Co; 1997.

TABLE 210.1. Concentration of Blood Clotting Factors Needed for Normal Hemostasis

Normally, the *vascular endothelium* provides a barrier between the fluid blood and the adhesive proteins collagen, von Willebrand factor (vWF), and fibronectin, which are synthesized in the endothelial cells and secreted into the extracellular matrix. It also prevents coagulation through the action of thrombin inhibitors, such as thrombomodulin, that are bound to the endothelial cell membranes. When the endothelium is disrupted by trauma, immune complexes, proteolytic enzymes, bacterial endotoxin, viruses, or other stimuli, the adhesive molecules are exposed.

Platelets adhere to these proteins through their glycoprotein (GP) 1b/IX complexes. Adherence stimulates pseudopod formation and release of various substances involved in the coagulation process from the alpha and dense granules of the platelets. During the release, granule cell membranes merge with the platelet cell membranes, exposing other glycoproteins that serve as binding sites for coagulation factors. The release induces a change in the GP IIb/IIIa complexes that allows them to bind fibrinogen and link one platelet to another (aggregation). Products released from the injured endothelium and from the platelets, in addition to the presence of binding sites and cofactors for coagulation on the platelet membrane, encourage the initiation of the *clotting factor* cascade, which terminates in the formation of the fibrin clot.

The cascade has two initially separate pathways that join to form the common pathway ([Fig. 210.1](#)). The intrinsic pathway uses components normally found in plasma; the extrinsic pathway requires initial activation by tissue factor, previously known as thromboplastin. This classic version of the cascade has been supplemented by information from new studies, which shows additional interactions between the two pathways and a predominant role for the extrinsic pathway in the initiation of factor activation. The tissue factor (of the extrinsic pathway) released from the injured endothelial cells forms a complex with factor VII that activates not only factor X, as previously known, but also factor IX. Activated factor IX can then proceed through the last step of the intrinsic pathway to activate additional factor X, which, in turn, contributes to the formation of thrombin. Thrombin can activate factor XI, reinforcing the activation of the factors of the intrinsic pathway. As the extrinsic pathway initiates the cascade, an inhibitor called “tissue factor pathway inhibitor” is formed and prevents further activation of factors IX and X through the extrinsic arm of the cascade, leaving the intrinsic pathway as the main route to the activation of thrombin. These newly discovered coagulation mechanisms explain such previous observations as the lack of bleeding diathesis in patients with factor XII and prekallikrein deficiency, as contrasted to the severe disease seen in patients with low levels of factors VIII and IX. Several steps in the pathways require the presence of calcium and a platelet phospholipid surface. Platelets thus are necessary not only to fill the endothelial defect initially, but also to provide elements needed for the operation of the clotting cascade, which serves to localize thrombus generation to the area of endothelial injury.^{2,12,18}

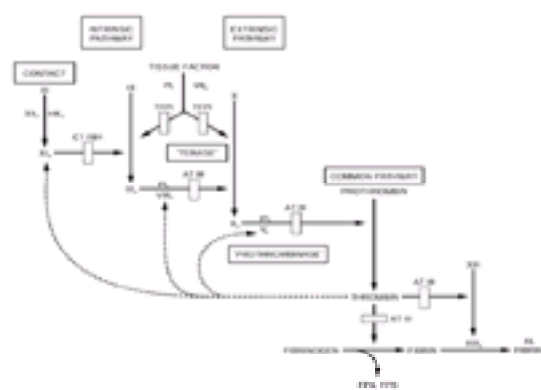

Figure 210.1. The clotting cascade. The central precipitating event is considered to involve tissue factor (TF), which, under physiologic conditions, is not exposed to the blood. With vascular or endothelial cell injury, TF acts in concert with activated factor VIIa and phospholipid (PL) to convert factor IX to IXa and factor X to Xa. The “intrinsic pathway” includes “contact” activation of factor XI by the XIIIa/activated high-molecular-weight kininogen (HKa) complex. Factor XIa also converts factor IX to IXa, and factor IXa, in turn, converts factor X to Xa, in concert with factors VIIIa and PL (the “tenase” complex). However factor Xa is formed, it is the active catalytic ingredient of the “prothrombinase” complex, which includes factor Va and PL and converts prothrombin to thrombin. Thrombin cleaves fibrinopeptides (FPA, FPB) from fibrinogen, allowing the resultant fibrin monomers to polymerize, and converts factor XIII to XIIIa, which cross-links (XL) the fibrin clot. Thrombin accelerates the process (interrupted lines) by its potential to activate factors V and VIII, but continued proteolytic action also dampens the process by activating protein C, which degrades factors Va and VIIIa. Thrombin activation of factor XI to XIa is a proposed but not yet proven pathway. Natural plasma inhibitors retard clotting: C1-inhibitor (C1 INH) neutralizes factor XIIa, TF pathway inhibitor (TFPI) blocks factor VIIa/TF, and antithrombin III (ATIII) blocks factors IXa, Xa and thrombin. Arrows, active

have a history of recognized head trauma; even in patients with known trauma, neurologic manifestations may be delayed 1 to 6 days.³ Therefore, hemophiliacs with any neurologic symptom or sign should receive a computed tomography (CT) scan, even in the absence of trauma. The same approach should be followed in patients with significant factor depletion due to an acquired disorder (e.g., coumadin therapy).

Several articles in the literature suggest that hemophiliac and anticoagulated patients who have no history of loss of consciousness or posttraumatic amnesia, and who have a normal mental status and neurologic examination, may not need a CT scan of the head. These studies have shown either no CT abnormalities or no clinical findings of neurologic injury on follow-up if CT not done.^{4,7,9,17} However, these studies are retrospective and involve small numbers of patients. The physician should consider the patient's past as well as recent history, social circumstances, and the availability of follow-up care, and err on the side of obtaining a CT if there is even the slightest suspicion of intracranial injury or any problem with follow-up.

Some bleeding disorders combine features of both platelet and clotting factor deficiencies. Examples include DIC, liver disease, and severe vWD. vWD results from a deficiency in the complex of two proteins, factor VIII and vWF, that circulate together in plasma. vWF promotes adhesion of platelets to the subendothelium of damaged vessels and induces platelets to bind fibrinogen, which facilitates the platelet interactions essential for formation of the hemostatic plug. Factor VIII plays its part in the clotting factor cascade in the activation of factor X. Most patients with vWD have bleeding typical of a platelet disorder, but those with severe disease display both mucosal and deep bleeding.

The physical examination is directed toward identifying all bleeding sites and recognizing signs of underlying illness. Jaundice, organomegaly, adenopathy, and abnormal masses are sought.²²

Laboratory Tests

When intelligently combined with a careful history and physical examination, a few basic laboratory tests are sufficient for the emergency evaluation of bleeding disorders: the activated partial thromboplastin time (aPTT), the prothrombin time (PT), and the platelet count. Other tests can pinpoint specific factor deficiencies or functional platelet disorders, but these assays are unavailable on an emergency basis and are unnecessary for emergency treatment.

The aPTT detects abnormalities of the intrinsic and common pathways and is prolonged by deficiencies of high-molecular-weight kininogen; prekallikrein; factors XII, XI, IX, VIII, X, V, and II; and fibrinogen. The aPTT is also prolonged in the presence of antiphospholipid antibody (formerly termed the *lupus anticoagulant*) and by heparin, coumadin, and fibrin degradation products. The test is performed by exposing plasma to an activating surface such as kaolin and adding calcium and the necessary phospholipid (partial thromboplastin). The time required for clotting in this test is usually 25 to 40 seconds.^{12,22}

The PT reflects the activity of the factors of the intrinsic and common pathways. It is prolonged by deficiencies of factors VII, X, V, and II and fibrinogen; by coumadin; and by heparin in high concentrations. The test is performed by adding thromboplastin (a phospholipid-protein extract of lung, brain, or placental tissue) and calcium to the plasma. The time required for clotting is normally 10 to 14 seconds, shorter than the aPTT because the initial time-consuming steps of the intrinsic pathway have been bypassed with the direct activation of factor X by thromboplastin-activated factor VII. The PT is more affected by reduced levels of factors VII, V, and X than by decreases in factor II and fibrinogen.^{12,22}

When the PT is used to monitor coumadin therapy, the PT ratio (the ratio of the patient's PT to a control's PT) has been superseded by the international normalized ratio (INR):¹⁰

$$\text{INR} = (\text{PT ratio})^{\text{ISI}}$$

The ISI is the international sensitivity index, which relates the thromboplastin's activity to that of a single batch of human brain thromboplastin, designated as the first international reference preparation by the World Health Organization in 1977. Using the ISI to standardize the PT ratio removes the variability in the determination of the PT caused by the use of thromboplastins manufactured from different organ sources and by different extraction techniques. The INR can be interpreted by the clinician as a reflection of the patient's degree of anticoagulation, whereas the PT ratio may reflect only the reactivity of the thromboplastin used to perform the test.

The thromboplastins now used in the United States are much less responsive to reductions in vitamin K–dependent clotting factors than those used from the 1940s through the 1960s. Hence, in the 1970s and 1980s, higher doses of coumadin were required to produce the desired PT prolongation; clinicians prescribed higher doses of coumadin to achieve the same laboratory value, but they were actually overanticoagulating their patients. The use of the INR has made it possible to avoid this error.

Another result of this change has been a reevaluation of the research that formed the basis for anticoagulant dosage recommendations. Revised recommendations published in 1989 use INR values and endorse lower PT ratios as the basis for safe and appropriate anticoagulation.¹⁰ Ratios of 1.3 to 1.5 are now recommended for most conditions. Less intense anticoagulation is effective for the prevention and treatment of venous thrombosis and pulmonary embolism and for use in patients with tissue heart valves, atrial fibrillation, myocardial infarction, and valvular heart disease; more intense anticoagulation is appropriate for patients with mechanical prosthetic valves and recurrent systemic embolism (Table 210.4).

Indication	INR	PT Ratio (ISI = 2.4)
Prophylaxis of venous thrombosis	2.0–3.0	1.3–1.5
Treatment of venous thrombosis		
Treatment of pulmonary embolism		
Prevention of systemic embolism		
Tissue heart valves		
Acute myocardial infarction	3.0–4.5	1.5–2.0
Valvular heart disease		
Atrial fibrillation		
Mechanical prosthetic valves		
Recurrent systemic embolism		

Adapted from Hirsh J, Poller L, Deykin D, et al. Optimal therapeutic range for oral anticoagulants. Chest 1989;95:75.

TABLE 210.4. Recommended Values for Anticoagulant Therapy Monitoring

Patients with factor VIII and IX deficiencies (hemophilia A, B, and vWD) have a prolonged aPTT and a normal PT. Patients with a normal aPTT and a prolonged PT have a factor VII deficiency, because that is the only factor of the extrinsic pathway not involved in the common pathway. Isolated factor VII deficiency occurs as a congenital abnormality and is seen in the acquired form in mild liver disease and in the initial stages of oral anticoagulation or vitamin K deficiency. Although the aPTT, as well as the PT, are prolonged in the fully coumadinized patient, the PT is used for monitoring because of its simplicity. Both the PT and the aPTT are prolonged in moderate-to-severe liver disease, vitamin K deficiency, heparin and coumadin use, afibrinogenemia, and consumptive coagulopathies such as DIC.^{12,22}

Specific factor assays can be done to confirm the diagnosis suspected from the history or from abnormalities of the screening PT and aPTT and to provide exact activity levels. However, these assays are rarely available on an emergency basis, and emergency treatment must be initiated without the benefit of such tests.

The platelet count is the first step in the evaluation of possible platelet disorders. Patients with counts less than 100,000/μL are considered thrombocytopenic; if platelet function is normal, the bleeding time increases in direct proportion to the decrease of the count below 100,000/μL. Patients with platelet counts below 5,000 to 10,000/μL are at risk for spontaneous bleeding. Platelet counts above 50,000 to 60,000/μL are usually sufficient to control bleeding caused by trauma or local pathology. However, the platelet count should never be the only criterion considered when assessing a patient's risk of hemorrhage. The underlying condition leading to thrombocytopenia must be sought, and platelet function must also be considered.¹⁹

No tests are available on an emergency basis that specifically screen for platelet function, as opposed to platelet number. A thorough history and physical

examination, however, may suggest that the patient is at risk for a functional platelet disorder (e.g., alcohol or aspirin use). The bleeding time, a laboratory test that evaluates both platelet number and function, is determined by measuring the time required for bleeding to stop after a standard incision 1 to 2 mm deep and 5 mm long is made on the patient's forearm while an inflated blood pressure cuff on the upper arm maintains venous pressure at 40 mm Hg. The normal bleeding time is 4 to 7 minutes. If the platelet count is normal, a prolonged bleeding time suggests a functional platelet disorder. ²²

A few bleeding disorders produce no abnormalities in the available screening tests. Patients with vascular disorders, simple and senile purpura, factor XIII deficiency, and mild forms of other factor deficiencies (factor levels greater than 20% to 25% of normal) have normal aPTTs, PTs, and platelet counts. ^{12,22}

EMERGENCY DEPARTMENT MANAGEMENT

Appropriate treatment of bleeding disorders depends on the physician's success in determining the most likely etiology of the bleeding.

The initial management of the bleeding patient includes airway control, if necessary, and adequate ventilation and oxygenation. If bleeding has led to hypovolemia, crystalloid resuscitation is started, and packed red blood cells given as needed. Local measures to control bleeding (e.g., pressure, packing, suturing, immobilization, gastric lavage) are used. As these basic measures are instituted, information from the history, physical examination, and laboratory tests can be combined to assess the probability that a platelet, coagulation factor, or mixed disorder is present.

If there is active bleeding typical of that caused by a platelet disorder and the platelet count is below 50,000/ μ L, platelet transfusions are given. ¹⁹ Active bleeding with a platelet count above 50,000/ μ L should prompt a search for another cause of bleeding, such as a functional platelet disorder or a coagulation factor deficiency. Controversy continues regarding the platelet count below which prophylactic transfusion to prevent spontaneous hemorrhage should be given. It is thought that platelets play an essential role in the maintenance of vascular endothelial integrity and that a minimum number are required to fulfill that function. Below this threshold, thinning and fenestration of the endothelium may lead to spontaneous bleeding. Studies suggest that 5,000 to 10,000 platelets/ μ L can maintain vascular integrity and that prophylactic transfusion should be given for values below that to prevent intracranial and other hemorrhage. However, factors such as fever, presence of an anatomic bleeding risk (e.g., a known GI lesion), rate of decrease of platelet count, presence of coexisting coagulation defects, and etiology of the thrombocytopenia affect the likelihood of bleeding and must be considered in the decision to transfuse. For these reasons, some experts recommend a higher level of 15,000/ μ L. ¹⁹

There are several benefits to decreasing unnecessary prophylactic platelet transfusions, including reduced cost and disease transmission. More importantly, avoidance of alloimmunization decreases the incidence of unresponsiveness to subsequent transfusions and may enhance the success of bone marrow transplantation, which may be a lifesaving procedure in some patients.

Patients who need prophylactic transfusion or who are actively bleeding because of thrombocytopenia should receive 10 bags of pooled random-donor platelets (RDPs) or a single-donor platelet (SDP) unit, which is equivalent to six to eight RDPs. One RDP unit raises the platelet count by 5,000 to 6,000/ μ L in healthy adults, and probably less in ill, bleeding patients and those with platelet-destructive or -consumptive disorders. A posttransfusion platelet count should be obtained to guide further transfusion. ^{11,19}

Although immune destruction or consumption of transfused platelets may occur in patients with certain disorders, the temporary effect of the transfusion may be lifesaving in the actively bleeding patient; thus, platelets should be given while attempts are made to treat the underlying disorder. Two conditions are exceptions to this recommendation. In thrombotic thrombocytopenia purpura and in heparin-induced thrombocytopenia, platelet transfusions are considered to be harmful, because they can lead to increased microangiopathic thrombosis. ¹⁹

Hemostatic defects in uremia are multifactorial, but are primarily related to defects in platelet function defects. Only in the severely nephrotic patient should significant coagulation factor deficiencies be suspected. Platelet counts are somewhat decreased, but rarely below 100,000/ μ L. The functional platelet defect is due to toxic retained metabolites, which can quickly reduce the effectiveness of newly transfused platelets. Dialysis at least partially reverses this toxic effect but may not be immediately available for the bleeding patient. Two pharmacologic adjuncts can help. ¹¹ DDAVP can shorten the bleeding time within 2 hours in uremia. The effect lasts only 12 hours and decreases with repeated doses. The mechanism of action is not known. Conjugated estrogens decrease the bleeding time within 6 hours, and a 5-day course will maintain the effect for 2 weeks. Along with the administration of platelets, these should be considered primary therapy of bleeding in the uremic patient. If they fail, cryoprecipitate can be given. Its efficacy is controversial, and its mechanism of action unclear.

Maintaining a hematocrit greater than 25% also appears to decrease bleeding time in uremia. It has been proposed that an adequate number of red cells distribute the platelets closer to vessel walls, where they can fulfill their function. ¹¹

If the clinical evaluation suggests a congenital single-factor deficiency (e.g., hemophilia A or B), the location of the bleeding determines the therapeutic approach. Bleeding into the central nervous system (CNS), neck, or retroperitoneal spaces is life-threatening. All hemophiliacs with suspected bleeding in these high-risk sites should receive immediate factor replacement therapy with 50 U/kg of the appropriate factor, without waiting for the results of the aPTT, factor levels, or head CT or other scans. If the bleeding is in the joint space, oral cavity, GI tract, soft tissues, or muscles, 20 U/kg of factor VIII or 15 U/kg of factor IX is recommended. The half-life of factor VIII is 12 hours, so maintenance therapy should be infused every 12 hours or given as a continuous infusion. (Factor IX maintenance therapy is given every 24 hours.) Factor administration should be continued for 14 days if bleeding is located in the CNS, neck, or retroperitoneum. ^{4,8,14} Admission for observation should be strongly considered in those patients with injury or suspected bleeding in the high-risk sites.

Recognition of the role of pooled plasma products in the transmission of hepatitis, the human immunodeficiency virus (HIV), and other viral diseases to a majority of severe hemophiliacs spurred the development of the safer and more highly purified products available today. The emergency physician should be knowledgeable about selecting the appropriate product for each patient. No HIV, hepatitis B, or hepatitis C seroconversion has been reported in previously unexposed hemophiliacs since 1987. However, there have been outbreaks of thermoresistant and non-lipid-enveloped hepatitis A and parvovirus B19 infection associated with virucidally treated factor VIII preparations. ¹⁵

Another problem associated with factor concentrates is the large amount of non-factor VIII plasma proteins included in the preparations. Repeated exposure to these contaminants has been associated with significant and progressive alterations in immune function (e.g., lowering of CD4 counts and development of anergy) in HIV-infected hemophiliacs. A purification method called "immunoaffinity," which uses monoclonal antibodies against factor VIII or vWF to separate the factor from the other proteins, produces an extremely pure product that should be used in the HIV-positive hemophiliac. ^{14,15}

Recombinant factor VIII (produced in hamsters) has been shown to have full hemostatic function and a normal half-life in humans. Although there has been concern that the recombinant factor may be more likely to induce the production of inhibitors than plasma-derived factor, these effects have generally been no greater than with any other factor VIII preparation. ¹⁴ Recombinant factor VIII products are usually more expensive than the other products.

The choice of appropriate factor VIII product for each hemophilic patient is one that should be made in concert with the patient's hematologist, if possible. All currently marketed factor VIII products are considered safe from the standpoint of HIV and hepatitis B and C transmission. High-purity products are those from which non-factor VIII protein contaminants have been removed. Intermediate-purity products contain plasma protein, but not viral contaminants.

Another approach to the treatment of non-life-threatening bleeding in patients with mild or moderate hemophilia A or with type I vWD is the use of DDAVP. The intravenous dose is 0.3 μ g/kg, and the intranasal dose is 1 spray in children and 1 spray in each nostril in adults. A two- to threefold increase in factor VIII and vWF is seen, peaking about 30 to 60 minutes after the dose. ¹⁴

Patients with types II and III vWD who have abnormal or absent vWF do not benefit from DDAVP, which simply stimulates factor release from the endothelial cells. A factor VIII preparation that also contains significant vWF, such as Humate P, must be used for these individuals. ¹⁴

Antibodies against factor VIII, termed *inhibitors*, develop in 15% to 35% of hemophiliacs, ²¹ usually early in life and after relatively few factor VIII transfusions. These inhibitors render the patient unresponsive to factor VIII given to treat bleeding episodes. In patients with low inhibitor titers, regular or high doses of factor VIII usually continue to be effective. Patients with high titers of inhibitors often require use of porcine factor VIII at starting doses of 50 to 100 U/kg. Another approach is

administration of activated prothrombin complex concentrates (aPCCs) (Autoplex T, FEIBA VH), which “bypass” factor VIII and are usually effective in stopping bleeding. However, repeated use is associated with thrombotic complications, and factor levels cannot be monitored to assess therapy.¹⁴ Most recently, recombinant factor VII has become available and has been shown to be safe and effective in patients with inhibitors.⁶

Inhibitors also occur *de novo* in nonhemophiliac patients, those directed against factor VIII being the most common. Treatment of life-threatening bleeding is similar to that described previously, which uses high doses of human factor VIII, porcine factor VIII, aPCCs, and recombinant factor VII. To arrest synthesis of the inhibitor, steroids and immunosuppressants, such as azathioprine or cyclophosphamide, are given. Spontaneous remission is thought to be fairly common.^{13,20,21}

Patients with complex conditions such as liver disease or DIC usually have deficiencies of multiple coagulation factors and, often, of platelets as well. If laboratory tests confirm these abnormalities and the patient is actively bleeding, fresh-frozen plasma and platelets are given to replace the needed components.

When heparin or coumadin is implicated as a cause of bleeding, a knowledge of the mechanisms by which it anticoagulates the blood helps the physician to treat the bleeding logically.¹⁶ Heparin acts immediately on administration by accelerating 1,000-fold the reaction by which factor II (thrombin) combines with the plasma protease inhibitor antithrombin III (AT III). The complex is inactive, and the AT III-bound thrombin cannot activate fibrinogen. Heparin is not consumed in the reaction and is available for further activity. Fortunately, the half-life of heparin is short, about 1 hour at usual doses and longer at higher doses. Therefore, when bleeding occurs in the heparinized patient, discontinuation of the drug leads to a rapid fall in the plasma heparin concentration. For severe bleeding, it may be necessary to administer protamine sulfate, a specific heparin antidote that combines with heparin to form a stable complex with no anticoagulant activity. One milligram of protamine neutralizes 100 U of heparin. The physician should estimate the amount of heparin remaining in the plasma and give the protamine at a rate no faster than 50 mg over 10 minutes.

The mechanism of action of coumadin is quite different. It interferes with the carboxylation of the vitamin K-dependent clotting factors II, VII, IX, and X in the liver. Factor synthesis is decreased 30% to 50%, and biologic activity is decreased to 10% to 40% of normal because of inadequate carboxylation.¹⁶ The onset of anticoagulant activity is delayed 8 to 12 hours because it depends on the gradual decrease in factor levels that is a consequence of the decreased rate of their synthesis, although their normal rate of degradation is unchanged. Factor VII has the shortest half-life (about 6 hours),¹² and some anticoagulant effect is noted as factor VII levels drop. However, the longest-lived of the four factors, factor II, has a half-life of 60 hours, so that 2 to 3 days are required before the full anticoagulant effect of coumadin can be expected.

The effects of coumadin cannot be reversed rapidly by discontinuing it, because time is required for synthesis of the factors. If severe hemorrhage occurs in a patient on coumadin, fresh-frozen plasma must be given to provide the needed coagulation factors immediately.

Because of the large volume and, possibly, repeated doses of fresh-frozen plasma needed to reverse an intensely anticoagulated patient, some authors recommend the use of aPCCs, which specifically contain the vitamin K-dependent coagulation factors.¹¹ There is a small risk of thrombosis associated with the use of this product because of the presence of activated factors. The risk is greatest in patients with liver disease or previous thrombotic events. Vitamin K, 5 to 10 mg by slow intravenous injection, should also be given to promote factor synthesis. One should always maintain an awareness of the risk of thrombotic complications occurring as a result of the reversal of anticoagulation, and careful judgment should be exercised.⁵

Because so many bleeding disorders are associated with underlying diseases, attention should always be directed to the potential associated condition while immediate lifesaving transfusions of blood components are provided.

DISPOSITION

An acutely bleeding patient should be transferred to another facility only if a service unavailable at the initial hospital can be provided at the second facility. For example, a child with a head injury and hemophilia would benefit from transfer to a hospital where neurosurgical services are available, despite the risk of transport. The ABCs must always be attended to and the hematologic parameters normalized as much as possible by transfusion of the appropriate components before transfer.

COMMON PITFALLS

- Bleeding is a common occurrence in the emergency department, and most patients have no bleeding disorder. In most cases, the history and a physical examination directed toward the identification of a congenital or acquired bleeding disorder constitute adequate screening. Such information should be recorded on the medical record of every patient with bleeding or injury.
- Delayed bleeding is characteristic of coagulation factor deficiencies. Because the initial stage of hemostasis is normal, these patients may appear to have their bleeding well controlled in the emergency department and may be discharged, only to experience life-threatening hemorrhage a few hours later. Factor transfusion should be given immediately in the emergency department to patients with potential bleeding in high-risk sites such as the CNS, neck, and retroperitoneal space without waiting for results of coagulation or imaging studies. Admission for observation should be considered in these patients.
- The emergency physician must use judgment in deciding whether to perform invasive procedures in patients with bleeding disorders. When possible, such procedures should be delayed until appropriate treatment has normalized clotting parameters.

A number of disease processes initiate tissue and vessel wall damage that leads to activation of the coagulation cascade and intravascular deposition of an obstructive mesh of fibrin strands. Red cells passing through these vessels are physically damaged, and the result is what is referred to as microangiopathic hemolytic anemia. Platelets and clotting factors are consumed to varying degrees, and may be responsible for thrombotic and bleeding complications that are usually more significant clinically than the associated hemolysis. With diffuse vascular involvement, these disorders often affect multiple body systems.

Disseminated intravascular coagulation (DIC), thrombotic thrombocytopenia purpura (TTP), and the hemolytic–uremic syndrome (HUS) are characterized by the combination of microangiopathic hemolytic anemia, thrombocytopenia, multisystem involvement, and varying degrees of coagulation factor depletion.

The presence of schistocytes on the peripheral blood smear should always alert the examiner to the presence of microangiopathic hemolytic anemia. The diagnosis is further supported by findings of decreased hematocrit, increased indirect bilirubin, decreased haptoglobin, and increased reticulocyte count. Thrombocytopenia is seen in DIC, TTP, and HUS; prolonged prothrombin time (PT) and partial thromboplastin time (PTT), decreased fibrinogen, and elevated fibrin degradation products are seen predominantly in DIC alone.

Microangiopathic hemolytic anemia can also be seen in malignant hypertension, eclampsia, collagen vascular disease, rejection of a renal allograft, disseminated carcinomatosis, and hemangiomas. In these conditions, anemia usually resolves with treatment of the specific disease.

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a condition of deranged and unbalanced activity of the clot-forming and clot-dissolving systems that normally function to maintain unimpeded blood flow through the body. DIC occurs only in conjunction with a variety of well-recognized conditions that have in common the release of procoagulant substances into the circulation. These conditions include sepsis; malignancy; trauma, including burns, crush injuries, and head injuries; obstetric conditions, such as abruptio placenta and retained fetus; and intravascular hemolysis, as seen with transfusion reactions^{3,18} ([Table 211.1](#) and [Table 211.2](#)).

Condition	% of Total
Infection	26-29
Malignancy	18-24
Surgery	18-20
Liver disease	8-10
Obstetric	4-6
Trauma	2-5
Other	18-23

Condition	Frequency
Infection	26-29%
Malignancy	18-24%
Surgery	18-20%
Liver disease	8-10%
Obstetric	4-6%
Trauma	2-5%
Other	18-23%

TABLE 211.2. Conditions Associated with DIC

The procoagulant substances released activate the coagulation cascade through the tissue factor pathway, leading to the formation of thrombin. Thrombin plays its normal pivotal role in coagulation, cleaving fibrinogen to form fibrin, activating factor XI of the intrinsic pathway, and activating platelets. Thrombin is also involved in the body's normal method of terminating the clotting process, by inhibiting coagulation through a number of mechanisms. As the procoagulant substances are continuously released into the circulation as part of the patient's illness, they drive the coagulation cascade and the coactive inhibitory mechanisms, yielding both fibrin clots throughout the vascular system and large amounts of inactivated factors. The fibrin mesh of the clots traps platelets as they flow past. An eventual depletion of factors, inhibitors, and platelets occurs, causing hemorrhage.

Further contributing to this clotting disorder is activation of the fibrinolytic system. Plasmin attacks fibrinogen and fibrin, producing fibrin degradation products (FDPs). FDPs interfere with the polymerization of fibrin, which is necessary to create functional clots, and they cause a severe functional platelet defect.

In most patients, fibrinolysis does not keep pace with the intravascular coagulation, so the microvasculature fills with occlusive thrombi. The resultant tissue ischemia and necrosis manifest as severe organ dysfunction, which is the usual cause of death in DIC. Although bleeding can be dramatic and many physicians think of DIC as a hemorrhagic disorder, it is essential to realize that it is a thrombohemorrhagic condition. Interventions to arrest the clotting process must be a part of the therapy.^{3,5,13,29}

These procoagulant substances that initiate the thrombohemorrhagic processes vary according to the underlying illness with which the DIC is associated. In sepsis, bacterial endotoxin and cytokines induce the production and surface expression of tissue factor by circulating monocytes and endothelial cells.^{5,7,29} Many tumor cells also make tissue factor in large amounts. Severe trauma, intravascular hemolysis, and obstetric conditions such as abruptio placenta all release large quantities of tissue factor into the general circulation from damaged cells.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

DIC occurs in an acute, fulminant form and in a low-grade, chronic form. The acute form usually is associated with sepsis, trauma, transfusion reactions, and acute obstetric events. The incidence of DIC in severe sepsis is 18% and in septic shock, 38%.²⁶ Bleeding in these clinical settings should cause suspicion of DIC. Bleeding may occur from surgical or traumatic wounds despite local treatment and from venipuncture and arterial puncture sites. Petechiae, purpura, hemorrhagic bullae, and subcutaneous hematomas can be seen. Gastrointestinal, urinary tract, and pulmonary bleeding are common. Typical patients with DIC bleed from at least three sites. They are often febrile and hypotensive. Signs of thromboses may be more subtle and manifest as abnormal mental status, dyspnea, abdominal pain, acral cyanosis, and gangrene.³

Patients with the chronic form of DIC usually have malignancy, liver disease, collagen vascular disease, or an obstetric condition such as retained fetus. Bleeding is rarely severe; instead, thrombotic disorders such as thrombophlebitis, pulmonary embolism, and nonbacterial thrombotic endocarditis predominate. Diagnosis of a thrombotic event, followed by recognition of typical laboratory abnormalities of DIC, may lead to the diagnosis of an occult malignancy.^{3,18}

EMERGENCY DEPARTMENT EVALUATION

An appropriate clinical setting with a typical physical examination is highly suggestive of DIC and should spur the physician to seek laboratory evidence of the diagnosis. To support a diagnosis of DIC, results should show abnormalities in four areas: (1) depletion of coagulation factors; (2) depletion of coagulation inhibitors; (3) activation of the fibrinolytic system; and (4) evidence of end-organ damage.³ The tests that are most sensitive and specific for detecting abnormalities in these areas may not be available on an emergency basis. Those that are available may not be sensitive or specific and must be used with an understanding of their limitations.

Examination of the peripheral blood smear will show schistocytes in 50% of patients with fulminant DIC.³ Thrombocytopenia is usually evident on the smear, and large platelet forms (young platelets) are commonly seen because of increased platelet turnover.

Readily available laboratory tests that confirm depletion of coagulation factors include the PT and PTT and the fibrinogen level.³ The PT and PTT are prolonged in only about 50% of cases of DIC, because activated factors and degradation products may interfere with these tests. Therefore, normal PT or PTT values do not rule out DIC. The fibrinogen level is less than 150 mg/dL in only 70% of cases, probably because it is an acute-phase reactant and its baseline level can be increased in acute illness. Other, more reliable tests exist but are not generally available in the emergency department.

The consumption of coagulation inhibitors can be measured directly by checking the antithrombin III (AT III) level, which is decreased in 89% of patients with DIC, but will rarely be available to the emergency physician.

Activation of the fibrinolytic system is best demonstrated by elevation of the D-dimer level, which is seen in 93% of patients with DIC and has an 80% specificity.^{3,5} D-dimer is produced by the action of plasmin on cross-linked fibrin. FDPs, which are increased in 75% to 100% of patients with DIC, are not as specific for DIC as the D-dimer level.

Laboratory tests reflecting end-organ damage are lactic dehydrogenase (LDH), serum creatinine, and arterial blood gases. Other useful tests are hemoglobin and platelet count, urinalysis, pregnancy test, and imaging studies as guided by history and examination to search for the inciting illness. Platelet counts range from 2,000 to 100,000/ μ L, averaging about 60,000/ μ L.³

Thus, of the laboratory analyses available to the emergency physician for the diagnosis of DIC, the most sensitive is D-dimer. The PT, PTT, fibrinogen, and FDP should be ordered, but may be normal in patients with early DIC. Similarly, in cases of mild or chronic low-grade DIC, the PT, PTT, fibrinogen level, and platelet count may all be normal, because the bone marrow and liver can increase the synthesis and release of the clotting components. FDPs and D-dimer are elevated, however, and the peripheral smear is abnormal.

Appropriate coagulation studies should be drawn early in patients with sepsis, trauma, and other conditions with high risk for DIC. Laboratory abnormalities are usually present before severe hemorrhage occurs.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment of DIC is an area lacking consensus and clarity. The heterogeneity of underlying causes has made it difficult to perform prospective clinical trials with results applicable to the individual patient. Treatment must be individualized and based on a current understanding of the pathologic basis of the condition underlying the DIC. An expanding choice of agents is becoming available as knowledge of hemostasis grows.

There is one area of universal agreement in DIC treatment. The underlying illness must be aggressively attacked with surgery, antibiotics, chemotherapy, or other appropriate therapy so as to stop the continuous release of the procoagulant factor and persistent activation of the coagulation cascade.^{3,5,7,19} For example, in abruptio placenta, DIC terminates immediately upon evacuation of the uterus. Correction of hypovolemia, hypotension, acidosis, and hypoxia should also begin in the emergency department, and disease-specific interventions should be initiated promptly whenever possible.

If the patient is bleeding, transfusion with packed red blood cells and platelets to correct anemia and thrombocytopenia is indicated. A platelet count less than 50,000/ μ L should prompt transfusion in the bleeding patient, and the additional contribution of functional platelet disorders to the bleeding tendency should be remembered.⁵ Although some clinicians fear "fueling the fire" of coagulation by giving fresh-frozen plasma (FFP) or cryoprecipitate to patients with DIC, this event has not been shown to occur in most cases, especially if concurrent therapy to arrest the consumption of coagulation factors is under way.^{3,5,7,19} Six units of cryoprecipitate will raise fibrinogen by about 50 mg/dL. A level of at least 100 mg/dL is desired.

Other specific treatments for DIC are generally initiated after admission. A number of agents, including heparin, AT III, antifibrinolytics, protein C, hirudin, tissue factor pathway inhibitor (TFPI), thrombomodulin, and tissue plasminogen activator (TPA), have been investigated. None so far has been shown to decrease mortality in humans, although several are associated with improvement in coagulation abnormalities, lung function, and duration of symptoms.

Heparin has shown neither significant benefit nor harm in acute DIC. Some recommend it in conditions such as purpura fulminans, in which devastating thrombi are obvious. Many specifically recommend against its use in cases in which potential central nervous system (CNS) bleeding is of concern (e.g., head trauma).^{3,7,19}

AT III appears promising. It has been shown to decrease duration of symptoms, improve coagulation parameters, improve oxygenation, and decrease intensive care unit (ICU) and ventilator days and the need for dialysis in patients with sepsis and trauma. It also has been associated with a trend toward decreased mortality. Most agree that it should be given in doses that achieve very high serum levels.^{3,5,7,12,18}

Fibrinolytic inhibitors such as epsilon amino caproic acid (EACA) or tranexamic acid are usually contraindicated in DIC because the thrombotic aspects of the

condition are those most associated with morbidity.^{3,5,7,19}

DISPOSITION

The primary role of the emergency physician in the management of DIC is to be aware of its association with severe illness and injury, to perform the appropriate physical examination and laboratory screening tests to identify its presence, and to initiate immediate stabilization of airway, breathing, and circulation. The importance of immediate specialty consultation once DIC is suspected cannot be overemphasized, owing to the importance of treating the underlying cause. Antibiotics and replacement blood component therapy (as well as preparation of the patient for surgery, if needed) should be initiated in the emergency department.

The prognosis in patients with DIC is poor, even with proper treatment, which is not surprising, because the appearance of DIC signifies severe illness or injury and extensive tissue damage. In trauma patients, mortality rises from 14% in those without DIC to 59% in those with it. Mortality quadruples from 10% to 40% in meningococcal sepsis in children when DIC supervenes.¹⁵

Patients with acute DIC are very ill and should not be transferred from an institution that has facilities to care for them. However, because treatment of the underlying condition is so essential to the termination of the coagulation abnormalities, transfer should be arranged after initial stabilization if the hospital does not offer the required surgical, obstetric, or intensive care services. If transfer is anticipated, the emergency physician must ensure adequate airway, breathing, and circulation and should initiate appropriate blood component replacement. Other modalities, such as antibiotic therapy, should also be started prior to transfer, preferably after consultation with the accepting physician.

COMMON PITFALLS

- Failing to consider DIC in the appropriate clinical setting. Because of its association with severe illness or injury and its effect on mortality, signs of DIC should be sought in all patients at risk. The identification of such signs should prompt the physician to order the appropriate laboratory tests to confirm the diagnosis.
- Allowing the bleeding associated with DIC to distract the physician from the search for and treatment of the underlying causative illness. Any therapeutic plan that fails to include measures directed against the underlying cause is likely to be unsuccessful.

THROMBOTIC THROMBOCYTOPENIC PURPURA AND HEMOLYTIC–UREMIC SYNDROME

TTP and adult HUS appear to be closely related disorders that each present with some of the elements of the classic pentad of microangiopathic hemolytic anemia, thrombocytopenia, neurologic abnormalities, fever, and renal dysfunction. In TTP, neurologic abnormalities predominate, and renal dysfunction is seen less often; the opposite is characteristic of HUS. These syndromes occur twice as often in women and peak in the fourth and fifth decades of life.¹⁷ U.S. mortality data from the years 1968 through 1991 seem to suggest that the incidence of TTP is increasing.²⁷

There is an epidemiologically distinct form of HUS seen in children 6 months to 4 years of age, with an equal distribution between the sexes. This childhood illness is often preceded by febrile, diarrheal, or respiratory symptoms and has been linked to infection with cytotoxin-producing strains of *Escherichia coli* and *Shigella* that damage the renal vascular endothelium. About 90% of cases of pediatric HUS are associated with *E. coli* enterocolitis.²

The etiology of adult TTP-HUS is unknown. It occurs in association with other conditions, such as pregnancy; autoimmune diseases; cancer; bacterial and viral infections, including the human immunodeficiency virus (HIV) and HTLV-1; and in conjunction with the use of various medications, including ticlopidine, and chemotherapeutic agents, mitomycin-C and 5-fluorouracil in particular.^{4,14,17,25} However, most cases occur in otherwise healthy patients, and no etiologic link has been convincingly drawn among the various associated conditions and TTP-HUS.

There is, however, a uniformity of pathologic findings in TTP-HUS. The characteristic lesion is the platelet thrombus found in the capillaries and arterioles of involved organs without evidence of vessel wall pathology or perivascular inflammation. The clot consists of platelets held together by von Willebrand factor (vWF) with very little fibrin deposition. This symptom corresponds to the laboratory findings of TTP, which include thrombocytopenia but no depletion of coagulation factors, as manifested by normal PT, PTT, and fibrinogen in 80% to 90% of patients. Focal necrosis and hemorrhage caused by ischemia are seen in the areas of occluded vessels.¹⁷

The pathophysiologic basis of the platelet thrombus is thought to be related to unusually large vWF (ULvWF) multimers seen in patients with TTP-HUS.¹⁷ These multimers are produced and stored in the endothelial cells and platelets in all people, but once released into the plasma, they are reduced in size by a cleaving protease enzyme. It has been shown that some patients with TTP have congenital absence of this enzyme and others have an inhibitor to the enzyme.^{8,16} The ULvWF multimers are more active in inducing platelet aggregation than are normal-sized multimers, so larger and more numerous platelet thrombi are formed. Both the platelet count and levels of ULvWF drop simultaneously during a TTP episode, suggesting that both are consumed in the clotting process. Patients in whom ULvWF is detectable after a clinical recovery from TTP are those who go on to have recurrent episodes of the disease.¹⁷

Two-thirds of patients have a single episode of TTP. One-third have intermittent, irregularly recurring episodes. A very small number has chronic relapsing TTP with frequent episodes that occur at regular intervals.¹⁷

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Although the pentad of symptoms and laboratory findings is considered classic in these diseases, it is important to realize that only about 40% of patients manifest all five criteria. In those with a diagnosis of TTP, 50% to 70% have neurologic dysfunction and 50% to 75% have renal involvement. Less than 15% have severe renal dysfunction with creatinine greater than 5 mg/dL.^{14,17} Only about one-third of HUS patients have neurologic dysfunction. Fever has been reported in 60% to 100% of patients.²⁶

The most frequent initial neurologic abnormality is altered mental status, which may be manifested by subtle personality change, lethargy, agitation, or confusion. Seizures, hemiplegia, aphasia, paresthesias, and visual disturbances occur in somewhat less than half of patients and more often in the later stages of the disease. Visual symptoms may be caused by thromboses in the CNS or in the retinal vessels.

Although 20% of patients may complain of gross hematuria, renal dysfunction is usually discovered only on laboratory studies. Bleeding (e.g., epistaxis, hematuria, gastrointestinal or vaginal hemorrhage) is seen in about 30% to 40% at initial presentation. Abdominal pain, usually without an identifiable source, may be part of the presentation in 30% to 40%.

This type of multisystem symptomatology requires the emergency physician to entertain a broad differential diagnosis that includes DIC, CNS infection, collagen vascular disease, bacterial endocarditis, and malignant hypertension, among others. History and physical examination directed to the identification of salient characteristics of each condition may narrow the differential. Laboratory studies can be very helpful in confirming the diagnosis of TTP-HUS, as the laboratory abnormalities of the pentad are more consistently present than the clinical symptoms.

EMERGENCY DEPARTMENT EVALUATION

Laboratory studies directed toward the etiology of fever, bleeding, and neurologic and renal abnormalities should be ordered. Complete blood count, platelet count, PT, PTT, fibrinogen, fibrin degradation products, D-dimer, and examination of the peripheral blood smear often suggest the diagnosis. All patients with TTP-HUS are anemic; 90% have hemoglobin less than 10 g/dL, and 40% have less than 6 g/dL. The peripheral smear reveals schistocytes and a decreased number of platelets; 50% of patients have a platelet count less than 20,000/ μ L. The PT and PTT are normal in 90%, and fibrinogen is less than 100 mg/dL in only 5% of TTP-HUS patients. In DIC, by contrast, tests reflective of coagulation factor consumption are usually abnormal.¹⁷

The LDH, blood urea nitrogen (BUN), creatinine, electrolytes, blood cultures, and computed tomography (CT) scan of the head can provide further important diagnostic information. Lumbar puncture should be considered, but severe thrombocytopenia may lead the clinician to defer this procedure. Serum LDH is uniformly

and greatly elevated in TTP-HUS patients; median levels are often six times normal. This is a much larger elevation than is seen in other hemolytic anemias, suggesting tissue sources in addition to red blood cell lysis. LDH measurements show LDH5 from liver and skeletal muscle to be the isoenzyme most elevated.⁶ It has been suggested that because LDH is greatly elevated in most cases and decreases rapidly in response to therapy, it should be considered a sensitive marker of TTP-HUS.²⁶ The combination of a greatly elevated LDH, microangiopathic hemolytic anemia, and thrombocytopenia is often considered sufficient to make a diagnosis of TTP-HUS, even in the absence of fever and renal or neurologic abnormalities.

Abnormalities of BUN and creatinine are universal in patients in whom HUS is diagnosed, and are seen in 40% to 50% of patients with TTP.

EMERGENCY DEPARTMENT MANAGEMENT

As always, airway, breathing, and circulation should receive primary attention. In febrile patients in whom infection is suspected, antibiotic therapy should be initiated after obtaining appropriate cultures in the emergency department. When the diagnosis of TTP-HUS is suspected on clinical and laboratory grounds, a hematologist should be consulted. The emergency physician should be aware that despite significant thrombocytopenia and clinical bleeding, platelet transfusions are contraindicated in TTP.¹⁷ Several case reports note clinical deterioration following platelet administration, and it is assumed that more thrombi are formed in the tissues when additional platelets are supplied. Platelet transfusions are sometimes given as a stopgap measure in patients with intracranial bleeding demonstrated on CT.

The mainstay of current therapy for TTP is plasma exchange.^{14,20} The specific mechanism of efficacy is unknown, but it is postulated that the enzyme needed to cleave vWF multimers is provided or an inhibitor removed by the exchange.⁸ An infusion of approximately 10 U of FFP per 24-hour period should be started, and arrangements made for plasmapheresis if there is not prompt improvement. An exchange of one plasma volume per day is recommended initially, with an increase or decrease according to the patient's response. Seriously ill patients with coma, cardiac failure, or renal dysfunction should have plasmapheresis as soon as possible.¹⁷

The benefits of plasma exchange using FFP are clear. In a study comparing plasma exchange with plasma infusion, 47% of those receiving exchange had an increased platelet count after the first treatment cycle, compared with 26% of those receiving infusion. The death rate was four times greater in the infusion group.²⁰ Another study noted an 81% reduction in the risk of development of end-stage renal disease in patients who received plasma exchange, compared with those who did not.¹¹ Red cell transfusions are rarely needed, but should be considered if the patient is symptomatic from severe anemia.

Prednisone in doses of 1 mg/kg/d or greater is often given on the basis of historic precedent. Thirty of 100 patients were noted to have complete resolution of symptoms and laboratory abnormalities after receiving prednisone only, without plasma therapy.³ Inhibitors of platelet function, such as aspirin, dipyridamole, sulfipyrazone, and prostacyclin, are often given, despite conflicting reports of their efficacy.¹⁷

Therapies under investigation include aurin tricarboxylic acid, which prevents binding of ULvWF to platelets, and exposure of plasma from TTP patients to immunoadsorbent substances to bind antibodies or immune complexes.^{9,17}

PEDIATRIC HEMOLYTIC–UREMIC SYNDROME

E. coli O157:H7 is now recognized as the leading cause of HUS in the United States, Canada, and Europe,² although cases associated with HIV infection, chemotherapeutic agents, and radiation therapy continue to be reported. The organism attaches to colonic cells and produces a so-called Shiga toxin that enters the circulation and destroys or damages endothelial cells, especially in the kidney and brain, where a specific glycosphingolipid receptor is found.^{22,24} This cellular damage may lead to the release of the ULvWF multimers that are thought to cause platelet aggregation, which leads to vessel obstruction by thrombi.^{17,22}

E. coli O157:H7 is transmitted by contaminated food and water. In the United States, the largest outbreak was associated with undercooked, contaminated hamburger meat. More recently, there have been outbreaks related to unpasteurized apple juice, lettuce, and alfalfa sprouts in the United States and to radish sprouts in Japan. Well water contaminated with run-off from cattle pastures led to infection of more than 100 people in New York in 1999. Person-to-person spread is also reported in institutions, childcare centers, and within families.²

Five percent to 14% of children with *E. coli* O157:H7 infection develop HUS with microangiopathic hemolytic anemia, thrombocytopenia, and renal dysfunction. Most laboratory abnormalities resolve within 2 weeks. Twenty-five percent of patients will have severe HUS with more than 7 days of anuria, more than 14 days of oliguria, or stroke. Five percent die, usually from thrombotic CNS involvement, which occurs in about 30% of pediatric HUS cases. Thirty-five percent to 50% of survivors have chronic kidney damage; 3% have end-stage disease.^{2,24}

A number of studies agree that use of antibiotics to treat the diarrheal illness does not prevent HUS.² However, most are retrospective analyses and involve a wide variety of antibiotics administered by intravenous and oral routes. It has been suggested that the use of oral fluoroquinolones to treat the diarrheal illness is associated with a lower incidence of HUS, absence of Shiga toxin in the gut, and eradication of *E. coli* O157:H7 from the gut.^{10,23} An orally administered Shiga toxin-binding resin is under study but, so far, has shown no efficacy in preventing HUS.^{2,24,28}

The general management of pediatric diarrhea-associated HUS is supportive, with careful management of fluids and electrolytes and dialysis when needed.²⁸ Plasma exchange is generally reserved for those more severe cases that resemble TTP with CNS involvement.^{21,24}

DISPOSITION

Patients with TTP-HUS require high levels of nursing care and blood bank support, and should be admitted to an ICU. If plasmapheresis is not available, transfer to another institution should be arranged while plasma infusion therapy is begun.

Response to plasma therapy generally follows a predictable pattern. Neurologic abnormalities are the first to resolve, usually within 3 days. LDH levels normalize in about 5 days, and platelet counts in 10 days. Renal function is the last to normalize, typically requiring about 2 weeks to return to baseline. It usually takes about nine plasmapheresis treatments to produce sustained improvement.²⁶

Other treatments that may be used by the admitting physician, if there is rapid deterioration or no response to plasmapheresis, include immunosuppressive agents such as vincristine and splenectomy.^{17,26} In one series of 44 patients, about 30% underwent splenectomy.

Relapse is fairly common. Most relapses (84%) occur within the first month after diagnosis, and 97% within 2 months. A small percentage of relapses occurs years after the initial episode.¹

Since the advent of plasma therapy, overall survival in patients with TTP-HUS has been about 80% to 90%. Recovery from neurologic, hematologic, and renal abnormalities is usually complete.

COMMON PITFALLS

- Only about a third of patients have all five criteria of the classic diagnostic pentad of TTP-HUS at the time of presentation. The clinical components of the syndrome are variable in their appearance, and may be subtle or absent.
- The multisystem abnormalities seen in cases of TTP-HUS suggest a wide variety of possible diagnoses. Despite its rarity, TTP-HUS should always be considered in patients with neurologic, renal, or hemostatic abnormalities.
- No specific laboratory abnormality is diagnostic of TTP-HUS. However, the combination of microangiopathic hemolytic anemia, thrombocytopenia, an extremely high LDH, and normal PT and PTT is characteristic of the syndrome and distinguishes it from DIC.
- Administration of platelets is associated with deterioration in TTP-HUS.

CHAPTER 212

Sickle Cell Disease

Donald M. Yealy and Larry D. Weiss

[Clinical Presentation and Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Sickle cell disease is a hereditary disorder of hemoglobin structure and function. Hemoglobin S (for “sickle”) differs from the normal hemoglobin A, in that valine is substituted for glutamic acid in position 6 of the globin beta-chain. Both hemoglobins function similarly in the oxygenated state, but deoxygenated hemoglobin S tends to polymerize and gelate, leading to red cell sickling. Erythrocytes with less total hemoglobin or less hemoglobin S are more resistant to sickling, as are younger and smaller cells.

Individuals who are homozygous for the sickle cell gene (SS) are said to have *sickle cell disease*. Their erythrocytes contain at least 90% hemoglobin S. Patients who are heterozygous for the sickle cell gene (SA) are said to have *sickle cell trait*. Their erythrocytes contain both hemoglobin A (50% to 60%) and hemoglobin S (30% to 40%). Common sickle variants include *SC disease* (in which patients are heterozygous for both hemoglobin S and hemoglobin C) and *sickle-thalassemia*. These variants display lower red blood cell (RBC) levels of hemoglobin S and are associated with less morbidity than sickle cell disease.

An estimated 8% to 10% of Black Americans carry the sickle cell gene, and about one in 400 to 600 manifests sickle cell disease. The sickle variant diseases are less common and are regarded as less severe disorders compared with homozygous disease.^{15,16} Most patients with sickle trait or variants have a normal lifespan and rare crises, although there is an increased risk of sudden death during exertion.

The anemia of sickle cell disease is due to both chronic and acute hemolysis. The red cell membranes are damaged with repeated episodes of sickling, leading to increased fluid and electrolyte permeability and fragility. RBCs have an average lifespan of about 10 to 20 days in SS disease, compared with 120 days in normal subjects.

During an acute painful crisis, the involved red cells undergo sickling. Initially, this is a reversible process, but after repeated episodes, the RBCs become irreversibly sickled and are destroyed. The microvascular circulation is slowed or obstructed because of the sickling, increased viscosity, and increased endothelial adherence of RBCs. Local tissue ischemia and acidosis lead to further sickling, and organ damage results because of tissue ischemia and infarction.

The clinical severity of sickle cell disease is variable. Some patients follow a mild clinical course with infrequent pain crises, but others are more severely affected. An increased frequency of painful crises, particularly chest crises (discussion follows), is associated with a shorter life expectancy.^{15,16} Most homozygous patients develop painful crises before the age of 1 year, and by 5 years nearly all sickle cell disease patients have experienced a crisis.

Neonates and infants are often spared from crisis symptoms because of the protective effects of fetal hemoglobin (HbF), which persists in significant amounts during the first 6 to 12 months of life. Patients with sickle trait may develop painful crises when they undergo physiologic stress or spend time at higher elevations.

Infection is a leading cause of mortality in patients with sickle cell disease. The life expectancy of these patients is increasing because of aggressive medical therapy, particularly treatment of infection. Currently, most sickle cell patients survive into middle adulthood.^{15,16} Patients with sickle trait, SC, and sickle-thalassemia all have near-normal life expectancies and suffer far fewer symptoms.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Painful vasoocclusive crisis is the most common presenting problem for sickle cell patients in the emergency department. Although a proximate inciting event is not always discovered, several triggers have been identified. These include infection, systemic acidosis, dehydration, hypoxia, cold exposure, pregnancy, and physical or emotional stress. Identifying one or more of these factors helps guide therapy and may prevent sequelae. Episodes of painful sickle crises commonly last 48 hours to several days.

Bony pain is very common during acute vasoocclusive crises. In young children, pain and swelling often occur in the metacarpal and metatarsal areas, whereas older children and adults usually complain of back and proximal extremity pain. When evaluating a patient with suspected bony vasoocclusive pain, other causes, such as trauma or infection, must be considered.

The association between sickle cell anemia and *Salmonella* osteomyelitis is well described, yet staphylococci remain the most common pathogen causing osteomyelitis. Repeated episodes of bony ischemia can lead to aseptic necrosis, particularly in the femoral head¹² and carpal navicular areas, causing persistent pain that is frequently mistaken for acute vasoocclusion.

Abdominal pain, nausea, and vomiting are common with episodes of vasoocclusion. Local ischemia is thought to be the cause of these symptoms. However, a careful evaluation to rule out other causes of abdominal pain is mandatory. Because of persistent hemolysis, sickle cell patients develop calcium bilirubinate gallstones and symptomatic cholelithiasis. In addition, other causes of acute abdominal pain, including pancreatitis, appendicitis, renal colic, and peptic ulcer disease, should be considered before concluding that a vasoocclusive crisis is the sole cause.

The presence of active bowel sounds and a lack of high fever or signs of peritonitis favor a nonsurgical etiology. The risk of infectious hepatitis is higher in sickle cell patients because of previous transfusion therapy and an increased incidence of drug abuse. Jaundice does not necessarily indicate liver disease, because it is commonly due to chronic hemolysis.

The pregnant sickle cell patient with abdominal pain poses a diagnostic and therapeutic challenge. Identifying appendicitis or cholecystitis is more difficult because of the anatomic changes associated with pregnancy. Preterm labor, placental ischemia and abruption, and spontaneous abortion are also more common in sickle cell patients than in the general population.

Low-grade fever during a vasoocclusive episode is not uncommon. If the temperature exceeds 38°C, an infectious source should be sought. Viruses probably account for most infections, but because of functional asplenia, these patients are at risk for bacteremia, especially with encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. The functional asplenia of sickle disease is due to autoinfarction of the spleen, which is usually completed by school age in those with homozygous disease. Patients with sickle trait or sickle cell variants generally have normal splenic function and immunity.

Chest pain is also common in vasoocclusive crises.^{1,13,15,16} and ¹⁷ Pleuritic pain is often due to vasoocclusion (with or without pulmonary infarction), although distinguishing it from an infectious etiology is difficult. Low-grade fever, hypoxemia, and leukocytosis are common in both vasoocclusive crisis and pneumonia. The radiographic diagnosis of an infiltrate is difficult because chronic interstitial changes are present in many patients and some new opacities represent atelectasis or infarction (the latter termed *sickle chest syndrome*). A productive cough, high fever, elevated total and immature neutrophil count, or Gram stain evidence of infection supports the diagnosis of pneumonia. The best clinical indicator of infarction is the absence of these infectious clues and the presence of occlusive symptoms in another area. *S. pneumoniae* and *H. influenzae* are the most frequent causes of pneumonia in sickle cell patients.¹⁷ In adults, chest pain can also result from myocardial ischemia.

Focal or generalized neurologic signs and symptoms (including seizures) can follow vasoocclusion in the cerebral circulation, with both small and large vessels

affected. Acute retinal ischemia with visual loss and “floaters” from vitreous hemorrhages secondary to vessel disruption are also reported in sickle cell patients.

Priapism is a manifestation of local sequestration and vasoocclusion and may present in all age groups. It often responds to vigorous medical therapy, including hydration, analgesia, local ice packs, or exchange transfusions. In refractory cases, surgical decompression is indicated. Testicular or ovarian ischemia can also result from vasoocclusion, presenting with pain in the affected area. Another complication of vasoocclusion is rhabdomyolysis, which requires aggressive fluid therapy to diminish the risk of acute renal failure.

Most patients with sickle cell disease and many with sickle trait or variants are at increased risk for dehydration because of a renal concentrating defect. Chronic renal failure (from repeated infarction and papillary necrosis) is common in sickle disease and may be associated with hypertension.

Besides painful vasoocclusive crisis, the patient with sickle cell disease is subject to other less common, episodic hematologic crises. These are categorized as sequestration, hemolytic, megaloblastic, or aplastic crises. In *sequestration crisis*, acute anemia, hypotension, and even shock occur because of sequestration of RBCs in the spleen. This often follows a viral illness and usually occurs in younger children with SS disease before autoinfarction, or in older patients with sickle cell variants. *Hemolytic crisis* can occur during a fulminant vasoocclusive episode, when large numbers of irreversibly sickled cells are lost. Severe anemia, with increased reticulocytosis and jaundice, is found. Marrow failure, resulting from either *megaloblastic crisis* (often from folate deficiency) or *aplastic crisis*, presents with a falling hematocrit and deficient reticulocytosis.

In addition to the organ ischemia induced by RBC sickling, sickle cell disease is frequently associated with enhanced coagulation, leading to arterial and venous thrombotic events. This is due to a variety of procoagulant syndromes seen more often in these patients, including protein C and S deficiencies and circulating antiphospholipid antibodies.²⁴

EMERGENCY DEPARTMENT EVALUATION

The rapid evaluation and treatment of the sickle cell patient with acute pain is a formidable challenge. Vasoocclusive crises are common and may mask other serious pathology, while other types of sickle crises are less frequent and easily overlooked.

The diagnosis of uncomplicated vasoocclusive crisis is one of exclusion. A common but dangerous error is to attribute all pain in sickle cell patients to this cause. The initial investigation should seek evidence of an acute infection or other precipitating event. Chest pain can result from pneumonia, pulmonary embolism, pulmonary infarction, or myocardial ischemia; abdominal pain may reflect a surgical emergency. By the third decade of life, many sickle cell patients have undergone cholecystectomy and appendectomy, either because of demonstrable pathology or because abdominal pain during a previous vasoocclusive crisis suggested an acute abdominal emergency.

A focused history and examination are the cornerstones of the evaluation of sickle cell patients. A knowledge of the frequency and severity of past crises and complications, the medication history, and baseline laboratory values are helpful in the initial evaluation and treatment of patients with acute pain. Especially ominous are any new neurologic signs or symptoms, which require computed tomographic (CT) scanning, transcranial ultrasound, or (rarely) lumbar puncture.

Based primarily on unquestioned dogma, a complete blood and reticulocyte count (CBC and RC) are commonly ordered in sickle cell patients presenting for emergency department care. These can help screen for marrow failure (from sickle disease or hydroxyurea therapy), sequestration crisis, or infection. In a clinically uncomplicated vasoocclusive crisis that is similar to previous episodes in patients not treated with hydroxyurea, these tests add little to the clinical management. In other patients, especially those with suspected infection or nonocclusive crisis, the CBC and RC should be obtained.

When interpreting a blood count, a few points must be kept in mind. Most sickle cell patients have a persistent mild leukocytosis and a moderate anemia (hematocrit of 20% to 30%, although lower values are seen in some individuals). The total leukocyte count should be adjusted for nucleated RBCs to avoid factitious elevation. Because of ongoing hemolysis and anemia, the reticulocyte count is elevated (usually to 8% or greater) compared with normal subjects. An abrupt drop in the hematocrit suggests a sequestration or hemolytic crisis, while an abnormally low reticulocyte count suggests marrow failure. The erythrocyte sedimentation rate (ESR) is low in most patients with SS disease and is not helpful unless it is extremely elevated.¹⁰

The urine should be screened for evidence of infection or infarction, especially in patients with pelvic or back pain. If symptoms of urinary tract infection are present, with pyuria or bacteriuria, a urine culture should be obtained to help guide follow-up therapy.

Some authors believe that all sickle cell patients with acute pain deserve routine chest radiography to screen for occult infection,¹⁷ but data validating this as a routine practice in low-risk patients are lacking. Clearly, fever, chills, or any pulmonary symptoms or signs suggesting a new abnormality mandate chest radiography, because the difference between sickle chest syndrome and pneumonia can be difficult to assess from clinical history and examination alone.^{13,17} Because of the risk of bacteremia and sepsis, blood cultures should be obtained when there is evidence of pneumonia or pyelonephritis, or when high fever or leukocytosis occurs without an apparent source.

Other tests may have a role, depending on the clinical presentation. An electrocardiogram is indicated with chest pain or other symptoms suggestive of myocardial ischemia. Serum electrolytes, blood urea nitrogen, and creatinine determinations are sometimes helpful to assess hydration and renal function, but they are not mandatory in clinically uncomplicated mild-to-moderate crises. In cases of unexplained abdominal pain, a serum amylase, liver enzymes, abdominal x-rays, gallbladder ultrasound, or CT scan may be indicated.²¹ In previously undiagnosed cases, a sickle prep and hemoglobin electrophoresis will confirm the diagnosis.

Although quantifying fetal hemoglobin levels may aid in assessing long-term prognosis, electrophoresis for this or other reasons is not helpful in the acute management of painful crisis. In patients with stroke, myocardial ischemia, or other arterial or venous thrombotic signs or symptoms, a hypercoagulable workup may be helpful, beginning with measurement of prothrombin and partial thromboplastin times.

An assessment of oxygen saturation is important, especially if there are any pulmonary or chest symptoms or abnormal physical findings. The pulse oximeter is minimally affected by sickle cell disease.¹⁴ Arterial blood gas analysis is indicated when an acid–base abnormality is suspected or when oximetry signals are inadequate or otherwise unreliable.

EMERGENCY DEPARTMENT MANAGEMENT

In unstable patients, airway stabilization and circulatory assistance are the primary concerns. Otherwise, routine emergency department management can proceed while an appropriate diagnostic workup is begun. Treatment is usually supportive, because definitive treatment of crisis based on the underlying pathophysiology is still lacking. Often, the best treatment is rehydration and analgesia, with oral regimens preferred whenever possible.^{1,4,23}

The choice of fluids is controversial. Patients with orthostasis or hypotension should receive isotonic saline initially. However, in the absence of significant volume depletion, hypotonic fluids have theoretical benefits. Experimentally induced hyponatremia decreases the mean corpuscular hemoglobin concentration and interferes with gelation of hemoglobin S. In one trial, desmopressin (DDAVP) combined with a diuretic and a low-sodium diet induced hyponatremia and decreased the frequency and duration of painful crises.¹⁹ Despite these investigations, there are no clinical data to support the routine use of parenteral hypotonic solutions in vasoocclusive crisis. Outside of the United States, oral regimens are often used successfully. Irrespective of the fluid chosen, the physician must pay attention to the total volume administered to avoid iatrogenic pulmonary edema.⁹

Traditionally, all sickle cell patients received supplemental oxygen during painful crises. Although oxygen reverses some sickling *in vitro*, it has never been shown to affect the incidence, duration, or severity of clinical vasoocclusive crises. Oxygen can depress erythropoietin levels and reticulocytosis, potentially interfering with a natural compensatory response and paradoxically increasing the number of irreversibly sickled cells.³

Currently, there are no clinical data supporting or refuting the routine use of oxygen, although pragmatism suggests that those with clinically important hypoxemia are most likely to benefit. The latter has not been defined rigorously, although an oxygen saturation of less than 85% or a drop of greater than 5% from a known baseline

is often used as a threshold at which to initiate therapy.

Achieving adequate pain control in vasoocclusive crisis is challenging.¹¹ By late adolescence, many patients with sickle cell disease require opioid analgesics in high doses to gain relief. Complicating the management of these patients are physician and nursing fears of drug abuse and secondary gain. Subjectively reported pain is generally the only tool available to measure discomfort; it is not possible to reliably identify “feigned” pain on clinical grounds. Optimal treatment of vasoocclusive pain is based on multifaceted, inexpensive regimens that offer the best chance of timely relief with a minimum of complications.

In addition, caregivers must encourage patients to participate actively in the process of pain relief, rather than reinforcing a passive “lie there and we’ll take care of it” approach. This means a frank discussion about the goals of therapy (pain relief, albeit not always extinction, without harm) and the need for nonpharmacologic adjuncts, including counseling and behavior modification. The goals of pain management in sickle cell disease and metastatic cancer are analogous, because both are incurable diseases.² Analgesia must be titrated to need rather than to arbitrary ceiling doses, using regimens that rapidly achieve and sustain effective drug levels.

Oral analgesics are the mainstays for most patients with mild-to-moderate pain, with parenteral regimens reserved for those who cannot tolerate oral agents or are in severe pain. Aside from young children, most older patients presenting for care in the United States receive opioids in addition to hydration and acetaminophen. Because the pain of vasoocclusion is caused by ischemia, the analgesic effects of nonsteroidal antiinflammatory drugs (NSAIDs) are less prominent than in other syndromes in which prostaglandin excess is the major biochemical trigger (e.g., inflammatory or postoperative pain).²⁶ Additionally, the risk of renal failure may be higher than in non-sickle cell patients due to the renal arterial ischemia frequently present.⁸ Given these considerations, NSAIDs are best avoided in these patients.²⁰

Hydrocodone, oxycodone, morphine, and hydromorphone are good choices of an opioid for patients with refractory or more intense pain who can tolerate oral therapy. Other agents that have been found useful in the management of other chronic pain syndromes (e.g., antidepressants or phenothiazines) have been suggested for sickle cell pain, but their effectiveness is not supported by controlled trials.

For those who require parenteral therapy, there is no ideal opioid. The key is choosing an adequate dose and dosing regimen based on individual patient response; the ceiling dose is whatever relieves pain or causes side effects. Intravenous regimens (by either repeated injections, continuous infusion, or patient-controlled administration) offer ease of titration, rapid analgesia, and less risk of side effects.⁶ Intramuscular injections should be reserved for selected cases when oral therapy is impractical and venous access unobtainable.

Meperidine is commonly used for sickle crisis but has some disadvantages, primarily related to its short duration of action and the accumulation of toxic metabolites, which can cause seizures. Morphine is inexpensive, but it is short-acting and frequently causes nausea, requiring the use of antiemetic agents. In patients who are not on outpatient opioid therapy, a mixed or partial opioid agonist (e.g., butorphanol, pentazocine, nalbuphine, or buprenorphine) offers analgesia with less euphoria and a ceiling on respiratory depression. For others, a longer acting opioid agonist (e.g., hydromorphone) may be an ideal choice.

A minority of sickle cell patients are deliberate opioid abusers. This has led some centers to initiate “contracts” with their patients in an effort to limit abuse while ensuring prompt and humane treatment when a painful crisis occurs. Often, the patient agrees in writing to take oral opioids only for severe pain and to contact a designated physician or emergency department during a crisis. The patient also agrees to not seek alternate opioid sources. This provides adequate care while limiting the total amount of opioid prescribed over a specified period.

For documented or suspected bacterial infections, a broad-spectrum antibiotic should be administered early while awaiting culture results. Sickle cell patients should take folic acid supplements daily to avoid megaloblastic crisis.

Transfusion therapy is indicated in selected sickle syndromes. In patients with priapism or aplastic, sequestration, or hemolytic crisis, exchange transfusion is preferable to simple transfusion because it avoids the risk of iron overload and is generally more effective. With central nervous system (CNS) vasoocclusion, exchange transfusion can reverse some neurologic symptoms and lower the incidence of recurrence.⁷ Prophylactic transfusion is best reserved for patients requiring immediate surgery and for those in impending or active labor. Anemia alone is not an indication for emergency transfusion, in the absence of signs or symptoms of deficient oxygen delivery to the heart or brain.

Several new approaches to the treatment of SS disease are currently under evaluation. Hydroxyurea disrupts RBC endothelial adhesion and enhances hemoglobin F production and can diminish the frequency and severity of crises.^{18,22} The long-term safety of this treatment is still not well defined, with marrow failure a limiting side effect. Other methods of altering hemoglobin production, through gene manipulation, bone marrow transplantation, or a combination of hydroxyurea and recombinant erythropoietin, show promise in reducing the frequency of clinical vasoocclusive crises.¹⁸

High-dose corticosteroids (dexamethasone 0.3 mg/kg every 12 hours for three doses) may augment inpatient analgesic regimens in children and adolescents with sickle crisis, especially the sickle chest syndrome.^{1a,5} The mechanism and true effect of steroids are debated, and there are currently no data confirming their utility in the treatment in acute sickle crisis. Similarly, inhaled nitric oxide may provide pain relief when used together with standard therapies, especially with chest syndromes, but it remains under investigation.

DISPOSITION

Patients with uncomplicated painful crises who are adequately hydrated and obtain sufficient pain relief in the emergency department can be discharged with close follow-up. There is no absolute rule to determine how long an “adequate” analgesia and hydration trial in the emergency department should be, because individual patients, physicians, and local resources vary. If pain relief is obtained in an uncomplicated vasoocclusive crisis, oral analgesics should be prescribed for 3 to 5 days, because crises commonly last this long. Each patient should be encouraged to obtain further care from the same institution or a single physician (or group) to ensure continuity.

The inability to control pain is the most common indication for admission in adults. Patients with proven or suspected sequestration, aplastic, or hemolytic crisis require admission. The presence of any new neurologic sign or symptom, priapism, or an acute abdomen also mandates hospitalization.

In general, bacterial infection mandates admission, because it is largely through the aggressive treatment of infections that the life expectancy for SS patients has been increased. Two groups of patients may be discharged home if close outpatient follow-up within 24 hours can be arranged: adults with a minor respiratory tract infection and non-toxic-appearing children (age 6 months to 12 years) with fever less than 40°C, no clinical evidence of pneumonia or pyelonephritis, and a leukocyte count between 5,000 and 30,000.²⁵ In the latter group, blood cultures should be obtained to screen for bacteremia, and ceftriaxone (50 mg/kg i.m.) should be given before discharge. In addition to these specific instances, admission is indicated for patients with fever, unexplained leukocytosis (especially with immature forms), or uncertain compliance with follow-up schedules.

Because continuity of care is especially important in sickle cell disease, the patient's primary physician should be contacted during the emergency department visit. Consultation with the internal medicine or hematology service is advisable for routine admissions, with other subspecialty consultation obtained as needed.

Finally, patients should be counseled to avoid any sympathomimetic drugs (including over-the-counter decongestants and illicit cocaine) and alcohol (which may suppress a stressed marrow). Pneumococcal and influenza vaccines can be offered or made available in follow-up, along with potential long-term oral penicillin prophylaxis for those with frequent bacterial infections.

COMMON PITFALLS

- Do not assume that abdominal pain is due to a vasoocclusive crisis without considering other causes, especially surgical pathology.
- It is easy to overdiagnose pneumonia in sickle cell patients, but underdiagnosis can be fatal. Because an acute infiltrate often represents an infarct rather than infection, other signs and symptoms of pneumonia should be sought. If the diagnosis is not clear, it is prudent to err on the side of caution and begin antibiotic therapy.
- Some complications of sickle disease are mistaken for crisis pain (e.g., osteomyelitis, aseptic necrosis of bone).
- Although transfusions are ordered too frequently and unnecessarily, exchange transfusion therapy is often not started early enough in the setting of neurologic

changes or priapism.

- Humane and adequate analgesia should be provided to each patient, with precautions to avoid abuse. Many patients benefit by entering into a written treatment contract with their primary care providers and emergency department staff.
- Patients should be educated about avoiding triggers, maintaining hydration, and initiating self-titrated analgesia early to limit the need for recurrent emergency department visits.

CHAPTER 213

Anemia

Louis S. Binder

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation and Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Anemia is defined as a decrease in the number of circulating red blood cells, with a concomitant decrease in the capacity of the blood to carry oxygen to tissues. Anemia is a manifestation of disease rather than a diagnostic entity in and of itself.

Anemia can be classified into disorders of decreased red cell production, disorders of increased red cell destruction, and anemia resulting from blood loss. ^{8,12} Each of these diagnostic groups has its own clinical presentation and differential diagnosis ([Table 213.1](#)) and, in general, requires its own approach to emergency department evaluation and management.

TABLE 213.1. Differential Diagnosis of Anemia

Anemia of any cause may present acutely or chronically, and the aggressiveness of intervention and management depends on the acuteness of onset and on the severity of the clinical presentation. For example, anemia secondary to acute gastrointestinal blood loss may require vigorous fluid resuscitation, transfusion therapy, and intensive care management; anemia secondary to chronic occult gastrointestinal bleeding leads to a well-compensated iron deficiency anemia that can be evaluated and treated on an outpatient basis. ^{1,11,14}

Defective red blood cell production may be due to interruption in the availability or synthesis of any of the three moieties of the hemoglobin molecule: iron, heme, and globin. Hence, anemia may result from iron deficiency, from toxins or enzymatic deficits that interfere with heme synthesis, or from genetic defects in globin synthesis. ^{12,14} Disorders and deficiencies that affect the proliferation of erythroid stem cells in the bone marrow may also result in anemia from decreased red cell production. ^{3,7,15}

Red cell destruction may result from either intrinsic or extrinsic causes. Intrinsic abnormalities of hemoglobin, enzymes, or red cell membranes may result in hemolytic anemia. ¹⁸ Extrinsic destruction may be due to immunologic, mechanical, or environmental causes, or to hypersequestration (hypersplenism). ^{6,16,18}

Blood loss resulting in anemia may be acute or chronic and may originate from intraperitoneal, retroperitoneal, pelvic, pleural, gynecologic, or gastrointestinal sources. ^{8,11}

CLINICAL PRESENTATION

Patients with anemia secondary to acute blood loss present with hypovolemia. A source of blood loss may be readily identifiable on clinical evaluation; menstrual blood loss and losses from the gastrointestinal tract are the most common sources for occult bleeding if the locus is unclear. ^{8,11} A history of underlying disease (e.g., cirrhosis, bleeding diathesis, malignancy, or infection) or of medication use (e.g., use of salicylates, nonsteroidal antiinflammatory drugs, or anticoagulants) may be useful in guiding initial evaluation and management. Hypovolemia may be relatively well tolerated in the young patient without underlying disease, but can be a significant stress to elderly or chronically ill individuals whose compensatory mechanisms may be overwhelmed and whose tissue perfusion may be marginal at baseline. ¹³

Patients with anemia secondary to chronic blood loss or to decreased red cell production often present with progressive fatigue, malaise, and a “washed-out” feeling. Dizziness, dyspnea on exertion, decreased exercise tolerance, or exacerbation of congestive heart failure may also be prominent symptoms. Gastrointestinal symptoms such as anorexia or nausea may reflect compensatory hypoperfusion of the splanchnic bed. Patients with asymptomatic underlying atherosclerotic vascular disease may present with angina pectoris, claudication, syncope, or focal neurologic deficits when decreased oxygen-carrying capacity is superimposed on local ischemia from vascular lesions. Other important historic information includes ethnicity and family history (predisposition to certain hemoglobinopathies and pernicious anemia), drug use, dietary history, use of ethanol, recent hospitalization (anemia of chronic disease is common in hospitalized patients), and history of underlying disease (renal, hepatic, thyroid, collagen vascular, or neoplastic disease; previous anemia; or recurrent jaundice). ^{4,5,12,13,17,18}

Pallor of the skin or mucous membranes is the cardinal sign of anemia, although it may be difficult to ascertain in some patients. Jaundice is suggestive of a hemolytic process. Tachycardia with a wide pulse pressure and hyperdynamic precordium (reflecting increased cardiac output) and a systolic ejection murmur may be present. ^{8,13}

Petechia and purpura may indicate a concomitant thrombocytopenia. Signs of chronic disease (rheumatologic, endocrine, hepatic, or neoplastic disease) manifest as lymphadenopathy, rash, thyromegaly, myxedema, or the stigmata of liver failure. ^{4,17} Hepatosplenomegaly may suggest underlying disease or extramedullary hematopoiesis. ¹²

Other signs may suggest specific causes of anemia. Vitamin B₁₂ deficiency affects exfoliating cell populations and demyelination of the dorsal columns, resulting in atrophy and tenderness of mucous membranes (particularly glossitis) and stocking–glove anesthesia of the distal lower extremities with impaired position and vibratory sense. ^{2,5}

The symptoms, signs, and laboratory findings of anemia may be the initial presenting manifestations of pancytopenia. ^{3,7,15} The etiology of pancytopenia is multifactorial. Pancytopenia is most commonly idiopathic (50%), but may result from chemical and physical agents, autoimmunity, or vitamin B₁₂ or folic acid deficiency. Pancytopenia may follow viral illness, including upper respiratory infection, hepatitis, Epstein-Barr infection, and human immunodeficiency virus infection. ¹⁵ It may also be associated with hypersplenism, myelodysplasia, bone marrow failure, or marrow replacement. ¹⁵ Clinically, pancytopenia may present as a viral illness, preceding the symptomatic presentation of anemia over several weeks, or as an insidious presentation of anemia with clinical evidence of thrombocytopenia

(petechia, purpura, or mucous membrane bleeding).^{3,7,15}

Patients with anemia secondary to acute hemolysis are likely to present with signs and symptoms similar to those seen with mild chronic anemia. In more severe presentations, there may be jaundice and dark urine. Fever, prostration, abdominal and back pain, and hemoglobinuria suggest acute intravascular hemolysis, similar to that associated with transfusion reaction.^{8,12} A family history of anemia suggests an intrinsic cause of hemolysis, whereas exposure to drugs or toxins suggests an extrinsic cause.¹⁸ Immunologic destruction of red blood cells may be due to autoantibodies.¹⁸ Mechanical destruction is seen in some patients with prosthetic heart valves.^{6,16,18} Disseminated intravascular coagulation leading to microangiopathic hemolytic anemia is suggested by diffuse bleeding.^{6,16} A finding of hepatosplenomegaly may suggest either sequestration or an autoimmune process.¹⁸

DIFFERENTIAL DIAGNOSIS

A complete differential diagnosis is presented in [Table 213.1](#).

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

After anemia is identified by a complete blood count or hematocrit determination in the emergency department, further laboratory evaluation includes the measurement of red blood cell indices and reticulocyte count. Examination of a peripheral smear may show heterogeneity of cells, evidence of hemolysis, basophilic stippling, ringed sideroblasts, or hypersegmented leukocytes.^{8,12} Additional diagnostic tests are normally neither necessary nor available in the emergency department. However, serum iron, total iron-binding capacity (TIBC), and serum ferritin determinations should be considered in hypochromic, microcytic anemia; folate and vitamin B₁₂ levels, liver function tests, and thyroid function tests in macrocytic anemia; and direct and indirect Coombs' tests, fractionated serum bilirubin count, and plasma and urine tests for free hemoglobin in hemolytic anemia.^{1,5,8,12,14,18} Inpatient evaluation may include further laboratory evaluation for specific disease and a bone marrow biopsy for evaluation of any unexplained anemia or pancytopenia.^{3,7,8,12,15}

Potential diagnostic errors of importance include the following:

1. Not suspecting acute blood loss and impending hypovolemic shock with any unexplained normocytic normochromic anemia
2. Confusing anemia with other entities that also cause constitutional symptoms (e.g., uremia, collagen vascular disease, fluid and electrolyte imbalance, infections, drug effects)
3. Confusing iron deficiency anemia, which presents with low iron, increased TIBC, and low ferritin, with anemia of chronic disease, which presents with low iron, low TIBC, and normal ferritin associated with a chronic disease or recent hospitalization^{1,4,14,17}
4. Confusing hemolytic anemia with other entities that also cause acute jaundice (particularly acute hepatitis)
5. Overlooking pancytopenia by focusing on a clinical picture of anemia and low hemoglobin, while neglecting findings of leukopenia and thrombocytopenia

The need for rapid intervention in both prehospital and emergency department patients is limited to identifying and treating hypovolemic shock. For certain anemic patients, treatment is best begun in the emergency department without waiting for definitive outpatient evaluation. Anemia of pregnancy is treated with prenatal vitamins (one daily) and iron replacement (ferrous sulfate 325 mg three times per day), and hypochromic microcytic anemia associated with an identified source of blood loss (presumed to be due to iron deficiency anemia) is treated similarly, with iron replacement therapy.^{1,14}

These patients should be reevaluated after 4 to 6 weeks to assess the adequacy of the therapeutic response.^{1,5,14} A reticulocyte count may be checked after a few days of therapy if more immediate confirmation of a therapeutic response is desired.^{8,9} and ^{10,12} In megaloblastic anemia presumed to be due to folic acid or vitamin B₁₂ deficiency, treatment may be initiated with 1 mg/d of oral folic acid or with 100 µg/d of cobalamin parenterally for 1 week, after specimens for serum vitamin B₁₂ and folic acid levels are drawn and follow-up is arranged.^{5,8,12,13} In mild or asymptomatic anemia of chronic disease, therapy is generally directed to control the underlying disease.^{4,17} For severe or symptomatic anemia, however, consultation and, usually, hospital admission are advisable.

In many cases of newly identified anemia, drug therapy and other interventions are frequently not indicated in the emergency department setting, and patients are referred to a consultant for further evaluation and management.

DISPOSITION

Consultation or referral for follow-up, in most cases, is to the patient's primary care physician. Most anemic patients have iron deficiency anemia, vitamin B₁₂ or folic acid deficiency anemia, or anemia of pregnancy; these cases can be treated and followed up on an outpatient basis.

Urgent consultation and hospital admission should be sought for the following indications^{8,12,13}:

1. Hypovolemia or ongoing bleeding
2. Need for urgent transfusion, generally because of a hemoglobin level less than 9 g/dL in a bleeding or symptomatic patient¹¹
3. Severe symptoms (e.g., chest pain, dyspnea, syncope) that impair the patient's ability to function at home
4. Pancytopenia requiring diagnostic evaluation^{3,7,15}
5. Anticipated need for extensive diagnostic or therapeutic intervention

Unless active bleeding is present or the patient is hemodynamically unstable, there is usually no contraindication to routine transfer for specialized evaluation.

COMMON PITFALLS

- Failure to suspect and identify bleeding and hypovolemia
- Failure to appreciate the possibility of anemia from the clinical presentation, and, hence, not ordering a hemoglobin or hematocrit determination. This is especially likely in hemolytic anemia or when chest pain, dyspnea, dizziness, or claudication is the presenting complaint.
- Failure to ensure referral or appropriate follow-up for evaluation of therapeutic response or the need for additional diagnostic testing

- [Acute, Minor Reactions](#)
- [Delayed Reactions](#)
- [Massive Transfusion](#)
- [Differential Diagnosis](#)
- [Emergency Department Evaluation](#)
- [Emergency Department Management](#)
- [Disposition](#)
- [Common Pitfalls](#)
- [Chapter References](#)

Each year, over 23 million units of blood components, including 11.4 million packed red blood cell (PRBC) units, are transfused to patients in the United States. ^{1,8} The incidence of transfusion reactions is estimated to be only 1%, and the majority of reactions are simple febrile or minor allergic reactions. ¹⁶ The exceptionally low rate of serious transfusion reactions is mainly due to strict adherence to blood-banking techniques, careful transfusion practices, and extensive testing of donated units.

Life-threatening reactions occur rarely, but it is critical that physicians recognize them quickly and respond appropriately in order to avert a disastrous outcome. Transfusion reactions may be categorized in many ways, but it seems most useful clinically to divide them by severity and time of onset ([Table 214.1](#)).

ACUTE, SEVERE REACTIONS
Acute hemolysis
Anaphylaxis
Sepsis
Transfusion-related acute lung injury
Congestive heart failure
ACUTE, MINOR REACTIONS
Simple febrile
Allergic
DELAYED REACTIONS
Delayed hemolysis
Crabtree reaction/fever disease
Hepatitis
HIV
CMV
Other infections: Epstein-Barr virus, cytomegalovirus, syphilis, hepatitis, toxoplasmosis, babesiosis, malaria, toxoplasmosis, brucellosis
MASSIVE TRANSFUSION
Coagulopathy
Hypothermia
Citrate toxicity (hypocalcemia)
Hypokalemia
Lactic acidosis

TABLE 214.1. Blood Transfusion Reactions and Complications

CLINICAL PRESENTATION

Acute, Severe Reactions

Acute Hemolysis

One of the most serious (and most preventable) blood transfusion reactions is acute hemolysis caused by incompatibility between recipient and donor ABO blood groups. The incidence is between one in 250,000 and one in 1 million PRBC units transfused. ⁸ The resulting IgM–antigen complex fixes complement, leading to rapid intravascular hemolysis, with massive release of hemoglobin, acute renal failure, disseminated intravascular coagulopathy (DIC), and cardiovascular collapse.

The most common cause is simple clerical error—the wrong unit is given to the wrong patient. For that reason, painstaking efforts must be taken to double-check every step in the identification process prior to a transfusion.

The clinical signs of an acute hemolytic reaction are usually not subtle in the awake patient but may be difficult to recognize quickly in the unconscious, intubated patient. Unfortunately, the latter is just the type of patient that emergency physicians often need to transfuse. In an acute reaction, patients experience a rapid onset of fever, chills, back pain, vomiting, tachycardia, and hypotension.

The most important aspect of care is early recognition and discontinuation of the transfusion, because the severity of the reaction is related to the volume of blood transfused. For this reason, a physician or nurse should be at the bedside during the first 5 minutes of transfusion. Although there is no specific remedy, treatment of acute hemolysis centers around aggressive supportive care to minimize shock and maximize renal perfusion ([Fig. 214.1](#)). In hemodynamically unstable patients, early use of invasive monitoring is warranted, along with vasopressors and forced diuresis with crystalloids and loop diuretics (e.g., furosemide). Dopamine may be added—in “renal” doses (2 to 3 µg/kg/min)—for its potential benefit in increasing renal blood flow. Other treatments, such as steroids, mannitol, or heparin for DIC, are more controversial.

Figure 214.1. Clinical algorithm for suspected transfusion reaction. Many hospitals have developed policies and guidelines for actions to be taken in case of a transfusion reaction. Physicians should be informed regarding local hospital policy. TRALI = transfusion-related acute lung injury.

Anaphylaxis

Anaphylaxis is, fortunately, rare during a blood transfusion, but when it does occur, it is most often in IgA-deficient individuals who react to the IgA present in the transfused unit. The incidence has been estimated to be between one in 20,000 and one in 150,000 transfusions. ^{14,16} Unfortunately, these reactions cannot be reliably predicted, even by testing for the presence of IgA antibody in the patient's serum. ¹⁴

The onset is generally within the first minutes of transfusion and may present as sudden flushing, pruritus, laryngospasm, bronchospasm, and hypotension.

Treatment must be rapid and consists of epinephrine (intravenous [i.v.] or subcutaneous), steroids (methylprednisolone 125 mg i.v.), diphenhydramine (50 mg i.v.), and nebulized albuterol if wheezing is present. Intravenous crystalloid boluses and vasopressors may be necessary to treat hypotension.

Patients with a history of serious allergic reactions to blood products may be given washed RBCs or frozen–deglycerolized RBCs in an effort to prevent allergic reactions. IgA-deficient donors are often available when the transfusion can be planned in advance.

Hypotensive reactions to platelet transfusions have also been reported. These are not thought to be allergic in origin but may initially lead the clinician to suspect anaphylaxis. These reactions appear to be uncommon and resolve quickly with cessation of the platelet transfusion. ⁹

Sepsis

Another potentially fatal transfusion reaction occurs when a contaminated blood product is transfused. This is a rare event with PRBC, with a risk between one in 500,000 and one in 2.5 million. ^{4,8,16} The risk is much higher, however, in platelet transfusions (between one in 1600 and one in 12,000) because they are stored at room temperature to maintain platelet activity. ^{4,8} Single-donor apheresis platelet units carry a lower risk for bacterial contamination than do random-donor pooled platelets, as do fresher units with less storage time. ^{4,16} Many bacteria have been implicated in platelet transfusions, including *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Serratia marcescens*, and *Staphylococcus epidermidis*, and the mortality has been reported at 26%. ⁸ The most common agent in PRBC units, however, is *Yersinia enterocolitica*, which grows well under refrigerated conditions. ^{2,4,8}

When the contaminated unit is transfused, it may produce the acute onset of a sepsis syndrome, with fever, chills, and hypotension. A septic reaction, especially when caused by a gram-negative organism, could easily be confused with the early stages of hemolytic or anaphylactic reactions in the early stages.

Treatment should consist of stopping the transfusion, sending cultures of the patient's blood, and immediately returning the donor unit to the laboratory for Gram staining, cultures, and hemolysis workup. The Gram stain is positive in most cases of bacterial contamination, but if the suspicion of a septic reaction is high, broad-spectrum antibiotics should be administered without waiting for these results. Antibiotic coverage for a contaminated platelet transfusion should include an antistaphylococcal agent as well as a third-generation cephalosporin. Coverage for a contaminated PRBC transfusion must include a third-generation cephalosporin or quinolone to cover *Yersinia*. Intravenous fluids and vasopressor support may also be necessary.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is a noncardiogenic pulmonary edema occurring unpredictably in one in 5,000 to one in 10,000 units of PRBC transfused. ^{8,16} It is probably caused by antileukocyte antibodies in the donor unit reacting with the patient's white blood cells (WBCs). This reaction leads to increased pulmonary capillary permeability and produces an adult respiratory distress syndrome (ARDS) during or just following transfusion. It should be differentiated from acute congestive heart failure (CHF) by the patient's history and the typical chest x-ray finding of diffuse interstitial edema without cardiomegaly.

Treatment is supportive and consists of oxygenation, ventilatory support, and intensive care unit (ICU) care. Diuresis and steroids are generally not effective. Such reactions should be reported to the laboratory so that donors found to have antileukocyte antibodies can be excluded from future donations.

Congestive Heart Failure

The cardiovascular systems of most patients can easily accommodate the rapid change in intravascular volume that a blood transfusion provides. Elderly patients, however, and those with preexisting cardiomyopathy or diastolic dysfunction may have difficulty handling an acute change in volume and preload, and the result is pulmonary edema. Transfusions are often necessary or even lifesaving in these patients, but they must be carried out with extra care and attention.

These patients must not be rapidly transfused and discharged home. In those with a low-to-medium risk for CHF, it may be sufficient to transfuse slowly (over 3 to 4 hours) and allow a period of time between each subsequent unit transfused. Administration of a loop diuretic (e.g., furosemide) between units may also be helpful. Vigilant observation and monitoring is the key. In high-risk patients, invasive monitoring of right or left ventricular filling pressures (or both) in the ICU may be necessary.

If a patient receiving a transfusion develops pulmonary edema, it should first be determined whether the patient has CHF or noncardiogenic pulmonary edema. The patient history and chest x-ray will be helpful in this determination. CHF should be treated as usual, with nitrates (i.v., sublingual, paste, etc.), diuretics (furosemide), oxygen, close monitoring, and ventilatory support, as needed.

Acute, Minor Reactions

Simple Febrile Reaction

This is the most common transfusion reaction, with an incidence of 1%. It is thought to be due to antileukocyte and antiplatelet antibodies, or to transfused pyrogenic cytokines that accumulate in stored blood as leukocytes break down. Patients who receive frequent transfusions or who have a history of febrile reactions may be given leukocyte-reduced units of blood to reduce the likelihood of this reaction. It is most important to carefully differentiate this benign reaction from the potentially lethal acute intravascular hemolytic reaction discussed earlier.

The simple febrile reaction should be treated with oral acetaminophen. There is controversy about whether the transfusion may be carefully resumed after clinical observation and appropriate laboratory testing have ruled out a hemolytic reaction.

Allergic Reaction

Minor allergic reactions occur largely in response to transfused plasma proteins. The incidence is estimated to be 0.1%, but it may be underreported. ¹⁶ The reaction is more common with platelet or plasma transfusions, but PRBC units also carry some residual plasma. The patient develops urticaria or flushing and pruritus, without any dyspnea or hypotension. As with other reactions, the transfusion should be stopped while the patient is assessed to be certain that the more dangerous anaphylaxis is not present. Diphenhydramine should be administered, and the transfusion may be carefully resumed with close monitoring for any sign of recurrence.

Delayed Reactions

Adverse transfusion reactions may occur days to months after the transfusion. These include delayed hemolysis, graft-versus-host disease (GVHD), and a number of infections. Many infectious diseases may be transmitted by blood transfusion, including the human immunodeficiency virus (HIV), hepatitis, syphilis, malaria, cytomegalovirus (CMV), Epstein-Barr virus (EBV), trypanosomiasis, toxoplasmosis, babesiosis, and brucellosis. ^{4,7,17} The most clinically significant in the United States are hepatitis, HIV, and CMV.

Delayed Hemolysis

Delayed hemolysis is unusual, but may occur 5 to 7 days posttransfusion. The incidence is between one in 1,000 and one in 2,500 units transfused. ^{4,7,17} It is most commonly caused by reactivation of antibodies to the minor RBC antigen systems such as Rh, Kell, Kidd, and Duffy. It presents in a less severe and dramatic way than the acute hemolytic reaction, though progression to renal failure is still a concern. In contrast to acute hemolysis, there is usually less free hemoglobin circulating at any given time, and thus the renal insult tends to be less severe. ¹⁶ Worsening anemia is the most common clinical problem that must be evaluated.

Laboratory studies should reveal signs of recent hemolysis (anemia, indirect hyperbilirubinemia, and a positive direct Coombs' test), and one or more new antibodies may be identified. However, the haptoglobin may be normal, and the serum and urine lack the pink discoloration of acute hemolysis. If further transfusion is required, units lacking the problematic antigen must be used.

Graft-Versus-Host Disease

GVHD occurs when lymphocytes from a donated unit of blood attack an immunocompromised host who is unable to combat the foreign cells, or when lymphocytes from an immunologically similar donor are not recognized as foreign by the host. Signs and symptoms may include fever, rash, nausea, and vomiting, as well as elevation of transaminases and pancytopenia. This is a particular danger in neonates and bone marrow transplant recipients.

Although there is no specific treatment beyond supportive care, preventive measures exist. Irradiation of PRBC and platelet units suppresses any white cells that may be transfused along with the desired component. This is the only effective means of preventing GVHD in these high-risk patient groups.

Hepatitis

Transfusion-associated hepatitis was a major problem in the 1970s and 1980s. It has been estimated that during the early 1970s, transfusion-associated hepatitis occurred in up to 33% of transfusions.¹¹ Since then, aggressive screening of donors and the development of specific assays for hepatitis B and C have greatly reduced the risk.

Donahue reported a decrease in the risk of posttransfusion hepatitis C from approximately one in 200 during 1985 to one in 3,300 in 1991, after hepatitis C testing became available.³ With further advances in testing, the current estimated risk of transfusion-transmitted hepatitis B is one in 63,000, and of hepatitis C is one in 103,000.¹⁵ Although the hepatitis C test successfully eliminated the majority of non-A, non-B hepatitis, the small risk of non-A, non-B, non-C hepatitis remains.

Human Immunodeficiency Virus

Although it is now exceedingly rare, the transfusion complication that has received the most public attention is HIV infection. It has been estimated that the risk of HIV transmission in some metropolitan areas was as high as one in 100 units transfused in 1983, before HIV testing was available to blood banks in March of 1985.⁸ Now, thanks to aggressive predonation screening, along with HIV-1 antibody and p24 antigen testing, the current risk is estimated to be between one in 450,000 and one in 660,000.⁴ Donated blood is also screened for HIV-2, although this strain is rare in the United States.

The use of concentrated pooled plasma products resulted in a majority of hemophiliacs in the 1980s contracting the acquired immunodeficiency syndrome or hepatitis. Highly purified, lyophilized factor VIII concentrate and recombinant products have eliminated these tragic complications of therapy.

Cytomegalovirus

Although CMV is generally not a significant pathogen in immunocompetent individuals, the immunosuppressed, especially premature neonates, HIV patients, and bone marrow and organ transplant recipients, are especially susceptible to CMV infection transmitted by blood transfusion. The risk may be greatly reduced through the use of blood collected from CMV-negative donors, or by using either leukocyte-reduced or frozen–deglycerolized units of blood.³

Massive Transfusion

Several alterations are present in stored blood that are insignificant in small transfusions but may become clinically relevant in the setting of massive transfusion. *Massive* is usually defined as transfusion of the equivalent of one blood volume, or 10 to 12 units of PRBC, within 24 hours. Fortunately, it is rare that the emergency physician would be faced with this situation, but it may occur in the setting of major trauma or gastrointestinal (GI) bleeding when definitive care is delayed for whatever reason.

Hyperkalemia and lactic acidosis may result from the transfusion of multiple units of older stored blood, but the effects tend to be relatively mild and transient. Citrate toxicity may result in hypocalcemia in the setting of massive transfusion, which caused substantial problems in the past when it was common to transfuse whole blood units. However, in the era of component therapy, whole blood is rarely (if ever) available or indicated, and units of PRBC contain far less citrate. Hypothermia may cause or make patients more prone to becoming coagulopathic. Blood warmers lessen this problem, but they also slow the rate of transfusion, which is problematic in the hypotensive, hemorrhaging patient. Methods of mixing PRBC units with heated crystalloids, making the transfusion both faster and warmer, have been described.^{5,10}

The coagulopathy associated with massive transfusion is multifactorial and difficult to predict prospectively. Clotting factors and platelets decrease, at least in part, because of dilutional effects after multiple units of PRBC are transfused, because these units contain negligible amounts of clotting factors and platelets. Coagulation times may rise beyond 1.5 times control, and clinically relevant bleeding occurs in some patients. Trauma patients who receive more than 10 units in 24 hours are more likely to develop serious coagulopathy in the presence of hypothermia, acidosis, or hypotension. Among severely injured patients who receive massive transfusion, virtually all become coagulopathic when all of the noted risk factors are present.⁶ Although platelet counts fall during massive transfusion, the decrease is much less than would be predicted from dilution alone.¹³ This is thought to be due to release of platelets into the circulation from storage in the spleen or from the bone marrow. Platelet counts usually remain above 50,000 until 20 units of PRBC are transfused, but coagulation times exceed 1.5 times control in patients receiving more than 12 units.¹²

Routine prophylactic administration of fresh-frozen plasma (FFP) and platelets is not usually recommended for patients receiving massive transfusion, because there is substantial variability in the number of units it takes to make a patient coagulopathic or thrombocytopenic. There is even more variability in whether the patient has only a laboratory abnormality or clinically significant bleeding. Physicians must, however, be vigilant for the development of coagulopathic bleeding and be prepared to treat it quickly.

In general, patients who are bleeding and have platelet counts of less than 50,000 should receive platelet transfusion, and those with prothrombin times or partial thromboplastin times greater than 1.5 times control should receive FFP.¹⁷ Cryoprecipitate may be used to replenish fibrinogen if it becomes depleted. One should consider the *prophylactic* administration of FFP after massive transfusion when there are other complicating factors, such as hypothermia, acidosis, or hypotension, because individuals with these conditions are at greater risk for developing significant coagulopathy.⁶

DIFFERENTIAL DIAGNOSIS

The patient who develops any adverse symptoms early in a blood transfusion must be carefully evaluated for the possibility of one of the acute, severe reactions. However, many patients who receive emergent transfusions have underlying disease that may have symptoms in common with transfusion reactions. For example, when trauma patients or those with GI bleeding become hypotensive during a transfusion, the hypotension may represent either increasing hemorrhage or an acute, severe transfusion reaction. Sepsis and some drug overdoses may also present with symptoms that are similar to those of a transfusion reaction.

Although many of the signs and symptoms of transfusion reactions are nonspecific and can be confused with many disease processes, most transfusion reactions occur during or soon after a transfusion. A delayed hemolytic reaction must be differentiated from other causes of jaundice and anemia, but the indirect hyperbilirubinemia should cue the physician that hemolysis has occurred.

EMERGENCY DEPARTMENT EVALUATION

In the patient with an acute reaction, the clinician must rapidly decide whether the signs and symptoms are consistent with one of the severe reactions or one of the more benign febrile or allergic reactions (see [Fig. 214.1](#)). Differentiation may sometimes be done clinically by evaluating the constellation of findings, without extensive testing. One may also employ quick, simple testing, such as observing the serum (after centrifugation of a blood sample) or the urine for pink discoloration

during a hemolytic reaction.

The evaluation should also involve immediate reporting to the laboratory and sending blood samples for testing. Based on the clinical setting, the laboratory will often confirm the ABO types of the patient and donor unit, perform a direct Coombs' test, and search for evidence of hemolysis (an elevated indirect bilirubin, decreased haptoglobin, schistocytes on a peripheral smear, or hemoglobinuria). Testing may also include Gram staining and cultures, especially after platelet transfusions, if bacterial contamination is suggested.

The transfusion should be stopped during this evaluation in case the patient is in the early stages of a severe reaction. In some cases of minor reactions, especially allergic ones, the clinician may choose to treat the symptoms and restart the transfusion after determining that a severe reaction is not present, although this procedure is controversial. One should quickly involve the laboratory and transfusion service for consultation when a reaction occurs. Most institutions have policies or guidelines to help the clinician in evaluating and reporting transfusion reactions.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment, of course, depends on which type of reaction has occurred (see [Fig. 214.1](#)). The first step is always to stop the transfusion and carefully evaluate the patient to determine whether a transfusion reaction is occurring and, if so, which type. The treatment of acute hemolysis is largely supportive, with special attention to maintaining renal perfusion. Anaphylaxis should be treated with epinephrine, steroids, diphenhydramine, and i.v. fluids, regardless of the cause. Sepsis from bacterial contamination requires aggressive supportive care, including i.v. fluids, vasopressors, and broad-spectrum antibiotics. TRALI and CHF are treated with ventilatory support, as well as nitrates and diuresis for CHF. Simple febrile and allergic reactions are treated with acetaminophen and diphenhydramine, respectively.

DISPOSITION

Most patients receiving blood transfusions in the emergency department are ultimately admitted to the hospital, whether or not they have a transfusion reaction. However, acute, severe reactions usually necessitate ICU admission, regardless of the patient's original disposition. Simple febrile or allergic reactions do not necessarily require a change in the patient's treatment plan.

COMMON PITFALLS

- Failing to carefully identify patients when drawing pretransfusion blood samples, and failing to carefully match identities of blood components, their paperwork, and the recipient. This is the most frequent cause of fatal hemolytic reactions.
- Failing to adequately evaluate a patient who develops symptoms during a blood transfusion. The large majority are simple febrile or allergic reactions, but the few dangerous reactions must be discovered and treated immediately.
- Failing to recognize a severe reaction in an intubated patient. Because the patient cannot complain of symptoms, it is more difficult to differentiate a transfusion reaction from underlying disease. An acute, severe reaction may initially appear as isolated hypotension or a change in urine color.
- Rapidly transfusing an elderly patient who is inadequately observed. Congestive failure can be avoided by slow, intermittent transfusion and diuresis.
- Failing to transfuse an appropriate patient because of the misconception that complications of transfusion are more common than they actually are. Blood transfusion is safer now than it ever has been, and it remains a lifesaving intervention.

[Hemorrhage](#)
[Hyperleukocytotic Syndromes](#)
[Other Complications of Hematologic Malignancies](#)
[Lymphoma](#)
[Polycythemia and Thrombocytopenia](#)
[Chapter References](#)

ACUTE LEUKEMIA

Acute leukemia is rarely overlooked or misdiagnosed.³ Most patients with acute leukemia present with complaints of fatigue, weight loss, or bleeding and are found on physical examination to have petechiae, lymphadenopathy, splenomegaly, or sternal tenderness.

A complete blood count with examination of the blood smear is usually sufficient to make a provisional diagnosis. In acute leukemia, the white blood cell count may be increased (in 50% of patients), normal, or decreased (in up to 33% of patients), but blast cells usually make up more than 5% of circulating white cells. The definitive diagnosis is made on examination of the bone marrow with the finding of more than 30% blast cells.

The most common complications of leukemia that precipitate emergency department visits are infection (responsible for 70% of deaths from acute leukemia) and bleeding.

Infection

In patients with acute leukemia, neutropenia is caused by replacement of normal marrow by leukemic cells or is the result of cytotoxic chemotherapy. In addition, most patients have qualitative defects of the circulating neutrophils. With prolonged neutropenia (less than 1,000 neutrophils per microliter), the mucous membranes and skin lose their effectiveness as barriers to infection. Infections in leukemic patients, therefore, tend to be due to bowel or skin flora. These include *Pseudomonas aeruginosa*, *Escherichia coli*, *Proteus* species, and *Staphylococcus aureus*. In patients with indwelling catheters, *Staphylococcus epidermidis* and *Streptococcus viridans* have become major causes of infection. Leukemia does not interfere with the ability to mount a fever and is rarely the primary cause of fever.

Any patient with known or suspected leukemia who presents with intermittent or sustained fever greater than 100.5°F should be assumed to be septic and promptly treated with broad-spectrum antibiotics after blood is drawn for cultures. In patients without an obvious source of infection, a combination of an antipseudomonal penicillin or cephalosporin and an aminoglycoside is commonly used. For patients with a history of allergy to penicillin or cephalosporin, broad-spectrum quinolone antibiotics (e.g., ciprofloxacin) or imipenem may be substituted.

Hemorrhage

Until platelet transfusions came into widespread use, hemorrhage was almost as important as infection as cause of death among leukemic patients. Even now, hemorrhage due to thrombocytopenia continues to account for more than 15% of deaths from leukemia. Most patients with thrombocytopenia present with petechiae and microscopic hematuria. With platelet counts below 20,000/mL, there is a high risk of intracranial hemorrhage.²

Transfusion of random-donor platelets is usually sufficient to prevent hemorrhage due to thrombocytopenia. The usual goal is to raise the platelet count above 50,000/mL. In nonimmunized patients, 1 U of platelets can be expected to raise the count by between 5,000 and 10,000, but the patient who has had repeated platelet transfusions may have become immunized to platelet-borne tissue antigens and may require human leukocyte antigen–matched platelets. The blood bank is usually aware of these individuals because of their previous transfusions.

Leukoagglutinin reactions, usually manifested by body aches, fever, rigors, or shortness of breath, are common in patients receiving pooled platelets, because pooled platelets contain a high concentration of viable leukocytes. Symptoms can usually be prevented by using a Leukapor filter and by administering acetaminophen 650 mg by mouth and diphenhydramine 50 mg intravenously 10 to 20 minutes before the transfusion.

A less common cause of hemorrhage is disseminated intravascular coagulation (DIC), which is seen most often in patients with acute promyelocytic leukemia or acute monocytic leukemia. DIC should be considered in leukemic patients who present with ecchymosis rather than petechiae. DIC causes prolongation of both the prothrombin and partial thromboplastin times. The diagnosis is confirmed by finding depressed levels of fibrinogen and high concentrations of fibrinogen degradation products. Patients with acute leukemia and DIC often require emergent replacement of plasma coagulation factors and platelets before being treated with cytotoxic drugs. Heparin is often administered to interfere with uncontrolled coagulation, but its usefulness is controversial and there is no compelling reason to administer it in the emergency department.

Hyperleukocytotic Syndromes

A small proportion of patients with myelogenous leukemia (5% of acute leukemias and 15% of patients with chronic leukemia) present with hyperleukocytotic syndromes. In these conditions, the high concentration of leukemic cells interferes with circulation to the brain, eye, lung, ear, or penis. Clinical features include tachypnea, dyspnea, pulmonary infiltrates, retinal hemorrhages, dizziness, stupor, visual blurring, and priapism. Intracranial hemorrhages are a rare but catastrophic manifestation. These problems usually occur when the white cell count is greater than 75,000/mL in acute leukemia or is greater than 250,000/mL in chronic myelogenous leukemia. Patients with chronic lymphocytic leukemia generally do not develop problems related to leukostasis until the peripheral white cell count exceeds 1 million per milliliter.

Patients with hyperleukocytotic syndromes can be treated with emergent leukapheresis. If this modality is not available in a timely fashion, cytotoxic drugs can be used to reduce the peripheral white blood cell count. Cytotoxic therapy, however, carries the risk of “tumor lysis syndrome,” manifested by the rapid onset of hyperuricemia, hyperphosphatemia, hyperkalemia, and lactic acidosis. A commonly used cytotoxic agent that is easy to administer is hydroxyurea, an oral medication given in doses of 500 to 2,000 mg four times per day. Patients with hyperleukocytosis who will be treated with hydroxyurea should be given allopurinol at least 3 to 6 hours before the first dose; the serum electrolytes and blood counts must also be monitored closely. Tumor lysis syndrome is also associated with rapidly growing lymphomas.

Other Complications of Hematologic Malignancies

Patients with hematologic malignancy can present with signs and symptoms referable to anemia. Infiltration of leukemic or lymphoma cells into various organs can also be a feature of the initial presentation and is often associated with relapse after treatment. Patients with Burkitt lymphoma often present with an abdominal mass, and sometimes with obstructive symptoms due to mesenteric infiltration by cancer cells. More than 75% of patients with acute leukemia have enlargement of lymph nodes, liver, and spleen.

In the patient who gives a history of cured leukemia or leukemia in remission, relapse of the disease must always be considered. A common site of relapse is the central nervous system; symptoms can include headache, cranial nerve dysfunction, or signs of meningeal irritation and carcinomatous meningitis. Meningeal leukemia is most often seen in children and in leukemia of lymphoid origin. It usually presents with signs of increased intracranial pressure. A computed tomography scan of the head is usually normal in these patients, and examination of the cerebrospinal fluid reveals a pleocytosis, often with identifiable leukemic cells. Patients

with meningeal leukemia require emergent hospital admission and intrathecal chemotherapy.

LYMPHOMA

Certain lymphomas are associated with medical emergencies. Patients with multiple myelomas often have extensive bone lesions, and bone pain is a presenting feature in 70% of patients. The emergency physician must maintain a high suspicion for fracture, even when presented with a story of pain that is gradual in onset or waxing and waning. Vertebral metastases are common in myeloma, and many patients report having already noticed a loss of height before the diagnosis of myeloma is made. Myeloma is a common cause of spinal cord compression.

More than 60% of patients with myeloma develop hypercalcemia during the course of their disease.¹ Symptoms such as anorexia, nausea, vomiting, polyuria, and constipation can develop rapidly, and patients may progress to develop lethargy and coma. Rarely, profound hypercalcemia may not be accompanied by these symptoms because circulating myeloma proteins are binding the calcium. It is thus useful to measure the free ionized calcium level before beginning therapy.⁶ Patients with hypercalcemia are usually volume-depleted, and initial therapy almost always includes saline infusion. Diuretics can be used if volume overload is a concern, but they should be avoided as initial therapy unless volume overload is present initially.

Another emergency related to lymphoid malignancies is hyperviscosity syndrome, which has an incidence ranging from 2% in patients with myeloma to 50% in patients with macroglobulinemia. The common manifestations are bleeding disorders (e.g., epistaxis, purpura, or gastrointestinal bleeding), visual impairment, and a broad range of neurologic symptoms.⁸ Serum viscosity is easily measured in the laboratory. The normal range of relative serum viscosity is 1.4 to 1.8. Symptoms usually appear at values greater than 4, and a relative viscosity of 6 or greater is associated with severe manifestations.⁷ Patients with severe hyperviscosity syndrome (e.g., central nervous system findings or hemorrhage) require emergent plasmapheresis.

POLYCYTHEMIA AND THROMBOCYTHEMIA

Overproduction of erythrocytes or platelets may also precipitate medical emergencies. A hemoglobin level greater than 17 g/dL or a hematocrit greater than 55% may signal polycythemia vera, an uncontrolled clonal overproduction of erythrocytes. Other conditions that should be considered in patients presenting with a high hematocrit include volume depletion, hypoxia, and polycythemia due to cigarette smoking or exposure to high altitudes. Patients with polycythemia vera are usually middle-aged and generally have a normal arterial oxygen saturation (greater than 92%) and splenomegaly. They often have leukocytosis (greater than 12,000 white blood cells/mL) as well as thrombocytosis (greater than 400,000 platelets/mL).

Emergencies due to polycythemia are related to hypervolemia and hyperviscosity. Patients may present with headache, vertigo, angina pectoris, or claudication. Thirty percent of patients with polycythemia vera suffer thrombotic episodes, and stroke is a common complication and cause of death. Elevated hematocrit findings can also interfere with platelet function; thus, some patients with uncontrolled polycythemia suffer hemorrhagic complications, most commonly in the gastrointestinal tract. Many patients with polycythemia also have thrombocytosis (platelet counts greater than 600,000/mL), a finding that is also associated with abnormal bleeding.

Polycythemic patients with signs or symptoms of hyperviscosity or thrombotic complications should have their blood volume and hemoglobin concentration reduced to normal as quickly as possible.

Even without symptoms, a hemoglobin level of 18 g/dL or a hematocrit reading of 60% or higher is also an indication for emergent phlebotomy or cytappheresis. Patients who are otherwise healthy can usually tolerate a rapid phlebotomy of 500 mL, although more gradual treatment may be required in the elderly or in those with known coronary artery disease. With the attainment of a normal hematocrit, the platelet defect that gives rise to thrombosis and bleeding is eventually corrected, but this can take weeks to occur. Elective surgery and dental procedures in polycythemic patients should thus be delayed until the red cell mass and platelet count have been normalized for at least 2 months. Polycythemic patients in need of emergency surgery require emergent phlebotomy or cytappheresis.⁴

Primary thrombocythemia is a myeloproliferative disorder characterized by platelet counts of more than 600,000/mL and a clinical course marked by hemorrhagic and thrombotic episodes. The disease may be associated with polycythemia vera. Other causes of thrombocytosis include chronic inflammatory disorders (e.g., rheumatoid arthritis, ulcerative colitis), iron deficiency, carcinoma, or recent administration of epinephrine. A thromboembolic event often brings the patient initially to medical attention. Neurologic symptoms are common and usually include headache, dizziness, paresthesia, or transient ischemic attacks. More than half of patients with primary thrombocythemia experience arterial thrombosis, most commonly in the legs, coronary arteries, and renal arteries. In addition, many suffer gastrointestinal hemorrhage.

Individuals with platelet counts greater than 1 million per milliliter and either thrombosis or hemorrhage require rapid plateletpheresis to reduce the platelet count to less than 500,000/mL. If plateletpheresis is not available, cytotoxic drugs can be used; nitrogen mustard, uracil mustard, and hydroxyurea are the agents of choice. The use of antiplatelet agents is controversial because of the increased risk of hemorrhage. Asymptomatic patients with platelet counts of less than 2 million per microliter should have prompt evaluation and treatment, but do not require emergent therapy.⁵

[Musculoskeletal Pain](#)
[Complications of Cancer Treatment](#)
[Neutropenic Fever](#)
[Chemotherapy-Induced Emesis](#)
[Cardiopulmonary Resuscitation in Cancer Patients](#)
[Common Pitfalls](#)
[Chapter References](#)

Patients who have been diagnosed with cancer have usually been warned by their oncologists that certain symptoms, such as fever while on chemotherapy, require emergent evaluation. When other symptoms appear, patients and their families are, as a rule, quite concerned about how the new problem may be related to the cancer or its treatment. These patients commonly suffer from chronic anxiety and uncertainty about their disease, its treatment, and its prognosis, and they pose a significant challenge to the emergency physician.

Cancer patients nevertheless deserve special attention for even apparently minor problems, because catastrophic oncologic emergencies often present with subtle complaints and findings. For example, mild radicular low back pain with a positive “straight leg-raising sign” may be the first sign of impending spinal cord compression in a patient with a history of lung cancer. Likewise, a vague complaint of dyspnea or malaise in a patient with a history of breast cancer may be due to a pericardial effusion that has progressed nearly to the point of frank tamponade.

Similarly, apparently minor aches and pains may herald the appearance of new metastases. Thus, a heightened sense of suspicion is always appropriate when treating a patient with a history of cancer. All cancers are not the same, however; for effective assessment, the emergency physician must determine the type of cancer involved and must have some familiarity with its natural history. The pattern of any metastasis or previous complications should be established, as well as specific details about therapy (e.g., which drugs have been administered, which sites have been irradiated, and when).

In the emergency department, it is important to set reasonable treatment goals that are consistent with the long-term treatment plan formulated by the patient's oncologist. They can range from immediate pain relief to complex treatments designed to restore functional status.⁷ As with all patients, the treatment should be tailored to the patient's physical and psychological state and prognosis. Is the patient responding to treatment? Is there hope for cure or sustained palliation, or is the patient terminally ill? Thus, early consultation with the oncologist is usually appropriate to ensure consistency and continuity of care.

What follows is a discussion of common oncologic emergencies, organized by the usual presenting complaint. These are often complaints that the emergency physician evaluates every day, but when any of them is coupled with a history of cancer, the malignancy must figure prominently on the list of potential etiologies. Some of the many complications of cancer therapy that can prompt visits to the emergency department are also addressed.

SHORTNESS OF BREATH

The emergency physician's first priority in dealing with shortness of breath is to assess the airway, seeking evidence of obstruction. Upper airway obstruction is seen with far-advanced hypopharyngeal and laryngeal cancers. Superior vena cava obstruction due to lymphoma or lung cancer can cause pharyngeal edema, but this symptom is very rare.¹

Usually, the patient with a malignant upper airway obstruction has a history of chronic, gradually worsening dyspnea that has progressed over weeks or months, and that is worsened by exertion. The patient may also have noted increasing hoarseness over the prior few weeks or months. Assessment can be carried out with laryngoscopy and soft-tissue radiographs of the neck. Treatment may involve surgery, radiation, or chemotherapy. It is also safe to administer a dose of steroids emergently and, if there is significant obstruction, to administer oxygen–helium mixtures to improve gas flow.

An exception to the pattern of gradually developing airway compromise is rapid obstruction due to fast-growing neck tumors, such as anaplastic thyroid cancers or Burkitt's lymphoma. In addition, partial upper airway obstruction from a laryngeal tumor may be exacerbated by infection, hemorrhage, or retained secretions and may present as a critical obstruction. In the critical situation, one must be prepared to establish a surgical airway, although there is usually time to use suction, to administer nebulized racemic epinephrine, and, if necessary, to attempt endotracheal intubation so that definitive intervention can be performed on a nonemergent basis.

In addition to obstructing the upper airway, tumors (usually lung, esophageal, or thyroid carcinomas) can also impinge directly on the trachea. The trachea is rarely the site of primary or metastatic tumor, however. Tracheal obstruction is usually due to complications of treatment, such as tracheomalacia following prolonged intubation or edema secondary to radiation therapy. Tracheostomy is often necessary in these patients, as endotracheal intubation is likely to be unsuccessful and the obstruction is below the level of the cricothyroid membrane. Attempts at bronchoscopy may worsen tracheal edema.

Bronchial obstructions are usually due to primary lung carcinoma or, rarely, endobronchial metastases from other primaries (notably breast, colon, and renal cancer). As with upper airway obstruction, bronchial obstruction is usually asymptomatic until there is greater than 75% obstruction. The usual presentation includes cough, hemoptysis, wheezing, or palpable rhonchi. Patients with a history of breast cancer who present with new-onset asthma and a nonspecific chest radiograph may have widespread endobronchial metastases that can respond to hormone therapy or chemotherapy; these patients should thus not simply be treated with bronchodilators without investigating this possibility.

Another cause of dyspnea in the cancer patient, especially the patient with a history of lymphoma or lung, breast, or ovarian cancer, is pleural effusion. Pleural effusions usually occur because of metastases that infiltrate the pleura and cause exudation of fluid and increased capillary permeability. These collections of tumor can also erode into blood vessels and block lymphatic outflow. Overall, about 30% of patients with cancer develop malignant pleural effusion.¹³ In a large series of patients with metastatic breast cancer, about half developed pleural effusion during the course of their disease, and half of these required specific treatment.

Malignant pleural effusion usually presents with dyspnea that worsens with exertion or when supine, and commonly with a dry cough. Chest examination typically reveals dullness to percussion, a pleural friction rub, and decreased breath sounds on the affected side. Radiographs of the chest confirm the diagnosis. An effusion that is visible on an upright radiograph has a volume of more than 300 mL; the threshold of detection on decubitus films is 100 mL. In the case of new pleural effusions, thoracentesis is both diagnostic and therapeutic. Pleural fluid samples should be sent for cytology, culture, cell count, and protein and lactate dehydrogenase determinations. The oncologist should be consulted for consideration of more definitive treatment modalities, such as sclerosis, pleurectomy, or chemotherapy.

Pericardial effusion also often presents with dyspnea and carries with it the danger of cardiac tamponade. Pericardial effusions are not uncommon in advanced cancer; they are usually found in the setting of lung or breast cancer but can occur in patients with lymphoma, leukemia, melanoma, sarcoma, or gastrointestinal tumors.⁶ Fewer than 30% of patients with malignant pericardial effusions have symptoms of pericarditis.⁷ As with the other malignant processes mentioned, pericardial effusions leading to tamponade are usually the result of long-standing processes that may evolve into critical clinical problems over the course of a few hours. The severity of tamponade is related to the rapidity with which fluid accumulates, because the pericardium can usually stretch a great deal to accommodate a slow-growing effusion. If the pericardium is thickened by fibrosis, as is often the case in patients who have received radiation therapy to the mediastinum, a small effusion can cause significant compression. Thus, a small heart on chest radiograph does not exclude cardiac tamponade.

Although a nonconstricting pericardial effusion usually does not cause specific symptoms, as the pericardium distends and compression worsens, patients develop dyspnea, chest pain relieved by leaning forward, cyanosis, or even dysphagia. Some patients with impending tamponade complain of hoarseness, epigastric discomfort, or hiccups. They often look like patients with congestive heart failure. On physical examination, the patient is typically anxious and diaphoretic, with

tachycardia and decreased systolic pressure and pulse pressure. The lungs are clear; the neck veins are often engorged, and the heart sounds may be muffled. An increased pulsus paradoxus and Kussmaul's sign (inspiratory swelling of the neck veins) may be noted. With chronic pericardial constriction, the patient may develop peripheral edema, hepatojugular reflux, hepatomegaly, and, eventually, ascites.

On chest radiograph, most of these patients have increased heart size, an irregular heart border, or a globular cardiac silhouette. The electrocardiogram (ECG) typically shows sinus tachycardia and may show low-voltage QRS complexes or global ST elevation. Electrical alternans is pathognomonic of significant pericardial effusion, but this finding can disappear as compression worsens. The diagnosis of tamponade can be made definitively by echocardiography or by right heart catheterization showing equalization of diastolic pressures. Vigorous administration of intravenous fluids to maintain filling pressure can usually buy enough time to get the patient to surgery for a pericardial stripping procedure. The indications for emergent pericardiocentesis include shock, cyanosis, decreased level of consciousness, or a pulsus paradoxus greater than 50% of the pulse pressure.²⁰

Superior vena caval obstruction also usually presents with a chief complaint of dyspnea, which is due to edema of the lower airway. The superior vena cava syndrome is not rare—it develops in 5% to 15% of lung cancer patients during the course of their disease. The manifestations of venous distention and facial swelling are well known, but most patients with superior vena cava syndrome do not have these signs. Superior vena cava syndrome can also cause hoarseness, dysphagia, headache, and chest pain. The symptoms are usually worsened by positional change, such as bending forward, stooping, or lying down. There is generally enough time to do diagnostic procedures if the identity of the primary tumor is unknown.

The indications for emergent therapy include decreased cardiac function, upper airway edema, or cerebral dysfunction secondary to brain edema, all of which are, fortunately, rare on presentation.¹ Nearly all patients with superior vena cava syndrome have evidence of a mass on chest radiograph (usually in the right hilum, but 20% have their lesions on the left). Superior vena cava obstruction can also cause pleural effusion (usually right-sided).⁴ The most common causes of superior vena cava syndrome are bronchogenic carcinoma (predominantly small cell cancer) and lymphoma, but it can also be caused by metastases from breast and testicular cancer. In patients without a lung mass, superior vena cava syndrome may be due to mediastinal fibrosis, goiter, tuberculosis, or thrombosis around indwelling venous catheters or pacemaker leads. Computed tomography (CT) scanning of the chest is a reliable diagnostic tool.

Because patients with cancer are generally at increased risk for thrombosis, pulmonary embolism must always be considered as a potential cause of dyspnea. One issue that may arise in the treatment of cancer patients with presumed pulmonary embolism is whether the presence of brain metastases precludes the emergent use of anticoagulants. Because of the greater dangers of pulmonary embolism, these patients are generally treated with anticoagulants.

Another diagnosis that should be considered in the cancer patient presenting with shortness of breath is pulmonary fibrosis, especially among patients who have received bleomycin, high-dose cyclophosphamide, or radiation therapy to the chest. Other reasons for dyspnea include pneumonia, sepsis, or metabolic acidosis, particularly in those who are immunocompromised because of their primary tumor (especially those with a history of leukemia and lymphoma) or because of immunosuppressive therapy with cytotoxic drugs, steroids, or radiation.

HEADACHE OR LETHARGY

When evaluating the cancer patient complaining of headache or lethargy, one of the first considerations is brain metastasis. The most common tumors that spread to the brain are lung, breast, and genitourinary cancers and melanoma. As the primary treatments for these diseases improve and prolong lifespan, emergency physicians can expect to see an increasing incidence of brain metastasis. For example, 10% to 30% of patients with metastatic breast cancer develop clinically significant brain metastases during the course of their disease. The symptoms often develop over weeks, and signs depend on the location of the metastases.

Because over 90% of brain metastases are located in the cerebrum, patients often present with a history of progressive lethargy, memory loss, aphasia, paresis, or sensory disturbance.¹⁶ Cerebellar metastases, which account for 8% of clinically important brain metastases, usually cause dysmetria or gait disturbance. A common complaint in all patients with brain metastases is headache, which is typically worse on awakening and may resolve during the course of the morning. Fewer than 25% of patients with clinically significant brain metastases have papilledema on presentation; about 15% present with new seizures.

Brain metastasis is easily diagnosed by CT scanning or magnetic resonance imaging (MRI) of the brain. Corticosteroids reduce headache and improve function in 60% to 75% of patients with brain metastasis. Dexamethasone is the drug of choice because of its high central nervous system (CNS) penetration; the usual starting dose is 4 to 10 mg intravenously. Steroid treatment should be initiated promptly. If there are physical or radiographic signs of increased intracranial pressure, an intravenous bolus of 50 g of mannitol should be given and the radiation therapist consulted emergently.

In the patient who presents with a history of seizure, anticonvulsant therapy should be begun, but it is important to keep in mind that dexamethasone reduces the serum half-life of phenytoin. Whether to begin anticonvulsant therapy in patients who have brain metastases but who have not had a seizure is a decision often left to the oncologist. However, because these patients are at increased risk for seizure, they should be warned against driving or operating machinery.

Carcinomatous meningitis can also present with headache or lethargy. It most commonly complicates breast, lung, or genitourinary tumors; leukemia; or lymphoma. Carcinomatous meningitis is especially insidious because it can develop in the face of a systemic remission. Symptoms are usually subtle and tend to develop gradually over weeks or months before the diagnosis is made. They may include headache, nausea, photophobia, back pain, memory loss, and nonspecific mental status, memory, or personality changes. Only 40% of patients with carcinomatous meningitis show evidence of cranial nerve dysfunction on presentation, usually diplopia, hearing loss, or facial numbness.

When confronted with vague CNS symptoms in a patient with a predisposing cancer, one should always include carcinomatous meningitis in the differential diagnosis, and, after ascertaining that there are no brain masses, a spinal tap should be performed. Carcinomatous meningitis should continue to be suspected even if the cerebrospinal fluid (CSF) is negative for malignant cells, because only 45% of patients with carcinomatous meningitis have the diagnosis made on the first tap; 30% of patients have the diagnosis made on the second tap, and 10% only on the third tap.⁸ An opening pressure greater than 160 mm, CSF leukocytosis, increased CSF protein concentration, and decreased CSF glucose should reinforce suspicions about the presence of meningitis, although these findings are not specific for a malignant cause.

Patients with impaired cellular immunity (e.g., a history of leukemia or lymphoma or recent steroid use) can present with lethargy or subtle changes in mental status due to meningitis caused by *Cryptococcus neoformans* or *Listeria monocytogenes*. These individuals are generally not neutropenic. In cryptococcal meningitis, examination of the CSF reveals mononuclear pleocytosis and a mildly decreased glucose. The India ink stain for fungus is positive in only 50% of patients, and serologic tests for cryptococcal antigen in the serum and CSF are often needed to make the diagnosis.

Patients with *Listeria* meningitis often present with a sustained course of low-grade fevers, personality changes, and, sometimes, headache. The CSF white cell count is usually 5,000 to 15,000/ μ L and can consist predominantly of either neutrophils or monocytes. The CSF protein concentration is usually increased (100 to 300 mg/dL). The CSF glucose is often only mildly decreased, and organisms (gram-positive rods) are often not identified on initial examination of the CSF smear. The organism is generally sensitive to penicillin or ampicillin and is resistant to third-generation cephalosporins.¹⁷

Other infections that can cause a change in mental status or lethargy in cancer patients include herpes simplex and varicella zoster encephalitis. The CSF may show a mild pleocytosis and the protein is usually elevated, but CSF glucose is usually normal. CT and MRI scans often show no specific findings. Treatment is usually started on the basis of clinical suspicion. Bacterial brain abscess can also present with headache or lethargy and is usually related to contiguous bacterial infections (e.g., sinusitis, otitis, or dental abscess). These are usually apparent on CT images, as are other CNS infections that can present with a subacute or chronic history, including toxoplasmosis, nocardiosis, aspergillosis, candidiasis, and mucormycosis.

Metabolic disturbances related to cancer and its treatment are often the cause of lethargy or a change in mental status.² Hypercalcemia is common, especially in patients with breast, lung, renal, head and neck, esophageal, or thyroid cancers or multiple myeloma.¹² Between 10% and 20% of cancer patients develop hypercalcemia during the course of their illness; a serum calcium level greater than 13 mg/dL is a medical emergency. These patients generally respond well to saline infusion; they will often also require magnesium and potassium repletion. Loop diuretics such as furosemide are reserved for patients who cannot easily handle the volume load, and should be administered only after rehydration with saline.¹⁵ If saline diuresis is not effective in lowering the serum calcium, other agents, such as calcitonin, mithramycin, steroids, or bisphosphates, can be used. In addition to saline diuresis, a common initial treatment for hypercalcemia is pamidronate 90 mg,

given intravenously over 4 hours, and hydrocortisone 250 to 500 mg intravenously every 6 hours.

Hyponatremia, another metabolic disturbance that presents with lethargy, is usually due to ectopic secretion of antidiuretic hormone in patients with oat cell, prostate, adrenal, pancreatic, or esophageal tumors; brain metastases; or recent treatment with vincristine or cyclophosphamide.³ Hypoglycemia should be suspected in lethargic patients, especially those with a history of insulinoma, islet cell tumors, sarcoma, hepatoma, or gastrointestinal or adrenal tumors.

Tumor lysis syndrome is a rare metabolic disorder that is associated with rapid necrosis of tumor, usually following treatment. It is most commonly seen in patients with lymphoma, acute lymphocytic leukemia, and myelogenous leukemia, but has also been reported in cases of small cell lung cancer and breast cancer. Widespread necrosis of tumor can cause severe hyperuricemia, hyperkalemia, and hyperphosphatemia, precipitating renal failure due to urate nephropathy. Metastatic calcification can exacerbate renal dysfunction and lead to cardiac dysrhythmias as well. The serum calcium may be low because of precipitation of calcium phosphate salts in soft tissues. Aggressive hydration and diuresis are the usual treatments. Urine alkalization can help enhance uric acid excretion, but in the presence of high phosphate levels, it can lead to calcium phosphate precipitation in the renal tubules. Patients with tumor lysis syndrome and severe electrolyte abnormalities or volume overload may require emergent dialysis.

MUSCULOSKELETAL PAIN

Musculoskeletal pain, a common complaint among patients in the emergency department, takes on special importance in the cancer patient. The sudden onset of pain, commonly in the upper arm, leg, or pelvis, may mean a pathologic fracture, especially in the patient with a history of prostate, breast, or lung cancer or myeloma. These fractures often occur within the sites of previous radiation therapy portals. A recent negative bone scan can be misleading in this regard, especially in cancers with purely lytic lesions, as occurs in most cases of myeloma and up to 10% of prostate cancers. The diagnosis is easily made with plain radiographs. Patients with pathologic fractures or with lytic lesions involving more than 25% of the cortex of a weight-bearing bone require immediate therapy, which calls for emergent consultation with an orthopedist and radiation therapist. Fractures often require internal fixation, because poor results are obtained with casting or bracing of these fractures.

Back pain of recent onset in the cancer patient should alert the emergency physician to the possibility of vertebral metastases, epidural metastases, and the potential for spinal cord compression. Ninety percent of cancer patients with spinal cord compression have back pain as a presenting symptom. The majority have back pain for weeks or months before neurologic signs become apparent. Patients with spinal cord compression face irreversible neurologic damage unless the diagnosis is made rapidly and therapy is initiated without delay. Most lesions causing spinal cord compression arise from tumor metastatic to the vertebral bodies; 70% of compressing lesions are in the thoracic spine, 20% are in the lumbosacral spine (especially metastatic colon cancer), and 10% occur in the cervical spine.⁵

Spinal cord compression develops in 1% to 5% of all cancer patients during the course of their disease. Patients with malignant spinal cord compression typically have a history of 1 to 6 months of back pain, which may have the features of radiculopathy and which may be made worse by the patient's lying down, bearing weight, coughing, or sneezing. The pain may radiate to the abdomen.

These patients can have many of the features of musculoskeletal back pain (e.g., paresthesias, positive straight leg-raising sign). The earliest specific sign of cord compression is motor dysfunction, usually manifested by lower extremity weakness. Subtle leg weakness cannot be assessed with the patient lying down. All patients with back pain must have their gait and the ability to walk on the toes and on the heels assessed.

On initial presentation, about half of patients with cord compression show some loss of light touch or temperature sensation. Loss of pain sensation and bowel or bladder dysfunction are usually late signs of cord compression. Patients with cauda equina syndrome typically exhibit saddle anesthesia, with sensory disturbances in the urethral, vaginal, and perianal regions. Deep tendon reflexes may be present, and even brisk, in the face of cord compression. They are usually diminished with nerve root compression.

More than 70% of patients with malignant spinal cord compression have positive spine radiographs, although those of patients with lymphoma or retroperitoneal sarcomas are generally negative. Epidural metastases are usually detectable before the onset of cord injury.¹⁹ Suspicion that epidural metastasis are causing cord compression should prompt the immediate involvement of the neurologist and neurosurgeon. Steroids should be started and a diagnostic procedure emergently arranged.

MRI scanning is very useful for assessing the spinal cord and is usually adequate for evaluation, but myelography (plain or CT scanning) is the most precise means of assessing the extent of compression and dural involvement. Suspicion of malignant cord compression is certainly an indication for an emergent MRI scan.

In the face of a positive study, treatment (usually radiation or laminectomy) must be initiated emergently, because compression by the tumor and surrounding edema can progress rapidly to cause irreversible paraplegia or bowel or bladder dysfunction. Lest the physician become nihilistic in treating impending cord compression, one study showed that more than half of the cancer patients referred for rehabilitative treatment after malignant spinal cord compression lived for more than 1 year after the initial injury.¹⁶

Pain is a feature of cancer in nearly all patients, but is almost always amenable to treatment. Mild-to-moderate pain is often relieved by nonsteroidal antiinflammatory drugs or acetaminophen; more severe pain requires opioids. Pain medication must be given in adequate doses and with adequate frequency. A patient who is still in pain 1 hour after a dose of parenteral narcotics is not at high risk of developing respiratory depression from an additional dose. Various drugs are available, but no opioid is more effective than morphine. Physicians should be familiar with the equianalgesic doses and different dosing regimens of oral and parenteral opioid preparations.¹⁰ Morphine allergy is rare (less than 1%); nausea and pruritus (secondary to the direct histamine-releasing effects of narcotic analgesics) are much more common, but can be avoided or managed with the use of antihistamines and antiemetics. Synthetic opioids, such as hydromorphone (Dilaudid), are as effective as morphine and generally have fewer side effects.

COMPLICATIONS OF CANCER TREATMENT

Nearly all cancer patients receive some sort of specific anticancer therapy, and many of these regimens can lead to complications requiring emergency treatment. The complications of cancer surgery, such as intestinal obstruction, form one broad category. The side effects of radiation therapy, another important category, depend on the site of treatment and the dose administered. A common complaint of the patient receiving mediastinal radiation is severe dysphagia. This may be mild enough to be treated with oral viscous lidocaine, or it may be severe enough to cause significant dehydration and require parenteral fluids and opioid analgesics. In general, it is reasonable to consult the radiation therapist or oncologist about complaints that relate to a site that was recently irradiated.

Patients with chronic lymphedema after cancer surgery or radiation therapy commonly present with complaints of increased swelling, pain, or redness in the involved extremity. Because of the very high risk of infection due to impaired lymphatic drainage, such individuals should be considered to have cellulitis of the limb until proven otherwise. Venipuncture, intravenous lines, and even blood pressure measurement should be avoided in the affected extremity, and antibiotics effective against staphylococci and streptococci should be started immediately.

Cytotoxic chemotherapy is fraught with side effects, some of which can be life-threatening. Because different chemotherapeutic agents have different side effects, it is useful to have some familiarity with the different agents and their side effects. The most common and serious side effect of chemotherapy is delayed-onset neutropenia. The fact that many of the drugs used in cancer treatment can also mask the clinical signs of infection helps to make acute bacterial infection the most common cause of death for patients under treatment for cancer.¹¹

NEUTROPENIC FEVER

Any patient with a recent history of chemotherapy and even a minimal fever (greater than 100.5°F) should be assumed to be neutropenic (and septic) until proven otherwise. Patients with fever and an absolute neutrophil count less than 1,000/μL should be hospitalized. Treatment should not be delayed; in neutropenic patients who die of gram-negative sepsis, death usually occurs within 48 hours of the development of fever.¹¹ Antibiotics should be started immediately after blood is drawn for counts and cultures. Because most lethal infections are caused by gram-negative bacilli, the febrile patient without an obvious source should receive antibiotic coverage for a broad spectrum of organisms that include *Escherichia coli*, *Enterobacter*, and *Pseudomonas* species. Initial treatment should include a combination of antibiotics with good gram-negative coverage.¹⁷ Table 216.1 lists several alternative regimens for the initial empiric therapy of cancer patients with fever and

neutropenia. The choice of initial antibiotic therapy must take into account the patient's allergies and hepatic and renal function.

SINGLE-DRUG REGIMENS	
Use of these antibiotics covers gram-negative organisms well and avoids the risk of nephrotoxicity. None of these covers staphylococci (eg, methicillin-resistant <i>Staphylococcus aureus</i> , enterococci), and <i>Acinetobacter</i> . Carbapenem has poor anaerobic coverage.	
Carbapenem (Meropenem, Ertapenem)	2 g q8h
Colistin (Colygram)	2 g q8h
Imipenem-cilastatin (Primaxin)	500 mg q6h
Meropenem (Meropenem)	1 g q8h
TRIPLE-DRUG REGIMENS	
These usually include an aminoglycoside (gentamicin, tobramycin, amikacin) and an antipseudomonal beta-lactam antibiotic.	
Aminoglycosides	
Gentamicin (Garamycin)	2 mg/kg loading dose, then 1.5 mg/kg q8h
Amikacin (Amikacin)	8 mg/kg loading dose, then 7.5 mg/kg q8h
Antipseudomonal Beta-lactams	
Ticarcillin (Ticar)	2 g q8h
Ticarcillin and clavulanate (Ticarcillin)	3.1 g q8h
Piperacillin (Pipracil)	3 g q8h
Piperacillin and tazobactam (Zosyn)	4 g q8h
Meropenem (Meropenem)	1 g q8h
Colistin (Colygram)	2 g q8h
Coliperone (Colobid)	1 g q12h

TABLE 216.1. Regimens for Initial Intravenous Therapy of Neutropenic Sepsis

In recent years, gram-positive infections have become more prominent with the increasing use of long-term indwelling intravenous catheters. Such infections have led to the frequent use of vancomycin in the emergency department, and antibiotics started on admission tend to be continued in the hospital until bacterial susceptibilities are available. The Centers for Disease Control has advised against the empiric use of vancomycin unless the patient has specific indications ([Table 216.2](#)). In patients who have been on prolonged courses of broad-spectrum antimicrobial therapy or on steroids, fungal infections must also be considered.

- Patients with clinically obvious catheter-related infections
- Patients with severe mucositis (especially those who have recently been treated with high-dose cytarabine [Ara-C], which increases the risk of viridans streptococci)
- Patients who had been receiving prophylactic treatment with quinolone antibiotics before the onset of fever
- Patients who are known to have been colonized with resistant pneumococci or methicillin-resistant *Staphylococcus aureus*
- Patients with hypotension or other evidence of cardiovascular instability

TABLE 216.2. Indications for Vancomycin for Initial Therapy of Neutropenic Sepsis

CHEMOTHERAPY-INDUCED EMESIS

Another common side effect of cancer therapy is severe nausea and vomiting that may not be amenable to treatment with the antiemetics usually used in the emergency department. The medications that most commonly cause delayed nausea (usually occurring 1 to 3 days after treatment) are intravenous cyclophosphamide, ifosfamide, and platinum. Ondansetron, high-dose intravenous metoclopramide, or parenteral benzodiazepines (e.g., lorazepam) are effective in treating the patient who is suffering from severe chemotherapy-induced nausea.⁹ Chlorpromazine and haloperidol are also very effective treatments for chemotherapy-induced nausea and emesis.

CARDIOPULMONARY RESUSCITATION IN CANCER PATIENTS

A cancer patient who has significant therapeutic options should have vigorous resuscitative measures applied, just as would any other patient without the diagnosis of cancer.¹⁴ Rates of successful resuscitation and hospital discharge for cancer patients who suffer sudden death are similar to those of patients without cancer.²¹ In fact, cancer is rarely a cause of sudden, unexpected death.²² Thus, in the absence of well-documented advanced refractory disease, an attempt at resuscitation should be undertaken. Conversely, patients who are known to have refractory advanced disease are not appropriate candidates for resuscitation, should sudden death occur.¹⁴

COMMON PITFALLS

- Failing to begin antibiotics promptly in febrile patients who are neutropenic
- Failing to treat pain aggressively. Severe pain is an emergency that requires timely treatment.
- In the cancer patient who presents with shortness of breath and a normal chest radiograph, failing to consider pulmonary embolism or cardiac tamponade
- Failing to evaluate patients with altered mental status or personality changes for treatable causes, such as hypercalcemia, hyponatremia, medication effects, carcinomatous meningitis, or subacute bacterial meningitis
- Failing to suspect spinal cord compression in a patient with cancer who presents with back pain, with or without associated neurologic complaints. Strong consideration of this entity and aggressive evaluation are imperative. The physician must keep in mind that, in patients with cord compression who have findings referable to the lumbosacral spine, the compressing lesion may be in the thoracic cord. It is therefore imperative that emergent MRI scans in these patients include the thoracic cord.
- Adopting a nihilistic attitude. Many patients with cancer have reversible illness and may have months or years of productive life ahead of them.

CHAPTER 217 Anaphylaxis

David N. Zull

- [Clinical Presentation](#)
- [Differential Diagnosis](#)
- [Emergency Department Evaluation and Management](#)
- [Disposition](#)
- [Indications for Admission](#)
- [Transfer Considerations](#)
- [Common Pitfalls](#)
- [Chapter References](#)

Anaphylaxis is an acute, life-threatening condition; immediate recognition and treatment are critical. Its manifestations may range from minor symptoms such as rash or lip swelling to sudden, life-threatening upper airway obstruction or shock. Even the patient who presents with urticaria alone can subsequently develop hypotension, bronchospasm, or laryngeal edema and should thus be treated with the same urgency as the patient with the full-blown anaphylactic syndrome.

The constellation of anaphylactic symptoms results from massive release of chemical mediators from mast cells and basophils throughout the body. For anaphylaxis to occur, there must have been previous sensitization to a foreign substance, against which immunoglobulin E (IgE) was made by antibody-producing B lymphocytes. IgE binds to mast cells and basophils. On reexposure to the foreign substance, antigen binds to the IgE, and chemical mediators are released from these cells. The term *anaphylactoid reaction* denotes a clinical syndrome that is identical to anaphylaxis but is distinguished by the fact that mast cell mediator release results from an IgE-independent mechanism.²⁰

Mediators released from activated mast cells include histamine, leukotrienes, prostaglandins, platelet activating factor, and cytokines. These mediators cause capillary leakage and vasodilation, thereby resulting in hypotension, urticaria, and angioedema of the skin, upper airway, and gastrointestinal tract. Leukotrienes are potent bronchoconstrictors as well.

Penicillin is the most feared cause of life-threatening anaphylaxis: More than 1% of the population is sensitive to penicillin. Reactions generally are manifested by urticaria alone, but an estimated 25 of 100,000 patients treated with penicillin experience a severe anaphylactic reaction; one will die.¹⁰ There is cross-reactivity among all penicillin derivatives, as well as imipenem, but not with aztreonam. Cephalosporin cross-reactivity in penicillin-allergic patients appears to be less than 2% overall, and is rare with second- and third-generation agents; however, caution is still advised in patients with a history of anaphylaxis to penicillin.^{1,10}

The reaction rate to bee stings is 0.4% to 5.0%, with at least 40 anaphylactic deaths per year.²⁰ The administration of iodinated contrast media (as in CT scanning with IV contrast) results in anaphylactoid reactions in 1% to 2% of patients, with one to ten fatalities per 100,000 patients, accounting for 40 to 50 deaths per year in the United States.⁸ Foods are an increasingly recognized cause of fatal or near-fatal anaphylaxis,¹⁵ and now appear to be the most common cause of anaphylaxis, accounting for one-third of cases overall and for more than one-half of episodes in children. Peanuts, other nuts, and shellfish are most commonly implicated, with highly allergic individuals reacting to the mere touch or smell of the food.^{9,13,16} Nonsteroidal antiinflammatory agents are the most common medications causing anaphylaxis, often unrecognized due to over-the-counter availability.¹⁴ Exercise, especially in combination with food or drug ingestion, can cause or aggravate anaphylaxis.²²

[Table 217.1](#) summarizes etiologic factors in anaphylaxis.

IgE-MEDIATED—PROTEINS	
Viruses: Herpesviruses (e.g., measles, varicella, Herpes B, Herpes A, Herpes G, cytomegalovirus, Epstein-Barr)	
Foods: peanuts, milk, shellfish, grains, eggs, almonds, sesame, soybeans, chestnuts	
Drugs: streptomycin, cephalexin, penicillin	
Human globulin, serum, A2, F2, serum albumin	
Epinephrine, benzocaine, novocaine, small amounts of procaine, tetracycline, penicillin, sodium bicarbonate, sodium chloride, sodium iodide, sodium metabisulfite, sodium sulfite, potassium iodide, potassium permanganate	
IgE-MEDIATED—CELLS	
Anti-Bovine gamma globulin, captopril, penicillin, sulfonamides, butyrophenones, ketazolam, ¹⁰	
PROTEIN AND NONPROTEIN ANTIGENS	
HEAVY METALS: mercury (oral, inhaled, intracutaneous, subcutaneous, intravenous, intraperitoneal, intravitreal, intrathecal, intracranial, etc.) ¹¹	
CROSS-REACTIVITY ANTIGENS	
Human globulin: gamma globulin, plasma, whole blood	
Drugs: penicillin	
IMMUNE COMPLEX ANTIGENS	
Drugs: aspirin, salicylates, curare, thiopental	
Viruses: Herpes, measles, mumps, rubella, cytomegalovirus, Epstein-Barr, etc.	
Human globulin: gamma globulin	
OTHER ANTIGENS	
Enoxacin-induced anaphylaxis ²²	
Food or drug-induced anaphylaxis associated by exercise	
Cold-induced urticaria and anaphylaxis	
IDIOPATHIC ¹²	

TABLE 217.1. Etiologic Agents in Anaphylaxis

Repeated intermittent exposure to a substance or drug increases the risk of sensitization; the more direct the route to the systemic circulation, the greater the likelihood and severity of a reaction. The possible routes of exposure, in descending order of severity of potential reactions, are intravenous, intramuscular, subcutaneous, intradermal, oral, through other mucous membranes, and topical.

The onset of symptoms of anaphylaxis usually occurs less than 30 minutes after exposure, but is often immediate. Antigens given orally may have a 2-hour delay before symptoms occur. In general, the more immediate the reaction, the more life-threatening it is. Symptoms may last only a few minutes, even without therapy, but, on the average, persist for 2 to 4 hours, with the exception of angioedema, which often persists up to 24 hours, regardless of the location. Rarely, the whole anaphylactic syndrome persists beyond 24 hours,^{3,7,9} and in about 3% of patients there is a biphasic course, with recurrent anaphylaxis within 24 hours, despite earlier complete resolution.⁴

CLINICAL PRESENTATION

Anaphylaxis is often heralded by premonitory symptoms ([Table 217.2](#)). Pruritus of the palms and soles, tingling about the mouth and tongue, generalized warmth, tightness in the chest, and a lump in the throat are commonly described. Dizziness or syncope secondary to hypotension may also be presenting manifestations of anaphylaxis in the absence of any other signs or symptoms of allergic reaction.

Reaction	Symptom	Sign
Urticaria	Itching	Raised wheals, diffusely, waxy, waxy, waxy
Angioedema	Nonpruritic stinging	Swelling of lips, eyes, hands, uvula, tongue
Laryngeal edema	Hoarseness Dysphagia Lump in throat Airway obstruction Sudden death	Inspiratory stridor Intercostal and clavicular retractions Cyanosis
Bronchospasm	Cough, dyspnea, chest tightness	Wheezing, tachypnea, retractions
Hypotension	Dizziness Syncope Confusion	Hypotension (mild to severe) Tachycardia Oliguria
Rhinitis	Nasal congestion	Mucosal edema
Conjunctivitis	Itching and fluid	Lid edema, injection, chemosis
Gastroenteritis	Itching Cramping Diarrhea Vomiting	Normal examination

TABLE 217.2. Symptoms and Signs of Anaphylaxis

More than 90% of patients have urticaria or angioedema. Urticaria (edema of the upper dermis) appears as raised erythematous wheals in evanescent pruritic patches. Angioedema represents edema of the deep dermis and appears as puffy, nonpitting areas of skin or mucous membrane. Angioedema is generally painless and nonpruritic; patients note only tingling and swelling in the affected areas. It tends to be most prominent about the face and lips, and less so on the hands and arms.^{3,7,25}

Laryngeal edema resulting in acute upper airway obstruction is the principal cause of death from anaphylaxis. The onset can be dramatic, and may be mistaken for a sudden dysrhythmic death or an apparent "café coronary." Angioedema of the lips, uvula, tongue, and oropharynx is less likely to obstruct the airway but must be treated aggressively because of the likelihood of concomitant edema of the larynx. Uvular edema, in particular, is a helpful marker for potential laryngeal involvement. Frequently, however, the patient complains of hoarseness and a lump in the throat, and the examination of the oropharynx is completely normal. Indirect laryngoscopy may reveal supraglottic or laryngeal edema, but this examination should not delay the prompt administration of epinephrine in a patient with these complaints.

Rhinitis and conjunctivitis are other common manifestations of mucous membrane involvement, but they are not life-threatening.^{3,8}

Bronchospasm is common in the anaphylactic syndrome, but it tends to be mild unless the patient has a preexisting history of asthma. Pulmonary edema, although reported in anaphylaxis, is generally considered a rare terminal event and not part of the syndrome.

Refractory hypotension is second only to laryngeal edema as a cause of death from anaphylaxis. A drop in blood pressure of 20 to 30 mm Hg is typical, but there is great variability. When sudden in onset, syncope or sudden death may occur.

Although it is usually overshadowed by other symptoms, abdominal cramping is common in anaphylaxis. Angioedema of the gut lining causes this colic as well as vomiting, diarrhea, and, rarely, hematochezia.

Myocardial infarction and ventricular tachycardia have been reported, and nonspecific ST-T wave changes are commonly seen on the electrocardiogram in patients suffering from anaphylaxis. These cardiac manifestations are generally attributed to hypotension, hypoxia, and overzealous epinephrine therapy, although histamine itself may induce coronary vasospasm and cardiac dysrhythmias.²³

DIFFERENTIAL DIAGNOSIS

The diagnosis of anaphylaxis is often obvious when antigen exposure is rapidly followed by urticaria, angioedema, bronchospasm, upper airway edema, and hypotension. Confusion in the diagnosis may occur when a delay in the development of symptoms obscures a cause-and-effect relation or when the syndrome is only partially expressed. Anaphylaxis often presents as the acute development of only one component of the syndrome. Differentiating acute, severe urticaria, for example, from anaphylaxis is a moot point. The greatest confusion may arise when anaphylaxis presents as isolated hypotension; it should therefore be considered in the differential diagnosis of syncope and vascular collapse.

The acute development of isolated angioedema of the skin and upper airway is a common presentation of anaphylaxis, but it may also be due to hereditary angioedema. This rare disease is characterized by the absence of a functional C1' esterase inhibitor, allowing free activation of the complement cascade. Hereditary angioedema is characterized by repeated episodes of angioedema of the skin, upper airway, and gut. Episodes generally date from adolescence and are often provoked by minor trauma. Gastrointestinal involvement is usually very prominent, often mimicking an acute abdomen. Both urticaria and hypotension are absent in hereditary angioedema, and the administration of epinephrine, antihistamines, and steroids is ineffective. A reduction in the C4 level is diagnostic. Fresh-frozen plasma, C1 esterase inhibitor concentrate, or epsilon aminocaproic acid are options in the treatment of an acute attack.⁶

Rapid development of edema of the upper airway may also result from viral or bacterial infection. However, pain, fever, and findings of erythema and exudate are not present in anaphylaxis.

Angiotensin converting enzyme inhibitors produce life-threatening tongue and palatal angioedema in 0.1% to 0.2% of patients. Although the appearance is indistinguishable from anaphylactic swelling, its development is more gradual and other features of anaphylaxis are absent.²¹

Rarely, patients may experience stridor and obstructive airway symptoms secondary to vocal cord dysfunction or as a manifestation of hysteria; indirect laryngoscopy is the only means to verify these suspicions.

Scombroid fish poisoning may mimic anaphylaxis, presenting with acute, severe urticaria, nausea and vomiting, headache, and dysphagia. This syndrome occurs shortly after eating fish with a high histidine content (such as tuna or mahi-mahi) that has spoiled slightly, so that the histidine has been broken down to histamine.

The flushing seen in monosodium glutamate reactions may be confused with anaphylaxis, but the prominence of headache and burning chest discomfort distinguishes it from an allergic reaction.

Systemic mastocytosis and the carcinoid syndrome may present with intense flushing and hypotension, mimicking anaphylaxis; prominent gastrointestinal symptoms, hepatomegaly, and provocation by alcohol help distinguish these entities.⁸

The systemic capillary leak syndrome is a rare disorder characterized by life-threatening episodes of hypovolemic shock, often accompanied by facial and extremity swelling. Transient polycythemia and hypoalbuminemia during attacks are pathognomonic; the presence of a monoclonal gammopathy may provide a clue to the diagnosis between attacks.¹⁹

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Evaluation of the upper airway and careful blood pressure monitoring are the immediate priorities in the care of the patient with possible anaphylaxis. Angioedema of the lips, tongue, uvula, and soft palate, as well as symptoms of hoarseness, stridor, dysphagia, or lump in the throat, should alert the physician to progressive airway compromise. Such patients are treated immediately with epinephrine 0.3 mL (1:1000 dilution) subcutaneously before attempting any further evaluation. Beta-adrenergic stimulation promotes the synthesis of cyclic AMP in mast cells, which blocks further release of chemical mediators. Epinephrine also exerts a therapeutic benefit by its alpha-adrenergic effect, causing vasoconstriction with resulting improvement in blood pressure and decreased swelling of edematous tissues.^{2,3,7}

The patient is placed on a cardiac monitor and given oxygen by cannula, and an intravenous line of normal saline is established. If hypotension is profound and unresponsive to saline loading, or if airway obstruction appears imminent (as evidenced by drooling and audible stridor), intravenous epinephrine is considered. The most common error made in this situation is to give too much epinephrine too fast, precipitating cardiac dysrhythmias. The recommended dose is 1.0 mL of 1:10,000 epinephrine diluted in 10 mL of normal saline, and given as a slow intravenous push over 3 to 5 minutes. If life-threatening symptoms persist, the intravenous dose may be repeated as clinically indicated.^{2,5,18} In this dire situation, a cricothyroidotomy may have to be performed if air exchange is further compromised. Aerosolized epinephrine may decrease supraglottic and laryngeal edema for a few minutes, thereby buying time while preparations are made to establish an airway and parenteral epinephrine is given. If symptoms are resolving, epinephrine can be continued in a dose of 0.3 mL subcutaneously at 20-minute intervals, or an epinephrine drip can be considered (1 to 10 µg/min intravenously).²

Hypotension generally responds to saline infusion, with most adults requiring 1 to 2 L over the first hour. Epinephrine is an important component of therapy and can be given intramuscularly or subcutaneously if perfusion is adequate, reserving the intravenous route for use only if shock ensues. If intravenous access is unavailable,

sublingual or intraosseous injection or endotracheal administration of epinephrine is considered. Other possibly helpful interventions include placing the patient in the Trendelenburg position and applying the MAST suit.^{3,12} Cimetidine, 300 mg intravenously, may be useful if hypotension is refractory to standard measures.^{3,5}

Most patients with anaphylaxis do not require such intensive therapy, however. In general, one or two doses of epinephrine subcutaneously at 15- to 20-minute intervals (based on symptom response) and 1 L of saline intravenously are adequate. Patients with acute, severe urticaria alone may benefit from a single dose of epinephrine, yet it is usually not necessary, because there is no life threat. Bronchospasm in anaphylaxis is responsive to epinephrine alone, but in patients with preexisting asthma, repeated albuterol nebulizations may be necessary.³

Corticosteroids are recommended in all patients with anaphylaxis. Although there is no immediate benefit to their administration, steroids speed the resolution of angioedema and urticaria, and are thought to prevent a biphasic course in anaphylaxis.^{3,4} Dosage recommendations are similar to those for status asthmaticus: methylprednisolone (Solu-Medrol), 125-mg intravenous push, repeated every 4 to 6 hours in patients whose symptoms persist despite standard therapy.^{3,7,8}

All patients with anaphylaxis should receive an antihistamine such as diphenhydramine (Benadryl), 25 to 50 mg, to a maximum of 100 mg, in more severe reactions. The route of administration depends on the severity of the reaction. An H₂ blocker such as cimetidine may be preferable to diphenhydramine if sedation is undesirable¹² or if hypotension is a prominent feature of the reaction. The combination of H₁ and H₂ blockers appears superior to either agent alone, especially in severe anaphylaxis.^{3,10,12} The use of intravenous famotidine 20 mg or ranitidine 50 mg is anecdotal, but the drugs are probably equivalent to cimetidine in effect. Antihistamines alone, however, are usually inadequate in the treatment of acute anaphylaxis and should not be relied on as the sole treatment.

Preventing further exposure to the antigen is critical; for instance, a tourniquet can be placed above an injection site, the stinger of a honey bee can be removed, and any offending chemicals can be washed off.

Throughout therapy, the vital signs are reassessed frequently and the airway is checked for edema of the uvula or oropharynx. The patient is asked about symptoms of laryngeal edema or bronchospasm and examined for signs of stridor, retractions, or wheezing. These assessments are made at 1- or 2-minute intervals at first, with the intervals lengthened as the patient stabilizes.

With patients over age 50 or those with a cardiac history, saline is given cautiously for hypotension, while monitoring closely for volume overload. Epinephrine should not be withheld in patients with potential upper airway obstruction or in those with hypotension unresponsive to volume loading. A test dose of epinephrine, 0.15 mL (1:1000) subcutaneously or intramuscularly, can generally be given safely. If no chest pain or cardiac dysrhythmias develop, another test dose or a full dose is then given. However, intravenous epinephrine should be avoided in these patients unless death appears imminent without its use.²

Another special situation arises when anaphylaxis occurs in a patient who is taking a beta-adrenergic blocker, in which case, epinephrine therapy may have a net alpha-adrenergic effect only, thereby limiting its efficacy. In this situation glucagon, 1 to 2 mg given intravenously over 5 minutes may be of great benefit. Terbutaline, 0.25 mg subcutaneously or an isoproterenol drip, may also be considered.^{3,5,7,12}

Table 217.3 summarizes treatment guidelines for anaphylaxis.

TABLE 217.3. Treatment of Anaphylaxis

DISPOSITION

Indications for Admission

If all symptoms of anaphylaxis resolve rapidly and completely with initial therapy, the patient can be observed in the emergency department without further treatment. If symptoms do not recur in the next 2 to 3 hours, the patient may safely be discharged and should continue on a 3-day course of prednisone (40 mg/d) and diphenhydramine (25 mg every 4 hours as needed) or cimetidine (400 mg every 8 hours as needed). Discharge instructions should caution the patient to avoid any suspected inciting cause, such as medications, foods, chemicals, or even exercise. The patient should be instructed to return to the emergency department immediately if hoarseness, dysphagia, wheezing, dyspnea, dizziness, or worsening rash and swelling develop. Follow-up with an allergist should be recommended, particularly if no obvious etiology has been identified in the emergency department.¹⁸

Patients who had a life-threatening manifestation on presentation (shock or upper airway obstruction), even if it resolved with acute therapy, should be admitted. Those who had a slow or incomplete response to therapy or any worsening of symptoms during emergency department evaluation and treatment also require admission, as do elderly or debilitated patients or those with serious underlying cardiac disease.

Transfer Considerations

Because anaphylaxis can progress in such a fulminant manner, transfer to another institution is not recommended unless prolonged observation in the emergency department has shown the patient to be stable.

COMMON PITFALLS

- Giving dangerously large doses or inappropriate concentrations of epinephrine intravenously²
- Withholding epinephrine therapy in the elderly or cardiac patient with imminent airway obstruction or refractory shock
- Not recognizing the possibility of recrudescence of symptoms 4 to 8 hours after an initial complete response to therapy¹⁶
- Not identifying common etiologies of anaphylaxis, such as antiinflammatory drugs (especially over-the-counter preparations), foods (shellfish, nuts), antibiotics (despite the lack of previous reactions and regardless of duration of therapy), antihypertensive drugs (beta blockers, angiotensin converting enzyme inhibitors), and exercise
- Not treating upper airway symptoms, such as hoarseness and dysphagia, with appropriate aggressiveness
- Not recognizing uvular and pharyngeal angioedema as warning signs of laryngeal involvement
- Misdiagnosing anaphylaxis as the flushing of a monosodium glutamate reaction or as scombroid fish poisoning
- Failing to recognize that anaphylaxis can present with shock or acute airway obstruction alone, without any other manifestations of the classic anaphylactic syndrome
- Failing to prescribe EpiPen and to provide allergy referral to patients with idiopathic anaphylaxis and those at high risk for recurrent episodes

CHAPTER 218

Angioedema

Joyce M. Mitchell-Savinsky

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Angioedema, characterized by areas of cutaneous and visceral swelling, has a predilection for the face, oral areas, distal extremities, and genitalia; it may also involve the larynx, gastrointestinal tract, and central nervous system. The swelling is deep rather than superficial. Unlike urticaria, the cutaneous lesions of angioedema are not usually pruritic.⁷

There are two main forms of angioedema: acquired and hereditary. The acquired form is more common, often occurring in association with urticaria, and is usually the result of a reaction to certain stimuli, such as food, drugs, infections, inhalants, insect bites, blood products, and physical factors (e.g., cold, heat, vibration, exercise), or systemic illness (e.g., collagen vascular disease).^{1,9,10,12}

Angiotensin converting enzyme (ACE) inhibitors have been recognized as a common cause of this disorder. Angioedema can first occur months or even years after the ACE inhibitor was first taken, and patients sometimes report having had previous episodes that subsided spontaneously while they continued taking the drug.² Acquired angioedema usually lasts for hours to days. A chronic form (by definition, persisting more than 6 weeks) is more common in middle-aged adults; often, no inciting factor can be identified.⁷

Hereditary angioedema (HAE), an inherited deficiency of the inhibitor of the activated first component of complement (C1 INH), is manifested by recurrent attacks of angioedema not associated with urticaria. Compromise of the airway occurs in up to two-thirds of these patients at some time and is the cause of death in many patients with the disease.^{5,14} A rare acquired form of C1' esterase INH deficiency is seen in association with hematologic and other malignancies.⁴

Histologically, both forms of angioedema show vascular dilatation and increased permeability with interstitial edema. These changes occur in the deep dermis and subcutaneous tissues, unlike those of urticaria, which are seen in the upper dermis.⁷

CLINICAL PRESENTATION

The clinical presentation depends on the sites or organ systems affected. Most commonly, there is localized swelling that develops acutely, typically on the face or upper lip, especially with ACE inhibitor-associated disease. Some patients complain of pruritus due to associated urticaria and tightness or burning in the angioedematous areas.⁷ Involvement of the gastrointestinal tract, seen more commonly in HAE, can cause abdominal pain, nausea, vomiting, and diarrhea. The pain is usually diffuse and colicky and may be associated with peritoneal signs, mimicking an acute surgical abdomen but without fever or leukocytosis. Radiologic findings suggestive of bowel wall edema may be seen.⁸ Neurologic involvement is rare but, when it occurs, may be associated with altered consciousness, headache, seizures, and focal deficits. These typically resolve without permanent sequelae.¹¹

The most emergent presentation of angioedema is life-threatening upper airway obstruction with dysphagia, a "tightness" in the throat, dyspnea, cough, hoarseness, and stridor. Airway involvement is unusual in acquired angioedema, it but can progress rapidly.⁹ Fatal airway obstruction has been reported with the use of ACE inhibitors.^{1,10} In HAE, airway edema can progress over several hours, with increasing hoarseness, difficulty swallowing, and aphonia prior to complete airway obstruction.¹³

DIFFERENTIAL DIAGNOSIS

Other entities that can cause swelling must be considered, including cellulitis and erysipelas, congestive heart failure, lymphedema, renal disease, and venous obstruction.

EMERGENCY DEPARTMENT EVALUATION

Evaluation in the emergency department is directed at identifying inciting agents, assessing the severity of illness, and considering the possibility of HAE or other underlying disorder.⁷ The crucial aspect of the physical examination is assessment of airway status. A common pitfall is to underestimate airway involvement and the potential for obstruction. Laboratory studies are seldom useful in acute episodes, except to eliminate other causes of edema.

EMERGENCY DEPARTMENT MANAGEMENT

For patients with upper respiratory involvement, the most important aspect of emergency care is maintenance of a patent airway. These patients should receive subcutaneous epinephrine (0.3 mL of 1:1000) and a parenteral H₁-blocker antihistamine. There is no reported added benefit of administering epinephrine intravenously. Continuous monitoring of airway status is critical. The decision to establish an airway is sometimes difficult. When in doubt, however, aggressive intervention should be undertaken, using orotracheal or nasotracheal intubation or cricothyrotomy.

The mainstays of drug treatment of acute acquired angioedema are epinephrine and H₁-blocker antihistamines such as diphenhydramine, hydroxyzine, and cyproheptadine.^{7,10} In chronic angioedema, corticosteroids have been used, with varying success, in conjunction with H₂ blockers.^{4,8,9} and ¹⁰ Patients presenting with uncomplicated cutaneous swelling should be treated with oral or intramuscular diphenhydramine (25 to 50 mg) or hydroxyzine (25 to 50 mg).⁷ If there is gastrointestinal involvement, additional symptomatic and supportive therapy should be provided. Patients taking ACE inhibitors should stop doing so and henceforth avoid taking that class of drugs.

Epinephrine, antihistamines, and corticosteroids have not been reported consistently to be useful in the treatment of acute attacks of HAE.¹³ Androgen derivatives (e.g., danazol) and antifibrinolytic agents (e.g., ε-aminocaproic acid and tranexamic acid) can decrease the frequency of attacks, but they do not arrest acute episodes.^{3,4,13} Significant improvement has been seen with infusion of C1 INH concentrates.^{3,6,13} No therapy is required for simple cutaneous episodes, and isolated gastrointestinal attacks likewise require only symptomatic and supportive care. With impending airway obstruction, maintenance of airway patency is the prime consideration. Infusion of C1 INH concentrate (or, less preferably, fresh-frozen plasma when the concentrate is unavailable) may be beneficial.^{4,6,13} Patients with acquired C1 INH deficiency may require much higher doses than those with the hereditary form.⁴

DISPOSITION

In patients with previously diagnosed HAE, management should be discussed with the patient's primary care physician.

In both acute and hereditary forms of angioedema, patients with simple cutaneous swellings who have shown no progression of symptoms during several hours of observation in the emergency department can often be discharged, with follow-up scheduled in 1 to 2 days. Because airway compromise occasionally develops unpredictably many hours after the episode of angioedema, some clinicians admit all such patients to the hospital for observation, particularly if there is any doubt as to the reliability of follow-up. Patients who are reliable and safe to be discharged, however, should be instructed to return immediately if airway symptoms develop.

Patients who have been taking ACE inhibitors should consult their primary care physician for initiation of a different antihypertensive medication.

Patients with airway compromise or worsening symptoms despite therapy require immediate hospital admission. These patients and those with severe neurologic symptoms should be placed in a critical care setting.

If the patient must be transferred to a facility offering a higher level of care, the airway must be secured before transport. The patient should be transferred by the most expeditious route and by personnel who are skilled in airway management.

COMMON PITFALLS

- The worst error made in the management of patients with angioedema is failure to establish airway control.
- Failure to recognize an ACE inhibitor as the underlying cause of angioedema may result in repeated episodes if the drug is not discontinued.
- The diagnosis of angioedema can be missed when the patient presents with gastrointestinal and neurologic complaints. Careful attention to associated cutaneous lesions or to a history of previous episodes should alert the physician to the diagnosis of angioedema.
- In acute attacks of HAE, epinephrine and antihistamines have not been proven to be beneficial, and their use may lead to a false sense of security.

[Bibliography](#)

Adverse drug effects occur in up to 15% of drug regimens and are said to be the basis of the majority of iatrogenic illness. Patients with acute symptoms are likely to present to the emergency physician for diagnosis and care.

Adverse drug reactions are predictable (80%) or unpredictable (20%). Predictable reactions are those related to known pharmacologic activity; they include side effects of immediate expression, side effects of delayed expression (carcinogenicity, teratogenicity), effects of overdosage or toxicity, secondary or indirect effects, and drug interactions. Unpredictable reactions are those related to individual immunologic response or genetic difference; they include drug intolerance, drug idiosyncrasy, allergic reaction and pseudoallergic reaction, plus psychophysiological reaction (vasovagal, hyperventilation).

DRUG ALLERGY

Drug allergy or hypersensitivity accounts for 5% to 10% of adverse drug reactions. Characteristically, allergic drug reactions occur in a minority of patients receiving a particular drug. There is typically a history of prior uneventful use of the drug, although allergic reactions can occur during the first course of therapy if continuing for more than about a week. There may be rapid reaction on reexposure to a small dose of the same or a related drug. Reactions typically conform to a characteristic pattern.

Risk factors for drug allergy include the degree of host reactivity, the characteristics of the drug, the degree of exposure, and the route of administration (topical and parenteral administration is associated with greater risk than oral administration.) Some drugs are complete antigens (e.g., insulin, strepto-kinase, and heterologous antisera), but most are low-molecular-weight incomplete antigens that must form a stable bond with tissue or plasma proteins to become immunogenic. Usually, it is one or more of the drug's metabolites that form the union. Because the metabolites of most drugs are not well identified (the notable exception being penicillin), tests to confirm specific drug sensitivity and to elucidate the mechanism of reactivity are limited.

Immunologic or allergic adverse drug reactions can be categorized according to the classification system of Gell and Coombs.

Type I: IgE-Mediated Immediate Hypersensitivity

Type I reactions are mediated by preformed drug-specific IgE antibodies attached to the surface of tissue mast cells and circulating basophils. Bridging of the IgE antibodies by the drug in antigenic form results in mediator release and clinical sequelae such as urticaria, angioedema, laryngeal edema, bronchospasm, and hypotension. Maculopapular rashes may also be type I reactions.

Type II: Cytotoxic Antibody Reactions

Cytotoxic reactions result when IgG or IgM antibodies interact with cell-bound drug and mediate cell injury through complement activation or mononuclear cell activation. Almost all type II reactions involve injury to formed elements of the blood, for example, manifesting as immune hemolytic anemia or thrombocytopenia.

Type III: Immune Complex–Complement Reactions

In type III reactions, circulating immune complexes (consisting of drug plus IgG or drug plus IgM) fix complement and lodge in tissue, where tissue injury ensues. Clinically, the reaction is characterized by fever, rash (ranging from urticaria to palpable purpura), arthralgia, and lymphadenopathy. Serum sickness is the prototype of the type III reaction; penicillins and foreign antisera are among the recognized causes. Other examples of type III reactions are drug-induced, lupus-like syndromes and infiltrative lung disease secondary to inhaled drug allergens.

Type IV: Cell-Mediated Delayed Hypersensitivity

Type IV reactions are mediated by sensitized lymphocytes that recognize a particular drug antigen and recruit other lymphocytes and mononuclear cells to the site of that antigen. Type IV reactions primarily occur as contact dermatitis.

Other Reactions

A number of drug reactions do not strictly fit the Gell and Coombs classification but are presumed to be immunologic. They include Stevens-Johnson syndrome, exfoliative dermatitis, toxic epidermal necrolysis, drug-induced fever, the anticonvulsant hypersensitivity syndrome, and certain cases of pulmonary, hepatic, and renal hypersensitivity. They also include vasculitis syndromes such as hypersensitivity angiitis and leukocytoclastic vasculitis.

A set of reactions that resembles type I IgE-mediated hypersensitivity reactions, but do not involve IgE, are termed *pseudoallergic reactions*. They are clinically indistinguishable from true allergic reactions because comparable mediators produce comparable target-organ sequelae. When life-threatening, they are termed *anaphylactoid*. Commonly used agents that can cause nonspecific mast cell and basophil release of preformed and generated mediators include iodinated radiocontrast media (RCM), opiates, and dextrans. Drugs such as succinylcholine, vancomycin, and ciprofloxacin can cause either IgE-mediated or non-IgE-mediated systemic reactions. The "red man syndrome" is a dose-dependent reaction to vancomycin caused by direct stimulation of mast cells to release histamine; it may be attenuated by reducing the infusion rate. Aspirin and non-steroidal antiinflammatory agents are hypothesized to cause pseudoallergic respiratory reactions through their effects on the cyclooxygenase pathway. Angiotensin converting enzyme (ACE) inhibitors are hypothesized to cause pseudoallergic reactions through their effects on the kallikrein system.

Diagnosis

The diagnosis of adverse drug reactions hinges on the history of drug exposure. Improvement of symptoms after withdrawal of the suspected drug is suggestive information. Confirmatory tests are generally unavailable. Skin testing to detect immediate hypersensitivity has only a limited role for some high-molecular-weight compounds and for penicillin. Patch testing may be performed for drug-induced contact dermatitis. *In vitro* radioallergosorbent or enzyme-linked immunosorbent tests are applicable in special circumstances. The indirect Coombs' test is a diagnostic aid in immune hemolytic anemia. Direct challenge is potentially hazardous and rarely indicated, but it occasionally has a role in evaluating local anesthetic reactions.

Management

The standard management of adverse drug reactions includes prompt discontinuation of the medication and provision of supportive care that is specific to the type and severity of manifestations. Mild pruritis, flushing, and rash may be treated with antihistamines. Corticosteroids are usually administered only for more severe systemic reactions. Early epinephrine is the mainstay of treatment for anaphylactic reactions. Oxygen and airway support, inhaled beta agonists, intravenous fluids, and pressors also may be required.

Certain steps can be taken to prevent or minimize drug reactions. Medications should be prescribed only when necessary; in one study of anaphylactic deaths, 40% of the cases involved drugs for which there was no clear indication. The oral route should be used when possible. Preparations that are less sensitizing (e.g., human insulin rather than pork insulin) are preferred when available. Drug history should be carefully elicited. Frequently, information that can prevent an adverse drug reaction is available from the patient, the patient's relatives, or previous medical records. Documentation in the medical record of any apparent reaction may help avert a similar or worse reaction. Finally, when potentially immunogenic parenteral agents are given in the emergency department, patients should be observed for at least 20 minutes after administration. Discharge instruction should include cautions regarding possible reaction.

PENICILLIN ALLERGY

Penicillin and its derivatives are among the most widely prescribed antibiotics and are the most common cause of drug-induced allergic reactions. Penicillin may be responsible for any of the four main types of reactions: IgE-mediated urticaria, angioedema, anaphylaxis (type I); cytotoxic hemolytic anemia, thrombocytopenia (type II); immune complex serum sickness (type III); or cell-mediated contact dermatitis (type IV). Penicillin may also cause other reactions, such as interstitial nephritis, exfoliative dermatitis, and drug fever.

The overall incidence of adverse reactions to penicillins is estimated to be 2% (range, 0.7% to 10%), and the incidence of anaphylaxis is thought to be 0.015% to 0.04% of treatment courses. Approximately 10% of anaphylactic episodes are fatal, accounting for more than 400 deaths annually in the United States and making penicillins the leading cause of anaphylactic death. Anaphylaxis is usually an immediate reaction (occurring within 30 minutes of administration), but, in approximately 10% of cases, symptoms begin more than 1 hour after administration.

IgG and IgM antibodies to penicillin-protein complexes are produced on first exposure to penicillins in virtually all individuals, whereas IgE antibodies develop in only a small subset. Sensitization may occur through medical use or through occult food, environmental, or medication exposure. There seems to be a genetic predisposition to formation of IgE antibodies, but atopy is not a risk factor. IgE production usually occurs within 1 to 3 weeks of exposure. Depending on the individual, the half-life varies from days to years.

Early reactions consistent with a generalized systemic response (e.g., generalized urticaria, angioedema, bronchospasm, or hypotension) are usually categorized as anaphylactic, even if they are mild, and these should be treated promptly. Therapy should be tailored to the severity of the reaction, and, after epinephrine, may include antihistamines, corticosteroids, intravenous fluids, and pressors. Penicillin and penicillin derivatives should thereafter be avoided in these patients. Regarding risk of future use of the other beta-lactam antibiotics, cross-reactivity is high with the carbapenems (e.g., imipenem), less with the cephalosporins, and minimal with the monobactams (e.g., aztreonam). If there is not an acceptable or effective alternative to penicillin (e.g., for central nervous system syphilis or gestational syphilis), the patient should be considered for penicillin skin testing and in-hospital desensitization.

When a patient develops a maculopapular rash after receiving penicillin, it may represent an allergic reaction, mediated by either IgE, IgG, or IgM. Alternatively, the rash may be an unrelated manifestation of the underlying disease. In some cases, the disease plus the penicillin drug result in the adverse reaction. For example, patients with infectious mononucleosis are likely to develop a morbilliform rash 3 to 8 days after commencing ampicillin or amoxicillin therapy. A similar rash may develop in patients with cytomegalovirus infection, hyperuricemia, or lymphocytic leukemia.

When a maculopapular rash attributable to penicillin allergy occurs, the antibiotic should be discontinued. Additionally, the patient should be instructed to avoid all penicillins. Even if the reaction were actually due to allergy to the specific side chain of a penicillin derivative (e.g., amoxicillin) and not the group common to penicillin drugs, this cannot be distinguished clinically (hence, the need to advise avoidance of all). Whether to use a cephalosporin antibiotic for future infections requires consideration of the risks and benefits in the clinical circumstances. The baseline risk of reaction to a cephalosporin is felt to be approximately 2%. The previously accepted estimate—an increase to 8% to 10% risk of reaction when first- or second-generation cephalosporins are used in patients with history of penicillin allergy—is being questioned. Recent information and analysis suggest that the incidence is much lower than this, and, for third-generation cephalosporins, it is not above the baseline incidence for the general population.

LOCAL ANESTHETIC REACTIONS

Local anesthetics are among the most frequently administered drugs in emergency medicine. They can be divided into two main chemical groups: the esters and the amides (Table 219.1). The amides have a longer half-life in tissues and are favored for local anesthesia. Although true allergic reactions are rare, many patients report "allergy to 'caines," because a variety of nonallergic reactions are associated with the administration of local anesthesia. The differential diagnosis includes hyperventilation, vasovagal reaction, sympathetic stimulation, and toxic drug levels.

GROUP I: ESTERS (MAY CROSS-REACT)
Benzocaine (Americaine)
Procaine (Novocain)
Proparacaine (Alcaine, Ophthaine)
Tetracaine (Pontocaine)
GROUP II: AMIDES (UNLIKELY TO CROSS-REACT)
Eupivacaine (Marcaine, Sensorcaine)
Lidocaine (Xylocaine)
Mepivacaine (Carbocaine)
Prilocaine (Citanest)
OTHERS: FOR MUCOUS MEMBRANES
Dibucaine (Nupercainal)
Dyclonine (Dyclone)
Prainosine (Tronothane)

TABLE 219.1. Local Anesthetic Chemical Groups

The approach to the patient who reports allergy to local anesthesia depends on the analysis of the available information. When the history supports prior nonallergic reaction to local anesthesia, any of the standard anesthetic agents may be used. When the suspected drug can be identified, an agent from a structurally unrelated group is preferred. Hypersensitivity and intragroup cross-reactivity occur more prominently with ester anesthetics.

When all local anesthetic agents seem contraindicated, local anesthesia may be provided by the use of diphenhydramine. Diphenhydramine 1% (1.5 to 5.0 mL intradermally) provides effective anesthesia for repair of minor lacerations. Pain during initial administration is greater than with lidocaine, but pain during the procedure is equally well controlled. Sleepiness occasionally occurs after anesthesia with 1% diphenhydramine. Lower concentrations (e.g., 0.5%) seem less effective for anesthesia, and higher concentrations (2% to 5%) have been associated with local irritation, burning, erythema, vesicle formation, skin sloughing, and prolonged anesthesia or paresthesias.

Patients for whom local anesthetics will be needed in the future, but which cannot be ascertained as safe by history, should be referred for allergy testing. There are protocols for testing serial dilutions of the agent in question. Experience has shown that true-positive reactions are rare (less than 1%) and that the sensitivity does not seem to correlate with the presence of paraben or methylparaben preservatives. Although serial testing could be conducted in the emergency department, time

constraints usually make it impractical.

RADIOCONTRAST MEDIA REACTIONS

More than 10 million radiographic evaluations using RCM are performed each year in the United States. Diatrizoates and iothalamates are the ionic contrast agents that have been most widely used. They are referred to as high-osmolality contrast media because their osmolality is several-fold higher than that of plasma.

In the 1970s, low-osmolality agents were introduced. Their osmolality is only approximately twice that of plasma; most of them are also nonionic ([Table 219.2](#)). Compared with their forerunners, these low-osmolality agents seem to provide comparable quality of opacification and to carry a lower overall risk of complications. They have not fully supplanted the high-osmolality agents, however, because of their expense.

	Approximate Osmolality (mOsmol/kg water)	Ionic
HIGH OSMOLALITY		
Diatrizoate sodium	1,500	Yes
Diatrizoate sodium (8%) and meglumine (52%)	1,500	Yes
Iothalamate meglumine (60%)	1,400	Yes
LOW OSMOLALITY		
Iohexol	300-800	No
Iopamidol	600	No
Ioversol	700	No
Ioxaglate sodium (19.6%) and meglumine (39.3%)	600	Yes

TABLE 219.2. Radiocontrast Media Categories

Immediate adverse effects from contrast media can be subdivided into two broad categories. The first consists of those reactions that are related to the physicochemical properties of the media, particularly hyperosmolality. Physiologic effects that correlate with high osmolality include vasodilation, hemodilution, erythrocyte deformity, disturbance of the blood-brain barrier, and alteration of left ventricular end-diastolic pressure and arterial pressure. Reduction in the incidence of cardiovascular side effects, heat sensation, and local pain have been demonstrated when low-osmolality (nonionic) agents are used in place of high-osmolality (ionic) agents. Overall rates of immediate adverse reactions attributable to physicochemical properties are estimated to be 1% to 3% for the former and 4% to 12% for the latter.

The other broad category of immediate adverse reactions is anaphylactoid reactions. They typically follow intravascular injection of RCM but, in rare instances, may occur after contrast is introduced into extravascular structures. The anaphylactoid reactions tend to be more severe and less dose- and concentration-dependent than the physicochemical reactions. Bronchospasm, laryngeal edema, widespread urticaria or angioedema, hypotension, and/or arrhythmias manifest within 30 minutes of the infusion. Although the initiating pathophysiology does not seem to be that of an IgE-mediated allergic reaction, there is comparable release of histamine and other mediators from mast cells. Therefore, the treatment is the same as for true anaphylaxis. Estimated rates of incidence are 0.22% for the high-osmolality (ionic) contrast agents versus 0.04% for low-osmolality (nonionic) contrast agents. Deaths have been reported with the use of each type of agent. Patients with allergic diathesis, asthma, or cardiac disease are at increased risk for these anaphylactoid reactions. Patients with a history of contrast reaction have more than five times the incidence of a subsequent reaction in comparison with previous nonreactors.

The most significant late-occurring adverse reaction is that of nephrotoxicity. The mechanism is not completely understood, but the clinical picture is that of an increase in the serum creatinine level that begins within 24 hours of exposure to the agent. Risk factors for nephrotoxicity include advanced age, dehydration, preexisting renal insufficiency, diabetes mellitus, diuretic therapy, hepatic insufficiency, multiple myeloma, recent large dose of RCM, and sickle cell anemia. Although the degree of protective benefit is not uniform or certain, low osmolality (nonionic) agents are recommended for patients with one or more of the risk factors for nephrotoxicity.

Fever, chills, rash, arthralgias, diarrhea, nausea, vomiting, headache, and other nonspecific symptoms may occur as a delayed reaction 30 minutes to 3 days after contrast media injection in 4% to 8% of patients. Fever typically abates within 8 hours and is speculated to represent a hypothalamic response to RCM injection. Patients who have recently received interleukin-2 seem to have an increased frequency and severity of delayed reactions. Treatment of delayed reactions is supportive.

The risk-to-benefit ratio of a contrast study should be considered before it is ordered and performed, especially in patients with a history of anaphylactoid reaction. In some situations, a study that does not require contrast (e.g., ultrasound or magnetic resonance imaging) can be substituted. In others, the radiocontrast test can be delayed for 12 to 36 hours, during which time the patient can be pretreated with corticosteroids and antihistamines to decrease the likelihood of recurrent anaphylactoid reaction. One established protocol is to administer methylprednisolone, 32 mg by mouth, 12 hours and 2 hours before contrast administration, and diphenhydramine, 50 mg by mouth or intramuscularly, 1 hour before contrast administration. Pretreatment can be expected to reduce the incidence of reactions to high-osmolality agents by approximately one-third. Simply using low-osmolality agents alone may reduce risk to a similar level. Combining pretreatment and low-osmolality agents may provide extra protection but extends the time until the test can be performed.

ANGIOTENSIN CONVERTING ENZYME INHIBITOR REACTIONS

The propensity of the ACE inhibitors to cause cough and angioedema has been increasingly recognized and studied in recent years. These reactions are not allergic in nature and appear to involve the kinin system.

Cough is the more frequent but less serious of the two adverse reactions and occurs in 5% to 20% of patients treated with ACE inhibitors. It occurs more often in females and may be dependent on dose. The onset of cough is typically within 1 week of initiation of therapy, but it may develop up to 6 months later. There is no associated alteration in pulmonary function. The diagnosis is a clinical one. In most cases, management consists simply of withdrawal of the ACE inhibitor, and the diagnosis is confirmed by resolution of the cough within a week. Subsequent challenge with the same agent or another ACE inhibitor almost always results in recurrence of cough.

Angioedema, typically of the face, neck, or upper airway, occurs in 0.1% to 0.2% of patients treated with ACE inhibitors (and also has been reported in patients treated with angiotensin II receptor antagonists). The reaction can progress rapidly to airway obstruction and death. The risk is highest in the first few hours to first week of treatment but can also occur in patients who have been taking the drug uneventfully for months to years. The risk abates within hours of stopping the drug.

When angioedema secondary to an ACE inhibitor occurs, administration of the standard allergic anaphylaxis treatment of subcutaneous epinephrine, diphenhydramine, and corticosteroids cannot be relied on to reverse the process. Furthermore, the progression of the edema is unpredictable, and there may be rebound. Early airway control is therefore recommended, because massive edema of the tongue and pharynx can make orotracheal and nasotracheal intubation difficult, and neck edema may make creation of a surgical airway difficult as well.

Monoarticular arthritis is a common emergency condition, the outcome of which depends on rapid diagnosis and treatment.¹ In the case of septic arthritis, delay or misdiagnosis may lead to joint destruction or even death.

Gout and disseminated gonococcal infection are the most common causes of monoarticular arthritis; infections due to *Staphylococcus aureus* and other bacteria are the most serious. Monoarticular arthritis may also be the initial presentation of a systemic polyarticular disease.

CLINICAL PRESENTATION

Gonococcal Arthritis

Gonococcal arthritis may be monoarticular, migratory, or poly-articular, and usually involves the wrist, knee, or ankle. At least half of patients exhibit a rash that consists of scattered hemorrhagic pustules on an erythematous base, usually on the extremities. Maculopapular and petechial lesions may also occur. Tenosynovitis frequently involves the extensor tendons of the hand and wrist and tends to be fleeting and migratory. The degree of toxicity varies greatly, and fever and leukocytosis may be absent.

Nongonococcal Septic Arthritis

Nongonococcal septic arthritis involves, in descending order of frequency, the knee, hip, shoulder, ankle, elbow, hand, or wrist. Patients with a history of intravenous drug use can present with involvement of unusual joints such as the sternoclavicular, sacroiliac, or manubriosternal joints. Septic arthritis may develop in a fulminant fashion, with marked toxicity, fever, and confusion, or may be subacute and insidious, with malaise, anorexia, and little or no fever. In the elderly or those with rheumatoid arthritis, the onset is often gradual, and multiple joint involvement occurs in up to 9% of patients.^{5,13} This combination of rheumatoid arthritis and septic arthritis is deadly; the mortality rate is reported to be as high as 19%.⁴

Crystal-Induced Monoarthritis

Most cases of acute gout affect a single joint, but the attack may be polyarticular in up to 40% of cases.¹⁰ Pseudogout, or calcium pyrophosphate deposition disease (CPPD), usually develops after the age of 50; attacks may be mono- or polyarticular, often affecting the knees, wrists, ankles, and elbows. In both disorders, patients may demonstrate systemic symptoms such as fever or confusion.¹¹

DIFFERENTIAL DIAGNOSIS

Monoarticular arthritis may be due to hemorrhagic, mechanical, neoplastic, ischemic, inflammatory, or infectious causes ([Table 220.1](#)). In patients with hemophilia or those who take anticoagulants, hemorrhage may occur spontaneously or in association with mild trauma. Patients without coagulopathy who develop acute traumatic hemarthrosis usually have significant injury to bone, joint, or ligament.

Infectious	Bacterial Coccidial Meningococcal Atypical bacterial (Mycoplasma, Chlamydia, Legionella, etc.) Fungal Viral (HSV, hepatitis B, rubella, etc.)
Crystal-induced	Gout (monosodium urate) Pseudogout (calcium pyrophosphate dihydrate) Calcium oxalate
Traumatic	Fracture Ligamentous injury Chondrolysis
Ischemic	Avascular necrosis Ischemic infarction of the joint Decompression illness
Hemorrhagic	Spontaneous Traumatic
Neoplastic	Systemic Local
Systemic disease	Rheumatoid arthritis Spondyloarthropathies (ankylosing spondylitis, psoriatic arthritis, enteropathic arthritis, reactive arthritis) Systemic lupus erythematosus Sarcoidosis, amyloidosis

TABLE 220.1. Differential Diagnosis of Acute Monoarticular Arthritis

The most common causes of crystal-related arthritis are monosodium urate (gout) and calcium pyrophosphate dihydrate (pseudogout). On occasion, a variety of other crystals, including apatites and calcium oxalate, may produce inflammatory joint changes. Gout develops when sodium urate crystals precipitate in joints and initiate an inflammatory reaction. Although chronic hyperuricemia is necessary for gout to develop, during an acute attack the serum uric acid may be normal, high, or low. Ninety percent of primary, or idiopathic, gout is due to underexcretion of uric acid; attacks are precipitated by excessive purine intake, joint trauma, or alcohol use. Secondary gout is associated with systemic disease, such as malignancy or diabetes, or with alcoholism or use of certain medications. Diuretics are frequent offenders. Gout occurs far more frequently in men than in women. It may occasionally develop in early adulthood, but males usually experience their first attack in their 40s, and women rarely contract the disease until well after menopause. Pseudogout is caused by disposition of calcium pyrophosphate dihydrate crystals, and is associated with osteoarthritis and diseases such as hyperparathyroidism, hemochromatosis, and acromegaly.¹⁷

A wide variety of inflammatory states, including rheumatoid arthritis and the seronegative arthropathies, although usually polyarticular, may affect a single joint. The seronegative arthritides, characterized by the absence of rheumatoid factor, include ankylosing spondylitis, psoriatic arthritis, enteropathic arthritis (associated with inflammatory bowel disease), and reactive arthritis (such as Reiter syndrome). Rheumatoid arthritis, gout, pseudogout, and the seronegative spondyloarthropathies may all display similar clinical pictures.

Trauma, foreign bodies, or osteochondral fragments in a joint lead to mechanical arthritis. Neoplasms may develop within the capsule (e.g., pigmented villonodular synovitis), or they may occur in juxtaarticular bone (e.g., osteoid osteoma or metastatic cancer). Ischemic arthritis, including that due to decompression illness, is rare. Systemic corticosteroids can lead to aseptic necrosis of the hip, shoulder, or knee.

Of all joint disease, infectious arthritis is of the greatest concern to the emergency physician. It can be due to bacteria, mycobacteria, fungi, and viruses, although bacterial processes are, by far, the most common and the most serious. The degree of inflammation varies among pathogens. Staphylococcal infections are the most destructive; gonococcal arthritides are usually much less devastating.

Disseminated gonococcal infection (DGI) is responsible for most cases of monoarticular arthritis in sexually active adults. Conversely, 3% of patients with gonorrhea may present with this syndrome.² Although the classic triad of DGI consists of dermatitis, tenosynovitis, and migratory polyarthritis, many patients have only monoarticular arthritis. Most cases of DGI are seen in young adults, but the syndrome occurs in sexually active octogenarians as well.

Women are more frequently affected, possibly because longer asymptomatic colonization increases the chance of dissemination; they are especially affected during the perimenstrual period and pregnancy. Gonococcal arthritis begins as an immune complex disorder that produces an inflammatory but sterile joint effusion. If left untreated at this stage, subsequent bacterial invasion may produce an infected joint.

Nongonococcal bacterial arthritis usually occurs in patients who have underlying medical problems such as diabetes, alcoholism, and malignancy. Rheumatoid arthritis, collagen vascular disease, and immunosuppressed states increase susceptibility, and patients who are elderly, malnourished, or being treated with corticosteroids are also predisposed to develop a septic joint. Prior joint abnormality, whether secondary to trauma, noninfectious arthritis, or a prosthetic joint, significantly increases the risk of septic arthritis, especially in the presence of bacteremia. Bacterial seeding may occur by direct inoculation from a puncture wound or skin ulcer overlying the joint, or it may result from hematogenous spread associated with a remote infection such as pneumonia, urinary tract infection, endocarditis, or cellulitis.

Contiguous osteomyelitis may erupt into a joint space. *S. aureus* is responsible for up to 75% of cases of nongonococcal bacterial arthritis, and other gram-positive organisms, such as *Streptococcus*, play a significant role.^{5,13} Gram-negative and anaerobic bacteria may be found in up to 20% of patients, particularly the elderly or immunocompromised. Rarely, *Salmonella* arthritis develops in patients with sickle cell anemia or systemic lupus erythematosus. Acute HIV infection, as well as other viral infections, may produce monoarticular viral arthritis, and fungal and tubercular arthritides occur occasionally, almost always in an immunosuppressed host. Spirochetal disease, such as syphilis or Lyme disease, must also be included in the differential diagnosis of infectious arthritis.

Monoarticular arthritis must be distinguished from periarticular conditions such as cellulitis, tendinitis, and bursitis. A significant proportion of patients with apparent monoarticular arthritis actually have a soft-tissue process, usually bursitis. Bursitis is characterized by pain over bony prominences, and little or no pain on range of motion. Trochanteric bursitis may masquerade as a septic hip, while rotator cuff injuries, subacromial bursitis, and adhesive capsulitis are common mimics of the septic shoulder joint. Olecranon bursitis must be differentiated from arthritis of the elbow.

The acute worsening of a patient with a prior joint abnormality presents a diagnostic challenge. A flare of rheumatoid arthritis may be clinically indistinguishable from acute joint infection, and it is very difficult to separate mechanical loosening of a prosthesis from an indolent septic process.⁷

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of acute monoarticular arthritis is greatly assisted by history, physical examination, and, above all, arthrocentesis. The emergency physician must recognize the infected joint during the first visit in order to prevent joint destruction and possible death. In contrast, most other monoarticular arthritides pose significantly less risk of acute or chronic morbidity and may be treated symptomatically pending definitive diagnosis.

The patient should be questioned regarding recent or remote joint trauma, a history of dysuria or urethral discharge (in men), or the presence of lower abdominal pain or vaginal discharge (in women). Fever, chills, or systemic symptoms suggest infection but are nonspecific. A history of inflammatory bowel disease, nephrolithiasis, psoriasis, lupus, or hemophilia implicates the associated types of monoarticular arthritis. The patient must be assessed for the presence of immunosuppression, alcohol abuse, diabetes, intravenous drug use, and human immunodeficiency virus (HIV) risk factors. The use of medications such as corticosteroids, immunosuppressive agents, and diuretics provides additional diagnostic clues. Recent antibiotic use raises the possibility of a partially treated septic arthritis in which cultures of joint fluid may be negative. In endemic areas, the history of a tick bite or the typical rash of erythema migrans suggests Lyme disease. Recent medical or dental procedures predispose to endocarditis and subsequent septic arthritis.

Rheumatoid arthritis is one of the most common predisposing factors for septic arthritis. In patients with rheumatoid arthritis, it should be determined whether intraarticular steroids have been administered within the last 3 to 6 months; as many as one in 2000 of such injections results in late septic arthritis.¹⁴ A history of other attacks of joint pain, recent joint instrumentation, or the presence of a prosthetic joint is also significant. The diagnosis of gout can be made on clinical grounds alone in patients who present with acute podagra and a history of gout. A family history of gout may be helpful.

The physical examination should not focus solely on the affected joint. A search for remote sites of infection may reveal pneumonia, endocarditis, urinary tract infection, or osteomyelitis, any of which may be associated with a septic arthritis. Tophi may be aspirated and examined under the microscope for sodium urate crystals. The skin lesions of psoriasis, erythema migrans (Lyme disease), erythema marginatum (rheumatic fever), and erythema nodosum (systemic lupus erythematosus, sarcoid, vasculitis) can provide strong clues to etiology.

Other informative rashes include the scattered pustules of DGI on the distal extremities and the characteristic eruptions of Reiter syndrome (keratoderma blennorrhagicum on the soles of the feet and circinate balanitis around the glans penis). Stigmata of parenteral drug use (e.g., needle tracks or skin-popping ulcers) suggest infection as the cause of arthritis, as do signs of bacterial endocarditis such as splinter hemorrhages, Osler's nodes, and Janeway lesions. Discharge or other evidence suggestive of infection should be sought on genital or pelvic examination.

The involved joint should first be examined to distinguish arthritis from periarticular inflammation. Pain on motion, whether active or passive, is the hallmark of joint inflammation. If the patient can move the joint through the full range of motion with minimal pain, acute arthritis is unlikely. One should also look for periarticular puncture wounds or ulcerations and for joint effusions. The presence of lymphangitis or nodes proximal to the involved area argues more for cellulitis than arthritis. The Patrick test or FABER test (pain on forced flexion, abduction, and external rotation of the hip) identifies involvement of the sacro-iliac joint.

Radiography is of variable utility in the evaluation of acute monoarticular arthritis. Plain films detect fractures or effusions, show foreign bodies or loose bone chips within the joint, and can demonstrate subchondral bone erosion, joint space narrowing, and, occasionally, intraarticular gas. Osteomyelitis, bone tumors, Paget disease, and osteochondritis dissecans are also visible. Calcification of the cartilage (chondrocalcinosis) may accompany pseudogout, but is not diagnostic of this condition. Advanced gout produces a characteristic pattern of punched-out bony erosions, juxtaarticular or periarticular soft-tissue swelling, and joint space narrowing.

A computed tomography (CT) scan may be useful in certain situations, such as juxtaarticular osteomyelitis, bony tumors, or periarticular abscesses, and can help to distinguish articular from periarticular processes.¹ Magnetic resonance imaging accurately detects ligamentous and cartilage damage, soft-tissue inflammation, and intramedullary osteomyelitis, but has little utility in the emergency setting. Radionuclide scans highlight joint inflammation, but are rarely necessary for acute evaluation, except in the case of a suspected prosthetic joint infection.

The evaluation of a painful *prosthetic joint* may require a variety of imaging studies. Plain films can detect fractures or loosening of the prosthesis, whereas a radionuclide scan can help to distinguish infectious from noninfectious etiologies of joint pain.

The emergency physician must recognize the limitations of the laboratory in the evaluation of acute arthritis. Blood tests cannot conclusively determine the etiology of monoarticular arthritis, nor can they distinguish articular from periarticular inflammation. The white blood cell (WBC) count is increased in fewer than 60% of cases of infection.¹³ The erythrocyte sedimentation rate (ESR) is elevated in 90% or more of cases; a normal sedimentation rate makes bacterial arthritis less likely, *but does not rule out the possibility*. Furthermore, elevated white counts and sedimentation rates are not specific for infectious arthritis, occurring commonly in crystal-induced arthritis and other inflammatory conditions. Likewise, the serum uric acid level is not helpful and, in fact, may be misleading in the emergency setting, because 40% of patients with acute gout have normal or low levels,¹² while many patients *without* gout have high levels.

When DGI is a consideration, urethral or cervical culture should be obtained, even if the patient denies a discharge. Gonorrhea is far more likely to be isolated from the genital tract than from joint cultures. Up to 80% of DGIs can be detected by genital cultures, whereas only 30% of patients have culture-positive joint fluid. Even

asymptomatic individuals should have genital cultures obtained, because nearly half of patients with DGI have no genitourinary complaints. Culturing of the rectum and the pharynx can be expected to increase the yield further.

Serologic tests for syphilis, Lyme disease, and HIV may occasionally be useful in establishing a diagnosis, but rarely affect emergency management. Lyme titers in particular can be misleading.

Synovial fluid analysis is the single most important test in the emergency evaluation of acute monoarticular arthritis. Arthrocentesis should be attempted in all cases of monoarticular arthritis, with the possible exception of classic recurrent gout. Most joints can be readily aspirated by the emergency physician, but for certain joints, such as the hip and sacroiliac joints, specialty consultation is generally required and aspiration is performed under fluoroscopic, CT, or ultrasonographic guidance. In the case of a dry tap, nonbacteriostatic saline may be injected into the joint and reaspirated for Gram staining and culture. When aspiration of the first metatarsal joint is attempted and no fluid is obtained, sodium urate crystals can sometimes be expressed from the needle bore onto a glass slide.

Synovial fluid analysis requires only 1 to 2 mL of fluid, but if only a drop is obtained, it should be sent for culture. Laboratory analysis should include cell count and differential, Gram stain, culture, and examination for crystals. Synovial fluid chemistries such as lactate dehydrogenase, glucose, and protein are traditionally recommended, but they provide little useful information and are often misleading or redundant.¹⁸ Arthrocentesis remains an accurate method of detecting infection in a prosthetic joint, but it should probably be performed only after orthopedic consultation.

The synovial fluid white cell count can be used to categorize effusions as (1) noninflammatory (less than 2000 WBC/ μ L), (2) inflammatory (2,000 to 50,000 WBC/ μ L), and (3) infectious (greater than 50,000 WBC/ μ L).¹³ In general, there is a broad overlap of the WBC count in inflammatory and infectious conditions. A significant percentage of patients with septic arthritis have synovial WBC counts of less than 50,000/ μ L, and patients with gout may have WBC counts of greater than 100,000/ μ L.

Gram stain and culture of the fluid are also critical components of the evaluation. The Gram stain is positive in 50% to 75% of nongonococcal septic arthritis, but in less than 25% of cases of gonococcal arthritis.² Culture yields similar percentages. In immunosuppressed patients, both aerobic and anaerobic cultures should be requested and the laboratory should be alerted if fungal, mycobacterial, or viral etiologies are suspected.

Polarized light microscopy is extremely helpful in the diagnosis of crystal-related arthropathies.¹⁵ Monosodium urate crystals appear as strongly negatively birefringent needles that may be either intra- or extracellular. Calcium pyrophosphate dihydrate crystals are more rod-shaped and have weak positive birefringence. Apatite crystals shine in nonbirefringent clumps and can be further demonstrated using special stains.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Gonococcal Arthritis

Because of antibiotic resistance, third-generation cephalosporins are preferred over penicillin in the management of gonococcal arthritis ([Table 220.2](#)). Ceftriaxone, 1 g parenterally every 24 hours, is the treatment of choice. Other Centers for Disease Control–approved regimens include cefotaxime 1 g intravenously (i.v.) every 8 hours, or ceftizoxime 1 g i.v. every 8 hours. Spectinomycin 2 g intramuscularly (i.m.) every 12 hours, or ciprofloxacin 500 mg i.v. every 12 hours, may be given to persons who are allergic to beta-lactam drugs. After the patient demonstrates clinical improvement with parenteral treatment, an approved oral regimen may be started (e.g., cefixime 400 mg orally twice a day, or ciprofloxacin 500 mg orally twice a day). Traditionally, patients with gonococcal arthritis have been treated as inpatients. However, compliant, nontoxic patients with involvement of a non–weight-bearing joint may be discharged after initial parenteral antibiotic loading with instructions to return for daily ceftriaxone therapy. Patients who are toxic-appearing or immunocompromised must be admitted for intravenous therapy.

Type	Treatment	Alternative
Infectious Septic and nongonococcal arthritis	PCNA-resistant synthetic PCN and 3rd-generation cephalosporin (ceftriaxone or cefotaxime)	Vancomycin
Infectious gonococcal	Ceftriaxone 1 g i.v. q24h Cefotaxime 1 g i.v. q8h Cefixime 400 mg orally b.i.d.	Spectinomycin 2 g i.m. q12h Ciprofloxacin 500 mg i.v. q12h
Crystal-induced	Indomethacin 50 mg PO t.i.d. or i.v. followed by open over 4-6 days	Colchicine 30 mg PO q1h until relief Clonidine 0.1 mg PO q1h or comparable NSAID 75 mg PO q1h Corticosteroids Prednisone 30-60 mg PO qd for 1-2 and taper over 10 days Sulfasalazine 500 mg PO b.i.d. with prednisone taper
Traumatic	Joint aspiration for toxic effusion Red, hot, compressive situation Orthopedic follow-up as needed	
Prosthetic	Conservative therapy Red, hot, compressive situation	
Infectious	Indomethacin 50 mg PO t.i.d. with taper for other symptoms NSAID High-dose NSAID for 10	

TABLE 220.2. Treatment of Monoarticular Arthritis

In any event, clinical improvement should occur within 48 hours. Patients should be treated for a total of 7 days, but oral therapy may be substituted once symptoms have resolved. All patients with presumed gonococcal arthritis should also be tested for concurrent chlamydial infection and syphilis and treated with doxycycline or tetracycline. All patients with a sexually transmitted disease should be counseled regarding the use of condoms and referred for HIV testing.

Patient comfort may be increased by immobilizing involved patients in the position of function, but passive range of motion exercises should be instituted as early as possible to avoid the development of adhesive capsulitis. Arthrocentesis is usually performed daily until the joint is no longer tense.

Nongonococcal Bacterial Arthritis

Nongonococcal septic arthritis represents a true emergency. Antibiotics should be started in the emergency department. Antibiotic selection depends on the findings on Gram stain of the synovial fluid, or on the organism that is suspected to be responsible based on such factors as a history of parenteral drug use, the patient's age, the presence of a prosthetic joint, and the history of a puncture wound. After blood cultures and joint cultures are obtained, empiric antibiotic therapy is most safely begun with a penicillin-resistant synthetic penicillin (e.g., nafcillin) and a third-generation cephalosporin. Vancomycin plus either an intravenous fluoroquinolone or an antipseudomonal aminoglycoside is appropriate therapy for patients who are suspected of having infection with methicillin-resistant *S. aureus* (MRSA), such as those with prosthetic joints. Rifampin may provide synergistic benefit.

All patients with nongonococcal arthritis must be admitted to the hospital. Orthopedic consultation is highly advisable, because certain joints, such as the shoulder and hip, may require arthrotomy and open drainage. While joints such as the knee and wrist are often treated with daily aspiration, formal arthrotomy or arthroscopic drainage may provide better results in certain circumstances.⁹ Intraarticular antibiotics may cause a chemical synovitis and should not be given.¹⁶ Infected prosthetic joints require orthopedic consultation for possible removal of the prosthesis.

Crystal-Induced Arthritis

Colchicine has been used for acute gout for decades. It complexes with microtubules to inhibit leukocyte function, blunting the intraarticular inflammatory response. The therapeutic effect of colchicine is reasonably specific for gout and pseudogout, but it may also work in sarcoid arthropathy. It is most effective when administered early in an attack. The usual dose is 0.5 to 0.6 mg orally every 30 to 60 minutes until joint pain resolves or gastrointestinal (GI) side effects supervene, but no more than 4 to 6 mg should be given in a 24-hour period. Side effects include abdominal pain, nausea, vomiting, and diarrhea, and occur in up to 80% of patients who receive the full therapeutic dose.²⁰

GI side effects are minimized with intravenous administration, which often yields very dramatic results, aborting painful attacks within 20 to 30 minutes, with minimal GI side effects. A single intravenous dose of 1 to 2 mg can be given over 10 minutes in a free-flowing intravenous line to prevent chemical thrombophlebitis. There

have been several deaths secondary to inappropriately large doses of intravenous colchicine in compromised patients, but it remains a safe and effective drug when used as directed. Colchicine should not be given to patients with leukopenia or to those with underlying liver or kidney disease. Patients who receive a full loading dose of colchicine (either intravenous or oral) in the emergency department should not take any additional colchicine for the next 7 days.

Nonsteroidal antiinflammatory drugs (NSAIDs) have substantially replaced colchicine as the primary treatment of acute gout.³ Side effects include GI irritation and azotemia and, occasionally, central nervous system (CNS) side effects such as confusion or lethargy, particularly in the elderly. Relative contraindications include peptic ulcer disease, gastritis, and renal insufficiency. Indomethacin is the most widely used agent to treat acute gout, but other nonsteroidal drugs may be equally effective.

Corticosteroids (parenteral, oral, or intraarticular) are useful in patients who are not candidates for NSAIDs or colchicine, or in those who fail to respond to other drugs. Oral prednisone is often given in a dose of 40 mg/d for 5 days, with a subsequent taper. Before using intraarticular corticosteroids, the emergency physician must be extremely confident that the patient does not have an infectious arthritis.

Patients with an acute gouty attack should not receive the uricosuric agent probenecid or the xanthine oxidase inhibitor allopurinol, as these drugs can exacerbate the attack. They may be started 10 to 14 days later, after the acute attack has subsided.

Like gout, pseudogout may be managed with NSAIDs, colchicine, or intraarticular steroids. Most patients with crystal-induced arthritis can be treated at home with oral agents, but if the patient appears toxic or the synovial fluid white count is very high, admission is advisable. Although rare, septic arthritis can coexist with crystal-induced arthropathy, particularly pseudogout. Patients with inflammatory arthritis benefit from elevation and short-term splinting, and should follow up with their caregiver within several days. They must be instructed to return to the emergency department immediately for any worsening of symptoms.

COMMON PITFALLS

- Failing to obtain synovial fluid for analysis
- Believing that a normal complete blood count and the absence of fever rule out septic arthritis Assuming that acute symptoms in the setting of chronic arthritis are due to a rheumatic flare or gout rather than infection
- Forgetting that any sexually active person can develop gonococcal arthritis
- Ordering a serum uric acid level in the emergency department to confirm or exclude gout
- Prescribing additional colchicine in the first week following maximal colchicine loading in the emergency department
- Prescribing allopurinol or probenecid for a patient with an acute gouty attack

The emergency physician encounters polyarthritis in two contexts: the patient with joint pain that is as yet undiagnosed and the patient with complications of a known rheumatologic disease, most commonly rheumatoid arthritis (RA).

Many polyarthritis syndromes have a gradual onset and sometimes defy precise diagnosis, despite months of sophisticated workup ([Table 221.1](#)). Many symptoms of systemic lupus erythematosus (SLE), RA, and other collagen–vascular diseases are overlapping, and laboratory test results are often equivocal. Thus, a definitive diagnosis is not usually made on any single emergency department visit. This discussion focuses on those polyarthritides that typically have an acute presentation ([Table 221.2](#)).

Rheumatoid arthritis
Symmetric, additive involvement initially of small joints; morning stiffness; positive rheumatoid factor 75%
Systemic lupus erythematosus
Multiple organ system involvement; symmetric evanescent involvement of any joint; serologic autoreactivity (e.g., anti-DNA)
Osteoarthritis
Lower extremity involvement; Heberden nodes; lack of inflammatory signs
Ankylosing spondylitis
Insidious involvement of spine (occasionally hips and shoulders); uveitis in 25%; HLA-B27 positive 90%
Colitic arthritis
Large joints; parallels course of ulcerative colitis or regional enteritis
Psoriatic arthritis
Distal interphalangeal joint involvement; symmetric or asymmetric; skin disease begins first; 80% have pitting of nails

TABLE 221.1. Polyarthritic Syndromes

Acute rheumatic fever
Migratory polyarthritis; carditis; erythema marginatum; subcutaneous nodules; chorea
Gonococcal arthritis
Early tenosynovitis and diffuse arthralgia; common wrist involvement; characteristic rash
Lyme disease
Brief, recurrent; involves knees; preceded by characteristic rash (erythema chronicum migrans); cardiac and neurologic involvement
Reiter syndrome
Asymmetric involvement of lower extremities; urethritis; conjunctivitis; skin lesions
Viral arthritis
Symmetric involvement of fingers, wrists, and knees
Serum sickness
Migratory involvement of large and small joints; associated rash

TABLE 221.2. Acute Polyarticular Arthritis: Clinical Features

EMERGENCY DEPARTMENT EVALUATION

In an undiagnosed patient, sudden onset of joint pain (developing over several hours, rather than days) strongly suggests gout (almost always monoarticular) or infection. The most important joint disorder to diagnose accurately and early is infectious arthritis.

Symmetric joint involvement is seen in RA or SLE; asymmetric joint involvement is seen in the seronegative arthritides (e.g., Reiter syndrome). Migratory involvement (leaving one joint before involving another) is typical of acute rheumatic fever (ARF). A family history of arthritis supports a diagnosis of RA or one of the seronegative spondyloarthropathies. Thiazides are known to increase the serum uric acid level and may precipitate gout. Hydralazine, procainamide, isoniazid, and phenytoin can induce a lupus-like reaction.

Inflammation in the periarticular soft tissues (tendons, bursae) can cause swelling and limitation of motion, simulating joint disease. Arthritis usually limits both active and passive motion equally, whereas acute tendinitis or bursitis usually limits active motion significantly more than passive motion. Synovitis is indicative of joint inflammation, but usually results from chronic disease and does not necessarily indicate an acute flare of activity. A diagnosis of polyarthritis demands objective evidence of inflammation in at least two joints.

To assess the pattern of involvement and chronicity, all joints should be examined, not just those that are symptomatic. Several acute polyarthritides are associated with a characteristic rash. Subcutaneous nodules are seen in 35% of patients with RA (2% to 3% of those with ARF). Psoriatic arthritis is usually associated with characteristic pitting of the nails, as well as the typical papulosquamous rash. A general physical examination may note such important findings as a pleural effusion in SLE or RA, or clinical signs of liver inflammation in the arthritis associated with hepatitis. A pelvic examination should be performed on all women with unexplained arthritis to rule out *Neisseria gonorrhoeae*. Generalized lymphadenopathy or oral thrush may suggest the human immunodeficiency virus (HIV).

For either the previously undiagnosed patient or the patient with diagnosed disease and a new acute complaint, the most important laboratory test is examination of the joint fluid. Specific diagnostic tests (e.g., antinuclear antibody, rheumatoid factor, HIV, hepatitis screen) are seldom available on an emergency basis. They should be ordered, however, in appropriate patients for use in subsequent evaluation. The erythrocyte sedimentation rate (ESR) can be elevated in any inflammatory condition and is of little help in the differential diagnosis, but it may be useful to monitor the activity of a chronic arthritis.

Radiographs help little in evaluating the patient with nontraumatic joint pain. Radiographically visible inflammatory changes (such as symmetric erosions of the wrist and metacarpophalangeal joints in RA) occur late in the course of disease, and a normal radiograph does not rule out a diagnosis of arthritis. The main use of

radiographs in the emergency department is to exclude complications in patients with chronic arthritis.

Rheumatoid Arthritis

The most commonly encountered etiology of chronic poly- arthritis is RA, characterized by symmetric joint inflammation, constitutional symptoms, and, in some cases, extraarticular organ involvement. The disorder ranges in severity from a mild nonprogressive arthritis to a fulminant, sometimes fatal illness, with destruction of joints and serious systemic and organ system involvement.

The onset of RA may be acute or insidious. Inflammation in multiple joints in almost any combination may be present, although symmetric involvement of the hands, wrists, and feet is most common. RA virtually never affects the thoracic or lumbar spine. Systemic manifestations include malaise, anorexia, fever, myalgia, weight loss, and Raynaud phenomenon. In some patients, especially those with high titers of rheumatoid factor and more severe joint disease, there is specific organ involvement, most commonly of the lungs and heart.

The diagnosis of RA is based largely on observation of the clinical course over a period of months to years. Rheumatoid factor, although not a specific marker for RA, is present in the serum of 75% to 80% of patients. Clinical criteria for review include morning stiffness, patterns of joint involvement, and rheumatoid nodules.

Acute Rheumatic Fever

Although the incidence of ARF has dramatically declined over the past 40 years, recent reports have described episodic outbreaks. The diagnosis of ARF requires fulfillment of the modified Jones criteria ([Table 221.3](#)).

Major Criteria	Minor Criteria
Carditis	History of acute rheumatic fever
Polyarthritis	Fever
Chorea	Arthralgia
Erythema marginatum	Elevated sedimentation rate
Subcutaneous nodules	Prolonged PR interval

The diagnosis of acute rheumatic fever requires two of the major criteria and one of the minor criteria, or one of the major criteria and two of the minor criteria plus evidence of recent group A streptococcal pharyngitis (positive culture or increased ASO titer).

TABLE 221.3. Modified Jones Criteria for Diagnosis of Acute Rheumatic Fever

Arthritis, the most common finding in ARF, is seen in more than 75% of first attacks. It is typically migratory and most often affects the large joints of the lower extremities, but rarely the hips, hands, or feet.

Carditis, seen in 40% to 50% of acute cases, is the most serious finding. The diagnosis of carditis requires one of the following: new organic heart murmur (usually mitral regurgitation), cardiomegaly, pericarditis, or congestive heart failure. A recent report found echocardiographic evidence of mitral regurgitation in many patients with no clinical evidence of carditis.

Chorea occurs in 5% of cases. It develops several months after streptococcal infection and is characterized by involuntary movements that cease with sleep.

Erythema marginatum (5% of cases) begins as a macule that extends outward, with central clearing. It may resemble erythema chronicum migrans, the rash of Lyme disease (LD). It is not painful or pruritic. It usually fades within hours but may recur.

Subcutaneous nodules, seen in less than 10% of patients, are firm, painless, and of variable size (2 to 10 mm). They are most commonly seen over the extensor joint surfaces.

The diagnosis of ARF requires laboratory confirmation of recent group A streptococcal pharyngitis. An elevated antistreptolysin-O (ASO) titer is seen in most patients.

Gonococcal Arthritis

Gonococcal arthritis (GA) is the most common bacterial arthritis among healthy young people. Disseminated gonococcal infection (DGI) is characterized by a clinical triad: dermatitis, tenosynovitis, and migratory polyarthritis. Joint involvement is predominantly asymmetric, often affecting the knee, elbow, wrist, and ankle. HIV patients are infected in unusual joints (hip and sternoclavicular) and may present with a more aggressive course.

A painless, nonpruritic skin rash is seen in roughly 50% of patients. *N. gonorrhoeae* is cultured in only half of affected joints. One is significantly more likely to obtain a positive culture from the mucosal surface of initial infectious contact (throat, cervix, urethra, or rectum). Polymerase chain reaction (PCR) may be useful in identifying gonococcal infection from a joint that is culture-negative.

Lyme Disease

LD is caused by the spirochete *Borrelia burgdorferi*, which is transmitted by the bite of the deer tick *Ixodes*. A characteristic rash, erythema chronicum migrans, develops in 60% of patients. It starts as a single red macule that expands to form a large annular lesion with a red outer border and central clearing. Two weeks to 2 years after the initial skin lesion, 60% of patients develop an acute arthritis, typically asymmetric and oligo- or monoarticular, involving large joints, most commonly the knee. About 10% of patients develop cardiac abnormalities, most often atrioventricular (AV) block. Although cardiac involvement is transient, some patients require temporary pacemakers. About 10% of patients develop significant neurologic abnormalities, including meningitis, encephalitis, and cranial neuropathies.

Reiter Syndrome

Reiter syndrome may occur as a reactive arthritis in young, often human leukocyte antigen (HLA) B-27–positive men. It classically presents as a triad: nongonococcal urethritis, asymmetric polyarthritis, and conjunctivitis. The arthritis is usually acute in onset, involving the large joints of the lower extremities, particularly the knees and ankles. Urethritis usually precedes the development of arthritis, although it is commonly asymptomatic; it may be suggested only by the finding of white blood cells on microscopic examination of a first-voided, morning urine. Conjunctivitis occurs in 30% of patients, and iritis in 10%. Two distinctive skin lesions are occasionally seen. Keratoderma blennorrhagica (15% of patients), scaling lesions on the palms and soles that begin as erythematous macules, may progress to lesions indistinguishable from those of psoriasis. Circinate balanitis (25% of patients) produces painless superficial ulcers of the glans penis. Reiter syndrome is usually associated with a fever and may be confused with GA. The synovial fluid is inflammatory but sterile, although chlamydial antigen has been detected in joint fluid in some cases.

Viral Arthritis/Postinfection Arthritis

Transient arthritis has been associated with viral infection, the two best documented being hepatitis B and rubella. The arthritis of hepatitis B is believed to be due to the deposition of circulating immune complexes in affected joints. It typically occurs during the prodrome of the illness, before the appearance of clinical jaundice. Liver enzymes are usually elevated, and HBsAg or anti-HBc may be positive. The most common presentation is that of a migratory symmetric arthritis potentially

involving the small joints of the hand, wrist, elbow, and ankle. It can be painful, with prominent morning stiffness, but seldom lasts more than 3 weeks.

Both natural and vaccine-induced rubella are associated with an asymmetric polyarthritis involving the large joints (knees, elbows, and ankles). It typically appears after the rash, is characterized as painful, with significant morning stiffness, and lasts 5 to 10 days.

Polyarthritis syndromes have also been described in association with enteric infections (*Yersinia*, *Shigella*, *Salmonella*, *Clostridium difficile*) and respiratory infection (mycoplasma).

Serum Sickness

Serum sickness, typically occurring 6 to 10 days after an antigenic stimulus, presents with the abrupt onset of fever, lymphadenopathy, and migratory arthralgia. Urticaria or angioedema may also develop. Less frequently, it is accompanied by glomerulonephritis, carditis, aseptic meningitis, or peripheral neuropathy. A more severe reaction tends to result after subsequent exposure to the same antigen. Penicillin is, by far, the most commonly implicated causal agent, but many other drugs have been implicated as well.

AIDS Arthritis

Several polyarthritic syndromes have been described in association with HIV infection. A painful, asymmetric, oligoarticular arthritis affecting the knees and ankles has been widely reported. Also seen are seronegative spondyloarthritis (particularly Reiter syndrome and psoriatic arthritis) and lupus-like syndromes. These polyarthritides may occur at any stage of HIV infection and have been reported to develop months or years before the actual diagnosis of HIV. Etretinate has been used to treat AIDS-related Reiter disease.

EMERGENCY DEPARTMENT MANAGEMENT

The mainstay of treatment for polyarthritis is nonsteroidal antiinflammatory drugs (NSAIDs). These agents control both pain and inflammation. A common mistake is to prematurely conclude that a drug is ineffective or to advance too rapidly to more potent agents, such as corticosteroids. Even if one NSAID fails to control symptoms, another in a different class may work well.

Recent research into the etiology of the inflammatory process has revealed that two enzymes, cyclooxygenase 1 and 2 (COX-1, COX-2), are fundamental. Aside from being a mediator of inflammation, COX-1 plays a cytoprotective role in the gastrointestinal (GI) tract. Typical NSAIDs inhibit COX-1 and thus place the GI tract at risk for erosive damage. COX-2 is also instrumental in the inflammatory process but has not been demonstrated to be cytoprotective to the GI tract. Recently developed COX-2 blocking agents thus appear to have a lower likelihood of causing gastric erosions while inhibiting the inflammatory process.

Several disorders, however, require more specific treatment. Patients with a first attack of ARF should be hospitalized and closely monitored for worsening carditis and arrhythmias, the most common of which is first-degree AV block. High-dose salicylates are used for arthritis. Steroids are reserved for patients with significant carditis. A course of penicillin is recommended to eradicate any remaining streptococci, and the patient should be kept on low-dose penicillin prophylaxis indefinitely thereafter.

Most patients with gonococcal arthritis should be hospitalized. Therapy is initiated with a parenteral third-generation cephalosporin, or spectinomycin if there is a history of a major allergic reaction to penicillin. Repeated joint aspirations may be required. In most cases, dramatic clinical improvement is noted in 2 to 4 days, and oral antibiotics may then be substituted for a total of 7 days of therapy. Most patients should be treated at the same time for chlamydia with doxycycline or azithromycin, or with erythromycin if the patient is pregnant.

LD is generally treated with doxycycline. Advanced cases may require treatment with ceftriaxone. Reiter syndrome, once diagnosed, is incurable, but treatment of the initial urethritis may prevent development of the full-blown disease. Arthritic inflammation is treated symptomatically.

RA that does not respond satisfactorily to NSAIDs may be treated with “disease-modifying agents,” which include antimalarials, gold salts, penicillamine, methotrexate, cytotoxic agents, and prednisone.

Complications of Rheumatoid Arthritis

RA, the most common and most serious of the chronic poly-arthritides, may be associated with a number of emergent complications ([Table 221.4](#)). In addition to suffering direct complications of the disease, patients are also subject to the potential toxic effects of treatment. The emergency physician must be aware of the potential for acute problems in patients with well-established RA.

Organ	Manifestations
Neurologic	Subluxation C-1, C-2 (cord compression); entrapment neuropathy (carpal tunnel); peripheral neuropathy; myositis; necrotizing vasculitis (central nervous system)
Musculoskeletal	Septic arthritis; tendon rupture; synovial cyst knee (pseudophibitis); rheumatoid nodules
Larynx	Cricoarytenoid arthritis (airway)
Lung	Pleurisy; effusion; fibrosis
Cardiac	Pericarditis; tamponade; conduction defects; valvular (nodules); myocardial infarction (coronary arteritis)
Hematologic	Anemia; leukopenia; hyperviscosity; Felty syndrome (splenomegaly, neutropenia)
Ocular	Sjögren syndrome; episcleritis; scleritis
Blood vessels	Vasculitis (usually dermal, can be widespread)

TABLE 221.4. Complications of Rheumatoid Arthritis

Radiographic abnormalities of the cervical spine are common, especially with subluxation of C-1 on C-2. Usually, these abnormalities are asymptomatic, but the appearance of neurologic symptoms or signs necessitates immediate neurosurgical consultation. Patients may note a peculiar slipping sensation with neck movements that is associated with either exacerbation or relief of symptoms. Flexion and extension views of the cervical spine aid in the diagnosis. A patient with RA who sustains even minor cervical trauma should have careful examination of the neck; similarly, the potential for cervical spine instability should be considered when intubating a patient with chronic RA.

Various entrapment neuropathies occur in RA; carpal tunnel syndrome is the most common. Patients initially complain of sensory changes over the distribution of the median nerve and a “toothache-like” pain at the wrist. Tinel sign, the induction of a tingling sensation in the same distribution upon tapping over the median nerve with a reflex hammer, is a useful physical finding. The diagnosis is confirmed with electromyography and nerve conduction studies. Treatment consists of splinting the wrist and arranging consultation with a rheumatologist or orthopedist. Local corticosteroid injection is occasionally performed; surgical release of median nerve entrapment is sometimes necessary. Generalized muscle wasting, weakness, and peripheral neuropathy in RA patients may also be manifestations of systemic vasculitis.

Rupture of the extensor tendons of the hand is not uncommon in advanced RA. Once one tendon ruptures, the increased strain on the remaining tendons may lead to rupture of others. Patients cannot extend the fingers actively at the metacarpophalangeal joints, but passive extension is still possible. The treatment is elective surgical repair.

The development of a synovial cyst behind the knee is common in RA. Synovial inflammation may result in large knee effusions, and high pressure generated during flexion of the knee may cause cyst formation in the popliteal fossa. These cysts may rupture, dissecting into the calf, or may obstruct venous return. Because the

resulting calf pain, swelling, and redness may be confused with thrombophlebitis, venography is usually required to rule out deep vein thrombosis. A careful history may reveal that the patient noted a fullness in the popliteal area that diminished a few days before the development of calf symptoms. The diagnosis is confirmed by an arthrogram of the knee joint. Ultrasonography may be helpful, but is less accurate. Treatment involves joint aspiration and local corticosteroid injection.

The cricoarytenoid joint is a synovial articulation and can be involved in RA. Patients may present with stridor and significant airway obstruction or, with less severe involvement, with dyspnea, dysphagia, painful speech, foreign-body sensation, or hoarseness. There may be tenderness over the thyroid cartilage. Indirect laryngoscopy reveals redness and edema over the arytenoids and abnormal bowing of the vocal cords during inspiration. Intubation may be difficult, and cricothyrotomy or tracheostomy is often necessary to secure the airway. Local or systemic corticosteroids and cool humidification are useful for milder cases. Extubation has been associated with acute airway obstruction.

The most common type of vasculitis associated with RA involves small dermal vessels, causing relatively benign infarctions in the periungual areas of the fingers. Occasionally, patients develop a necrotizing vasculitis, which can follow a fulminant course; the presenting manifestations may be large ulcerations, digital gangrene, neuropathies, mesenteric ischemia, or coronary arteritis. Patients with systemic vasculitis usually have fever, leukocytosis, high titers of rheumatoid factor, an elevated ESR, and antinuclear antibodies. They should be admitted to the hospital for initiation of high-dose corticosteroids. At times, cytotoxic agents or apheresis is useful. The prognosis in patients with extensive vasculitic involvement is poor.

Sjögren syndrome (keratoconjunctivitis sicca), which is not uncommonly associated with RA, is characterized by dry eyes and dry mouth and is caused by decreased lacrimal and salivary gland function. Patients complain of grittiness in the eyes and thick mucus beneath the eyelids. The diagnosis is made by the Schirmer test, which measures tear production, or by noting filamentous keratitis on slit-lamp examination. Treatment consists of the use of artificial tears, humidified air, and eye goggles to minimize tear evaporation.

Episcleritis, also associated with RA, is usually benign, but should be followed by an ophthalmologist because it can lead to scleritis. A brief course of topical corticosteroids, prescribed by an ophthalmologist, is usually beneficial.

With scleritis, which is a more diffuse process that can lead to uveitis, glaucoma, and rupture of the globe, patients complain of a deep aching sensation and have tenderness on gentle palpation of the globe. Slit-lamp examination reveals a cellular exudate in the anterior chamber. Prompt ophthalmologic consultation is indicated.

Hematologic problems, including anemia, leukopenia, and hyperviscosity occur in RA. Felty syndrome (the triad of RA, splenomegaly, and neutropenia) is associated with severe disease. These patients are prone to recurrent infections and usually have hepatic dysfunction and recurring cutaneous ulcers; splenectomy is occasionally beneficial.

Pleurisy and pleural effusions are common in RA but are not usually life-threatening. Pericarditis is also common, but only rarely does pericardial tamponade or constrictive pericarditis occur. Rheumatoid nodules may affect the heart valves or cardiac conduction system. Myocardial infarction secondary to vasculitis involving the coronary arteries has been reported.

COMMON PITFALLS

- Failure to analyze synovial fluid in a patient with undiagnosed arthritis or in one with new joint tenderness, warmth, and swelling
- Failure to recognize an acute septic joint in a patient with underlying polyarthritis
- Failure to recognize rheumatic fever and initiate appropriate therapy to prevent cardiac damage
- Failure to recognize symptoms due to therapy rather than to underlying disease
- Failure to appreciate extraarticular manifestations of chronic polyarthritis
- Failure to consider underlying HIV infection in a person with a newly diagnosed, seronegative spondyloarthropathy or lupus-like syndrome

Patients with multisystem autoimmune disorders may present for initial medical evaluation with a bewildering array of symptoms or complaints. Many of the tests needed to diagnose these “rheumatic disorders” cannot be performed during an emergency department visit. However, the emergency physician must recognize that an autoimmune disorder may be responsible for the patient's clinical picture and must decide which patients require admission and which can safely undergo an outpatient evaluation. Likewise, when a patient with known multisystem autoimmune disease presents to the emergency department with new symptoms, the physician must determine whether they represent an exacerbation of known disease, a manifestation of an unrelated disorder, or a complication of therapy.

Evolving therapies and variations in individual response to treatments make rheumatologic consultation appropriate in many cases. Although the ultimate cause of the autoimmune disorders remains a mystery, it is increasingly clear that specific autoantibodies directed against cellular components are markers for, and probable causes of, many of the manifestations. Positive tests for these antibodies not only correlate with current symptoms, but are also predictive of the patient's course. The use of these specific disease markers can improve accuracy in diagnosis and can guide therapy directed at specific pathologic entities.

Despite the fact that definitive therapies for most autoimmune disorders are lacking, there is often much that can be done to alleviate symptoms and prevent progression of tissue damage. Nevertheless, every pharmacologic treatment has a potential for toxicity that must be balanced against the potential benefit it may provide to the patient.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is the prototypical autoimmune disease. Its prevalence is one in 2,000, with a 10:1 predominance of women over men and a predilection for non-Whites. The prevalence is one in 750 for Black women between the ages of 20 and 64. ⁶

The cause of SLE remains unknown; hormonal, metabolic, genetic, environmental, and infectious factors have all been proposed as etiologic agents. The pathophysiology of SLE involves the production of autoantibodies initiated by an unknown stimulus. These antibodies react with cell constituents and initiate an inflammatory response that results in the fixing of complement and the elaboration of chemotactic factors and other inflammatory mediators. Antibody-dependent cytotoxic leukocytes are also activated.

Antinuclear antibodies (ANAs) are almost invariably detected in patients with SLE. Although ANAs are found in low titers in many other autoimmune and nonrheumatologic disorders, high titers are more specific for SLE; high titers of antibodies to double-stranded DNA are seen only in patients with SLE. ¹⁶ Antibodies to the Smith antigen are also specific for SLE, as well as being associated with more severe symptoms. During active SLE, complement levels are depressed and may be helpful in following the course of disease. ⁶

CLINICAL PRESENTATION

SLE can affect any tissue or organ and, in fact, has been said to have replaced syphilis as “the great imitator” of other diseases. ⁶ Patients often make multiple visits to physicians before SLE is initially recognized. Some of the more common manifestations are listed in [Table 222.1](#).

System	Presentation
Constitutional	Fever, fatigue, malaise, weight loss
Vascular	Raynaud's phenomenon, arterial occlusion, extremity ulcers
Dermatologic	Diffuse alopecia, malar rash, discoid rash, photosensitivity
Hematologic	Hemolytic anemia, leukopenia, thrombocytopenia, thrombosis
Immunologic	False-positive serologic test for syphilis
Gastrointestinal	Nausea, vomiting, oral ulcers
Cardiac	Pericarditis, myocarditis
Pulmonary	Diffuse interstitial pneumonitis, pleuritis, pleural effusion
Musculoskeletal	Nonerosive arthritis
Renal	Glomerulonephritis, nephrotic syndrome
Reproductive	Spontaneous abortion, preeclampsia
Neurologic	Psychosis, depression, mania, seizures, headache, organic brain syndrome, aseptic meningitis, peripheral neuropathy

TABLE 222.1. Systemic Lupus Erythematosus: Characteristic Features and Suggestive Signs and Symptoms

The most typical initial complaints are fatigue and arthralgias, but fever, anemia, anorexia, and a malar rash are other common presenting symptoms. The arthralgias are commonly fleeting and migratory, typically appearing in the proximal interphalangeal and metacarpophalangeal joints, the wrists, and the knees, but they may also be due to frank synovial inflammation.

The rash of SLE varies from a slight blush to a well-demarcated and somewhat edematous maculopapular erythematous eruption covering both cheeks and the bridge

of the nose. It tends to spare the nasolabial folds, but can cause scarring and atrophy of skin structures. It is characteristically exacerbated by sun exposure and may often cause a patient to seek medical attention before any other symptoms of SLE have developed.

Although the kidneys are commonly affected in SLE, nephrotic syndrome and peripheral edema are rarely seen before other manifestations of disease have led to the diagnosis of SLE.¹² Patients with SLE frequently present with acute, potentially life-threatening problems. Complaints of chest pain, abdominal pain, and neurologic dysfunction can indicate an acute flare of disease or a serious complication of therapy. Patients with acute chest pain, with or without fever, may have pleuritis, pericarditis, or pneumonitis. Abdominal pain may indicate an acute flare of polyserositis.

Neurologic problems of virtually any type may be seen in SLE. Most common are central disorders ranging from mood disorders to frank psychosis. Seizures are also common, especially in younger patients. SLE should be in the differential diagnosis of new-onset seizures, especially in young women.

The lupus anticoagulant, also called the anticardiolipin antibody or antiphospholipid antibody, is an antibody that produces an artifactually prolonged partial thromboplastin time *in vitro*, but a "paradoxical" procoagulant effect *in vivo*. Although antiphospholipid antibodies are associated with SLE, they may occur as a part of a distinct pathologic entity referred to as the antiphospholipid syndrome.^{1,8} Both conditions can lead to deep venous thrombi, pulmonary emboli, stroke, chronic ulcers of the extremities, and thrombocytopenia.^{1,8} Patients with recurrent or unusual thrombosis should be evaluated for antiphospholipid autoantibody and SLE.¹³

Patients with *known* SLE may present to the emergency department with either exacerbations of their disease or complications of therapy.

DIFFERENTIAL DIAGNOSIS AND EMERGENCY DEPARTMENT EVALUATION

Given the variety of possible presentations, the differential diagnosis of SLE is exceedingly broad. A thorough history and physical examination are required to identify multisystem involvement and recurrent symptoms. The differentiation of SLE from the other autoimmune syndromes may require repeated rheumatologic evaluation and specific autoantibody testing.

Tan and associates²⁰ have published a list of 11 criteria diagnostic for SLE (Table 222.2); the diagnosis is established if four or more of these findings are present serially or simultaneously. A medication history must be elicited to rule out drug-induced lupus. Attention to detail in evaluating the patient with nonspecific symptoms may lead one to suspect the diagnosis of SLE. The diagnosis should be particularly entertained in women of childbearing age who have recurrent or vague symptoms that do not clearly point to a discrete disease entity.

1. Malar rash	Fixed erythema, flat or raised, over the malar eminences
2. Discoid rash	Erythematous raised patches with adherent keratotic plugging; atrophic scarring may occur
3. Photosensitivity	
4. Oral ulcers	Includes oral and nasopharyngeal, observed by physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	Pleuritis or pericarditis documented by electrocardiogram or rub or evidence of pericardial effusion
7. Renal disorder	Proteinuria greater than 0.5 g/d or greater than 3+, or cellular casts
8. Neurologic disorder	Seizures without other cause, or psychosis without other cause
9. Hematologic disorder	Hemolytic anemia or leukopenia (less than 4,000/ μ L) or thrombocytopenia (less than 100,000/ μ L) in the absence of offending drugs
10. Immunologic disorder	Positive lupus erythematosus cell preparation or anti-dsDNA or anti-Sm antibodies or false-positive VDRL
11. Antinuclear antibodies	An abnormal titer of ANAs by immunofluorescence or an equivalent assay at any point in time in the absence of drugs known to induce ANAs

^a If four of these criteria are present at any time during the course of disease, a diagnosis of SLE can be made with 95% specificity and 95% sensitivity.

TABLE 222.2. Diagnostic Criteria for Systemic Lupus Erythematosus^a.

Drug-induced SLE is a distinct entity that has been associated with many medications, including procainamide, hydralazine, anticonvulsants, chlorpromazine, isoniazid, methyl dopa, penicillamine, quinidine, propylthiouracil, and sulfasalazine. Drug-induced SLE has a milder course than idiopathic SLE and does not cause renal and central nervous system involvement.¹⁸ Specialized ANA testing panels reveal only histone-binding ANAs rather than the multiple varieties characteristic of SLE.⁶

The evaluation of patients with established SLE should focus on the presenting complaint. However, attention should also be given to signs and symptoms of the potentially life-threatening complications of SLE, such as thrombotic disease, pleural and pericardial effusions, and infections secondary to immunosuppressive therapy.

Patients presenting with new-onset monoarthritis or oligoarthritis generally require diagnostic arthrocentesis to rule out infection or crystal-induced arthritis. Fluid should be sent for Gram stain, culture, cell count and differential, and examination for crystals. The synovial fluid in autoimmune arthritis is typically inflammatory, with an elevated white cell count (20,000 to 80,000/ μ L mixed polymorphonuclear cells and lymphocytes), a negative Gram stain, and no crystals.

The specific organs affected by SLE and the severity of the disease vary widely between individuals and over time in any given individual. Not only does the variability of the disease make diagnosis difficult but, with the exception of the characteristic rash, each of the manifestations of lupus may occur from other causes. Although a presentation of one of these conditions alone would not prompt consideration for autoimmune disease, recurrent symptoms or the sequential development of multiple conditions associated with lupus warrants referral for ANA testing.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

The specific clinical presentation dictates the management indicated in the emergency department. Patients presenting with mild symptoms may require nothing more than screening for renal and hematologic involvement with a urinalysis and complete blood cell count. More severe symptoms are managed as in any other disease. For example, a large pleural effusion should be tapped, and heparin should be given for thromboembolic disease.

ST elevations and PR depressions seen on the electrocardiogram that are associated with a pericardial friction rub indicate pericarditis. If pericarditis is suspected, a careful evaluation should be made for signs of pericardial tamponade. Elevated neck veins, elevated pulsus paradoxus, or hypotension should prompt an urgent echocardiogram to rule out tamponade. Infectious complications should be considered in patients with established disease who are taking chronic immunosuppressive medications.

Patients with significant pleural or pericardial effusion, or any thrombotic complication, require hospital admission and rheumatologic consultation. Immunosuppressed patients with documented infection require admission for parenteral antibiotics.

Neuropsychiatric complications are frequent in SLE. Cerebritis, aseptic meningitis, seizures, ischemic strokes, peripheral neuropathy, and acute psychosis are all recognized manifestations of SLE. In addition, corticosteroid treatment and other immunosuppressive agents predispose to infectious meningitis and corticosteroid-induced psychosis.

The acute presentation of an SLE patient with a neuropsychiatric complaint is always a challenge. The diagnosis of lupus flare should be made only after infectious etiologies have been ruled out. Patients presenting with severe disease are often treated with "stress" doses of corticosteroids (hydrocortisone, 100 mg intravenously; or methylprednisolone, 125 mg intravenously) and often receive empiric broad-spectrum antibiotic coverage after samples of blood, urine, and sputum are obtained for culture.

Patients with established disease who present with a flare of symptoms may require the initiation of corticosteroids or an increase in the dose. When more than 5 to 10 mg of prednisone a day is required, many rheumatologists prescribe combination therapy in an effort to limit adverse effects. Medications commonly used include

nonsteroidal antiinflammatory drugs (NSAIDs), antimalarial agents, azathioprine, and cyclophosphamide. Because every therapeutic agent has adverse effects, the risks of medication must be weighed against the morbidity of the clinical presentation. The aggressiveness and urgency of treatment depends on the presence of major organ involvement. Changes in a patient's usual medication regimen are best carried out in conjunction with the patient's rheumatologist.

Patients with suspected or newly diagnosed SLE may be managed as outpatients if the manifestations are mild and a life-threatening pathologic process is absent. An ANA panel should be ordered. Rheumatologic consultation can be obtained by telephone concerning any further studies, initiation of corticosteroid therapy, and appropriate follow-up. Newly diagnosed patients with SLE should be educated about the importance of adequate sleep and avoidance of ultraviolet light. Ibuprofen and estrogens may exacerbate disease and should be avoided.¹² Hypertension should be controlled rigorously because it appears to have a synergistic effect in exacerbating renal disease. In drug-induced lupus, after the medication is discontinued, symptoms usually resolve within days to weeks.^{9,18}

COMMON PITFALLS

- Failure to recognize vague, atypical complaints as a presentation of SLE or other autoimmune disease
- Failure to include SLE in the differential diagnosis of patients with pericarditis, pleuritis, renal dysfunction, neurologic symptoms, or recurrent venous thrombosis
- Failure to differentiate disease exacerbation from an adverse effect of therapy
- Failure to suspect infection in an immunocompromised patient

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic autoimmune disorder characterized by widespread synovial inflammation and, often, progressive destruction of joints. It affects women three times as often as men; its prevalence increases with age and is approximately 1%.

The pathophysiology of RA involves the production of immunoglobulins against native IgG; these are referred to as rheumatoid factor. Helper T cells are also activated and produce lymphokines that promote cellular proliferation.¹⁵ Activation of the inflammatory response leads to the elaboration of vasoactive substances, chemotactic factors, and complement in synovial tissues. Mononuclear cells infiltrate the subsynovial stroma, and polymorphonuclear cells appear in the synovial fluid. A "pannus" of inflamed, thickened, redundant synovium invades and replaces cartilage and periarticular bone and tendon. Polymorphonuclear cells in the synovial fluid release lysozymes, which break down hyaluronic acid polymers in the synovial fluid and articular cartilage.⁶ Although the symptoms and signs are primarily related to the joints, RA is a multisystem autoimmune disease that frequently involves the heart, lungs, and blood.

CLINICAL PRESENTATION

RA typically presents initially as constitutional symptoms such as low-grade fever, weight loss, fatigue, and lymphadenopathy. Stiffness in the morning or after periods of inactivity may also be a complaint.

Articular symptoms initially involve any number or size of joints. Either arthralgia (pain) or arthritis (inflammation) may be present in an unpredictable pattern. Later, in established disease, the typical symmetric pattern of arthritis develops.

The most commonly affected joints are the metacarpophalangeal and proximal interphalangeal joints, wrists, knees, and upper spine. Although some cases of RA remain mild or even resolve, the typical course is one of unpredictable exacerbations and remissions, with progressive deformity and disability.

As tissue damage progresses, typical ulnar deviation of the carpometacarpal joints and valgus deformity of the knees develop. Baker cysts may develop in the popliteal fossa. Of prime importance for the emergency physician is the development of instability of the atlantoaxial joint, with laxity and even rupture of the transverse ligament. The result is an unstable cervical spine, which may lead to spinal cord compression following even apparently trivial injury.¹³

RA, however, is a systemic disease. Over time, subcutaneous nodules over the elbows, occiput, and sacrum, thought to be vasculitic in origin, develop in 20% to 25% of patients. Pericarditis, pleuritis, pulmonary fibrosis, scleritis, Sjögren syndrome, nerve entrapment, and vasculitis may also occur. Felty syndrome, consisting of splenomegaly, anemia, thrombocytopenia, and granulocytopenia, sometimes complicates RA.

DIFFERENTIAL DIAGNOSIS AND EMERGENCY DEPARTMENT EVALUATION

RA is rarely misdiagnosed when it reaches the stage of symmetric polyarthritis in characteristic joints. At earlier stages, or with milder involvement, the clinical picture may be suggestive of inflammatory or infectious joint disease or other autoimmune diseases. When joint manifestations become apparent, infectious and crystalline synovitis must be considered.

In practice, most patients presenting to the emergency department with oligoarthropathy should have joint aspiration to rule out infection or crystal-induced arthritis. Although RA or another autoimmune disorder may be suspected, the definitive diagnosis is made at follow-up, when further data, such as final culture results, rheumatoid factor tests, and response to antiinflammatory therapy, are available.

The American Rheumatism Association has developed a set of seven criteria, four of which must be present to establish the diagnosis ([Table 222.3](#)).² In practice, most such patients presenting to the emergency department must have other significant disease ruled out (e.g., infectious arthritis, SLE); and although there may be a suspicion of RA, the definitive diagnosis is usually made on further evaluation at follow-up.

1. Morning stiffness ^a
2. Arthritis of three or more joints ^a
3. Swelling of proximal interphalangeal, metacarpophalangeal, or wrist joint ^a
4. Symmetric arthritis ^a
5. Rheumatoid nodules
6. Presence of rheumatoid factor
7. Erosions or periarticular osteopenia in radiographs of hands or wrists

^aDuration of at least 6 weeks required.

TABLE 222.3. Criteria for the Diagnosis of Rheumatoid Arthritis

Patients with known RA who present with an exacerbation of joint inflammation require evaluation for possible secondary infections or crystalline arthropathy. Others may present with new systemic symptoms. Although the problem may be related to RA, this should not be assumed to be the case until other serious causes have been excluded. Evaluation based on presentation should be pursued as in any patient without RA. Special consideration should be given to complications of therapy; for example, pulmonary interstitial disease may be a result of either RA or treatment.

If a diagnosis of RA is considered, a rheumatoid factor titer should be ordered. If other autoimmune disorders are considered possible, other autoantibody titers, complement levels, and an erythrocyte sedimentation rate (ESR) may be indicated. Monoarticular or oligoarticular arthritis should cause one to consider crystalline and infectious arthritis. Joint aspiration is indicated, as well as oropharyngeal and genital cultures for *Neisseria gonorrhoeae*.

Few laboratory tests results are abnormal in RA, and, in general, the results tend to be nonspecific. The ESR is elevated and parallels disease activity. There may be

a mild normocytic anemia. A test for mixed cryoglobulins, reflecting large amounts of circulating immune complexes, may be positive, but complement levels are usually normal. Arthrocentesis of involved joints typically yields sterile fluid with hallmarks of inflammation: decreased mucin clot formation and 20,000 to 80,000 white blood cells per microliter, of which 50% to 70% are polymorphonuclear cells.³ The classic laboratory finding of a positive serum rheumatoid factor is found in 80% of patients, but a positive rheumatoid factor can also be found in 1% to 5% of persons without RA (e.g., patients with other rheumatic disorders, leprosy, tuberculosis, liver disease, or bacterial endocarditis).

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

NSAIDs are the mainstay of chronic treatment of RA. Patients experiencing a flare of known disease often require second-line therapy in addition to NSAIDs. These include heat modalities, antimalarial agents, sulfasalazine, gold salts, D-penicillamine, azathioprine, cyclophosphamide, chlorambucil, methotrexate, and surgical replacement of joints.

Corticosteroids are usually reserved for the treatment of extraarticular manifestations. Each of the therapeutic agents has associated adverse effects. Sulfasalazine may cause leukopenia. Gold salts and D-penicillamine have renal and myeloid toxicity. Gold may also cause a pruritic rash and mouth ulcers. The antineoplastic agents can all cause myelosuppression and a host of other adverse effects.⁵ Second-line agents should be initiated only after discussion with a rheumatologist who will be observing the patient.

Appropriate disposition depends on the severity of the presenting symptoms. Outpatient treatment is appropriate in individuals who do not appear toxic, even those with a new diagnosis of RA. These patients should be started on a standard dose of an NSAID and have rheumatologic follow-up arranged. Patients who appear ill require hospital admission for more intensive evaluation, particularly to rule out infectious disorders, and rheumatologic consultation. Hospitalization may be required for social reasons or if disability prevents adequate functioning at home.

COMMON PITFALLS

- Prescribing corticosteroids as a first-line therapy for RA
- Failure to recognize nonspecific complaints as a manifestation of autoimmune disease
- Failure to recognize a monoarticular flare of RA as a possible septic joint
- Failure to consider the possible severity of cervical spine trauma in an RA patient
- Failure to consider possible C1-C2 instability when intubating an RA patient

SCLERODERMA

Scleroderma (or systemic sclerosis) is an autoimmune disorder characterized by abnormal collagen production that results in pathologic fibrosis of the skin and internal organs. It occurs equally in all races and geographic areas, but it is four times more common in women than in men. In most cases, the onset is during the third decade of life.¹⁷ The course is typically progressive over decades, but it may be fulminant and fatal. Collagen accumulation and endothelial cell proliferation in the vascular intima lead to severe narrowing of the arterial lumen.

Scleroderma can be classified according to its predominant manifestations. The CREST syndrome consists of subcutaneous calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia and is associated with a specific antibody.^{14,19} "Diffuse scleroderma" denotes the full systemic disease. A third subset is mixed connective-tissue disease or undifferentiated connective-tissue disorder, which combines features of SLE, scleroderma, and polymyositis.⁴ Clinical criteria have been developed for the diagnosis of systemic sclerosis ([Table 222.4](#)).

MAJOR CRITERION	
Proximal scleroderma	Typical sclerodermatous skin changes involving areas proximal to the metacarpophalangeal or metatarsophalangeal joints, affecting other parts of the extremities, face, neck, or trunk, usually bilateral, symmetric, and almost always including similar changes in the digits
MINOR CRITERIA	
Sclerodactyly	Sclerodermatous skin changes limited to the digits
Digital pitting, scars, or loss of substance from the finger pad	Depressed areas at the tips of digits or loss of digital pad substance from the finger pad tissue as a result of digital ischemia rather than trauma or exogenous causes
Bibasilar pulmonary fibrosis	Bilateral reticular patterns of linear or interlobular densities that are most pronounced in basilar portions of the lungs on standard chest roentgenograms, may assume appearance of diffuse mottling or "honeycombing lung," and should not be attributable to primary lung disease

Classification as definite systemic sclerosis requires the presence of (1) the major criterion or (2) two or three of the minor criteria.

TABLE 222.4. Clinical Criteria for the Diagnosis of Systemic Sclerosis

CLINICAL PRESENTATION

Patients with scleroderma most commonly present to the emergency department because of painful fingers due to Raynaud's phenomenon, dyspnea due to restrictive lung disease, or dysphagia due to esophageal dysfunction. Malignant hypertension due to scleroderma renal disease is a true emergency.

Raynaud's phenomenon is present in virtually all cases of scleroderma and is the initial manifestation in 70% of cases. Skin involvement is usually first manifested as edema of the fingers. As the disease progresses, the skin becomes shiny and taut, with loss of the normal skin folds. Joints become immobilized from tight encasement in thickened skin, as well as from contractures of muscles, tendons, and palmar fascia.

DIFFERENTIAL DIAGNOSIS AND EMERGENCY DEPARTMENT EVALUATION

Established scleroderma causes a characteristic taut, smooth appearance of the hands and face. This sign should be apparent to the physician, although the patient may not have noticed the gradual changes.

Early disease may be difficult to recognize, however. The most common early symptom is painful fingers due to Raynaud's phenomenon, but this is a nonspecific feature of many autoimmune disorders that may also be due to occlusive arterial disease, repetitive trauma to the fingers, cryoglobulinemia, neurogenic lesions, or vasospastic drugs. In fact, Raynaud's phenomenon unassociated with scleroderma is extremely common in women. Specific autoantibody testing may distinguish early cases of scleroderma from other causes of Raynaud's phenomenon. Radiography of the hand may also be helpful. Subcutaneous calcinosis and resorption of the tufts of the distal phalanges are pathognomonic findings. More than 90% of patients with scleroderma have a positive ANA test.

An awareness of the systemic manifestations of disease is important in the evaluation of the patient with known scleroderma. Systemic collagen deposition may result in cardiac conduction abnormalities or cardiomyopathy, restrictive lung disease and pulmonary hypertension, gastrointestinal dysmotility and malabsorption, and renal arteriolar necrosis leading to malignant hypertension. Recognition of these manifestations in patients with advanced illness is critical.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

The majority of patients with Raynaud's syndrome do not have symptoms requiring treatment in an emergency department. Patients with persistent vasospasm may, however, respond to simple interventions, such as warming of the hands or oral administration of nifedipine. Only rarely are more invasive maneuvers, such as interarterial or local phenoxylbenzamine or prazosin, required.

Systemic manifestations may require evaluation for dysfunction caused by scarring in many organ systems. Intestinal hypomotility may be treated with metoclopramide. Esophageal reflux should be treated with antireflux maneuvers and medications, as necessary. Patients with increased blood pressure, renal failure, and internal organ involvement are frequently treated with angiotensin converting enzyme inhibitors.

Most patients with scleroderma do not require hospitalization, but admission may be necessary for dehydration due to gastrointestinal dysfunction or for pulmonary compromise. Patients with hypertensive emergency due to renal crisis should be placed on nitroprusside and admitted to an intensive care unit.

Only those women with severe Raynaud's phenomenon and those men without a history of trauma to the hands require periodic monitoring for the development of scleroderma. Patients should be instructed in the importance of keeping the hands warm and avoiding nicotine and caffeine. Suppressing pharmacologic therapy may be necessary if attacks are frequent.

Patients with signs and symptoms beyond Raynaud's phenomenon should be referred for diagnostic autoantibody testing, occupational therapy, or orthopedics.

COMMON PITFALLS

- Failure to consider the systemic manifestations of scleroderma
- Failure to recognize scleroderma as the cause of a hypertensive emergency

GIANT-CELL ARTERITIS

Giant-cell arteritis is characterized by inflammation of branches of the carotid artery (temporal arteritis) or the aortic arch (Takayasu's arteritis), and can present with emergent manifestations.

CLINICAL PRESENTATION

Temporal arteritis usually occurs in women over 50 years of age. Symptoms may be nonspecific: fever, headache, myalgias, and fatigue. Patients may have the syndrome of polymyalgia rheumatica, manifested by chronic stiffness and aching of the neck, shoulder, and hip girdle. However, chronic or subacute headache is often the presenting complaint.

The temporal artery may be tender and nodular,⁷ and there may be jaw claudication. The chief complication of temporal arteritis is monocular visual loss due to ischemic optic neuritis. Visual loss or impairment generally occurs 3 or 4 months after onset of initial symptoms.¹⁰

Takayasu's arteritis has a predilection for involvement of branches of the aortic arch. It is a rare disease. Patients are usually young women who present with nonspecific symptoms of fever, night sweats, fatigue, myalgias, and weakness. Signs of large vessel occlusion with decreased peripheral pulses, cerebrovascular accidents, or myocardial ischemia occur only months to years after initial presentation.¹¹

DIFFERENTIAL DIAGNOSIS AND EMERGENCY DEPARTMENT EVALUATION

The differential diagnosis of patients with temporal arteritis is wide because of the nonspecific symptoms. Mild anemia is typical. A markedly elevated ESR in a patient over 50, with headache and nonspecific symptoms, particularly polymyalgia rheumatica, should prompt further evaluation.

Takayasu's arteritis, although rare, should be considered in any young female patient with signs of large vessel ischemia (e.g., cerebrovascular accident, upper extremity ischemia, cardiac ischemia).

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Patients with suspected temporal arteritis rarely need admission to the hospital. However, prompt diagnosis and treatment is essential in order to prevent visual impairment. In the emergency department, patients should be started on 40 to 60 mg of prednisone daily. Arrangements should be made for definite follow-up and semiurgent temporal artery biopsy. Response to corticosteroid treatment is usually dramatic, with relief of systemic symptoms and headaches within days. Treatment is generally continued for 1 to 2 years.

The diagnosis of Takayasu's arteritis is not usually made in the emergency department. The diagnosis should be entertained in young women who need admission for large vessel occlusive disease. Angiography of the affected vessels shows narrowing or occlusion of large vessels, with well-developed collateral circulation.²¹ No treatment has been proven effective, but corticosteroids and cyclophosphamide have been used.

COMMON PITFALLS

Failure to initiate corticosteroid therapy in the emergency department in a patient suspected of having temporal arteritis

DERMATOMYOSITIS AND POLYMYOSITIS

Dermatomyositis and polymyositis are inflammatory disorders of skeletal muscle, characterized by weakness in the muscles of the pharynx, neck, shoulder, and hip. Women are affected twice as often as men. There is a bimodal peak of incidence: in the early teen years and around age 50. Infection with toxoplasmosis and coxsackievirus has been implicated. Ten percent of cases of polymyositis and 15% of those of dermatomyositis are associated with malignant tumors, most commonly of the breast, lung, ovary, and stomach.

CLINICAL PRESENTATION

An insidious onset of muscular weakness may bring patients to the emergency department. Careful questioning for specific dysfunction typically reveals a history of proximal muscle weakness. Patients complain of difficulty getting out of a chair, climbing stairs, combing the hair, and raising their heads from the pillow.

Dermatomyositis presents as a characteristic rash consisting of heliotrope (violet) plaques over the eyelids and knuckles. Muscle wasting becomes evident later in the course, and dysphagia and dysarthria may develop. Interstitial lung disease may develop as an associated manifestation.

DIFFERENTIAL DIAGNOSIS AND EMERGENCY EVALUATION

The differential diagnosis includes many causes of muscular weakness: polymyalgia rheumatica, fibrositis, muscular dystrophy, myasthenia gravis, thyroid disease, metabolic defects, and corticosteroid myopathy.

Evaluation centers on differentiating the type of muscle process involved. Patients with polymyositis have elevated levels of creatine phosphokinase, myoglobin, and transaminases, whereas enzyme levels are normal in polymyalgia rheumatica and fibrositis. The ESR may be elevated but does not correlate with clinical disease severity. Autoantibodies are detectable in 90% of patients; tests for ANA and extractable nuclear antigen should be ordered. Although there is an association of these disorders with malignancy, the search for a tumor is rarely productive. Unless the clinical evaluation discloses signs and symptoms of a specific tumor, further evaluation in the emergency department is not necessary.

A referral for electromyography may reveal characteristic changes. A muscle biopsy in an area with abnormal electromyographic activity confirms the diagnosis.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

The treatment of choice for polymyositis unrelated to malignancy is corticosteroids. Prednisone, 60 to 100 mg/d, is used initially. The dose is tapered when the enzyme levels have returned to normal. Azathioprine is used as a second-line agent. Because this drug has severe immunosuppressive, gastrointestinal, and neoplastic adverse effects, it should be given only under the direction of the rheumatologist who will be observing the patient. If an associated tumor is found, symptoms of polymyositis often resolve after resection.

Patients able to carry out activities of daily living can usually be managed as outpatients. Patients with an unstable gait or who are unable to navigate stairs in their homes require hospital admission.

COMMON PITFALLS

- Considering weakness a normal senile change
- Considering only endocrine and electrolyte imbalances as causes of weakness
- Confusing disease exacerbation with corticosteroid myopathy

Papulosquamous lesions are characterized by papules and scaly desquamation of the skin. The lesions may also be macular and erythematous. Diseases in this group include psoriasis, seborrheic dermatitis, pityriasis rosea, lichen planus, and secondary syphilis. Other diseases that may be part of the differential diagnosis include tinea, discoid lupus erythematosus, mixed connective-tissue diseases, and scabies. Papulosquamous eruptions are the most common cutaneous manifestations of human immunodeficiency virus (HIV) infection, and their appearance may be the first clue of HIV infection in an otherwise asymptomatic host.¹ In addition, a large number of drugs are known to cause papulosquamous eruptions.

When evaluating a papulosquamous eruption in the emergency department, the physician should look for clues to help differentiate the possible etiologies. Is the rash disseminated or localized? Does it appear on specific areas of the body, such as the elbows, knees, scalp, palms, soles, web spaces, or sun-exposed areas? Is it a well-margined, ring-shaped, or isolated lesion (herald patch)? Are the papules pruritic or purple? Answering these basic questions and using the algorithm in [Fig. 223.1](#), most papulosquamous diseases are diagnosed without dermatologic consultation.

Figure 223.1. Algorithm for papulosquamous diseases. (From Flowers FP, Krusinski PA. *Dermatology in ambulatory and emergency medicine*. Chicago, Year Book Medical, 1984.)

PSORIASIS

Psoriasis, the most common papulosquamous dermatosis, is found in 1% to 2% of the general population.⁵ It is equally distributed between males and females, but is more common in Whites than in Blacks. Although it is more common during the second and third decades, it may manifest itself at any age. The etiology of psoriasis is not known, although genetic predisposition appears to play an important role.¹¹ There is a family history of psoriasis in one-third of those affected. Psoriasis may also have a neuroimmunologic etiology.⁴ Three factors that are implicated as disease triggers are psychological stress, skin injury and infection.⁶

CLINICAL PRESENTATION

Psoriatic lesions are characterized by well-delineated, salmon-colored papules that are soon covered by silvery-white scales ([Fig. 223.2](#)). They involve both the dermis and epidermis; the depth of involvement depends on their age and location. As the lesions age, the epidermal layer thins, exposing underlying capillary beds. These capillary beds may bleed when the overlying keratotic epidermis is sheared away by mechanical force. This phenomenon, known as the Auspitz sign, is diagnostic of psoriasis. Common sites for psoriasis are the scalp, extensor surfaces of the extremities, presacral region, palms, soles, and nails. Arthritis is seen in 5% to 7% of patients with psoriasis, and nail abnormalities are seen in up to 50% of patients.⁶ The nails are commonly pitted and show a brownish or whitish discoloration and an accumulation of scale on the nail bed.

Figure 223.2. Well-defined erythematous, scaling plaques on the extensor surface of the arm in a patient with psoriasis.

Pustular psoriasis is characterized by erythematous areas covered with pustules. It may be localized or general, and may affect the hands and feet in addition to the trunk and extremities. Generalized pustular psoriasis has an acute onset associated with malaise, pyrexia, and leukocytosis, and it is potentially fatal if untreated. Factors known to induce generalized pustular psoriasis include a tapering of the dose of systemic corticosteroids, withdrawal of potent topical steroids, nonsteroidal antiinflammatory agents, pregnancy, viral upper respiratory tract infections, and beta-hemolytic streptococcal infections.⁶

Guttate psoriasis usually follows streptococcal infections; lesions appear on the trunk and extremities.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of psoriasis includes tinea cruris, candidiasis, secondary syphilis, pityriasis rosea, cutaneous lupus erythematosus, and seborrheic dermatitis,⁵ as well as intertrigo when the eruption occurs in the intertriginous areas. Seborrheic dermatitis may resemble psoriasis of the scalp, but usually has finer and more widespread yellow scaling. A helpful clue in differentiating psoriasis from other conditions is the presence of psoriatic nail changes: pitting of the nails and separation of the nail from the underlying nail bed.⁵ Guttate psoriasis on the trunk is easily confused with pityriasis rosea.

EMERGENCY DEPARTMENT MANAGEMENT

Psoriasis is a chronic disease that waxes and wanes, often for no apparent reason. Minor cases may respond to lubricants and emollients, exposure to sunlight, and avoidance of stress. More commonly, crude tar 2% and tar paints such as Zetar, which are added to bath water, are needed. Ultraviolet light exposure, in conjunction with topical tar application, is often effective, even in severe cases.

Large, thick lesions on the trunk and extremities may be treated with a fluorinated corticosteroid ointment. Hydrocortisone 1% is not strong enough to treat these lesions, but it may be used to treat lesions in the intertriginous areas, where striae and atrophy occur, with stronger preparations.¹⁶ Newer treatments include calcipotriene ointment, anthralin ointment, and tazarotene gel.⁵ Methotrexate has been used in severe cases of psoriasis, but up to a third of patients develop liver toxicity. In PUVA therapy, psoralen (P) is combined with long-wavelength ultraviolet light (UVA) to interfere with the DNA synthesis of psoriatic lesions. This treatment should be performed only in a hospital or physician's office. Immunotherapeutic agents (e.g., cyclosporine) and drugs approved for other indications, such as zidovudine, may also be initiated by a dermatologist.⁸ Pustular psoriasis requires systemic antibiotics (e.g., penicillin 500 mg four times a day for 10 days) and a topical antibiotic steroid ointment. Often, pustular psoriasis is difficult to treat, and methotrexate, retinoids, hydroxyurea, and other antimetabolites may be required for severe cases.⁹ Guttate psoriasis is usually self-limited but may be helped by coal tar or steroid preparations.

DISPOSITION

Psoriasis is rarely dangerous or life-threatening and is usually best cared for by a dermatologist who can follow the patient over time. Topical steroids or coal tar may be initiated in the emergency department, but treatment with UVA or methotrexate should be performed under the direction of a dermatologist, usually in the hospital. The patient who appears toxic should be admitted for intravenous antibiotics.

COMMON PITFALLS

- Psoriasis of the trunk and extremities is rarely confused with other diseases, but in the intertriginous areas, it may be confused with tinea cruris, candidiasis, or intertrigo. Close examination with a Wood's light and potassium hydroxide (KOH) preparation should help differentiate these diseases.
- If steroids are used to treat psoriasis, systemic steroids should be avoided. They are very effective but can cause long-term side effects, and the disease often rebounds when steroids are stopped.
- New cases of psoriasis; sudden, severe exacerbations; or cases recalcitrant to treatment should alert the clinician to the possibility of HIV infection.¹

PITYRIASIS ROSEA

Pityriasis rosea is an acute, self-limited, inflammatory dermatosis seen most commonly in children and young adults, although it can appear at any age.⁷ It affects both sexes equally and accounts for about 1% of patients seen by dermatologists.¹² The incidence is lowest during the summer.⁷ The etiology is unknown, although it is presumed to be related to a viral infection.⁶

CLINICAL PRESENTATION

Pityriasis rosea is characterized by oval, salmon-colored, pruritic, scaling patches on the neck and trunk that follow skin cleavage lines ([Fig. 223.3](#)). On the back, this produces a so-called Christmas tree pattern. The rash is rarely found on the palms and soles,¹⁶ and it may involve the oral mucosa and gingiva.¹⁷ Characteristically, this generalized eruption is preceded by a 2- to 5-cm herald patch, but it is absent in 10% to 15% of patients. Within 7 to 14 days, other lesions appear, which, in young children, may involve the face, scalp, and distal extremities.⁹ An atypical presentation (inverse pityriasis rosea) spares the trunk, only affecting the face and extremities.⁶ The rash usually lasts 4 to 7 weeks.

Figure 223.3. Circular and ovoid papules and plaques with scaling on the trunk and proximal extremities in a patient with pityriasis rosea.

The most common complaints associated with pityriasis rosea are pruritus and mild constitutional symptoms such as malaise, fever, and lymphadenopathy. It poses no risk to the fetus if it occurs in pregnant women. It does not appear to be contagious.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes tinea corporis when there are a few lesions, and secondary lues when there are many (although luetic lesions tend to be less pruritic). The herald patch is commonly misdiagnosed as ringworm. A KOH preparation of scrapings from the lesions is negative, however. Examination of tinea corporis with a Wood's light produces a bright green fluorescence, but no fluorescence is seen with pityriasis rosea. Guttate psoriasis, which is distributed mainly on the trunk, has thicker, more silvery scales than does pityriasis rosea. Lichen planus may have a similar appearance, but the lesions are purple, not salmon-colored. Eruptions resembling pityriasis rosea may be caused by gold, bismuth, methopromazine, metronidazole, captopril, barbiturates, nonsteroidal antiinflammatories, and clonidine.⁷ Because the skin eruption of secondary syphilis may mimic that of pityriasis, a VDRL or rapid plasma reagin (RPR) should be drawn.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Pityriasis is a benign, self-limited disease that does not require therapy. Symptomatic treatment for pruritus may include antihistamines and intermediate-strength topical steroids. UVA may accelerate resolution of the lesions.

If the diagnosis is made with certainty, consultation with a dermatologist is unnecessary. The patient may be discharged to follow-up with the family physician. If the diagnosis is in question, the patient should be referred to a dermatologist.

COMMON PITFALLS

- Pityriasis rosea is often misdiagnosed. The herald patch can resemble tinea corporis and may be incorrectly treated with antifungal medication until the generalized rash appears. Later, the generalized rash may be mistaken for lichen planus or a drug eruption. A careful history and physical examination decrease the likelihood of these errors. The wise clinician draws a VDRL or RPR to rule out “the great masquerader.”

LICHEN PLANUS

Lichen planus is a relatively uncommon inflammatory dermatitis characterized by violaceous, flat-topped papules. The disease is most common between ages 30 and 60 and is seen with equal frequency in men and women. It is responsible for about 1% of visits to dermatologists.⁷ Viral and bacterial agents, as well as genetic predisposition,¹⁵ have been suggested as causes. Drugs have also been implicated in causing a lichen planus–like eruption ([Table 223.1](#)).²

Beta blockers	Captopril
Methyldopa	Thiazides
Furosemide	Gold
Antimalarials	Quinidine
Oral hypoglycemic agents	Phenytoin
Carbamazepine	Antituberculous agents
Antihistamines	Phenylbutazone
Antipsychotics	Bismuth
p-Aminosalicylic acid	Lithium

TABLE 223.1. Drugs Causing Lichenoid Drug Reactions

CLINICAL PRESENTATION

The lesions of lichen planus are flat-topped, slightly scaly, polygonal, and purple, with a fine reticular pattern of white dots and lines on their surface ([Fig. 223.4](#)). They are commonly found on the wrist, volar surface of the forearms, and pretibial areas, but may also appear on the palms, soles, lips, and penis. On the palms and soles, they are commonly yellowish and nonpruritic. The lesions commonly develop at sites of trauma (Koebner phenomenon). For this reason, they are often found in a linear pattern, presumably due to scratching. Over half of patients with cutaneous lichen planus have oral mucosal lesions as well. These are whitish plaques with a lacy, whitish, reticular pattern (Wickham striae).

Figure 223.4. Gray to violaceous flat-topped papules (some with Wickham striae) on the flexural surface of the forearm in a patient with lichen planus.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of lichen planus includes psoriasis, fungal infection, secondary syphilis, pityriasis rosea, and discoid lupus erythematosus. When the mucous membranes are involved, leukoplakia and candidiasis are considerations.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Lichen planus is a self-limited disease that may last weeks to years. Most patients experience a spontaneous resolution within a year. A few cases of squamous cell carcinoma have been reported in association with oral lichen planus. Treatment includes antihistamines for pruritus and topical steroids for inflammatory lesions. Occasionally, with widespread lesions, systemic steroids may be used. Patients with lichen planus should be referred to a dermatologist for long-term follow-up, although treatment may be initiated in the emergency department.

COMMON PITFALLS

- Lichen planus frequently involves the oral mucosa; in fact, 15% to 25% of patients with oral lichen planus never develop skin lesions. It is also one of the few rashes that may affect the palms and soles. A close physical examination, not only of the obvious lesions on the arms and trunk, but also of the mouth, palms, and soles, is important in making the correct diagnosis.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a chronic, superficial, inflammatory process affecting regions of the body with increased sebaceous gland activity. It is more common in males, and occurs in infants under 12 months, among adolescents, and in elderly persons. It is more severe in winter. It is particularly common in patients with HIV infection. The etiology is unclear, but it may be caused by dysfunctional sebaceous gland activity⁷ or a reaction to the common skin yeasts *Malassezia ovalis*¹⁴ and *Pityrosporum ovale*.³

CLINICAL PRESENTATION

The lesions of “oily” seborrheic dermatitis are characterized by poorly defined margins, mild erythema, and greasy yellow scales. “Dry” seborrheic dermatitis exhibits small, dry, powdery scales and little or no erythema.³ Secondary lesions due to scratching may be seen around the primary lesions. Areas commonly affected include the scalp, face (especially the eyebrows and nasolabial folds), axilla, groin, buttocks, and inframammary folds. In infants, the scalp is frequently affected and is known as cradle cap. When the scalp is affected in adults, it is called dandruff.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes psoriasis, tinea, and atopic dermatitis in children. Lesions affecting the scalp, axilla, and groin may be difficult to differentiate from psoriasis.¹² Involvement of the knees, elbows, and nails favors psoriasis. Persistent pruritic lesions that do not respond to therapy may be tinea. In infants, seborrheic dermatitis is commonly seen on the scalp, axilla, and diaper area. Lesions on the forearms and shins favor atopic dermatitis.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Antiseborrheic shampoos containing sulfur, salicylic acid, coal tar, or selenium sulfide provide adequate therapy for most patients. They should be used daily and rubbed into the scalp, with a 5- to 10-minute wait before rinsing. Involvement of the face or intertriginous regions may be treated topically with hydrocortisone 1% to 2% or another nonfluorinated corticosteroid twice daily. The use of 2% ketoconazole cream has been reported to provide satisfactory relief of this chronic dermatitis.¹⁰ Patients with seborrheic dermatitis may be treated on an outpatient basis by the emergency physician, and then referred to a dermatologist or the patient's family physician. The possibility of HIV infection should be considered.

COMMON PITFALLS

- Seborrheic dermatitis is often misdiagnosed. It occurs in infancy as cradle cap and usually does not appear again until puberty. It is associated with an oily complexion and is often precipitated by fatigue or stress.

SECONDARY SYPHILIS

Syphilis is a sexually transmitted infectious disease caused by *Treponema pallidum*. The rash of secondary syphilis appears 9 to 90 days after the onset of the chancre; the average is 3 weeks.¹³ Most individuals contract the disease from sexual activity with a person in the early stages of syphilis. The risk of transmission ranges from 10% to 60%, and approximately one-third of individuals with a single exposure to early syphilis become infected.¹³

CLINICAL PRESENTATION

The rash of secondary syphilis is generalized, painless, and nonpruritic. It involves the skin as well as the mucous membranes in 30% to 50% of the cases.¹³ On the skin, it tends to follow the lines of cleavage, especially on the trunk. It has a special predilection for the palms and soles. The lesions are scaling, red-brown papules and plaques that are discrete and sharply demarcated rather than confluent (Fig. 223.5). Annular plaques on the mouth, nose, and lip areas are virtually diagnostic.¹⁶ The patient's presenting complaint may be an apparently unrelated other symptom, such as headache, sore throat, malaise, and generalized arthralgia.

Figure 223.5. Diffuse erythematous papules and plaques with scaling in a patient with the rash of secondary syphilis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of secondary syphilis includes pityriasis rosea, Rocky Mountain spotted fever, meningococcemia, drug reaction, and lichen planus. Palmar lesions that mimic secondary syphilis may be secondary to drug eruption.¹⁶

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Diagnostic studies such as VDRL or RPR should be ordered. Dark-field examination of scrapings from lesions may also be performed. If either test is positive, the patient is treated in the emergency department with either benzathine penicillin G (2.4 million units intramuscularly) or aqueous procaine penicillin G (600,000 units intramuscularly daily for 8 days). Patients allergic to penicillin may be treated with tetracycline or doxycycline for 2 weeks.

If the diagnosis of secondary syphilis cannot be made in the emergency department, the patient should be referred to a private physician or clinic pending the results of VDRL or RPR testing. Hospital admission is unnecessary for secondary syphilis, but the patient should be instructed to abstain from sexual contact until the diagnosis is clear and any necessary treatment has been administered, and to refer all sexual partners to testing and treatment, as indicated.

COMMON PITFALLS

- Failing to elicit a history of a primary lesion preceding the rash. This history and an adequate sexual history are helpful in the initial diagnosis.
- Failing to appreciate the typical erythematous, hyperpigmented, scaly papules on the palms and soles may lead to an inappropriate diagnosis
- Because of the strong association of HIV and syphilis, patients newly diagnosed with syphilis should be referred for HIV testing. ¹³

ACKNOWLEDGMENT

The authors thank Howard Goldman, DO, Associate Professor of Dermatology at Philadelphia College of Osteopathic Medicine, for contributing the photographs used in this chapter.

[Common Pitfalls](#)
[Chapter References](#)

Vesicular lesions are commonly seen in the emergency department. Like other dermatologic lesions, vesicles can present a challenge in determining their etiology, contagiousness, and proper treatment.^{3,4,5 and 6}

Vesicles are circumscribed epidermal elevations 1 to 4 mm in diameter that usually contain clear fluid. Several characteristics help distinguish the lesion from other vesicular disorders, including the nature of the contained fluid (seropurulent, serosanguineous), the shape of the lesion's apex (rounded, acuminate, umbilicated), the pattern of the eruption (discrete, irregularly scattered, grouped, linear), and the distribution over the body and associated mucous membrane involvement.

In this discussion, there are two types of vesicular disorders: those appearing in groups and those that are individual or disseminated. Algorithms for each appear in [Fig. 224.1](#) and [Fig. 224.2](#).

Figure 224.1. Algorithm for vesiculobullous diseases. (From Flowers FP, Krusinski PA. *Dermatology in ambulatory and emergency medicine*. Chicago: Year Book Medical, 1984, with permission.)

Figure 224.2. Algorithm for vesicular dermatoses. (From Flowers FP, Krusinski PA. *Dermatology in ambulatory and emergency medicine*. Chicago: Year Book Medical, 1984, with permission.)

GROUPED LESIONS

Herpes Simplex

The lesions of herpes simplex are typically tightly clustered on an erythematous base and evolve into pustules and erosions over 5 to 7 days. Grouped, crusted erosions are the typical presentation. Associated symptoms may include fever, local pain, regional lymphadenopathy, fatigue, and malaise. Urinary retention occasionally occurs with genital lesions and generally requires hospital admission.

Primary lesions usually are not tightly clustered, but are more widespread with a bilateral distribution. Recurrent lesions more typically are tightly clustered, are unilateral, and occur in the same location as previous episodes of infection. Approximately 50% of patients with recurrent lesions have a 24-hour prodrome of local itching, burning, tingling, and stinging. Precipitating factors for recurrence appear to include upper respiratory infections, fever, sunburn, menstruation, trauma, or other stress.

Primary lesions usually resolve in 2 to 3 weeks, but the duration may be longer in immunocompromised patients. Typical sites of involvement are the oral, genital, and periorbital areas and the fingertips (herpetic whitlow). With periorbital lesions, fluorescein staining of the cornea is necessary to rule out herpetic keratitis. These patients should be referred to an ophthalmologist. A Tzanck smear or viral culture may be helpful in the diagnosis.

With the increasing incidence of the acquired immunodeficiency syndrome and the growing use of bone marrow and solid organ transplantation, more severe manifestations of herpes infections are being seen.⁸ Acyclovir is the most widely used antiviral agent in clinical use. Treatment with 200 mg of oral acyclovir five times per day for 10 days is indicated for primary genital herpes. However, the duration of symptoms is decreased only minimally with this therapy and only if started within 24 hours after onset of the rash. Time to crusting decreases from 2.7 days to 2.2 days. In immunocompromised patients, a dose of 400 mg is recommended. Other medications that are effective and available for treating herpetic infections are famciclovir, valacyclovir, and topical penciclovir 1% cream. The latter can minimally reduce average time to healing of recurrent orolabial herpes simplex virus infections by 0.7 days and the duration of pain by 0.6 days.¹⁰ Intravenous therapy (5 mg/kg every 8 hours) should be considered for patients with urinary retention, compromised immunity, or disseminated infection, which might be life-threatening. Topical viscous lidocaine preparations may be useful for short-term pain control of oral or genital lesions. All three oral agents have been shown to reduce the frequency of

symptomatic recurrences of genital herpes. Recommended doses are acyclovir 400 mg b.i.d., famciclovir 250 mg b.i.d., and valacyclovir 500 mg b.i.d. ¹¹ Importantly, patients receiving suppressive antiviral medication should be counseled that they may still transmit herpes simplex virus to their sexual partners.

Herpes Zoster

Herpes zoster (shingles) occurs in individuals with a history of chickenpox when varicella-zoster virus that is dormant in dorsal root ganglia is reactivated. Patients are most often older, with a peak age of 50 to 70 years. Thoracic and trigeminal nerve dermatomes are the most common sites of involvement, with tightly clustered lesions on an erythematous base present in a linear fashion distributed along one or two adjacent dermatomes. A prodrome of painful hyperesthesia is often described in the same dermatomes 5 to 7 days before the lesions appear. Resolution generally occurs within 3 weeks. The pain associated with herpes zoster is the principal reason that patients seek medical care. Traditionally, pain that is present while the rash persists or in the first 30 days from onset has been termed *acute pain*. Pain that is present after this period is generally termed *postherpetic neuralgia* and may persist for more than 6 months. The incidence of postherpetic neuralgia increases sharply with increasing age. Nearly half of patients older than 60 years have this complication. Postherpetic neuralgia is also more severe and persists longer in older patients than in younger individuals.

A metaanalysis found that acyclovir reduces pain duration and prevalence, especially in patients 50 years of age or older. ¹⁵ The treatment generally recommended is acyclovir 800 mg five times a day for 7 days. It is unclear whether treating longer with acyclovir or adding prednisolone is of added benefit. ^{13,14} Famciclovir 750 mg or valacyclovir 1,000 mg t.i.d. for 7 days has also been shown to decrease the median duration of postherpetic neuralgia. ^{2,12} Symptomatic treatment with Burow solution—soaked compresses three times a day is often helpful as well. Ophthalmologic consultation is indicated if the ophthalmic division of the trigeminal nerve is involved. Dissemination beyond the original dermatomes should raise the suspicion of immunodeficiency.

Hospital employees who are exposed to patients with herpes zoster should be tested for antibody to the varicella-zoster virus. Isolation for 8 to 21 days after exposure is recommended when antibody is not detected. If antibody is present, isolation is unnecessary. ⁹

Allergic Contact Dermatitis

Because allergic contact dermatitis is a result of delayed hypersensitivity, skin lesions may appear hours to days after exposure to the offending antigen, and it is often difficult to identify that antigen. Commonly identified etiologic agents include poison ivy, oak, and sumac; soaps; detergents; and perfumes. Pruritus is the initial symptom, which is quickly followed by erythema and vesiculation. Areas with a thin stratum corneum (such as eyelids and genitalia) may swell severely. Without treatment, symptoms may persist for 2 to 3 weeks.

Mild contact dermatitis may be treated with topical corticosteroids. For severe cases, oral prednisone (40 to 60 mg/d for 7 days) accelerates resolution of symptoms (usually within 24 to 48 hours) and poses minimal risks of adverse effects.

Fixed Drug Eruption

Like herpes simplex, fixed drug eruption causes recurrent episodes of skin lesions in one location. Unlike herpes simplex, however, fixed drug eruption generally leaves persistent slate-gray to brown hyperpigmentation after the attack resolves. The most commonly implicated drugs include phenolphthalein (e.g., Ex-Lax, Feen-a-Mint), tetracycline, sulfa, and barbiturates. Symptoms usually arise 1 to 2 days after ingestion. Pruritus generally occurs first, followed by the appearance of clusters of vesicles or bullae in a hyperpigmented macule. The process resolves in 2 to 3 weeks, after discontinuation of the offending agents.

Other Causes of Vesicular Eruptions

Dyshidrotic eczema (pompholyx) usually occurs on the medial and lateral aspects of the fingers and sometimes on the palms and soles. It is intensely pruritic and responds to topical corticosteroids. If severe, oral steroids can be used.

The vesicular eruption of tinea pedis may usually be diagnosed clinically by potassium hydroxide staining of vesicle fluid. Treatment is with a topical antifungal agent such as clotrimazole. Accompanying involvement of the hands is often an eczematous reaction.

Atopic dermatitis is generally accompanied by a personal or family history of eczema, allergic rhinitis, asthma, or urticaria. Nonetheless, the eruption is usually precipitated by physical irritation (wool gloves, soap and water) or emotional stress. Treatment with topical steroids is effective.

Dermatitis herpetiformis (unrelated to the herpes viruses) may be confused with scabies or neurotic excoriations. It generally presents with broken, excoriated vesicles on an erythematous base. It usually begins on extensor surfaces and is pruritic. Treatment is with dapsone and oral antihistamines.

INDIVIDUAL OR DISSEMINATED VESICLES

Varicella

Varicella (chickenpox) is not uncommon in adults. It presents with a polymorphic rash, predominantly on the trunk, consisting of vesicles, umbilicated pustules, and hemorrhagic crusts, which heal to leave atrophic scars. A key diagnostic feature is the simultaneous presence of lesions in all stages of development. It is often accompanied by a prodrome of fever, malaise, myalgia, and coryza, and there may be a clear history of exposure 10 to 14 days before the rash. Pruritus may be severe, and excoriations may be evident. The patient is considered contagious until all of the lesions have crusted over, generally 5 to 6 days after the first appearance of the eruption.

A Tzanck smear and viral culture may aid in making the diagnosis. Pneumonia and encephalitis are uncommon and rarely life-threatening complications. Patients who have pneumonia but no respiratory distress or significant comorbid disease can probably be safely treated as outpatients. ¹ Treatment is symptomatic, with oral antihistamines and tepid compresses.

Coxsackievirus and Echovirus Infections

Coxsackievirus and echovirus infections may cause papulo-vesicular lesions that are evenly spread across the face and torso. Associated symptoms may include fatigue, malaise, fever, vomiting, and diarrhea. Resolution occurs spontaneously in 10 to 14 days, and treatment is symptomatic.

Hand-foot-mouth disease caused by coxsackieviruses presents with tender, flat-topped, whitish vesicles 3 to 4 mm in diameter on the palms and soles and in the mouth. It is commonly associated with mild systemic complaints. The duration is generally 4 to 5 days, and no treatment is necessary.

Scabies

Scabies, an infestation by *Sarcoptes scabiei*, causes pruritus and a mild, disseminated, papulovesicular dermatitis that develops insidiously over several weeks. The pruritus typically worsens at night. Vesicles typically appear on the volar aspects of the wrists, the medial palms, and the interdigital web spaces, but they also may be seen on the areolae, glans penis, elbows, and axillary folds. The face and scalp are not affected in adults. Skin scrapings from the lesions may demonstrate mites, eggs, or feces. Burrows may be identified by applying ink to suspected areas and then wiping clean with alcohol; the burrows retain the color of the ink.

Treatment of scabies has two components. First, lindane (Kwell) solution is applied after bathing, allowed to remain on the skin for 8 to 12 hours, and then washed off. The patient is rendered noninfective 24 hours after treatment, but this procedure should be repeated after 1 week. Recurrence implies reinfection or, possibly, resistance to lindane. Because the incubation period may be 1 to 2 months, asymptomatic contacts and family members should be treated. Pregnant women should be treated with crotamiton (Eurax) twice a day for 2 to 3 weeks. The anthelmintic agent ivermectin, 200 µg/kg, has been found to be effective in treating scabies in both healthy and human immunodeficiency virus-positive individuals. ⁷

The second component of treatment is laundering of all clothes and bedding. Items that cannot be washed can be used safely after being set aside for 3 days, because the female mite dies after 2 to 3 days without human contact.

Insect Bites

Vesiculobullous skin lesions may occur as hypersensitivity reactions to insect bites, commonly those of fleas, bedbugs, and mites. A clue to the diagnosis is a linear or grouped pattern of lesions; some may have central puncta. Treatment is with topical corticosteroids and oral antihistamines, and avoidance of further contact with the insect.

COMMON PITFALLS

- Failure to instruct patients with contagious disorders, such as herpes simplex virus, about measures to prevent transmission to others
- Failure to admit patients with herpes who are immunocompromised or have urinary retention or disseminated infection
- Failure to consult an ophthalmologist if there is periorbital herpetic infection

CHAPTER 225 *Purpuric Eruptions*

Steven M. Joyce and Stephen C. Hartsell

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The term *purpura* (Latin, meaning “purple”) refers to any skin or mucous membrane eruption caused by bleeding into the skin. Purpura is a sign of underlying disease, usually a disorder of platelets or small vessels and only rarely of clotting factors. The cause of purpura varies, ranging from the trivial (e.g., actinic purpura in the elderly) to the life-threatening (e.g., thrombotic thrombocytopenic purpura) ([Table 225.1](#)).

TABLE 225.1. Disorders Causing Purpura

The lesions of purpura vary in size, consistency, and distribution. Lesions smaller than 3 mm are called *petechiae* and usually result from platelet or vascular abnormalities, whereas larger lesions are termed *ecchymoses* and generally are secondary to trauma or clotting disorders.⁷ Lesions vary from red to purple and do not blanch with pressure, because the lesions represent extravasated blood in the dermis rather than erythema due to dilated vessels. Lesions may be flat and nonpalpable when inflammation is absent (as in thrombocytopenic purpura) or palpable papules or macules when inflammation is present (as in septic embolic disease or vasculitis).⁸ Purpura may appear with a variety of other lesions, again depending on the underlying cause (e.g., immune-mediated vasculitis may progress from areas of urticaria to necrotic, confluent ecchymoses). The skin and mucous membrane lesions are the outward signs of a systemic process in most cases, and the effects of visceral bleeding, infection, and inflammation must be considered.

Purpura may occur in any age group, may be rapidly or slowly progressive, and may be accompanied by either few or many systemic manifestations.

In addition to various medical conditions, purpura may be caused by a variety of drugs, which can cause small vessel or platelet disorders by direct toxicity, inhibition of function, or immune-mediated mechanisms. Almost every class of drug has been implicated as a cause of purpura ([Table 225.2](#)).

TABLE 225.2. Common Drugs That May Cause Purpura

CLINICAL PRESENTATION

Patients with purpura present to the emergency department for a variety of reasons. Some patients may simply be concerned about the rash itself, whereas others present because of manifestations accompanying the rash (e.g., abnormal bleeding, easy bruising, or constitutional symptoms such as fever, malaise, and arthralgias). Less commonly, severe manifestations of the underlying illness, such as spontaneous bleeding or mental status changes due to intracranial hemorrhage or meningococcal meningitis, are the reason the patient presents to the emergency department.

Regardless of the appearance of the rash or associated symptoms and signs, the presence of spontaneous bleeding (“wet” purpura) is a grave diagnostic sign requiring immediate intervention.² Bleeding gums, epistaxis, intraocular hemorrhage, guaiac-positive stool, menorrhagia, or hematuria are all included in this category. The cause is usually thrombocytopenia.

The immediate threat to life is intracranial hemorrhage. Severe anemia and shock from blood loss are possible but not common. Patients without spontaneous bleeding (“dry” purpura) may have extensive petechiae or ecchymoses on the skin and mucous membranes, but are in less immediate danger. Spontaneous bleeding may develop at any time, so rapid determination of the cause is indicated.

Any patient presenting with purpura and mental status changes requires immediate evaluation for intracranial hemorrhage or central nervous system (CNS) infection. Empiric treatment (e.g., platelet transfusion or intravenous antibiotics) based on the presumptive diagnosis and preliminary laboratory results (complete blood count [CBC] with platelets, prothrombin time, partial thromboplastin time [PTT]) may be instituted during such evaluation.

DIFFERENTIAL DIAGNOSIS

The lesions of purpura are characteristic and difficult to mistake for other disorders. Some lesions appear purpuric but do not reflect an underlying illness. Normal bruising resulting from trauma is technically a form of ecchymosis. Purpuric lesions may be created by pressure or suction in normal skin. Examples include facial and conjunctival petechiae due to increased venous pressure (as with protracted vomiting or sneezing) or isolated ecchymosis from suction applied to the skin (as with “love bites” or electrocardiographic suction cups). These lesions are classified as mechanical or factitial purpura.^{5,6} Other erythematous rashes, such as viral

exanthems and urticaria, can be differentiated from purpura by their light red color and in that they blanch with pressure (because they represent hyperemia rather than extravasation of blood). Similarly, telangiectases and hemangiomas are discrete collections of abnormally dilated blood vessels that appear bright red and usually blanch with pressure. Diascopy, the use of a glass slide to apply pressure over a lesion, is a simple visual method to differentiate lesions due to vascular dilation (which blanch with pressure) from those due to purpura (which do not).

The lesions of Kaposi's sarcoma begin as reddish macules and evolve in 1 to 2 weeks into purple or brown rounded lesions measuring from several millimeters to centimeters in size.³

EMERGENCY DEPARTMENT EVALUATION

The history and physical examination should be directed toward identifying the underlying cause of the purpura. The history should include recent infections, recent drug ingestion, radiation or chemical exposure, and systemic symptoms. A personal or family history of purpura or abnormal bleeding after surgical or dental procedures or trauma, as well as hepatic, renal, rheumatologic, or hematologic disease or malignancy, should also be elicited.

A complete list of medications and allergies should be obtained. Except for hereditary coagulation disorders, which rarely present as purpura, and rare hereditary thrombocytopenias, the family history is usually unremarkable. The social history should include questions regarding alcohol and drug use and risk factors for human immunodeficiency virus (HIV) infection. Patients may report easy bruising, prolonged bleeding after surgical or dental procedures, or spontaneous bleeding such as epistaxis, menorrhagia, or melena.

The physical examination should allow rapid differentiation between trivial and serious causes of purpura. The distribution of the rash may be an indicator of the cause of the purpura. Senile or actinic purpura occurs on sun-exposed areas, usually the forearms, of elderly patients. Vasculitic purpura is usually symmetric and predominates in the lower extremities (e.g., Henoch-Schönlein purpura) (Fig. 225.1). A more generalized distribution of discrete petechiae may be noted when purpura is associated with bacterial illness such as meningococemia or subacute bacterial endocarditis. Purpuric lesions in thrombocytopenia tend to occur in areas of minor trauma or areas of pressure, such as the belt line or over bony prominences.⁷ The purpura of scurvy classically appears as perifollicular petechiae, whereas that of Rocky Mountain spotted fever begins over the distal joints and spreads centrally. The lesions of purpura fulminans are large, symmetric ecchymoses of the lower extremities and buttocks, often with infarcted areas or bullae.

Figure 225.1. Henoch-Schönlein purpura. (From John Zone, MD, with permission.)

The morphology of purpuric lesions may likewise suggest their cause. Raised or “palpable” purpura signifies dermal inflammation, usually caused by a vasculitis, whether infectious or immune-mediated (see Table 225.1). Flat, nonpalpable petechiae or ecchymoses usually indicate thrombocytopenia or coagulation defects. When bacterial infections cause purpura, the lesions may have a central purulent papule (e.g., disseminated gonococemia). Immune-mediated vasculitides often have lesions of erythema, bullae, or urticaria in association with purpura. Coumarin-associated vasculopathy results in necrotizing ecchymoses.

The physical examination may further reveal specific abnormalities in certain causes of purpura. In thrombocytopenia, the optic fundi and mucous membranes may show petechiae. Painful joint effusions may accompany various types of immune-mediated purpura, disseminated gonococemia, and coagulation disorders. Lymphadenopathy or lesions characteristic of Kaposi's sarcoma may be indicators of HIV seropositivity, which may present with purpura in up to 9% of cases.⁹ Lymphadenopathy may also be found in patients with lymphoma, infectious mononucleosis, and leukemia. Splenomegaly, as well as other forms of hypersplenism, may also be noted in these same illnesses, but is absent in most other types of thrombocytopenic purpura and coagulation defects.⁷

All but the trivial causes of purpura (e.g., actinic, mechanical) require laboratory studies to elucidate the underlying cause. Initial emergency department studies should include a CBC with differential (to screen for anemias, bone marrow disorders, various malignancies, infection, or hemolysis), platelet count (to screen for thrombocytopenia, although purpura and spontaneous bleeding rarely occur until the platelet count drops below 50,000/ μ L), and prothrombin times and PTTs (to screen for coagulation or mixed platelet and/or coagulation disorders).^{10,14}

Determination of bleeding time may be of limited use in the emergency department in confirming platelet dysfunction or vascular disorders. The fibrinogen level, along with fibrin-fibrinogen degradation products (FDP, D-dimer), may also be useful.¹⁰ Because therapy with blood products is often necessary, and their use may confound subsequent diagnosis, extra tubes for type and screen and for other platelet and coagulation assays should be obtained before treatment.

On subsequent (usually as an inpatient) evaluation, the following tests may be indicated, depending on the suspected etiology: bone marrow aspiration (almost always necessary in suspected anemia or thrombocytopenia), skin biopsy, bleeding time, autoimmune disease screening tests, clotting factor assays, and platelet function tests.¹⁴

EMERGENCY DEPARTMENT MANAGEMENT

First, life-threatening complications of spontaneous bleeding should be stabilized, and efforts should be made to ascertain the cause of purpura. As described, the history, physical examination, and laboratory studies should allow rapid determination of the category of illness causing the purpura and associated symptoms.

When thrombocytopenia is the cause of purpura, platelet transfusion should be considered only when there has been abnormal bleeding. Generally, each unit of platelets may be expected to raise the platelet count by about 5,000 to 10,000/ μ L.¹² Spontaneous mucous membrane or CNS bleeding can usually be controlled when the platelet count is restored to more than 20,000/ μ L. Platelet transfusion is relatively contraindicated in disorders caused by intravascular thrombosis (such as disseminated intravascular coagulation [DIC]), because platelets may contribute to further thrombosis.

When immune-mediated thrombocytopenia is likely, as in idiopathic thrombocytopenic purpura or posttransfusion purpura, the half-life of transfused platelets is short (in hours) compared with that for other disorders (in days).² In these cases, alternative inpatient therapy, such as splenectomy or plasmapheresis, may eventually be indicated.

If purpura is thought to be due to a drug, regardless of the suspected mechanism, that drug should be discontinued. Anticoagulants or platelet inhibitors (in proper dosages) may be reinstated, if indicated, when the disorder is controlled.

Specific therapy directed to underlying disorders should be initiated once those etiologic factors have been defined.

DISPOSITION

Because purpura may reflect hematologic, rheumatologic, or infectious disorders, once trivial causes of purpura have been ruled out, consultation is obtained from appropriate specialists. When the diagnosis is unclear, a dermatology consultation can be helpful.

Because the underlying disorders that are responsible for purpura often have the potential for progressing to life-threatening emergencies, patients with purpura are often admitted to the hospital for confirmation of the diagnosis and definitive treatment. For example, patients with thrombocytopenia usually require a bone marrow biopsy or aspirate to confirm the exact cause of illness. If vasculitis secondary to penicillin is suspected, however, and signs and laboratory abnormalities are mild, the drug may be withdrawn and outpatient follow-up provided. In general, however, the consultant should choose between inpatient and outpatient treatment. Patients presenting with spontaneous bleeding or life-threatening complications, such as septic shock or CNS hemorrhage, require immediate hospital admission, usually to an intensive care unit.

Emergency transfer of patients with life-threatening complications of purpuric illness is indicated when the needed blood products, specialty consultation, or level of care is not available. Stabilization with intravenous fluids and emergently indicated blood products (when available) should be accomplished before transfer, after consultation with the accepting physician. Patients whose illness may progress rapidly (e.g., meningococcemia, DIC) should be considered for air ambulance transfer when ground transport times would be prolonged.

COMMON PITFALLS

- Failure to recognize the trivial causes of purpura may result in unnecessary time and expense spent in pursuing a diagnostic workup.
- Drugs are a common cause of purpura and, unless an adequate history of drug exposure is obtained, the causal agent may initially be missed.
- When spontaneous bleeding is noted, consultation should be obtained immediately and platelet transfusion (when indicated) should be initiated to minimize the chance of CNS hemorrhage.
- Premature administration of drugs or blood products may delay laboratory diagnosis and, in some cases, may worsen the disease process causing purpura.

CHAPTER 226

Urticaria

Theodore A. Christopher and Joseph D. Kim

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Urticarial rash may be the most common skin lesion seen in emergency medicine. Making the diagnosis is not nearly as challenging to the emergency physician as defining the etiology, which very often remains elusive.

Urticaria, or “hives,” is a vascular reaction of skin, resulting in wheals, raised white or red welts that itch and sting. It can occur in any age group, but young adults are most commonly afflicted. An estimated 20% of the population experiences at least one attack of urticaria in a lifetime.

Acute urticaria is characterized by symptomatic attacks lasting 6 weeks or less. It occurs with equal frequency in men and women and is often associated with an atopic history or an allergic etiology. *Chronic* urticaria is more common in middle-aged women and is characterized by attacks that last longer than 6 weeks; the attacks tend to be less frequent and less severe than acute attacks. Half of the patients with chronic urticaria have the disease for 5 years, and 25% have it for 20 years. In 90% of cases, no specific etiology can be identified.

Histologically, the fact that urticaria involves the superficial dermis only distinguishes it from angioedema, which involves the deeper dermis. Perivascular lymphocytic and mast cell infiltration are also features. Mast cell degranulation, with release of mediators such as histamine, acetylcholine, serotonin, neuro-peptides, cytokines, prostaglandins, anaphylatoxins, leuko- trienes, eosinophilic chemotactic factor, platelet activating factor, and bradykinin, appears to be responsible for the pathogenesis of urticaria.^{9,12} Degranulation is initiated by immunologic (type I, type III) and nonimmunologic (chemicals, foods, drugs) mechanisms, but numerous modulating factors also undoubtedly play significant roles.

CLINICAL PRESENTATION

Urticaria presents as pruritic, edematous, slightly erythematous, raised wheals or papules that persist for less than 24 hours on unexposed areas of skin. Urticaria can be circumscribed, annular, or serpiginous; central clearing may or may not be present. The lesions commonly blanch with pressure, reflecting local vasodilatation.

[Table 226.1](#) summarizes types and causes of urticaria. Foods and drugs are probably the most common causes of both acute and chronic urticaria. Among foods, nuts, berries, shellfish, chocolate, fish, tomatoes, and eggs are frequent offenders in acute urticaria. In chronic urticaria, milk, cereals, beef, pork, cheese, garlic, onions, and spices may be responsible. Food additives, both natural and synthetic, also appear to be important etiologic factors. Acute reactions occur within minutes of ingestion, whereas delayed symptoms may develop several hours later, presumably when a reactive antigen is formed by the digestive actions of proteolytic enzymes.

ACUTE URTICARIA
<ul style="list-style-type: none"> • Allergic (immune) reaction • Physical • Cholinergic • Dermatographism • Prostaglandin synthase • Penicillin • Aspirin • NSAIDs • ACE inhibitors • Beta-blockers • Diuretics • Antidepressants • Antipsychotics • Chemotherapy • Radiation • Infections • Endocrine • Autoimmune • Idiopathic
CHRONIC URTICARIA

DERMATOGRAPHISM
<ul style="list-style-type: none"> • Physical • Infections • Autoimmune • Idiopathic

TABLE 226.1. Classification of Urticaria

Penicillin heads a lengthy list of drugs that cause urticaria; both immunologic and nonimmunologic mechanisms are thought to be active.

Aspirin intolerance has been identified in 20% to 50% of patients with urticaria and is thought to act by a nonimmunologic mechanism.² Increased prostaglandin levels have been found in affected patients. Urticaria may occur 15 minutes to 20 hours after aspirin ingestion and is often accompanied by wheezing, increased bronchial secretions, rhinorrhea, and flushing. Many other drugs cause urticaria by inducing histamine release, most notably morphine, codeine, d-tubocurarine, and many oral and topical antibiotics.

Another class of urticaria is physical urticaria, in which wheals and itching develop at sites of a physical stimulus.⁸ *Dermatographism* is defined as a whealing reaction of skin within 10 minutes of receiving a moderate stroke stimulus of less than 36 g/mm.^{2,3} Clinically, dermatographism typically occurs within seconds after stimulation and usually fades within 30 minutes. It is often due to contact with seatbelts, garters, or brassieres. In contrast to dermatographism, pressure urticaria occurs when more sustained physical pressure applied to the skin produces itchy, often painful wheals. These lesions can present as early as 30 minutes after application of pressure, but typically present in 6 hours and often last up to 72 hours.³ Common causes are tight-fitting garments and prolonged walking (feet) or sitting (buttocks).

Cholinergic urticaria is characterized by pruritic 1- to 4-mm wheals surrounded by a red flare and produced within 15 minutes of any stimulus that causes an increase in core temperature.³ Exercise, hot baths, and emotional stress can precipitate episodes of cholinergic urticaria, which usually begins on the upper thorax and neck before spreading to the entire body, usually sparing the palms and soles. The exact pathophysiology is unclear, but appears to involve the release of acetylcholine and degranulation of histamine from mast cells.¹⁴ Clinically, patients can present with varied symptoms, including lacrimation, salivation, diarrhea, abdominal pain, weakness, flushing, and headache. Rarely, severe, life-threatening symptoms (e.g., angioedema, bronchospasm, vascular collapse, and hypotension) can occur.¹⁴

Solar urticarias present as a whealing response within 10 minutes in skin exposed to ultraviolet or visible radiation from any source.³ In addition to hives, symptoms may include wheezing, dizziness, and (rarely) hypotension; all resolve within 1 to 3 hours after the light stimulus is removed. Both histamine and prostaglandins have been implicated.¹

Cold urticaria occurs on exposed areas, such as the face and hands, and is commonly induced by swimming. It occurs within minutes of exposure, usually during rewarming, and can be elicited by placing an ice cube on the skin, holding cold objects in the hand, or drinking cold fluids (leading to lip swelling). It also may be associated with other symptoms, including syncope and shock.¹⁵

Other physical urticarias include generalized aquagenic urticaria, which is induced by contact with water of any temperature; vibratory urticaria, in which localized swelling occurs within minutes of local vibration; and adrenergic urticaria, a variant of stress-related urticaria, characterized by increased blood levels of

norepinephrine and epinephrine.¹⁰

The third major class of urticaria consists of those associated with infection (bacterial, fungal, viral, and parasitic). In most cases, urticaria does not appear to be related to hypersensitivity to the infectious agent.

Insect bites can cause widespread urticarial lesions that are distinct from the common local erythematous and vesicular reaction. Wasps, hornets, fleas, gnats, mites, mosquitoes, and bedbugs are common offenders.

Contact urticaria is whealing of the skin due to exposure to certain substances in susceptible patients. A diverse range of agents has been implicated, including food, metals (nickel, platinum, rhodium), and hair-care products.¹⁶ Of particular concern to health-care workers is the emergence of natural rubber latex allergy, which presents as a local or generalized urticaria but can rapidly progress to angioedema and anaphylaxis.

Finally, several underlying systemic diseases may be responsible for unexplained chronic urticaria. Malignancies (leukemia, lymphoma), collagen vascular disease, serum sickness, and C1 esterase inhibitor deficiency are all recognized causes. Hepatitis B and C, Lyme disease, and chronic tinea pedis have also been associated with urticaria.⁴

DIFFERENTIAL DIAGNOSIS

Urticaria must be differentiated from angioedema, which involves the deeper dermis and mucous membranes, is often associated with abdominal symptoms, and is more often life-threatening. The two most common causes of angioedema are angiotensin converting enzyme inhibitors and hereditary angioedema.⁵ Cutaneous vasculitis causes lesions that may be clinically indistinguishable from urticaria, but they last 24 to 72 hours and are generally nonpruritic; secondary pigmentation and scaling are common, as are systemic symptoms. Serum sickness usually begins 7 to 14 days after antigenic exposure and is associated with fever, arthralgia, and lymphadenopathy. Finally, urticaria must be distinguished from other cutaneous lesions, such as erythema multiforme, bullous pemphigoid, dermatitis herpetiformis, and urticaria pigmentosa.

EMERGENCY DEPARTMENT EVALUATION

The evaluation of urticaria in the emergency department consists of a detailed history to identify any of the previously mentioned inciting factors, paying particular attention to medications, exposures, contacts, underlying illness, allergies, diet, and family history. A general physical examination follows. The patient is undressed and the skin examined thoroughly to localize characteristic lesions. All urticarial lesions are described in detail as to size, shape, number, pattern, color, and temperature. Evidence of systemic illness is sought. If deep cutaneous edema is noted, the physician must ensure that the airway is patent and uninvolved.

In 75% of cases, an underlying cause of urticaria cannot be identified.¹¹ Thus, beyond a good history and physical examination, extensive evaluation in the emergency department is not indicated. However, simple maneuvers, such as placing an ice cube on the forearm (cold urticaria), immersing a hand in warm water (cholinergic urticaria), or "writing" on the skin (dermatographism), may be performed in an attempt to elicit symptoms if the clinical history is suggestive.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment of urticaria depends on the severity and extent of the reaction. All identifiable offending agents and exposures should be eliminated, especially because reexposure often results in a more severe reaction. Nonspecific vasodilators (alcohol, aspirin, heat, exertion, stress) should also be avoided, although broad elimination diets are seldom helpful. Opiates are also another commonly prescribed class of drugs that exacerbate urticaria.

First-generation H₁ antagonists such as diphenhydramine (Benadryl, 25 to 50 mg), chlorpheniramine (Chlor-Trimeton, 4 mg), and hydroxyzine (Atarax, 10 to 25 mg) are commonly prescribed to relieve intense pruritus when sedation is desired; they may also be given in liquid or parenteral formulations when necessary.⁷ Patients should be instructed to repeat the dose whenever hives return, or after 30 minutes if hives are not relieved.

Second-generation H₁ antagonists such as cetirizine (Zyrtec, 10 mg/d) and loratadine (Claritin, 10 mg/d) are now the first line of treatment in urticaria. These antihistamines have only minor sedative and anticholinergic side effects and have longer half-lives, permitting once-a-day dosing. Astemizole (Hismanal) should not be prescribed if a patient is taking macrolide antibiotics, imidazole antifungal agents, or quinine, because of the risk of inducing torsade de pointes.¹³ First- and second-generation antihistamines may be prescribed together, with a first-generation antihistamine given at bedtime and a second-generation agent during the day.

The H₂ antagonists cimetidine (300 mg) and ranitidine (150 mg) alone are ineffective in urticaria and may actually increase the incidence of hives. In refractory cases, however, when combined with an H₁ antihistamine, they may suppress urticarial reactions more completely.⁹

Other agents used for treatment of urticaria include calcium channel blockers such as nifedipine. In combination with antihistamines, dosages from 10 mg twice a day to 20 mg three times a day have been shown to be effective in some cases,¹³ but the routine use of such a regimen is not recommended. Doxepin is a tricyclic antidepressant with both H₁ and H₂ activity, and at dosages of 10 mg three times a day, it has been shown to be efficacious in treatment. Because of its side effects, however, it is best taken only at night.⁴

Severe pruritus unresponsive to antihistamine therapy may be managed by adding antipruritic lotions (phenol or menthol preparations), colloidal oatmeal baths, and cool showers or baths. Sympathomimetics such as ephedrine, metaproterenol, and terbutaline (commonly in combination with a barbiturate to control tremor) have been most successful when used in combination with an H₁ antagonist.¹²

Corticosteroids have a role in the treatment of acute urticaria. A course of prednisone 40 to 60 mg a day for 5 days can relieve symptoms of severe urticaria. Steroid therapy is not typically recommended for patients with chronic urticaria, but short-term therapy is effective in controlling an acute exacerbation. Prednisone at dosages of 20 to 30 mg/d for less than 5 days is recommended. Exacerbations of urticaria can occur after treatment if steroids are given to patients with chronic urticaria for more than 5 days.¹³

Life-threatening urticaria accompanied by laryngeal edema, hypotension, or wheezing requires the administration of intravenous fluids and epinephrine (1 to 2 mL of 1:10,000 solution intravenously over several minutes, repeated cautiously as necessary or followed by a drip of 2 µg/min). In less extreme circumstances, epinephrine can be given subcutaneously or intramuscularly (0.2 to 0.5 mL of 1:1000 solution every 15 to 20 minutes for a maximum of three doses). Antihistamines and corticosteroids should also be given. Some urticarial syndromes respond well to specific agents and modalities.⁶

DISPOSITION

Most acute urticaria begins to respond to treatment within 2 hours. Patients should generally be observed for at least this period of time, or until definitive improvement is documented, but discharge is the rule. Only patients with airway compromise (i.e., laryngeal spasm, bronchospasm) or hemodynamic instability (hypotension) require admission. Antihistamines and steroids, if necessary, should be continued on an outpatient basis.

COMMON PITFALLS

- Urticaria is commonly undertreated with H₁-blocker antihistamines, often resulting in poor control of symptoms and another visit to the emergency department. Patients who respond to antihistamine therapy in the emergency department should be given an adequate supply on discharge. Those who do not respond require the addition of another antihistamine; the administration of steroids should be strongly considered.
- Expensive laboratory workups in the emergency department should be discouraged. A thorough history and physical examination are more likely to identify an etiology.
- Urticarial skin lesions may be the first manifestation of infection, infestation, or systemic diseases such as systemic lupus erythematosus, pemphigoid, dermatitis

herpetiformis, vasculitis, and occult malignancy, particularly lymphoma.

CHAPTER 227

Life-Threatening Dermatoses

Alan T. Forstater and Kenneth J. Neuberger

Diffuse Red Rashes
 Vesicobullous Diseases
 Localized or Discrete Lesions
 Purpuric or Hemorrhagic Lesions
 Common Pitfalls
 Chapter References

Cutaneous lesions are often the first clinical sign of serious systemic disease. In this chapter, the focus is on the recognition and acute management of the common life-threatening dermatoses listed in [Table 227.1](#). These disorders can be conveniently grouped into diffuse red rashes, vesicobullous eruptions, localized or discrete lesions, and purpuric or hemorrhagic lesions.

DIFFUSE RED RASHES	VESICULOBULLOUS DISEASES
Erythema with arthropalms	Pompholyx*
Toxic shock syndrome*	Stevens-Johnson syndrome*
Kawasaki disease*	Toxic epidermal necrolysis*
Toxic epidermal necrolysis*	Disseminated zoster
Staphylococcal scalded skin syndrome*	Disseminated herpes simplex
Generalized exfoliative erythroderma*	
Postular pemphigus	
Contact dermatitis	
Systemic lupus erythematosus	
LOCALIZED OR DISCRETE LESIONS	PURPURIC OR HEMORRHAGIC
Erythema nodosum	Acute hemorrhagic edema*
Erythema gangrenosum*	Disseminated intravascular coagulation
Staphylococcal impetigo	Purpura fulvans*
Staphylococcal folliculitis	Stevens-Johnson syndrome*
Kaposi sarcoma and AIDS	Rocky Mountain spotted fever*
	Atypical hemorrhagic dermatologic disorders

* Discussed in chapter.

TABLE 227.1. Life-Threatening Dermatoses

Several entities are not discussed in detail here but deserve brief mention. Palpable purpura is a skin manifestation of vasculitis; it is not a manifestation of thrombocytopenia or clotting disorder. Involvement may be limited to the skin or may be systemic. Treatment is for the underlying vasculitic disorder.

Generalized exfoliative erythroderma (formerly called exfoliative dermatitis) is a diffuse, widespread dermatitis that covers most of the body surface. This condition not only causes pruritus and pain, but also may be complicated by hypothermia; fluid, electrolyte, and protein loss; invasion of bacteria and opportunistic organisms through the skin; and high-output congestive heart failure secondary to severe vasodilatation. The causes of exfoliative erythroderma include previously existing skin diseases (e.g., psoriasis, atopic eczema, contact dermatitis) (50%); drug eruptions (10%); lymphoproliferative disorders (e.g., Hodgkin disease, leukemia, Sézary syndrome) (15%); and idiopathic (25% to 40%). Mortality is less than 5%.

Other potentially life-threatening entities, such as angioedema and disseminated herpetic infection, are discussed in other chapters.

DIFFUSE RED RASHES

Staphylococcal scalded skin syndrome (SSSS) ([Fig. 227.1](#)) occurs in children and, rarely, adults, and is caused by an exotoxin from an infecting strain of coagulase-positive *Staphylococcus aureus*. The disease may present as a prodrome of fever, irritability, malaise, and exquisite skin tenderness; in other cases, the child presents with the sudden onset of generalized erythema. The skin is red, warm, and very tender. Flaccid bullae that are ill defined and hard to see then desquamate in large sheets. Gentle lateral stroking of the skin causes the epidermis to separate (Nikolsky sign).

Figure 227.1. Staphylococcal scalded skin syndrome. The skin becomes raw and eroded. The similarity to impetigo is clear. The condition responds rapidly to antibiotics. (From du Vivier A. *Atlas of clinical dermatology*. London: Gower Medical Publishing, 1986, with permission.)

Therapy consists of systemic antibiotics effective against penicillinase-producing *Staphylococcus*. Children older than 1 year and with mild symptoms may be treated as outpatients. Children who appear toxic and infants should be admitted. Despite proper treatment, most of the superficial body surface will desquamate; but because the site of blister cleavage is in the superficial layer of the dermis, healing occurs rapidly over 10 to 14 days.

Toxic epidermal necrolysis (TEN) ([Fig. 227.2](#)) is a disease of adults in which the skin also sloughs in large sheets. Although it is very similar in appearance to SSSS, it is quite different. It may actually represent the most severe form of erythema multiforme and begins, like erythema multiforme, with constitutional symptoms of fever, malaise, and myalgia. The skin is initially diffusely painful, hot, and red. Within 24 hours, blisters and large areas of denuded skin develop; erosive, sloughing lesions of the oral mucosa are common. The Nikolsky sign is positive.⁶

Figure 227.2. Toxic epidermal necrolysis. There is “sheeting” of the skin, leaving a raw, denuded area. This was secondary to a barbiturate. (From du Vivier A. *Atlas of clinical dermatology*. London: Gower Medical Publishing, 1986, with permission.)

The differences between TEN and SSSS are noteworthy. SSSS almost always occurs in children and is secondary to staphylococcal infection. TEN almost always occurs in adults and is precipitated by drugs such as phenytoin, sulfas, penicillins, and some nonsteroidal antiinflammatory agents ¹⁷ or by graft- versus-host reactions (e.g., after bone marrow transplantation) or blood product transfusions. Mucous membrane involvement in SSSS is rare and limited to the lips, but, in TEN, erosive oral lesions are common. Although SSSS sloughs only the superficial layers of epidermis, TEN desquamates the entire thickness of the epidermis, accounting for the high associated mortality rate: The mortality rate in SSSS is very low, while that of TEN is more than 50%. ⁷

The diagnosis of TEN is made by clinical presentation and confirmed by biopsy. Treatment is removal of the precipitating agent, if possible, and, as in burn patients, judicious fluid and electrolyte therapy and prevention of infection. Early transfer to a burn center is associated with significantly decreased bacteremia and mortality. ²² Corticosteroid treatment is controversial because it may not speed recovery, yet may predispose the patient to infectious complications. ^{18,19}

Toxic shock syndrome (TSS) is an acute, febrile illness associated with localized infection by strains of *S. aureus* that produce an exotoxin (TSST-1) believed to be the cause of the clinical signs and symptoms. Characteristic signs and symptoms include an early macular rash, hypotension, abnormalities in multiple organ systems, and acral desquamation occurring 1 to 2 weeks after the onset of the illness. About 90% of the *S. aureus* isolates from patients with TSS produce the exotoxin. Eighty-five percent to 90% of cases are reported in menstruating women. ¹² In fact, the disease was originally described in association with the use of highly absorbent vaginal tampons that could be kept in place for many hours before being discarded. Other cases are associated with localized infection in men, children, and nonmenstruating women. ⁴

The early cutaneous rash is scarlatiniform and blanches with pressure; it can be difficult to appreciate because it is often quite pale. Coincident with the rash, there is often erythema of the mucous membranes of the oropharynx, conjunctivae, and vagina. Desquamation of the skin of the distal extremities occurs 1 to 2 weeks after the onset. Hair and nail loss follows 1 to 2 months later. ¹

Strict criteria for the diagnosis of TSS are fever, hypotension or orthostasis, an erythematous macular rash, involvement of at least three organ systems ([Table 227.2](#)), and the presence of an *S. aureus* infection. Most patients have facial and extremity edema. Hypoalbuminemia and hypocalcemia not accounted for by the decreased albumin level have been described. ¹³ The illness can proceed rapidly. Hypotension may appear early; most patients present to the hospital with at least orthostasis.

<p> Revised Case Definition of Staphylococcal Toxic Shock Syndrome 1. Fever—temperature $\geq 38.3^{\circ}\text{C}$ (101°F) 2. Rash—diffuse macular erythroderma 3. Hypotension—systolic blood pressure ≤ 90 mm Hg for adults or ≤ 70 mm Hg for children (by age for children below 16 years of age); orthostatic drop in diastolic blood pressure ≥ 15 mm Hg from lying to sitting; orthostatic syncope, or orthostatic dizziness 4. Mucous Membrane Involvement—Erythema of one or more of the following: a. Oropharynx b. Conjunctivae c. Vagina d. Mucous membranes of the mouth 5. Skin Desquamation—Peeling or sloughing of $\geq 1\%$ of total body surface area in any one of the following: hands, feet, or distal extremities 6. Laboratory Findings—At least one of the following: a. Hemoglobin $\leq 100\text{ g/L}$ (10 g/dL) b. Platelet count $\leq 100,000/\text{mm}^3$ c. Serum albumin $\leq 3.0\text{ g/dL}$ d. Serum creatinine $\geq 1.5\text{ mg/dL}$ e. Serum calcium $\leq 8.5\text{ mg/dL}$ f. Serum sodium $\leq 135\text{ mEq/L}$ g. Serum potassium $\geq 5.0\text{ mEq/L}$ h. Serum bicarbonate $\leq 22\text{ mEq/L}$ i. Serum lactate $\geq 2.0\text{ mmol/L}$ j. Serum ferritin $\geq 1,000\text{ ng/mL}$ k. Serum ferritin $\geq 1,000\text{ ng/mL}$ l. Serum ferritin $\geq 1,000\text{ ng/mL}$ m. Serum ferritin $\geq 1,000\text{ ng/mL}$ n. Serum ferritin $\geq 1,000\text{ ng/mL}$ o. Serum ferritin $\geq 1,000\text{ ng/mL}$ p. pruritus.

Further along the spectrum is Stevens-Johnson syndrome: bullous erythema multiforme accompanied by constitutional symptoms and involving at least two mucous membranes.⁶ A prodrome of fever, malaise, and myalgia is followed by the explosive appearance of blisters on mucous membranes and skin. Symmetric blistering begins on the dorsa of the hands and feet and on extensor surfaces. Erosive lesions begin on oral mucosa, lips, and bulbar conjunctiva and can extend to the pharynx, larynx, esophagus, and genital mucosa (Fig. 227.3). Ocular lesions can result in corneal ulceration, panophthalmitis, and even blindness, requiring early recognition and treatment. The prognosis of Stevens-Johnson syndrome is usually excellent.¹⁶ However, the disorder may progress to an illness clinically indistinguishable from TEN, with large confluent bullae and sloughing of epidermis in sheets.

Figure 227.3. Stevens-Johnson syndrome. Severe blistering and ulceration of the mucous membranes occur. Ulceration is present on the lips and in the mouth. (From du Vivier A. *Atlas of clinical dermatology*. London: Gower Medical Publishing, 1986, with permission.)

Milder cases of Stevens-Johnson syndrome can be treated with oral antihistamines and topical corticosteroids; more severe cases require hospital admission. The use of systemic corticosteroid therapy is controversial.^{17,18}

Pemphigus vulgaris, a rare disease, occurs mostly in adults 40 to 60 years old and is distinguished from other blistering diseases by its fulminant course. Early identification and aggressive treatment may avert a poor outcome. Initially, blisters may be localized to small areas of the mucous membranes or skin; lesions may be present for months before the blistering becomes generalized. The lesions are typically painful flaccid bullae that may rupture easily or painful erosions where bullae have ruptured. The Nikolsky sign is positive. Half of patients present initially with oral lesions; 90% have oral lesions at some time during the course of the illness. These painful erosions or collapsed bullae can persist despite successful treatment of skin lesions.⁶

The diagnosis of pemphigus is made by biopsy of intact skin adjacent to a bulla. Direct immunofluorescent staining for antiepithelial antibodies localized to the epidermal cell membrane are confirmatory. Indirect immunofluorescence of the patient's serum or blister fluid detects a pemphigus antibody that reacts with epithelial cell membranes of most species. Therapy is with corticosteroids and immunosuppressive agents.

Bullous pemphigoid is an autoimmune blistering disease occurring mostly in the elderly. The bullae of bullous pemphigoid, unlike those of pemphigus vulgaris, are tense rather than flaccid, and oral lesions are less common (Fig. 227.4). The Nikolsky sign is positive. Bullous pemphigoid is characterized by spontaneous remissions and exacerbations and a low mortality rate; most patients experience complete remission.⁶ As with pemphigus vulgaris, the diagnosis is made by biopsy of the skin adjacent to a blister. Direct immunofluorescence studies reveal antibodies bound to the basement membrane; these antibodies can often be found in the serum as well. Mild cases are treated with erythromycin, topical corticosteroids, or intralesional injections; severe cases require systemic corticosteroids with or without immunosuppressive agents.⁷

Figure 227.4. Bullous pemphigoid. Large, tense blisters are characteristic, in contrast to the flaccid blisters of pemphigus. (From du Vivier A. *Atlas of clinical dermatology*. London: Gower Medical Publishing, 1986, with permission.)

LOCALIZED OR DISCRETE LESIONS

Patients with gram-negative sepsis may manifest the skin lesions known as ecthyma gangrenosum (Fig. 227.5). Originally described in *Pseudomonas* septicemia, they may also occur with bacteremia due to *Escherichia coli* or *Klebsiella* and have been reported in the absence of disseminated infection.¹⁹ Because the lesions of ecthyma gangrenosum are manifestations of life-threatening illness, the diagnosis must be made early. Ecthyma gangrenosum is a true dermatologic emergency; patients with it are critically ill and usually immunocompromised (e.g., with leukemia or lymphoma).

Figure 227.5. Ecthyma gangrenosum. Deep-seated hemorrhagic necrotic nodules on forearm. (From Greene S, et al. Ecthyma gangrenosum: report of clinical histopathologic and bacteriologic aspects of eight cases. *J Am Acad Dermatol* 1984;11:781, with permission.)

The appearance of the lesion can vary, depending on the stage of the illness at presentation. Beginning as a painless macule or vesicle, it indurates and assumes the appearance of a pustule or bulla on a blue or red base. The lesion then sloughs, leaving a gangrenous ulcer. These solitary or multiple lesions usually occur on the arms, hands, and feet or in the perineal region.

Disseminated gonococcal infection (DGI) usually occurs in individuals with asymptomatic infection of the pharynx, rectum, or genitalia. The patient commonly presents with fever, skin lesions, arthritis, peri-arthritis, tenosynovitis, or any combination of these signs. DGI occurs most commonly in women during menstruation or pregnancy, but it can occur in any patient with gonococcal infection.

The skin lesions are pustules or vesicles on an erythematous base about 5 mm in diameter, but they may also be petechial, bullous, papular, or hemorrhagic. There are usually relatively few (fewer than ten to as many as 30), and they typically appear on the extremities and resolve rapidly (usually in less than a week). The peri-arthritis of DGI presents with joint swelling and tenderness, which are often transient and migratory. Septic arthritis occurs most commonly in the larger joints (knees, hands, ankles, and elbows, in descending order of occurrence). Complications such as endocarditis, meningitis, and sepsis are rare.

The diagnosis of gonococemia ([Fig. 227.6](#)) is a clinical one. Any sexually active person with polyarthritis, tenosynovitis, and typical skin lesions can be given a presumptive diagnosis of gonococemia with little doubt as to its accuracy. Gonococcal cultures should be performed on specimens obtained from all mucous membrane surfaces, as well as blood and (when appropriate) joint fluid. The diagnosis can also be made on the basis of a response to empiric treatment; DGI responds quite promptly to antibiotic treatment (see [Chapter 185](#)).

Figure 227.6. Gonococemia. The lesions are hemorrhagic pustules on an erythematous base. The extremities, particularly the hands, are affected. (From du Vivier A. *Atlas of clinical dermatology*. London: Gower Medical Publishing, 1986, with permission.)

The differential diagnosis should include Reiter syndrome (a syndrome of urethritis, conjunctivitis, and arthritis that usually occurs after a diarrheal illness, has dissimilar skin lesions, and does not respond to antibiotics), meningococemia (which has more numerous petechial lesions), immune complex diseases (which may have joint manifestations but a different type of skin lesion), and rheumatic fever.

Admission is probably required only for patients with severe systemic signs and symptoms or severe joint involvement (especially of weight-bearing joints) and those who cannot be followed closely as outpatients.

Erysipelas is a superficial cellulitis that progresses rapidly in extent and involves the associated lymphatic channels. The classically described offending organism is the group A streptococcus, but groups C and D streptococci and *S. aureus* have also been isolated.¹⁴ The infection is most common in infants and children and in the elderly. The source, in most cases, is probably an inapparent wound. Erysipelas may range from a self-limited process that resolves spontaneously, even without antibiotics, to a rapidly progressive and severe infection leading to bacteremia. Admission is indicated for patients with extensive facial or neck involvement or for patients with fever and a toxic appearance.

The involved skin is erythematous, warm, and tender to palpation and has an advancing margin that is slightly elevated. Fever is common. The diagnosis is usually clinical, because local aspiration is rarely positive. Punch biopsy may be useful, but it is usually not readily available. The differential diagnosis includes cellulitis, maxillary or frontal sinus infections (if localized to the face), and erysipeloid (if located to the hands).

Treatment with penicillin is rapidly effective if erysipelas is due to streptococci, but, because it is rarely easy to identify the causative organism, either a first-generation cephalosporin or a penicillinase-resistant penicillin should be used to cover *Staphylococcus*. Clindamycin or vancomycin may be used in the penicillin-allergic patient. Hospital admission is based on the patient's clinical status. Some affected individuals may be treated as outpatients with close follow-up, and admitted if there is no response or any worsening after 1 to 2 days of oral antibiotic therapy.

Cellulitis, an acute, spreading inflammation of the skin and subcutaneous tissue, appears as a warm, tender, erythematous area with indistinct margins. Its differentiation from erysipelas is based on the appearance of the advancing edge of the infection: In cellulitis, the edge is not raised. In practice, the clinical management of patients with erysipelas and with cellulitis is similar. Erysipelas is more likely, however, to require prompt initiation of antibiotic therapy because it can progress so rapidly.

PURPURIC OR HEMORRHAGIC LESIONS

Neisseria meningitidis colonizes the nasal mucosa in humans (5% to 15%) but may invade the bloodstream and cause disease. Most cases occur in children and adolescents, although any age group may be affected.¹¹ The mortality of meningococemia is higher than that of meningococcal meningitis.

Meningococemia usually follows an upper respiratory tract infection with flu-like symptoms of headache, myalgias, nausea, and vomiting. The severity of the disease can range from an indolent, slowly evolving infection to a fulminating illness causing prostration within a few hours after the onset of symptoms. The classic skin lesions can be petechial, macular, or maculopapular with pale gray vesicular centers. All are a few millimeters in size but may progress to a confluent hemorrhagic rash.² They are most commonly localized to the extremities and trunk but may appear on any part of the body. Meningitis presents with the usual symptoms of meningeal irritation—neck soreness, photophobia, headache—while, in meningococemia, meningeal signs are typically absent.

Gram stain and culture of scrapings of the skin lesions are positive in only about half of cases.¹¹ The diagnosis must often rest on clinical findings and is confirmed by positive cultures of blood or cerebrospinal fluid.

One should entertain the diagnosis of meningococemia in any patient who presents with fever, malaise, and a petechial or maculopapular rash, and include it in the differential diagnosis of other bacteremias (e.g., *H. influenzae*, *S. pneumoniae*, *S. aureus*), subacute bacterial endocarditis, gonococemia (few distal papular, hemorrhagic lesions), vasculitis (usually distal purpuric lesions), enteroviral exanthems, and RMSF.

The treatment of choice for meningococemia is high-dose intravenous antibiotics. Penicillin G (2 million units every 2 hours), ampicillin (2 g every 6 hours), chloramphenicol (4 g/d), and ceftriaxone (up to 4 g/d [100 mg/kg] in children) have all been shown to be effective. Complications such as shock, disseminated intravascular coagulation, adult respiratory distress syndrome, or metabolic acidosis require aggressive supportive care. Prophylaxis is recommended for close school and household contacts. Rifampin, 600 mg (10 mg/kg for children, 5 mg/kg for infants younger than 1 month old), is given orally twice daily for 2 days.

A related syndrome, chronic meningococemia, presents as periodic fever, localized rash, myalgia, and arthralgias lasting for several days. The number of skin lesions is small. Episodes may recur over a period of weeks to months. The diagnosis is established by positive cultures (especially of blood) during the febrile episodes. A fair percentage of patients proceed, if untreated, to an acute phase of disease. The differential diagnosis includes subacute bacterial endocarditis,

rheumatic fever, gonococcemia, and Henoch-Schönlein purpura.

Treatment is the same as for acute meningococcal disease, except that lower doses of intravenous antibiotics are generally considered sufficient to eradicate the infection. All patients suspected of having meningococcal disease should be admitted to the hospital for evaluation and treatment, regardless of clinical appearance.

RMSF is an acute infectious disease caused by *Rickettsia rickettsi* and transmitted by the bites of several species of ticks (*Dermacentor andersoni* in the western United States, *Dermacentor variabilis* in the eastern United States, and *Amblyomma americanum* in some southwestern areas). It is not limited to the Rocky Mountain area; in fact, the areas of highest incidence are in the south-Atlantic region and western south-central states.¹⁵ The organisms can be introduced directly into the skin by a tick bite or may enter broken skin with the tick's feces. Once the infection is established, the organisms invade vascular endothelial cells, causing localized thrombosis and necrosis. The disease is manifested clinically by fever, rash, myalgia, and headache. It ranges in severity from a mild, self-limited illness to severe, life-threatening disease.¹⁰

RMSF is seen most commonly in the late spring and early summer. The incubation period ranges from 3 to 12 days. There is an abrupt onset of fever, chills, arthralgia, and headache and sometimes nausea, vomiting, and photophobia. The rash appears between the second and sixth days of the illness, beginning peripherally on the wrists, ankles, and forearms as a macular erythematous rash and extending to the palms, soles, and torso. The lesions become maculopapular in a few days in most cases and become petechial shortly thereafter (2 to 4 days after the start of the rash). The rash may be absent in 12% to 17% of cases and may be difficult to appreciate in dark-skinned individuals.¹⁵ Areas of decreased circulation, such as the distal extremities, nose, and ear lobes, may develop areas of infarction; finding such lesions on the scrotum or vaginal area can be an additional clue to the diagnosis.

In severe cases, multiple organ systems are involved. Manifestations of central nervous system involvement can range from headache to coma and seizures. The cerebrospinal fluid may show a mildly increased protein level and a pleocytosis, but these findings are nonspecific. Disseminated intravascular coagulation can occur. Due to the early capillary invasion, capillary permeability is increased; there may be third-spacing of fluids and concomitant edema, hypoalbuminemia, and hypovolemia. Hyponatremia due to the syndrome of inappropriate secretion of antidiuretic hormone is noted in 20% of cases but occurs most commonly in those who are critically ill.¹⁰ The white blood cell count is usually normal.

The diagnosis of RMSF is a clinical one based on the findings of fever, headache, rash, and other associated symptoms and signs. However, it is critical to keep in mind that only about 70% of patients with the disease give a history of tick exposure.¹⁵ Although serologic testing can confirm the diagnosis, seroconversion is not apparent early in the disease. (The indirect fluorescent antibody titer has a sensitivity of 94%, and indirect hemagglutination has a sensitivity of 96%. The Weil-Felix, latex agglutination, and complement fixation tests are considerably less sensitive.⁹) Another promising diagnostic modality (particularly for rapid diagnosis) is immunofluorescent staining of skin biopsy specimens.¹⁵

The differential diagnosis of RMSF includes TSS, meningococcal meningitis, Kawasaki disease, measles, leptospirosis, Colorado tick fever, enteroviral infections, any cause of disseminated intravascular coagulation and vasculitis, mononucleosis, rat-bite fever, atypical measles, and other rickettsial diseases. Among the latter are murine typhus and epidemic typhus, which both have rashes that usually begin on the trunk rather than on the distal extremities.

The treatment of choice for RMSF is tetracycline (25 to 50 mg/kg in divided doses four times daily, not to exceed 2 g/d) or doxycycline (100 mg every 12 hours) for 7 to 10 days. Because of concern over dental effects of tetracycline, chloramphenicol (50 to 100 mg/kg/d in four divided doses) may be used to treat children. Tetracycline usually does not affect enamel formation in the incisors, canines, and bicuspid teeth after age 7.⁸ Moreover, in children younger than 5 years old, it is unlikely to result in any apparent change in tooth color when fewer than five courses of therapy are given in the usual oral dosage.⁸

Most patients require inpatient care due to the severity of the illness, but some patients with mild disease have been treated as outpatients on oral medication and with close follow-up.¹⁶ Most patients improve after a few days of treatment; antibiotics should be continued for 2 to 4 days after fever abates. Lifelong immunity appears to develop after infection.

COMMON PITFALLS

- TEN can easily be confused with SSSS. TEN requires the removal of any possible precipitating agent, most commonly a drug; SSSS must be treated with appropriate antibiotics. The prognosis of the two diseases is markedly different.
- The rash of TSS may be indistinct. The diagnosis should be considered in any patient with fever and signs of volume depletion, even in the absence of a history of tampon use. The disease can occur in men and children.
- Bullous pemphigoid can easily be confused with pemphigus vulgaris. Early consultation with a dermatologist may be necessary to avoid misdiagnosis and inappropriate treatment.
- In a febrile, seriously ill patient, skin lesions may be a manifestation of sepsis. The lesions should be opened and their contents Gram stained and cultured.
- Rapid identification and treatment are crucial in ecthyma gangrenosum. The underlying septic process can be fatal if not treated promptly.
- The diagnosis of gonococcemia is often overlooked in persons presenting with tendinitis without any history of injury.
- The early rash of meningococcemia may be macular or maculopapular as well as petechial, as classically described.
- In RMSF, the rash is absent in a significant proportion of cases. An increased index of suspicion is necessary for any patient presenting with a viral-like illness in the late spring or early summer.

PIGMENTED LESIONS

Pigmentation of the human skin is influenced by a variety of factors, most importantly, the relative quantity and depth of the pigment melanin. The production of melanin, a protein-bound polymer derived from tyrosine, is influenced by genetic and environmental factors as well as intrinsic regulators. Other factors contributing to skin pigmentation include the thickness of the horny layer, the degree of vascularity, and the oxygen saturation of blood hemoglobin. ¹²

Patients do not commonly present to the emergency department with the chief complaint of hyperpigmented or hypopigmented skin lesions. However, such lesions are frequently encountered by emergency physicians during a physical examination or are mentioned by patients while a history is being taken. It is therefore important for emergency physicians to be familiar with the differential diagnosis of such lesions, particularly those that are malignant or have malignant potential.

Hypopigmented Lesions

Skin hypopigmentation may result from a defect in one of several pathways in the synthesis, transport, and deposition of melanin. ¹² Such lesions may be secondary to an intrinsic dysfunction in one of these pathways or, occasionally, may be manifestations of an otherwise occult systemic disorder.

CLINICAL PRESENTATION

Although patients with hypopigmented lesions may complain of “white spots,” they may have presenting complaints unrelated to their skin lesions. The patient may therefore not relate the presence of lesions to the emergency physician. Fortunately, they are usually recognized easily on physical examination, prompting a careful search to delineate their extent and to discover other skin findings.

DIFFERENTIAL DIAGNOSIS

Tinea versicolor, or pityriasis versicolor, is a common fungal infection of the skin. Lesions begin as small, well-circumscribed circular macules that may be white, pink, or even hyperpigmented. Most commonly encountered on the trunk, they are rarely found on the face. The color is uniform in each individual. Although they may be pruritic, lesions are usually asymptomatic. Potassium hydroxide preparation reveals hyphae and yeast forms, with Wood's light examination revealing pale yellow to white fluorescence. ⁷

Pityriasis alba is an idiopathic, usually asymptomatic disorder characterized by round or oval, white or pink scaly patches. The most commonly affected areas are the face, upper trunk, shoulders, and arms. Lesions may become more obvious in summer months, as they fail to tan after sun exposure. Young children, particularly atopic individuals, are commonly affected. ¹⁵

Vitiligo is an idiopathic, possibly multifactorial, disorder characterized by progressively enlarging, circumscribed, hypopigmented macules. Melanocytes are absent from the affected areas. Lesion distribution is variable, but frequently affected areas include bony prominences, perioral and periorbital regions of the face, the dorsum of the hands, and body folds such as the axillae and genitalia. The macules have a well-defined border, which may be rimmed with hyperpigmentation or a red halo. ⁷ Often familial, vitiligo can be associated with a host of systemic diseases, including adrenal insufficiency, hypothyroidism, diabetes mellitus, and pernicious anemia. Spontaneous repigmentation occurs in up to 25% of cases.

Albinism is characterized by congenital absence of pigment in the skin, hair, and eyes (oculocutaneous albinism) or in the eyes alone (ocular albinism). The skin is a milky pinkish-white, and scalp hair is pale yellow with a fine texture. The eyes are striking because of red pupils and bluish or pink irides. Photophobia and nystagmus may be present. These patients suffer from the constant threat of sunburn and are prone to basal cell and squamous cell carcinomas. ⁷

Piebaldism is a congenital disorder characterized by patches of hypopigmentation (similar to vitiligo) most commonly located the chest, abdomen, and midregion of the upper and lower extremities. The characteristic feature of piebaldism is the striking white forelock present on the frontal scalp or forehead. Islands of hyperpigmented macules may frequently be found within hypopigmented areas as well as on normal skin. ⁷

Tuberous sclerosis is an autosomal dominant disease characterized by hypopigmented, oval or “ash-leaf” shaped macules in association with early onset seizures, mental retardation, facial angiofibromas, periungual fibrosis, and the so-called shagreen patch. The shagreen patch is a soft, yellow or lightly colored plaque with an irregular surface that has been likened to pigskin, occurring most commonly in the lumbosacral region. Shagreen patches represent the earliest sign of tuberous sclerosis. ¹⁵

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

For tinea versicolor, treatment should be directed at the underlying infection, with the use of topical antifungal agents such as clotrimazole or miconazole, or selenium sulfide (2.5%) lotion or shampoo. ² Systemic therapy is generally not recommended. Although weak topical steroids and tar solutions have been used to treat pityriasis alba, the hypopigmentation is self-limited and gradually improves after puberty. Therefore, no therapy other than skin lubrication is needed.

Patients with newly diagnosed vitiligo should be referred to a dermatologist. Therapeutic options include cosmetic cover-up, photochemotherapy, and repigmentation. Before disposition, an underlying systemic cause for the lesions should be considered. Albinotic and other patients with severe hypopigmentation have a least a partial melanin deficiency, and therefore lack the protection that melanin normally provides from the sun's ultraviolet radiation. These patients are exquisitely sensitive to sunlight and are at risk for severe sunburn as well as skin tumors. ¹⁵ Proper skin shielding (and eye protection for albinotic patients) is essential, and these patients

should be under the care of a dermatologist.

COMMON PITFALLS

- Whether the skin lesions are the presenting complaint or an incidental finding, the possibility of an underlying systemic illness in these patients should be considered.
- Hypopigmentation can dramatically affect the patient's lifestyle, especially when lesions are located on visible areas. Such patients should be referred to a dermatologist.

Hyperpigmented Lesions

Skin hyperpigmentation results from disorders of melanin production, whether from augmented synthesis or transport, or from an increase in the size of melanosomes. A variety of skin lesions may result.¹⁵

While maintaining a high degree of suspicion for malignancy, emergency physicians should be able to diagnose many benign dermatoses, thereby allaying patient anxiety and avoiding inappropriate dermatologic referral. This section deals with hyperpigmented lesions, excluding skin tumors, which are discussed in the next section.

CLINICAL PRESENTATION

As with most other dermatoses, patients frequently mention hyperpigmented lesions as a secondary complaint while in the emergency department, or they may be unaware of lesions detected during physical examination. However, it is not uncommon for patients to present to the emergency department, expressing concern about such a lesion being malignant.

DIFFERENTIAL DIAGNOSIS

When skin tumors are excluded, the differential diagnosis of hyperpigmented lesions is not extensive. Ephelides, or freckles, are irregularly shaped tan macules that form on sun-exposed areas, most notably the nose, cheeks, hands, and upper trunk. Typically less than 5 mm in diameter, they occur in genetically predisposed persons who are susceptible to sunburn. Freckles are benign lesions, and therefore require no treatment.⁷

Senile or solar lentigos, also known as "liver spots," are discrete, irregularly shaped macules occurring on sun-exposed skin. Common sites of involvement include the forehead and dorsum of the hands. Sparing of the knuckles and phalanges is characteristic. They are of cosmetic significance only and require no treatment.⁷

Juvenile lentigos, or lentigo simplex, are sharply defined brown or black macules that appear anywhere on the skin or mucosa, and are clinically indistinguishable from junctional (*vide infra*) nevi. There is no predilection for sun-exposed skin. They may appear in patients of any age but often arise in childhood. Because there is no tendency for neoplastic change, no therapy is indicated.⁸

Peutz-Jeghers syndrome is an autosomal dominant disorder characterized by brown-to-black macules from 1 to 5 mm in diameter, involving the oral mucosa, lips, and perioral area. The sacral region may also be involved. Lesions are associated with gastrointestinal polyps.³ The color and size of the macules in Peutz-Jeghers syndrome are not affected by sunlight, as they are in freckles.

Mongolian spots are bluish-gray macules or patches that vary from 2 to 8 cm in diameter. Lesions occur in Asian, African-American, Native-American, and southern European patients. Although multiple lesions may occur in a widespread distribution, they are typically solitary and located in the sacral region of newborns. Mongolian spots usually disappear during childhood.

Café-au-lait spots are uniformly hyperpigmented pale-brown macules with sharply circumscribed borders. They may be present at birth, and occur in up to 20% of normal children. They range in size from a few millimeters to 20 cm, and increase in number and size with age.¹⁵ The presence of six or more spots greater than 1.5 cm in diameter is presumptive evidence of neurofibromatosis (von Recklinghausen disease), although most people with café-au-lait spots do not have this disorder. Macules that mimic café-au-lait spots but are darker and have a more irregular border are seen in Albright syndrome in association with fibrous dysplasia of the long bones and precocious puberty in girls.^{12,15}

Melasma, also known as the "mask of pregnancy," is an irregular, brown, macular hyperpigmentation usually noted on the back and neck. It occurs during the second or third trimester of pregnancy, fades after delivery, and darkens with subsequent pregnancy. Melasma worsens with sun exposure and is therefore more obvious in the summer. Melasma may also occur in women taking oral contraceptives.¹²

Acanthosis nigricans is characterized by symmetric brown or "velvety" hyperpigmentation located most commonly along skin folds, including the axillae and groin, as well as the flexural area of the neck. The skin may become thickened and develop leathery or warty patches. Commonly idiopathic, acanthosis nigricans may be associated with endocrinopathies and gastrointestinal malignancies.⁷

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Although often not part of the presenting complaint, pigmented skin lesions should always prompt a careful search to delineate their extent and the extent of other skin findings, as well as to detect the presence of underlying illness. If the lesion is benign and systemic illness is not suggested, patients can be discharged with follow-up as needed only.

Some benign pigmented lesions can mimic malignant melanoma. Although emergency physicians should be familiar with the lesions discussed here, it is frequently not possible to completely exclude malignant or premalignant lesions from the differential diagnosis. If the nature of a pigmented lesion is questionable, dermatology referral is indicated.

COMMON PITFALLS

- Despite their nonemergent nature, potentially malignant skin lesions should never be ignored. Dermatologic referral is indicated when any uncertainty exists.
- As with other dermatoses, the possibility of an associated underlying disease should be considered.

SKIN TUMORS

The incidence of skin cancer continues to rise annually, accounting for over 500,000 cases each year in the United States. Melanoma of the skin accounts for over 7,000 deaths each year in the United States, and affects young as well as older individuals. It is projected that, within the next few years, one in 90 people will develop melanoma (an increase from a one in 123 risk in 1987).³ A number of factors, including depletion of the ozone layer (with resultant increase in radiation exposure), increased longevity, and increased recreational sun exposure, have been implicated.^{4,13}

Historically, primary care physicians have had difficulty making the diagnosis of skin cancer clinically. Furthermore, access to specialists may be restricted by the widening influence of managed care, and has always been difficult to obtain for indigent patients. Nevertheless, even highly malignant skin tumors may be curable if detected early. The emergency physician is in an excellent position to prevent serious morbidity and mortality by considering the presence of, and diligently searching for, suspicious lesions.⁵

CLINICAL PRESENTATION

Unlike many problems encountered in the emergency department, skin tumors are generally asymptomatic and may be an incidental finding on physical examination. As such, the emergency department physical examination provides an opportunity to screen for suspicious lesions. Bleeding, ulceration, or pain is sometimes associated with malignancy, generally in the later stages, and may be a presenting complaint.

Most skin tumors are easily recognized as benign lesions and present no diagnostic dilemma, but some are concerning to the patient and challenging for the emergency physician. Early tumors can often be treated successfully, whereas more advanced ones (particularly in the case of melanoma) can be devastating.

DIFFERENTIAL DIAGNOSIS

The most important distinction to make is the one between benign and malignant lesions. A familiarity with several of the more commonly encountered tumors and their characteristics is thus essential.

Benign Tumors

Nevi, commonly known as “moles,” are the most common benign tumors of the skin. They vary in size, shape, and color, but each nevus tends to remain uniform in surface characteristics. Although various shades may be present in a single lesion, the colors are distributed over the surface uniformly. Lesions are typically round or oval, with regular borders. They may be macular (intraepidermal or junctional nevi) or raised (dermal or compound nevi). They may be present at birth and tend to increase in number during childhood, reaching a peak at puberty. There is a strong correlation between sun exposure and the number of nevi. Except for certain types of nevi, such as dysplastic nevus and large congenital nevus, most nevi have little malignant potential unless encountered in large numbers.^{6,9}

Several types of vascular tumors occur on the skin, including hemangiomas, nevus flammeus, Kaposi's sarcoma, and pyogenic granulomas. Kaposi's sarcoma is discussed in the section, “Nonmelanoma Malignant Tumors.”

Hemangiomas represent a broad category of vascular lesions caused by proliferation of vascular endothelium in the dermis. They usually develop during the neonatal period, and their appearance and growth rate vary. Ulceration is the most common complication, although profuse bleeding is rare. Hemangiomas often resolve with minimal scarring.²

Nevus flammeus (port-wine stain) is a vascular malformation, usually unilateral, that frequently occurs on the face. The lesion appears as an irregular red-to-purple patch. It may be a component of neurocutaneous syndromes, such as Sturge-Weber syndrome (encephalotrigeminal angiomas), in association with mental retardation, epilepsy, visual impairment, and angioma of the meninges. Salmon patches (stork bite, angel's kiss) are variants of nevus flammeus. They are red irregular patches most commonly located on the nape of the neck.

Pyogenic granulomas are rapidly growing, yellow-to-bright red, dome-shaped lesions that are thought to result from trauma. Most often seen on the extremities, especially the fingers, they have a fragile surface that bleeds easily.

Telangiectases are permanently dilated vessels consisting of arterioles, capillaries, or venules. They accompany a wide variety of diseases.

Hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber disease) is an autosomal dominant disease characterized by telangiectases involving the lips, tongue, nasal mucosa, and gastrointestinal tract. Recurrent bleeding represents the most serious complication.

Nevus araneus, or spider angiomas, are prominent arterioles (spider's body) that radiate capillaries (spider's legs). Though sometimes seen in normal individuals, they are more common and may increase in number during pregnancy and in patients with liver disease.⁸

Seborrheic keratoses are oval or round plaques of variable color with sharply circumscribed borders. They vary from a few millimeters to more than 3 cm in diameter. Lesions are usually seen on the head, trunk, and extremities of patients older than 40 years.¹² Sometimes rough in texture, seborrheic keratoses often appear “stuck on” the skin surface. They originate in the dermis, are of unknown origin, and have no malignant potential. Lesions can occasionally become darkly pigmented and irregular, thereby resembling melanoma. In addition, their sudden appearance or an increase in their number or size has been reported as a marker for internal malignancy (Leser-Trélat sign).⁹

Lipomas are fatty tumors that are usually solitary and tend to occur more in women. They usually appear during the fourth or fifth decade of life and commonly affect the posterior neck, trunk, abdomen, forearms, buttocks, and thighs. Most are soft, mobile, subcutaneous masses 2.5 to 5.0 cm in diameter. The tumor is encapsulated and composed of adipose tissue, which has the same appearance as normal subcutaneous fat.⁸

Acrochordons, or “skin tags,” are papules or pedunculated lesions that range in color from the patient's skin tone to hyperpigmented. They are of no significance, other than cosmetic.

Dermatofibromas are benign, sometimes slightly pruritic, pink–brown hyperpigmented papules. They are characteristically firm and will dimple when lateral compression is applied. Lesions most commonly occur on the anterior surface of the legs.²

Injury or surgery can cause abnormally prominent scarring in some individuals. Keloids, to which African Americans are more susceptible, extend beyond the wound margins and do not regress. Hypertrophic scars are abnormally large but remain confined to the wound site and regress over time.

Milia are 1- to 2-mm white cysts usually found on the face of middle-aged patients, especially around the eyes. Epidermal cysts, also called sebaceous cysts, are similar to milia in that epidermal tissue is trapped within the dermis. The cyst wall is lined with stratified squamous epithelium, which produces keratin. However, epidermal cysts are larger and deeper, and frequently prompt visits to the emergency department when they become inflamed or infected. They occur primarily on the face, posterior neck, chest, and back. Pilar cysts are similar to epidermal cysts except that they occur on the scalp. Syringomas are small papules, yellow or matching the patient's skin, that occur primarily on the lower eyelids. They are benign sweat duct tumors that appear during the third and fourth decades.

Keratoacanthoma is a benign epithelial tumor, possibly of viral origin, that occurs in the elderly. It appears as a smooth, dome-shaped red papule resembling molluscum contagiosum, which then develops a central keratin-filled crater that is frequently covered with crust. It frequently regresses over a period of 2 to 12 months and heals with scarring. Most common locations are sun-exposed areas, such as the back, face, and dorsum of the hands. Clinical differentiation from squamous cell carcinoma may be difficult.⁸

Tumors with Malignant Potential

Dysplastic nevus was initially identified in families with a high incidence of melanoma as a cutaneous marker for increased malignancy risk. It may also occur in patients without a family history of skin cancer. The presence of ten or more dysplastic nevi is associated with a 12-fold increase in the risk of developing melanoma.¹⁸ Dysplastic nevi are larger than common moles. The surface has a mixture of colors, with an irregular, indistinct border that fades into the surrounding skin. A characteristic presentation is an irregular pigmented papule surrounded by an irregular macular collar of pigmentation, giving a “fried egg” appearance. The lesions, not present at birth, begin to appear during childhood as common moles. However, their appearance changes at puberty and newer lesions continue to appear throughout life. Dysplastic nevi occur not only in sun-exposed areas, as do common moles, but also at unusual sites, such as the scalp, buttocks, and breast. They are most commonly seen on the back.

Congenital nevus is present at birth and may vary in size from a few millimeters to several centimeters in diameter. It may cover wide areas of the face, an extremity,

or the trunk. It may contain hair (congenital hairy nevus). Very large lesions have potential for malignant transformation.⁹

The most common premalignant skin tumor is actinic keratosis, also known as solar keratosis or senile keratosis. It is a hyperpigmented, well-circumscribed, and usually scaly macular lesion occurring in middle-aged or older patients and especially in light-complected individuals.^{8,12}

Malignant Melanoma

Malignant melanoma is one of the most frequently encountered cancers among many age groups, and the incidence is increasing. Although melanoma represents less than 2% of all skin cancers, it accounts for over 60% of all skin cancer deaths.^{1,8,10,14} The incidence of melanoma continues to rise, possibly due to an increase in recreational exposure to the sun's ultraviolet radiation. People who experience acute episodic exposures may be at greater risk than those with constant exposure.

Melanoma arises from the pigment-producing melanocytes of the basal layer, from melanocytes in dysplastic nevi, and from malignant transformation of large congenital nevi. It can metastasize widely. Because there is a high cure rate when melanoma is detected early, it is important for the primary care physicians to screen for the disease and for patients to perform self-examination.

The "ABCD" method recommended by the American Academy of Dermatology (Table 228.1) is a commonly used guide for the early identification of malignant melanoma. Melanomas tend to have asymmetry, irregular borders, variegated color, and greater diameter than benign lesions. Patients with lesions that meet any of these criteria should be given follow-up for dermatologic evaluation and possible biopsy.¹¹ Other characteristics that should raise suspicion are the development of bleeding, tenderness, and pruritus. Although clinical suspicion depends primarily on direct visual inspection of a lesion without much regard for its evolution, certain traits are known to place individuals at higher risk for melanoma. These include fair complexion, red or blonde hair, excessive sun exposure, a positive family history, previous melanoma, and the presence of a large congenital nevus or dysplastic nevus syndrome.^{1,7}

Asymmetry	Two halves of lesion do not appear identical
Border	Uneven, notched, scalloped, or ragged
Color	Different shades of black/brown/red/white/blue
Diameter	Greater than 6 mm in diameter or changing in size

TABLE 228.1. "ABCD" Method as a Guide for Early Detection of Malignant Melanoma

Nonmelanoma Malignant Tumors

By far, the most common cutaneous malignancy is basal cell carcinoma. It arises from the epidermis and consists of histologically normal-appearing basal cells. Typical lesions are hyperpigmented, smooth or waxy nodules, often with irregular borders and uneven pigmentation. They are classically described as pink pearly papules with prominent telangiectatic vessels. There may be central ulceration. However, there are a variety of forms, and lesions may be indistinguishable from Bowen disease, psoriasis, or even eczema. About 90% of basal cell carcinomas occur on sun-exposed areas of the neck and face, particularly the nose. Metastasis is rare, although local extension of the tumor into cartilage, bone, nerve, and other tissues may produce complications.¹³

Squamous cell carcinoma accounts for about 20% of all cases of skin cancer.¹⁴ Like basal cell carcinoma, it arises from the epidermis and is common on sun-exposed areas. However, it grows more rapidly and can occur at any anatomic site. Although there is no classic lesion, many are firm, scaly papules with ulcerations or crusting.¹³ Lesions may mimic a patch of psoriasis. Squamous cell carcinoma may arise on skin that has been chronically damaged by sun exposure (actinic keratosis) or chronic inflammation (Marjolin ulcer). Several strains of human papillomavirus are associated with squamous cell carcinoma and may lead to increased risk of developing a malignancy.¹⁴

Kaposi's sarcoma is a vascular neoplasm with several different forms. It is described in genetically predisposed individuals of European or African descent, as well as in immunocompromised patients (particularly patients with acquired immune deficiency syndrome [AIDS]). Usually beginning on the feet as red, bluish, or purple macules and papules, lesions may occur in a variety of forms and locations, particularly in AIDS patients.

Marjolin ulcer refers to squamous cell carcinoma that arises from malignant changes in chronic ulcers of the skin or sinuses, or in previous burn scars. A majority occur on the extremities. These tumors are typically more aggressive than those that develop from actinic keratosis or Bowen disease.

Bowen disease is also referred to as squamous cell carcinoma *in situ*. It occurs more frequently in light-complected individuals, but lesions are equally distributed between sun-exposed and nonexposed skin. Lesions are characteristically red, scaly plaques with well-defined borders. Erythroplasia of Queyrat of the penis resembles Bowen disease and is thought to be the same entity, although metastases may occur more frequently than from lesions at other sites. It appears under the foreskin of the uncircumcised penis. Vulvar lesions are described but are rare.¹⁴

Verrucous carcinoma, a variant of squamous cell carcinoma, is a slow-growing, exophytic, fungating tumor that rarely metastasizes. In the early stages, it is often mistaken for a common wart.

Paget disease of the breast results from invasion of the epidermis of the nipple and surrounding skin by malignant cells originating from a ductal carcinoma. The process begins insidiously with a small area on the nipple that may drain and form a cyst. The inflammation initially may be attributed to trauma, and partial healing may support this false impression. The appearance may be similar to eczema, but Paget disease of the breast is a unilateral disease, whereas eczematous inflammation of the nipple is nearly always bilateral.⁸

Mycosis fungoides, a form of cutaneous T-cell lymphoma (CTCL), can present with skin lesions that initially may be confused with eczema, contact dermatitis, or psoriasis. Visceral involvement occurs much later in the course. Other forms of CTCL include Sézary syndrome and lymphoma cutis.

Finally, metastases to skin may develop in 1% to 2% of patients with underlying malignancy.¹⁷

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

The emergency physician should carefully inspect any questionable skin lesion, delineate the number and extent of coexisting lesions, and question the patient regarding their development and any associated conditions.

Nevi are generally easily diagnosed and require no special follow-up, but may rarely be found in association with melanoma. Therefore, any nevus undergoing suspicious changes or arising for the first time in patients more than 20 years old, should be referred for biopsy.

Patients should be reassured that most hemangiomas resolve spontaneously without therapy, whereas therapeutic interventions often produce scarring.¹⁶ However,

referral is warranted in order to follow the lesion. Treatment for pyogenic granuloma consists of curettage and electrodesiccation.²

Except for cosmetic considerations, lipomas, acrochordons, and dermatofibromas require no treatment or referral. Keloids can be treated with cryotherapy or intralesional steroid injections. Surgical excision may lead to keloids that recur and are larger than the original lesion. For milia and syringoma, the cyst may be opened and contents expressed for cosmetic reasons. Epidermal cysts may be opened and drained, although in order to achieve long-term results, the cyst wall must be excised as well.¹⁶

None of these entities requires urgent treatment in the emergency department. However, if malignancy is suspected, the patient should be promptly referred for biopsy. Therapeutic options for the various malignant tumors include excision, curettage and electrodesiccation, radiation therapy, systemic or topical chemotherapy, micrographic surgery, and cryosurgery.¹³

COMMON PITFALLS

- Patients with skin lesions suspicious for malignancy require prompt specialty referral for further care. A “watch and wait” attitude in these cases can be disastrous.
- Pigmented lesions that are asymmetric, painful, pruritic, increasing in size, irregularly colored, or otherwise atypical should be considered malignant until proven otherwise by biopsy.

Delirium that manifests with hallucinations, delusions, language disturbances, and agitation must be differentiated from primary mental disorders, including brief psychotic disorder, schizophrenia, and mood disorder with psychotic features, among others. Psychotic symptoms that fluctuate, are fragmented, and are not particularly systematized are likely to be secondary to delirium. Memory impairment, disorientation, and reduced ability to maintain and shift attention are not usually present in primary mental disorders.¹⁰

EMERGENCY DEPARTMENT EVALUATION

Emergency physicians are often called on to medically clear patients judged to have primary mental disorders before their psychiatric care begins. As discussed, the physician's judgment that a patient has been medically cleared is often inaccurate. In one study, 33% of patients bearing this label did not even have vital signs recorded on the chart, and almost half had no mental status examination recorded.¹⁹ No physical examination at all was noted in 8% of patients, and at least one standard portion of the physical examination was missing in 80% of patients. Only 8% of patients had a complete neurologic examination.

A thorough evaluation must include a complete history and physical examination, with special attention to the neurologic and mental status examinations. The entire workup should be well documented on the patient's chart in the place of the phrase "medically clear." Laboratory data also should be well documented.

Useful laboratory studies include a complete blood count, serum glucose evaluation, electrolytes study, blood urea nitrogen, and creatinine. In some cases, blood alcohol level, toxicology screen, chest radiograph, electrocardiogram, and arterial blood gas measurement will be appropriate. Patients who present with an acute change of behavior and clouded consciousness that is not explained by this laboratory evaluation may require computed tomography, followed by a lumbar puncture and, in some cases, an electroencephalogram (EEG).

The EEG is helpful in making the diagnosis of delirium, as certain EEG changes are typical of delirium, including generalized slowing.^{6,16} Also, the EEG can occasionally unexpectedly reveal that the patient's altered mental status is due to nonconvulsive status epilepticus.

EMERGENCY DEPARTMENT MANAGEMENT

Extreme agitation is often part of the syndrome of delirium and can significantly interfere with evaluation. Rapid tranquilization (RT) is a safe and effective method for controlling agitated, potentially assaultive, or overtly violent delirious patients.⁵ RT is accomplished by administering a standard dose of a high-potency antipsychotic medication, such as haloperidol or droperidol, in 30- to 60-minute intervals. Research indicates that the combination of antipsychotic medication with lorazepam is more effective than either medication alone, though the synergistic effects may cause excessive sedation.⁸

Table 229.2 outlines suggested doses. Most patients respond after one to three doses, each dose being double the previous dosage until an effective dose is reached. No ceiling dose has ever been established for RT; even in severely ill medical patients, high doses of antipsychotic medication alone or in combination with lorazepam are safe and well tolerated.⁴

Medication is given in 30-60-minute intervals, up to 6 doses/24 h
Haloperidol (Haldol) 5 mg i.m. or 10 mg concentrate
Droperidol (Inapsine) 2.5-5.0 mg i.v. or i.m.
Thiothixene (Navane) 10 mg i.m. or 20 mg concentrate
Lorazepam (Lorazepam) 10 mg i.m. or 25 mg concentrate
OR
Lorazepam (Ativan) 2-4 mg i.m. combined with haloperidol (Haldol) 5 mg i.m. or thiothixene (Navane) 10 mg i.m.
^a With older or debilitated patients, the recommended doses should be reduced by 50%.
i.m., intramuscularly; i.v., intravenously.

TABLE 229.2. Recommended Doses for Rapid Tranquilization^a

The most common side effects of RT are dystonic reactions or akathisia. These are effectively treated with benztropine (Cogentin) 2 mg, intramuscularly or intravenously, or diphenhydramine (Benadryl) 50 mg, propranolol 20 to 40 mg or lorazepam 1 to 2 mg.

DISPOSITION

The treatment of delirium is based on detection of the underlying cause. Hospital admission is necessary if the patient's behavior jeopardizes further medical evaluation or care. If no specific cause can be found while in the emergency department, the patient should be admitted for further workup, with psychiatric consultation as needed. A patient should be discharged only after a cause has been identified, treatment has been initiated, and adequate follow-up has been ensured.

The fluctuating time course of delirium must be considered, because a patient may initially improve only to have symptoms recur when inadequate resources are available.

Identified illnesses associated with a risk of morbidity or mortality also warrant hospital admission.²³

COMMON PITFALLS

- Delirious patients who present to the emergency department are often inappropriately referred to a psychiatrist. This is especially true for those who present with bizarre and agitated behavior. There are several reasons for misdiagnosis and premature psychiatric referral.
- Psychiatric patients who behave in a bizarre, disruptive manner may not be approached with the same sense of urgency or seriousness as are patients with cardiovascular disease or trauma. Often, such decisions are based on a single symptom or item of history, or on a previous diagnosis. Out of a sense of discomfort and an urgency to get to the "really sick" patients, the physician may decide that the patient is "medically clear" without conducting a complete and thorough evaluation.
- A common misunderstanding is that delusions, hallucinations, and disorganized thoughts are diagnostic of primary mental disorders. On the contrary, such symptoms, like fever or pain, are nonspecific and occur in both primary mental disorders and mental disorders caused by a medical condition, as well as in certain personality disorders.
- There is a tendency to refer violent patients prematurely to a psychiatrist. Yet, like disordered perception, violence is etiologically nonspecific. A significant proportion of violence that occurs in psychiatric settings results from underlying medical illness or drug intoxication.²⁰ Thus, the evaluation of the violent patient must include a search for these conditions.
- The least tolerated patients are those who are believed to create their own disease (e.g., alcoholic patients, drug abusers, and suicidal patients).²² Thus, a patient who overdoses on tricyclic antidepressants and is fully alert and clinically stable may be treated with an inappropriate lack of urgency. Similarly, Wernicke encephalopathy is rarely given consideration in confused, belligerent patients who present with chronic alcoholism.¹⁸
- Finally, clinicians often fail to take seriously the complaints of elderly patients, commonly attributing their symptoms to "old age."⁹ This attitude is particularly unfortunate when the patient is demented, because 60% of all dementias are treatable or reversible.³ For many clinicians, dementia implies a chronic, progressive, irreversible deterioration of higher intellectual functions. Dementia is not etiologically specific, however, and does not imply irreversibility. Premature labeling tends to preclude the exhaustive physical, neurologic, and laboratory evaluation necessary to identify potentially reversible causes of

dementia or delirium.

CHAPTER 230

Depression and Suicide

Robert S. Hockberger and Roger Yang

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation and Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Depression is the most common psychological disturbance affecting humankind. Its prevalence is 10% to 20% in the general population and 20% to 50% in patients seen by physicians in general practice settings.¹ Suicide, the most notable sequela of depression, is the eighth most common cause of death in the United States, accounting for approximately 30,000 deaths annually.^{1,2} The overall incidence of suicide nationwide does not appear to be increasing; however, recent epidemiologic studies have shown an increase among certain groups, including the young (particularly adolescents), inner-city minorities, and patients with acquired immune deficiency syndrome (AIDS).^{1,2}

Patients frequently seek nonpsychiatric medical care shortly before committing suicide. It is sometimes difficult for physicians without formal psychiatric training to recognize and evaluate depression and suicide potential in their patients, because many of these patients do not specifically complain of depression or readily admit their suicidal ideation or intentions unless specifically questioned.^{12,13} Emergency physicians are further hampered by the hectic environment of an emergency department, constantly changing priorities that limit one's ability to spend significant time with individual patients, and the difficulty in obtaining after-hours psychiatric consultation. Nevertheless, the emergency physician's ability to make these assessments and to decide when to seek urgent psychiatric referral or hospitalization for potentially suicidal patients is a vital link in the effective management of a highly disabling and often fatal affliction.

CLINICAL PRESENTATION

Depressed patients commonly complain of multiple vague, ill-defined somatic symptoms such as weakness, malaise, weight loss, headache, and back pain; however, a thorough medical evaluation should be made before attributing such physical complaints to a psychological cause. Depressed people frequently admit to a diminished sense of self-esteem and general physical and mental well-being; loss of interest in or lack of enjoyment of pleasurable activities; loss of energy; poor appetite; sleep disturbances, including insomnia or hypersomnia; decreased attention span and ability to concentrate; decreased effectiveness or productivity at school, work, or home; episodes of tearfulness or crying; irritability or excessive anger; a pessimistic attitude toward the future; and recurrent thoughts of death.¹²

The potential for suicide should be considered in the following groups of patients, among others:

Patients who have made a recent suicide attempt or have experienced recent suicidal ideation. While most completed suicides involve firearms, drug overdose accounts for 70% to 90% of all suicide attempts.² Major and minor tranquilizers and antidepressants have replaced barbiturates and other sedatives as the major agents involved in intentional overdose.

Patients who state that they are depressed or who complain of symptoms of depression

Patients who present with problems related to chronic alcoholism, drug withdrawal, or any psychiatric disorder (particularly affective disorders, psychosis, and panic attacks)

Patients who present with apparently unintentional overdoses or self-inflicted gunshot wounds, lacerated wrists, falls from heights, or motor vehicle accidents of unclear cause, particularly when only one vehicle and one victim are involved

DIFFERENTIAL DIAGNOSIS

A number of psychiatric and medical disorders may present with symptoms of depression. Approximately 80% of people suffering bereavement have one or more symptoms of depression for 1 year or more following the death of a loved one.² Persons suffering from an adjustment disorder may develop similar symptoms within several months of the onset of psychosocial stresses (e.g., economic loss, physical illness, or trouble with interpersonal relationships) with which they are unable to cope. The diagnosis of organic affective syndrome is made when symptoms of depression are found to accompany organic neurologic disease such as organic brain syndrome, stroke, tumor, or trauma. Symptoms of depression may be exacerbated or even caused by medications, including antihypertensive drugs (beta blockers, clonidine, methyl dopa, and reserpine), anti-depressants, antihistamines, neuroleptic agents, sedative-hypnotic drugs, cimetidine, and alcohol.¹⁰

When these diagnostic possibilities have been eliminated in a patient exhibiting symptoms of depression, a final diagnosis of dysthymic disorder (depressive neurosis, or minor depression) or major affective syndrome (major depression) should be considered. The difference is one of degree, and establishment of the final diagnosis is best left to a psychiatrist.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The clinical assessment of depression and suicide potential is an art as well as a science. Patients feel at ease to talk about difficult personal issues when health professionals exhibit a friendly, nonjudgmental, supportive attitude and convey their willingness to listen to problems and understand feelings. Several studies have shown that this is frequently not the case, however, particularly among emergency department staff. Reasons cited for these lapses include inadequate time and staffing, patient behavior that is perceived as either abusive or manipulative, value conflicts, and staff frustration regarding ineffective disposition and follow-up options.^{6,8} Expression of a negative or hostile attitude by a respected authority figure, such as a physician or nurse, reinforces a depressed patient's feeling of diminished self-worth and may actually increase the likelihood of another suicide attempt.

Patients who are not overtly depressed or suicidal but who exhibit one or more high-risk presentations should be assessed in a sympathetic but direct manner. First, the presenting complaint should be addressed by asking general questions about the patient's home, work, and social situation. This can be followed with specific questions regarding the signs and symptoms of depression. Finally, the physician should ask direct questions regarding suicide, such as, "Have you ever felt so bad that you thought about killing yourself?" or "Do you have thoughts of harming yourself now?" and "What plans have you made to do this?" Physicians are occasionally reluctant to ask patients directly about suicidal thoughts, fearing that this type of questioning will surface subconscious thoughts and result in suicidal acts. There is no evidence to support this concern; to the contrary, most depressed patients are relieved at the opportunity to discuss their problems openly when the clinician demonstrates an interest and a willingness to listen.

Patients who are judged to be markedly depressed or who present a potential immediate suicide risk should be relieved of medications or weapons and placed in a quiet area of the emergency department that is free of potentially dangerous objects, and where they can be kept under observation by a staff member at all times. No potentially suicidal patient should be allowed to leave the emergency department before an evaluation is completed; all states have statutes permitting detention by physicians of individuals deemed to be dangerous to themselves or others. Mechanical restraints should be used only if they are necessary to protect the patient or health-care providers. Chemical restraints may inhibit psychiatric evaluation and should be avoided, if possible.

Following the medical management of a patient's overdose, injury, or associated medical problems, the patient's degree of depression and potential for suicide should be assessed. Many studies have attempted to identify patients likely to engage in self-destructive behavior. Although no combination of clinical characteristics has been found that accurately identifies all patients likely to manifest suicidal behavior, a number of high-risk characteristics have been isolated. For example, a young woman who takes a few aspirin after fighting with her boyfriend is usually at low risk for actually committing suicide; an elderly man who takes the same action on the anniversary of his wife's death is another matter. Most patients fall somewhere between these two extremes, and estimating any particular patient's risk for self-harm

is often difficult.¹¹

Several high-risk characteristics have been incorporated into the mnemonic SAD PERSONS, which can help the clinician assess potentially suicidal patients ([Table 230.1](#)).^{3,7} In a nonintoxicated patient whose history can be corroborated by family or friends, the numerical SAD PERSONS score appears to be correlated closely with the need for hospitalization as determined by a psychiatrist after an in-depth evaluation. In one study, hospitalization was deemed necessary in almost all patients with a high SAD PERSONS score (greater than 8), in approximately half of patients with intermediate scores (6 to 8), and in almost none of the patients with low scores (less than 6).³ While the SAD PERSONS score is a convenient tool to help organize, document, and communicate the assessment of a patient's suicide potential, a low score should not preclude emergent psychiatric consultation when the physician is uncomfortable with his or her assessment or when the patient requests to see a psychiatrist.

	Description	Points
S = Sex	Male	1
A = Age	<19 or >45 years old	1
D = Depression or hopelessness	Admits to depression or decreased concentration, appetite, sleep, libido	2
P = Previous attempts or psychiatric care	Previous attempt, or previous inpatient or outpatient psychiatric care	1
E = Excessive alcohol or drug use	Signs of chronic alcohol or recent/frequent use	1
R = Rational thinking loss	Organic brain syndrome or psychosis	2
S = Separated, divorced, or widowed	Recent or an anniversary	1
O = Organized or serious attempt	Well-thought-out plan or life-threatening presentation	2
N = No social supports	No close family, friends, job, or active religious affiliation	1
S = Suicidal future intent	Determined to repeat attempt, or ambivalent	2
		TOTAL
		Score
		Risk
		<6 Low
		6-8 Intermediate
		>8 High

TABLE 230.1. SAD PERSONS Score

DISPOSITION

Potentially suicidal patients generally require admission to an inpatient psychiatric unit. Discharge from the emergency department should not be considered unless the following conditions have been met:

- The patient's injuries or associated medical problems do not necessitate hospitalization.
- The patient states that he or she is no longer suicidal, and is not intoxicated, demented, or psychotic.
- The acute precipitant of the crisis has been identified and, in some way, addressed.
- The patient has cooperated with an evaluation and is deemed to be at low risk for suicide. In general, nonpsychotic younger patients whose attempts involve low risk, high likelihood of rescue, and high manipulative intent can be discharged safely.
- Psychiatric consultation has been obtained (at least by telephone) and hospitalization has been judged unnecessary or inadvisable.
- Short-term outpatient follow-up (within 1 to 2 days) has been arranged. The reliability of such patients in scheduling and keeping follow-up appointments is poor. When emergency department personnel demonstrate a positive, supportive attitude and when the patient is given a scheduled outpatient follow-up appointment at the time of emergency department discharge, patient compliance with follow-up improves markedly.^{4,5,9}
- The patient agrees to return to the emergency department immediately if further self-destructive urges arise.
- A positive, supportive environment with family or friends is available into which the patient can be released. Arrangements should be made to remove all pills, poisons, and weapons from the patient's home.

A potentially suicidal patient should not be transferred to another medical facility or to a psychiatrist's office unless accompanied by medical personnel or family members who have agreed to deliver the patient to the stated destination and to maintain close observation of the patient during transport.

COMMON PITFALLS

- "Accidental" trauma may be a manifestation of self-destructive behavior. When the stated mechanism of injury is questionable or inconsistent with the injury seen, a more in-depth evaluation of the patient's mental state and motives is warranted.
- The information obtained from a potentially suicidal patient must be corroborated with family or friends. Patients who vehemently deny suicidality, give abrupt answers to questions, or appear anxious to leave the emergency department may be committed to finishing the act they began.
- Anxiolytics, antidepressants, or any other potentially lethal medication should not be prescribed to patients who are depressed or potentially suicidal. More than half of patients who die by intentional overdose use a single prescription drug.

The prevalence of psychiatric illness in a typical emergency department population is significant. In some cases, the psychiatric illness is the basis of the primary complaint; in others, it is an associated condition. The major goals of the emergency physician's evaluation are immediate stabilization and patient restraint, as necessary; diagnosis of life-threatening medical conditions that present as abnormal thought and behavior; and determination of a disposition that effectively addresses the patient's medical and psychiatric needs.

ANXIETY DISORDERS

Anxiety is a prominent complaint in 10% to 15% of all medical outpatient visits. It is subjectively experienced as a terrible sense of apprehension, worry, and nervousness and is often accompanied by physical symptoms that reflect intense sympathetic activity (e.g., palpitations, dry mouth, dizziness, paresthesia, faintness, and exhaustion). Anxiety is a pathologic condition when the patient's physical and emotional responses surpass the normal response to a perceived threat, and can interfere with optimal functioning. Anxiety may be triggered by a specific source and thus may be expected when that source is present (i.e., cued anxiety). Sometimes, however, anxiety is free-floating; in such cases, anxiety attacks may be unexpected and occur without a recognizable cue (i.e., uncued anxiety).²

Most medical conditions are associated with some degree of anxiety, but certain conditions can present with anxiety as a predominant feature. Examples include hypoglycemia, pulmonary embolism, myocardial infarction, hypoxia, drug intoxication or withdrawal, caffeine toxicity, mitral valve prolapse, paroxysmal atrial tachycardia, thyrotoxicosis, pheochromocytoma, and carcinoid syndrome.³ In addition, anxiety itself may cause comorbidity because its associated symptomatic responses create demands on previously impaired organ systems. Ruling out a primary or comorbid medical disorder is an important aspect of the initial and ongoing assessment. A focused history and physical examination initiate the assessment when medical illness or comorbidity is suspected. Screening laboratory tests typically include complete blood count, urinalysis, renal and hepatic studies, thyroid function tests, serum calcium and phosphorus tests, pulse oximetry, and a standard 12-lead electrocardiogram. Other tests can then be ordered, based on the findings of the initial evaluation.

DIFFERENTIAL DIAGNOSIS AND EMERGENCY DEPARTMENT EVALUATION

Anxiety that is not associated with general medical illness or substance abuse may be due to any of a number of reasonably well-defined disorders. The emergency physician should have a general understanding of the varying diagnostic criteria for these disorders, the generally used chronic treatment modalities, and the emergency department assessment and management of acute presentations.

Panic Attack

A panic attack is a sudden or "out of the blue" discrete period of intense fear or discomfort, in which at least four of the following symptoms develop abruptly and reach a peak within 10 minutes: (1) palpitations, pounding heart, or accelerated heart rate; (2) sweating; (3) trembling or shaking; (4) sensations of shortness of breath or smothering; (5) a feeling of choking; (6) chest pain or discomfort; (7) nausea or abdominal distress; (8) feeling dizzy, unsteady, light-headed, or faint; (9) derealization (a feeling of unreality) or depersonalization (being detached from oneself); (10) fear of losing control or going crazy; (11) fear of dying; (12) paresthesia; and (13) chills or hot flashes. Panic attacks can also be seen in association with any of the medical conditions previously discussed. These attacks are an extremely common psychiatric cause for presentation to the emergency department, with patients typically feeling unable to breathe or having atypical chest pain.

Panic attacks are the predominant feature of panic disorder, but also may be seen in depression, social phobia, simple phobia, and posttraumatic stress disorder (PTSD). Panic attacks associated with panic disorder and depression may occur without an associated trigger, the so-called unexpected or uncued panic attacks. Situational-bound or cued panic attacks occur immediately after exposure to, or in anticipation of, the specific situational trigger and are characteristic of social and specific phobias. A third type of panic attack is called situational-predisposed, which is most likely to occur when the patient is exposed to the situational trigger (cue) but is not invariably associated with the cue. In addition, it does not necessarily occur immediately after the exposure. Situational-predisposed attacks are most frequently seen in patients with panic disorder, but may, at times, occur in association with a specific or social phobia.

Panic Disorder

Panic disorder is characterized by four panic attacks per month, or recurrent, unexpected panic attacks that are followed by 1 month (or more) of persistent concern about having additional attacks, worry about the implications of the attacks or their consequences, or a significant change in behavior related to the attacks. The disorder may be associated with agoraphobia, which is an anxiety about being in places or situations from which escape might be difficult or embarrassing, or in which help may not be available if an unexpected or situational predisposed panic attack occurs. Agoraphobic fears typically involve characteristic clusters of situations that include being outside the home, being in a crowd or standing in a line, being on a bridge, and traveling in a bus, train, or car. The frequency and severity of the attacks vary, but the illness is generally chronic. Rates of suicide attempts among individuals with panic disorder have been found to be more than twice as high as those among patients with other psychiatric disorders, and 18 times higher than that occurring in a nonpsychiatric population.¹⁴ Such comorbidity must be considered when treating such patients in the emergency department and deciding on their disposition.

Specific Phobia

Specific phobia is a marked and persistent fear that is excessive or unreasonable, cued by the presence of a specific object or situation (e.g., flying, heights, animals, receiving an injection, seeing blood). Exposure to the stimulus almost invariably provokes an immediate anxiety response, which may take the form of a situationally predisposed panic attack. In this disorder, the patient recognizes that the fear is excessive, but feels powerless to prevent it, except by avoiding the trigger. This “phobic avoidance” then significantly interferes with normal, routine occupational, social, or relationship functioning.

Social Phobia

Social phobia is similar to specific phobia, except that the cue or trigger involves a marked or persistent fear of one or more social or performance situations. Patients fear that they will act in a humiliating or embarrassing manner. The anxiety generated by this fear may lead to a situationally bound or predisposed panic attack.

Obsessive Compulsive Disorder

Patients with obsessive compulsive disorder suffer from obsessions or compulsions (most commonly, both). They usually recognize that their behavior is excessive or unreasonable and are distressed because their behavior causes marked impairment in everyday function. Obsessions are recurrent or persistent thoughts, impulses, or images that are experienced as intrusive and inappropriate and cause severe anxiety. These are not excessive worries about real-life problems, and the patient attempts to ignore, suppress, or neutralize them with other thoughts or actions. Patients recognize that the obsessional thoughts, impulses, or images are products of their own mind. Compulsions are repetitive behaviors (e.g., repetitive hand washing, ordering, or checking) or mental acts (e.g., repetitively praying or counting, or repeating words silently) that the patient feels driven to perform in response to an obsession, or according to rules that must be rigidly applied. This behavior significantly impairs normal functioning.

Posttraumatic Stress Disorder

Patients with PTSD have usually experienced or witnessed an event that involves actual or threatened serious personal injury, death, or a threat to the physical integrity of self or others. The response to such an event involves intense fear, helplessness, or horror. The traumatic event is typically reexperienced by either recurrent and intrusive recollections of the event or distressing dreams of the event. The patient may act or feel as if the event were recurring, or may experience intense psychological distress at exposure to internal or external cues that resemble some aspect of the event. Such feelings are then acted out by persistent avoidance of stimuli associated with the trauma and a general numbing of responsiveness to any event, related or not. Such patients manifest symptoms of increased arousal, with difficulty falling or staying asleep, irritability or outbursts of anger, difficulty concentrating, hypervigilance, or an exaggerated startle response. The diagnosis is made only if the disturbance has persisted for more than 1 month and has caused significant social or occupational dysfunction.

Acute Stress Disorder

Acute stress disorder is similar to PTSD, except that there is a closer temporal association between the traumatic event and the onset of symptoms, typically a period of less than 4 weeks. Patients experience dissociative symptoms during or immediately following the event. Symptoms may include a subjective numbing, detachment, or absence of emotional responsiveness; a reduction in awareness of the surrounding environment, such as “being in a daze”; feelings of derealization or depersonalization; and dissociative amnesia.

Generalized Anxiety Disorder

Patients presenting with generalized anxiety disorder display excessive anxiety and worry that occur on most days for at least 6 months. Patients have difficulty controlling the worry and have associated symptoms of restlessness or feeling on edge, fatigability, difficulty concentrating, irritability, muscle tension, or sleep disturbances. To classify the anxiety as a disorder, the symptom should significantly impair everyday functioning.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Reassurance is the first-line intervention in patients with anxiety disorder. Patients should be assured that they are safe and that they are going to receive help. A firm, direct approach in a quiet, comfortable environment helps the patient feel secure and in better control. If a supportive interview does not work, pharmacologic intervention should be considered.

The benzodiazepines have long been considered the drugs of choice in the treatment of acute anxiety.¹ As a group, benzodiazepines are similar in their clinical effect, although they differ in pharmacokinetic properties. Short-acting benzodiazepines (half-life, 5 to 20 hours) include lorazepam (Ativan) and alprazolam (Xanax). The long-acting benzodiazepines (half-life, 20 to 200 hours) include diazepam (Valium), chlordiazepoxide (Librium), and clonazepam (Klonopin). These medications are usually effective for anxiety disorders.

When used chronically, however, benzodiazepines can cause physical dependence. Furthermore, when used acutely in the emergency department, administration of the medication can reinforce the belief that the only way to control anxiety is by the use of a chemical substance. The patient may subsequently turn to alcohol and nonprescription drugs when the prescription medication expires or no longer provides the needed relief. Patients may also begin to medicate themselves in anticipation of anxiety. This is often the beginning of a cycle of dependency.

For this reason, a new emphasis has been placed on the use of interpersonal psychotherapies, neurolinguistics, biofeedback, and behavior modification in the chronic management of such conditions.¹⁴ Although not all forms of anxiety are successfully treated by such techniques, there is a growing attitude that they should be tried, because they often bring partial, if not total, relief of symptoms.

Propranolol and other beta blockers have been used to control the autonomic symptoms of anxiety, such as tremor, tachycardia, and palpitations. If such symptoms can be relieved, the anxiety itself often abates. Propranolol is the treatment of choice in mitral valve prolapse–associated panic attacks and in the prevention of performance anxiety or stage fright.

Selective serotonin reuptake inhibitors (SSRIs) are now commonly used for many anxiety disorders, such as generalized anxiety disorder and panic disorder, even in the absence of depression. This is generally a safe and effective alternative to benzodiazepine use. They require approximately 1 month to take effect, however, so the more rapidly acting benzodiazepines may be needed concurrently in the short term.

The high rate of suicide attempts among patients with panic disorders must be considered, especially because approximately half of those who attempt suicide by overdose do so by using medication prescribed within the week prior to the attempt. If benzodiazepines are prescribed, only a small quantity should be prescribed, and close follow-up and subsequent psychiatric evaluation should be arranged. More importantly, the patient should first be assessed for suicidal potential.

Administration of intravenous benzodiazepines is appropriate in two particular anxiety states. The first is the patient who is so anxious that a threat is posed to self or others, especially if there is a history of poor impulse control. The second indication involves nonpathologic anxiety states, such as in a patient ready to undergo a potentially painful emergency department procedure.⁸ For such indications, lorazepam (Ativan), a short-acting benzodiazepine, can be given in doses of 0.5 mg every 20 minutes.

COMMON PITFALLS

- Assuming that an acutely anxious patient who is known to suffer from an anxiety disorder has no medical problem. Patients presenting with anxiety must be presumed to have a medical condition as the cause until it is ruled out by an appropriate emergency evaluation.
- Discharging the patient with anxiety disorder before suicidal and violence potential has been assessed. Patients who are actively suicidal, violent, or significantly disabled by their anxiety should be admitted to the hospital. Likewise, when the cause of acute anxiety is unclear, short-term admission for further

medical and psychiatric evaluation should be considered.

SCHIZOPHRENIA AND OTHER PSYCHOTIC DISORDERS

Psychosis is the predominant clinical feature of schizophrenia and the other psychotic disorders. The central clinical feature of psychosis involves an impaired perception of reality. The psychotic patient incorrectly interprets internal and external stimuli, even when there is evidence to the contrary. Characteristic features of schizophrenia and similar disorders include delusions, hallucinations, disorganized speech, grossly disorganized (or catatonic) behavior, and abnormal affect.³ Schizophrenic patients who have come to the emergency department may be actively hallucinating, delusional, or agitated. Such behavior is likely to have attracted the attention of family, friends, bystanders, bartenders, police, or a social worker who has brought the patient to the emergency department for evaluation.

Delusions are ideas that are fixed, false beliefs. The delusions of schizophrenia and related disorders are typically bizarre, patently false, and seem strange to others.¹² Persecutory and paranoid delusions may involve beliefs that the patient is being followed, watched, or controlled by machines or “outside forces.” Patients may have somatic delusions (“my body is rotting away”) or delusions of reference (“the television is talking about me”). Hallucinations are typically auditory and well organized. A voice may keep up an ongoing commentary on the person’s behavior or thoughts, or voices may converse with one another. Such voices sometimes insult the patient about sexual topics or may instruct the patient to act in bizarre or even dangerous ways. The schizophrenic patient’s speech can be incoherent or rambling and typically displays shifting of ideas without any apparent association (looseness of association). Behavior may be disorganized and may be manifested, among other ways, by a disheveled appearance. In schizophrenia, apparent emotion (affect) is impaired. *Flattened affect* refers to an apathetic or unemotional tone. Lack of volition or apparent thought (alogia) may also be present.

DIFFERENTIAL DIAGNOSIS AND EMERGENCY DEPARTMENT EVALUATION

There are several subtypes of schizophrenia, including paranoid, disorganized, catatonic, undifferentiated, and residual. Related psychotic disorders have been termed *schizophreniform disorder*, *schizoaffective disorder*, *delusional disorder*, and *brief psychotic disorder*. Detailed psychiatric evaluation is typically required to differentiate among these disorders.

The primary focus of emergency department evaluation is the differentiation of psychiatric illness from life-threatening medical conditions. Such conditions include meningitis, encephalitis, central nervous system hemorrhage, hypoglycemia, hypoxia, shock, hypertensive encephalopathy, poisoning (e.g., anticholinergic), and Wernicke encephalopathy. Other common medical conditions causing abnormal thought or behavior include drug intoxication or withdrawal, alcohol syndromes, liver or kidney failure, seizure, and ictal or postictal states. The suggested evaluation strategy for such entities is detailed in [Chapter 229](#).

The psychiatric evaluation includes a brief interview consisting initially of open-ended or undirected questions about the patient’s chief complaint or reason for being in the emergency department. The physician should be understanding, calm, and nonjudgmental. The patient’s speech and behavior are observed for signs of disorganization, delusions, or hallucinations. The second phase of the interview involves some questioning about medical history, the onset of illness, previous psychoactive medications, psychiatric hospitalizations, and other psychiatric care. The mental status should be assessed as part of the evaluation for acute medical illness. This should include, at a minimum, an assessment of general appearance, level of consciousness, spontaneous speech, and orientation to time and place. Additional testing for memory, calculation, and judgment should also be performed, if possible. The third phase of the psychiatric interview involves a brief summary by the physician and a statement of the plan for subsequent management, for example, telling the patient that a psychiatrist will be called in to help with additional evaluation. Answers to the patient’s questions should be clear, concise, and straightforward.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

The acutely psychotic patient needs psychiatric evaluation and, probably, hospitalization if the potential for violence or self-harm is suspected. The psychotic patient who expresses suicidal or self-harming thoughts or who has attempted suicide is at risk because he or she can exhibit unpredictable behavior in the immediate future.

New psychiatric symptoms (not caused by medical illness) or worsening symptoms (suggesting some kind of crisis or management failure) should ideally be managed in the emergency department by a psychiatrist.

Patients with chronic, stable psychiatric illness that is apparently under good control can probably be referred for outpatient management as circumstances dictate, but telephone consultation with the patient’s psychiatrist may facilitate evaluation and help ensure adequate follow-up.

COMMON PITFALLS

- Missing a life-threatening medical condition that presents as abnormal thought and behavior
- Neglecting to consider suicidal potential. Patients with certain psychiatric illness have a much higher suicide rate than those without such illnesses. Psychiatric conditions that place a patient at risk for suicide include major depressive disorder, bipolar disorder, alcoholism, panic disorder, borderline personality disorder, and schizophrenia.
- Neglecting to consider the potential for violence. The psychotic patient can suddenly and unexpectedly become explosively violent.

ACUTELY AGITATED OR VIOLENT PATIENT

A patient presenting to the emergency department who manifests violent or potentially violent behavior represents a threat to the safety of other patients and staff members. Measures to bring such a situation under control must be instituted immediately and usually involve summoning security personnel or police. A “show of force” may quiet the agitated patient and may be sufficient to bring the situation under control. If this is not successful, physical restraint, involving the minimum force needed to control the patient, becomes necessary.

DIFFERENTIAL DIAGNOSIS AND EMERGENCY DEPARTMENT EVALUATION

The evaluation of the violent patient involves the differentiation of psychiatric from medical causes ([Table 231.1](#)) and, specifically, an assessment for potentially life-threatening medical illness. Vital signs, general appearance, and mental status examination are among the most helpful aspects of such an evaluation. The differentiation of psychiatric from medical disorders is discussed in [Chapter 229](#).

Psychiatric illnesses associated with violent behavior include schizophrenia, affective disorder, personality disorders, adjustment disorders, and intermittent explosive disorder.

Schizophrenic Disorders

In psychotic episodes associated with the schizophrenic disorders, patients may react to stimuli unseen or unheard by the medical staff members. Violent outbursts may, therefore, be unexpected. Those with paranoid delusions may be attempting to protect themselves from others who are perceived as enemies. Mute and catatonic patients can be unpredictable and should be approached with caution.

Mania, Depression

Both mania and depression can be associated with hostile or violent behavior, but manic patients are more likely to present with agitated, hyperactive behavior. Such patients may become hostile if they feel their plans are being thwarted or they are not being taken seriously (e.g., being kept in the hospital away from things they need or want to do). Such persons may experience psychosis and may become visibly hostile. A show of force is often sufficient to suppress physical violence in these situations.

Antisocial Personality

Antisocial personality is often the diagnosis in those who have a history of lying, stealing, cheating, defying authority, pyromania, truancy, childhood aggression, excessive drinking, and substance abuse. It is not surprising, therefore, that such persons often are in prison or have a prison record. By definition, such patients feel little or no remorse for their actions, and so are among the most dangerous of hostile patients. They can be extremely difficult to manage because they often make promises to the staff but quickly break the agreement. Talking therapy is typically unsuccessful.

Adjustment Disorder

The essential feature of adjustment disorder is an emotional or behavioral response to a known psychosocial stressor. The response may include the symptom of anxiety, depression, or a disturbance in conduct, or some combination of these three. Disturbances in conduct result in a violation of the rights of others or of major age-appropriate societal norms and rules. Adjustment disorder is common, occurring in all age groups and in either gender equally. Talking with patients about the stressors in their lives and the options available to deal with them may help to avoid violent behavior.

Intermittent Explosive Disorder

Intermittent explosive disorder is a rare condition characterized by episodes of failure to resist aggressive impulses, resulting in serious assaultive acts or destruction of property. It is more common in men than in women. The degree of aggressiveness is out of proportion to any precipitating psychosocial stressor. The patient often feels remorseful or embarrassed by the violent outburst. The behavior usually causes significant impairment in both personal and work environments.

EMERGENCY DEPARTMENT EVALUATION AND PRECAUTIONS

Providing a safe physical setting minimizes the chance of harm by violent patients. This can be achieved only if the patient is quickly dispatched to an appropriate treatment area. Security personnel, the physician, and the head nurse should be notified. The use of a separate, isolated, quiet room tends to decrease the patient's agitation. The room should allow constant monitoring, either via shatterproof glass or a television camera. The room should be empty of any medical equipment and be sparsely furnished. Anything that could possibly be used by patients to harm themselves or others should be removed.

Both the history of the illness and the medical history are vital to accurate diagnosis. Other than the patient, who is often uncooperative, important sources of information include the patient's family and friends, paramedics, police, and possibly a mental health worker who knows the patient. Topics of particular relevance include the onset and course of agitated or violent symptoms, a history of previous threats or violence, a history of psychiatric illness, history of present drug or alcohol abuse, recent stressors, work-related problems, a family history of violence, or any childhood problems.

As in any life-threatening disease, the vital signs are among the most important parameters to assess. A brief, focused physical examination is helpful, when possible. On neurologic examination, any lateralizing signs may indicate an intracranial pathologic condition. Changes in pupil size or reactivity may indicate toxic ingestion. A brief mental status examination that assesses general appearance, affect, attention, language, orientation, and the presence of paranoid delusions, hallucinations, or other frankly psychotic symptoms is similarly helpful.

Any patient who requires an examination may need to be restrained first. The emergency department staff should be cautious, especially because physical contact is the most threatening form of interaction for an agitated patient. Considerable verbal reassurance may be required before an unrestrained patient submits to physical examination.

In addition to overtly violent behavior, indicators of possible violent actions by the patient include hostile behavior, verbal aggressiveness, statements about violent intent, or violent behavior immediately before arrival at the emergency department.

EMERGENCY DEPARTMENT MANAGEMENT

A presence of security officers conveys the message that aggressive behavior is not tolerated. Security staff members should be properly trained in their role, and they should not behave aggressively.

All staff members should be trained in the use of physical and chemical restraint before a crisis arises. The use of a code word to alert security, nursing, and physicians may be helpful. For example, calling for "Dr. Armstrong" when staff members feel that a patient is imminently dangerous can provide the same cohesive response provided by a trauma code in the appropriate setting.¹¹

A threatening patient evokes many emotions, including fear, anger, disgust, and pity, among emergency department staff members. Their actions or attitudes may be perceived by the patient as a threat to an already fragile ego. The patient's personal space and boundaries should be respected initially. A reasonable amount of space between patient and staff members helps to protect the staff and does not threaten the patient unnecessarily. Space can be reduced as the patient deescalates and develops some trust that the staff is there to help and not to harm, threaten, or demean. Assuming a nonconfrontational physical posture and moving and speaking slowly help to create an atmosphere of safety. Direct eye contact should be avoided as much as possible. Active listening, especially in the beginning, allows the patient to vent and ultimately feel that the staff members are concerned.⁹

Active listening refers to a technique in which patients are allowed to talk, and their words are then fed back by the interviewer in a slightly different way. This allows patients to feel heard and provides the opportunity for them to hear their thoughts expressed in a more objective way. Using a patient's own language creates a feeling of empathy. A confident style of active listening helps to put the patient more at ease. The staff members provide safety by letting the patient know, through their own behavior, that they will maintain control and will not tolerate certain behaviors.

Patients who are most likely to require physical restraint include the intoxicated, the actively psychotic (especially those with paranoid delusions), the antisocial personalities, those who are manic, and those with nonpsychiatric causes of their behavior. The most common pitfall in the use of physical restraint is in hesitating to act after it becomes evident that restraint is needed. The use of physical restraint is humane, safe, legal, and ethically appropriate for patients who pose a threat to themselves or others. Physical restraint should be carried out in the same coordinated manner as a trauma or cardiac arrest code. A team of at least five staff members must act together under the direction of one experienced team leader. Each team member is responsible for control of one limb, preferably at the major joint, and the team leader is in control of the head.

In a coordinated effort, the team leader directs the staff while letting the patient know exactly what is happening. The less hesitation exhibited by the staff, the more

safely restraint can be accomplished. Such coordination can be accomplished only when staff members are trained and practiced. A predesigned flowsheet aids in coordinating the team's actions and is an important source of documentation. Many patients feel calmer after being restrained, when uncontrollable impulses are diminished. Restraints are applied with the minimum amount of force necessary. The patient should be secured on his or her side if there is a danger of aspiration. A weapons search should immediately follow restraint, if one has not already been performed.

Physical restraint is often made unnecessary by effective chemical restraint, if it can be administered without risk to the patient or staff members. If physical restraint is the only option initially, once accomplished, it should be followed immediately by appropriate pharmacologic intervention.

The butyrophenones are the most widely used neuroleptic agents in the emergency department. Haloperidol (Haldol) has higher potency, is less sedating, and has a lower incidence of hypotension and cardiotoxic side effects than other neuroleptic agents.⁵ A typical dose for chemical restraint or rapid treatment of psychosis is 5 mg intramuscularly every 30 to 60 minutes, up to a total of six doses in 24 hours. Most patients respond to one to three doses. Haloperidol is a Food and Drug Administration class C drug and, as such, is not recommended for use in pregnant or lactating women. The primary side effects are extrapyramidal syndrome (EPS), usually presenting as an acute dystonia that can be treated with benztropine (Cogentin) 1–2 mg IM or diphenhydramine 50 mg IM or IV. Some clinicians administer benztropine prophylactically with the first dose of halperidol. Neuroleptic malignant syndrome is a rare complication.

Benzodiazepines have been especially effective in manic patients and those with alcohol and drug intoxication. Lorazepam (Ativan), 2 mg intramuscularly, has gained favor in recent years. Using haloperidol 5 mg in combination with lorazepam 2 mg provides effective control of most acute symptoms in most situations.⁶ The two can be mixed in the same syringe and be given as a single intramuscular injection.

Droperidol (Inapsine), given intramuscularly or intravenously, can also be used for chemical restraint. It works within minutes but has a shorter duration of activity than haloperidol (half-life, 2.2 hours vs. 10 to 19 hours). Droperidol is more sedating than haloperidol, and its major side effect is hypotension, which is usually transient but can be treated with the Trendelenburg position or intravenous fluids.¹³ An often-missed side effect of both agents is akathisia, an intense sense of restlessness or inability to sit still. If determined to be present, it is best treated with a benzodiazepine or a beta blocker, both of which are preferred to an anticholinergic agent.

DISPOSITION

Any patient who is a threat to self or others may be involuntarily detained. The amount of time a patient may be detained without court intervention varies from state to state; all emergency physicians should be aware of the provisions of their state's laws. Heroic measures often lead to harm to patient and staff, and should be avoided. The patient should be allowed to leave if no organized restraint is immediately available. If a suicidal or homicidal patient does leave the emergency department, the physician is under an ethical and legal obligation to notify the police and any persons specifically threatened.

Most patients who require physical or chemical restraint require psychiatric consultation and admission to the hospital, usually through a psychiatrist, after nonpsychiatric illness has been excluded. The one common exception is the alcohol- or drug-intoxicated patient who, after being restrained, "sleeps off" the intoxication and is no longer violent or agitated.

The emergency physician is often under pressure from staff members, police, and family to make a quick disposition. Careful and conservative management is the best course to take with potentially violent patients. Even psychiatrists have been shown to be not particularly good at predicting future violence.⁷ All patients who pose a threat to self or others, who are under the influence of alcohol or drugs, or who are actively psychotic should be detained until expert consultation directs otherwise.

COMMON PITFALLS

- Waiting for the agitated patient to become violent before intervening with physical or chemical restraint. The agitated patient who has not yet become violent is considerably easier to sedate than the actively violent patient.
- Assuming that agitation is due solely to a psychiatric condition. The use of physical or chemical restraint necessitates a more careful evaluation for the presence of a medical condition that may be responsible for abnormal behavior.

Factitious illness, malingering, and conversion disorder constitute a spectrum of medical conditions in which the patient's symptoms are false, pretended, or grossly exaggerated. The patient's symptoms may be voluntary (malingering and factitious illness) or may be an involuntary expression of an underlying psychological conflict (conversion disorder).² Distinguishing the physiologic conditions from the functional while addressing the patient's psychological issues is a test of the emergency physician's diagnostic acumen and therapeutic skill.

FACTITIOUS ILLNESS

CLINICAL PRESENTATION

Factitious illness is classified by the American Psychiatric Association according to whether the patient's presenting symptoms are psychological or physical.² In the syndrome of factitious illness with psychological symptoms, which is not discussed here, the patient presents with pretended psychological complaints, such as hallucinations, suicidal ideation, memory loss, or dissociative feelings.

The syndrome of factitious illness with physical symptoms is better known as Munchausen syndrome, named by Asher³ after the character in a book who had a penchant for telling fabricated stories, based on an actual eighteenth-century, retired German cavalry officer. In the novel by Rudolf Raspe, the baron enjoyed a series of fanciful, fantastic, and fabricated adventures. Like the baron, the patient with Munchausen syndrome is often a peregrinating impostor, that is, a wanderer and a liar.

Munchausen patients are impostors who invent bizarre and often fantastic stories and accept painful and potentially dangerous procedures (e.g., cardiac catheterization, exploratory laparotomy) to reach their presumed goal: to become a patient admitted to the hospital. There seems to be no other secondary gain, thus distinguishing the Munchausen patient from the malingeringer.

Munchausen patients typically present to the emergency department in a dramatic fashion, with a constellation of physical symptoms, plausibly suggesting the presence of substantial pathologic illness that is not present. Munchausen patients may simulate signs of disease (e.g., mixing a drop of their own blood into their urine sample) or actually induce a disease state in themselves (e.g., injecting exogenous material in themselves to produce fever and infection). They are typically young or middle-aged men (although the age range spans the pediatric to the geriatric), have a history of extensive travel, and report a medical history of previous hospitalizations and operations that have usually been performed in other cities. They are knowledgeable about hospital routines, but are often vague or inconsistent about medical details. Although Munchausen patients are clever, realistic, and facile in their simulation of clinical reality, the extent and severity of symptoms are often out of proportion to physical findings and demeanor, and may seem almost too classical in their constellation. Even about subjects other than their illness, Munchausen patients often exhibit pathologic lying (pseudologia fantastica).

Munchausen patients have been characterized as hostile, dependent persons with poor impulse control and a history of self-destructive behavior. They tend to be socially isolated, rarely are accompanied to the emergency department by friends or family, and, once admitted to the hospital, usually have no visitors. When confronted, they usually become hostile and querulous, deny the allegation of factitious illness, and sign out of the hospital against medical advice.

Munchausen patients simulate the broad spectrum of illnesses with varying degrees of authenticity. They may offer a history of advanced human immunodeficiency virus but have a normal physical appearance, or simulate life-threatening gastrointestinal hemorrhage or placenta previa.^{4,5,13} The different and often fantastic clinical presentations of the Munchausen patient have been described as laparotomophilia migrans, cardiopathic fantastica, neurologica diabolica, hyperpyrexia figmentatica, lithiasis nephrologica, dermatitis autogenica, and hemorrhagica histrionica.^{3,9,10}

When parents falsify illness in their children, the disorder is termed *factitious disorder by proxy* (FDBP) or *Munchausen syndrome by proxy* (MBP). MBP describes abuse in which the perpetrator (most often the mother) is motivated by the desire to assume the sick role by proxy or to seek attention from the hospital staff. Whenever this diagnosis is considered, it is important to define the specific abuse to the child. FDBP refers to the context of the abuse and the disorder of the parent. FDBP is child abuse and should be treated as such.¹¹ FDBP often presents with apnea, cyanosis, and seizures (from smothering and poisonings) in infants, whereas older children frequently present with toxin-induced diarrhea and vomiting. Child protective services need to be involved in these cases, and inpatient admission may be warranted. Children may suffer permanent disability or death.⁶

Less likely to present to the emergency department is the patient, usually a young woman, and often a nurse, with a distinctive subtype of chronic factitious illness. In contrast to the typical Munchausen patient, these patients tend to have persistent unexplained symptoms accompanied by documented self-induced physical abnormalities. These patients often have stable social and professional lives, and they usually develop strong attachments to individual physicians as their "illnesses" persist over time. Their medical problems include self-induced infections, nonhealing wounds, fevers, endocrine disorders (e.g., from self-administration of insulin or thyroxine), water intoxication, anemia, and bleeding disorders (e.g., from self-administration of anticoagulants).¹ Admission to the hospital is sometimes required to observe the patient in a controlled environment.

DIFFERENTIAL DIAGNOSIS

Munchausen syndrome must be distinguished from organic disease and malingering, and from three conditions in which the production of nonorganically based symptoms is not voluntary: conversion disorder, somatization disorder, and hypochondriasis.

In the absence of explicit evidence to the contrary, the clinician should presume that there is an organic basis for the patient's complaints. When the patient fits the pattern of presentation for Munchausen syndrome, however, evidence should be sought to confirm or disprove that suspicion.

An accurate delineation of the patient's medical history is generally the most useful information for making the diagnosis. The patient commonly relates a history of previous hospitalizations and physician contacts, all of which need to be either confirmed or identified as false. This activity may require a dogged devotion to tracking

down medical records at other hospitals and contacting the patient's previous physicians, many of whose names are misrepresented.

In contrast to the Munchausen patient, the malingerer has a clearly understandable external incentive and goal other than wanting to be a patient (e.g., to receive room and board, to receive drugs, to avoid work). Once that goal is met, the feigned illness resolves. Malingering may overlap with Munchausen syndrome in that a component of drug-seeking behavior exists in both; a substantial percentage of Munchausen patients want, as a secondary goal, to acquire narcotic analgesics. ¹²

In the three somatoform disorders (conversion disorder, somatization disorder, and hypochondriasis), the patient's symptoms are neither consciously willed nor voluntary. Conversion disorder is discussed in subsequent paragraphs. The patient with somatization disorder has a chronic history of multiple symptoms involving different organ systems in a fluctuating and recurrent pattern that is not adequately explained by a physical disorder. The hypochondriacal patient presents with fear and concern about the presence of disease and, despite reassurance, misinterprets normal bodily sensations and physical signs as pathologic conditions.

EMERGENCY DEPARTMENT MANAGEMENT

Until a diagnosis of Munchausen syndrome is confirmed, the patient should be treated as if an organically based disease is present. The usual diagnostic and therapeutic procedures should be followed.

If Munchausen syndrome is suspected but not confirmed, the physician may treat the patient in a modified manner (e.g., withhold large doses of morphine in patients with persistent chest pain and a normal electrocardiogram).

When Munchausen syndrome is confirmed, the patient should be managed with the goal of ameliorating symptoms. The physician may elect to confront the patient in a supportive and nonthreatening manner, although the establishment of a therapeutic alliance between patient and physician is unlikely.

Patients who are labeled with Munchausen syndrome can still become organically ill. Procedures that have been performed because of their imposture may predispose them to real illness (e.g., a small bowel obstruction may occur as a result of adhesions from a previous exploratory laparotomy for abdominal pain). Other patients may need medical treatment for self-induced physical ailments. The physician must not neglect to care for these patients because of their underlying psychopathologic condition.

DISPOSITION

If any doubt exists about the diagnosis of Munchausen syndrome and if the purported illness warrants admission, the patient should be admitted to the hospital for further evaluation. If the diagnosis of Munchausen syndrome is certain, however, the patient should be denied admission to the hospital for the presenting complaint. The refusal can be couched in medical terms (e.g., stating that the chest pain is noncardiac in nature), or the physician may confront the patient gently with the fact that there is a history of imposture. The physician may offer the option of psychiatric care, although it is likely to be refused.

MALINGERING

CLINICAL PRESENTATION

Malingering is the voluntary and conscious presentation of false and exaggerated physical or psychological symptoms in pursuit of a recognizable goal. Such goals typically include avoiding work or other unpleasant obligations, obtaining shelter, obtaining controlled substances, or obtaining financial compensation through litigation. Malingerers may either exaggerate or invent symptoms.

In contrast to factitious illness, in malingering, the goal is clear and understandable, the behavior is conscious and situationally appropriate, and the symptoms abate once the goal is attained.

Malingerers present to the emergency department with a variety of demands or complaints. Some patients who complain of migraine headache, renal colic, or sickle cell crisis are seeking narcotic analgesics. The evaluation of renal colic may be impeded by an inability of the patient to void under direct observation or by a volunteered history of allergy to intravenous contrast media. Other individuals may present to the emergency department after missing several days or even weeks of work and request a retroactive "sick slip" because of a medical problem, the presence of which is difficult to document definitively. Patients who have been in minor motor vehicle accidents may present with exaggerated symptoms of cervical or lumbar strain in an effort to document damages and collect financial compensation.

Patients with underlying psychiatric disorders may feign exacerbations of mood and thought disorders in order to be hospitalized for secondary gain. As many as one-fourth of emergency department psychiatric visits may represent malingering. These patients can be difficult to evaluate; often, they are admitted to the psychiatric service with a comorbid psychiatric diagnosis, with malingering strongly suspected. ¹⁸

DIFFERENTIAL DIAGNOSIS

Malingering is suggested if the patient overdramatizes complaints, symptoms, or physical signs; overreacts during the physical examination; is uncooperative during the diagnostic evaluation; declines to appear when scheduled for diagnostic testing; or is reluctant to accept a favorable prognosis. The history, physical examination, and laboratory data may not support the severity of the patient's complaints, particularly those that lack objective correlates for diagnosis (e.g., migraine headache). During their evaluation, some patients may reveal their true objectives (e.g., a prescription for narcotic analgesics or a medical excuse from work).

Patients apparently suffering an acute neuromuscular syndrome may complain of symptoms that do not fit an anatomically consistent pattern or may exhibit weakness during testing that is belied by their ability to carry out other activities when they are not being examined. Patients complaining of low back strain may demonstrate a large disparity between the "straight leg-raise" test performed in a sitting versus supine position, and, while in the supine position, the patient may not make an appropriate effort at raising the affected leg (detectable by placing a hand under the contralateral heel and feeling for the expected downward pressure associated with true effort).

If drug-seeking behavior is suspected, telephone contact with other emergency departments or a review of past medical records may reveal that the patient has exhibited a suspicious pattern of similar behavior.

EMERGENCY DEPARTMENT MANAGEMENT

Because the malingering patient may become defensive, angry, and hostile when confronted with the suspicion that the symptoms are false or exaggerated, the physician is often tempted to comply with the patient's demands rather than risk a confrontation. Furthermore, the diagnosis of malingering can rarely be made with complete certainty. Because each patient reacts to illness or injury differently, the degree of volition or willfulness that underlies the patient's exaggeration of symptoms is not always clear.

Perhaps the most prudent way to deal with a suspected malingerer is to give the patient a minimal amount of gratification and to invoke general rules or established policies that prevent the physician from filling the patient's demands completely. It is worthwhile to record on the patient's chart suspicions or questions about the patient so that the next treating physician is aware of the concerns. In flagrant cases, neighboring emergency departments should be contacted.

DISPOSITION

The usual criteria for admission to the hospital should apply, depending on the patient's complaint. If the physician is convinced that the patient is malingering, a firm stand should be taken against admission, despite the patient's wishes, although there are times when, in order to avoid a disruptive confrontation, it may be more prudent to admit the patient to the hospital and allow the details to be sorted out later.

CONVERSION DISORDER

CLINICAL PRESENTATION

Patients with conversion disorder present with physical symptoms that are not under voluntary control, that cannot be explained as a manifestation of a physical disorder or on the basis of a pathophysiologic mechanism, and that are unconscious expressions of underlying psychological conflict. Often, these symptoms are immediately preceded by an acute psychological stress, and that precipitant should be sought. Conversion disorder was previously called "hysterical neurosis, conversion type."

The most typical conversion symptoms involve loss of neurologic function: blindness, aphonia, pseudoseizures, paralysis, anesthesia, tunnel vision, gait abnormality, unresponsiveness, and amnesia.¹⁴ The conversion disorder symptom usually has a sudden onset. *La belle indifférence*, an attitude of relative unconcern despite the seriousness of the symptom, may be present, but its diagnostic importance is minimal. Patients with conversion disorder may also present with vomiting or symptoms of pregnancy (pseudocyesis).

The diagnosis of conversion disorder depends on demonstrating that the patient's symptoms are not due to organically based malfunction. With most neurologic presentations of conversion disorder, this is not difficult, because the patient's deficits usually do not make neuroanatomic sense. The physician's knowledge of neuroanatomy is usually better than the patient's; moreover, the patient is not consciously trying to fool the physician.

Typical "mistakes" made by the conversion disorder patient with neurologic symptoms include the following:

Acute onset of sensory loss in a sharp stocking-glove pattern (although this may be mimicked by the peripheral neuropathies of diabetes or alcoholism, and vascular lesions such as aortic dissection or subclavian vein thrombosis)

Complete paralysis and sensory loss of one leg, with preservation of deep tendon reflexes and antigravity muscle activity

Hemianesthesia without contralateral pain-temperature loss or with nonanatomic midline splits in vibratory sensation

Complete loss of motor function on one side of the body, with inability to turn the head to the side of paralysis (indicating contralateral sternocleidomastoid muscle dysfunction)

Pseudoseizures: seizure-type movements unaccompanied by characteristic electroencephalographic (EEG) patterns. Patients with a true seizure disorder may also experience pseudoseizures. Features suggestive of pseudoseizures include the presence of fluttering eyelids, thrashing of extremities or side-to-side head movement, dramatic vocalizations, and evidence of responsiveness to environmental stimuli during an apparent grand mal seizure. In addition, there is typically absence of tongue biting, incontinence, physical injury, or postictal depression. Differentiating a pseudoseizure from a true seizure can be difficult; for example, a complex partial seizure, with its seemingly purposeful behavior, may be mistakenly identified as a pseudoseizure.⁸

Cogwheel response on manual muscle testing^{8,17}

Slowness of motion. Patients with nonorganic muscle weakness may exhibit a general slowing of motor movements, not realizing that certain tests require more strength when performed slowly (e.g., deep knee squat).¹⁶

Inconsistencies in physical signs during unresponsiveness. The patient with nonorganic unresponsiveness often does not permit an upraised and suspended arm to strike the face when released, but rather allows it to glide harmlessly over the face (note that substantial injury can occur to the nose and mouth if the arm does drop directly onto them). Such a patient often vigorously resists manual eye opening by the physician; if opened, the eyes may be closed actively, in contrast to the smooth, effortless glide seen in the organically unresponsive patient.¹⁶

Nonorganically unresponsive patients always demonstrate both the fast and slow components of nystagmus on oculovestibular stimulation (cold calorics). Patients with a cortical lesion but an intact brainstem show only tonic deviation of the eyes; patients without either cortical or brainstem function show no deviation of the eyes whatsoever.

Inconsistencies in blindness. The patient for whom blindness is a conversion symptom demonstrates a remarkable ability to avoid injury and misstep. For patients complaining of tunnel vision, the visual field extending into space may be described as cylindrical rather than cone-shaped.

Nonneurologic presentations of conversion disorder are uncommon. Persistent unexplained vomiting may be a manifestation of revulsion and disgust; a psychological conflict that triggered the symptom should be sought. False pregnancy can be confirmed with a negative pregnancy test; the task is then to assess the patient's underlying psychiatric diagnosis.

DIFFERENTIAL DIAGNOSIS

Conversion disorder must be distinguished from organic illness, malingering, and Munchausen syndrome, as well as from somatization disorder and hypochondriasis.

The tendency should be strongly resisted to diagnose conversion disorder in any patient with vague symptoms. Up to 30% of patients who, at some time, have been given a diagnosis of conversion disorder are eventually found to have organic disease that could explain these symptoms.⁷ Illnesses such as systemic lupus erythematosus, multiple sclerosis, and hyperthyroidism may present in the emergency department as subtle perturbations of physical functions; hypoglycemia can present in myriad different guises.

The diagnosis of conversion disorder should not be made solely on the basis of a negative organic workup; the precipitating emotional stress and the unconscious conflict that the symptoms are designed to solve must be identified.⁹

Patients with conversion disorder lack the characteristic features of the Munchausen patient: There is no tendency to submit to multiple procedures, and there is a lack of sophistication with respect to medical terminology. Unlike the malingering patient, there is no conscious fabrication of illness or disability.

EMERGENCY DEPARTMENT MANAGEMENT

Patients with conversion disorder must be handled delicately, deftly, and with respect. It is unacceptable to confront the patient with an assertion or proof that the illness is faked or not real. The patient should be told that, although the symptoms are bothersome, they do not appear to be manifestations of a serious illness. Symptoms can sometimes be relieved by planting the suggestion that they will improve over the next several hours. Patients with aphonia can be told that they will be able to whisper; patients with paralysis can be told that they will begin to experience movement in their toes.

Simultaneously, the physician can probe for underlying psychosocial conflicts that might have led to the appearance of the symptom. Hypnosis may aid in identifying the underlying emotional conflict. An amobarbital interview may be useful in the management of the psychogenically unresponsive patient and in certain types of discrete conversion disorder.¹⁵

DISPOSITION

The neurologic consultant may assist the physician in differentiating organic from nonorganic illness. If the diagnosis of conversion disorder is secure and the patient's symptoms persist and prevent the patient from carrying out the activities of ordinary living, a psychiatric consultant may assist in the process of symptom

resolution in the emergency department, using talk therapy, hypnosis, or amobarbital.

Many patients with conversion disorder experience resolution of their physical symptoms during their emergency department stay, but some require admission to the hospital. If the diagnosis of conversion disorder is uncertain and if the presenting symptom could signify dangerous illness, hospital admission is warranted. Even when the diagnosis of conversion disorder is clear, patients whose manifestations persist and who cannot manage on their own (e.g., psychogenic unresponsiveness or paralysis) require inpatient care.

COMMON PITFALLS

- Failing to appreciate that the patient has an unusual presentation of an organic illness
- Permitting unpleasant aspects of the patient's personality to result in dismissal of the patient's problem as "psychogenic"
- Inadequately distinguishing among malingering, conversion disorder, and Munchausen syndrome
- Classifying all patients with symptoms having no discernible anatomic cause as "crocks"
- Losing interest in caring for the patient once it has been determined that the patient's symptoms are not organically based

Approximately 5% to 10% of all newborns require resuscitation following birth to establish spontaneous respirations.^{1,6} However, newborns delivered in or transported to the emergency department are considered high risk, and nearly 40% receive some form of resuscitation.⁷ Fortunately, the majority of these infants will respond to simple maneuvers such as drying, suctioning, oxygen, and gentle stimulation. Occasionally, more invasive resuscitation efforts are required. The key to successful neonatal resuscitation in the emergency department is to anticipate the special needs of the newborn, organize equipment, and prepare personnel to deliver appropriate, timely care.

PATHOPHYSIOLOGY

The goal of newborn resuscitation is to facilitate the transition from fetal to extrauterine life. Prior to delivery, fetal lungs are fluid-filled, gas exchange occurs through the placenta, and intra- and extra-cardiac circulation shunts blood through the foramen ovale and ductus arteriosus, largely bypassing the left side of the heart and lungs. After clamping the umbilical cord and the newborn's first breath, physiologic changes occur to allow survival in the extrauterine environment.

During the first initial respirations, fetal lung fluid is displaced, functional residual capacity is established, and pulmonary vascular resistance decreases. Clamping of the umbilical cord leads to increased systemic vascular resistance, resulting in closure of the foramen ovale and ductus arteriosus. The combination of these events leads to increased pulmonary blood flow and the establishment of normal extrauterine circulation. This normally smooth transition can be precluded by antepartum events that cause asphyxia.¹

There are many factors associated with neonatal asphyxia, but all asphyxiated newborns undergo a well-defined sequence of events. Initial deprivation of oxygen leads to a period of rapid breathing, followed by progressive bradycardia, decreased neuromuscular tone, and, finally, primary apnea.^{2,7} Oxygen and stimulation will induce spontaneous respirations in most newborns at this stage. If asphyxia continues, however, irregular gasping respirations occur with profound bradycardia, hypotension, and flaccidity until the infant takes his or her last gasp and enters into secondary apnea. Once secondary apnea occurs, death is imminent unless resuscitation with assisted ventilation and oxygen is initiated. From a practical standpoint, it is difficult to distinguish primary from secondary apnea; therefore, all apneic newborns are assumed to be in secondary apnea and are treated with ventilatory assistance.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Resuscitation of the newborn follows an orderly approach based on heart rate (HR), respiratory effort, and color. Though most newborns do not require invasive resuscitation, all should receive certain interventions (drying, warming, positioning, suctioning, and stimulation). Of those who require more advanced resuscitation, the majority will respond to supplemental oxygen or bag-valve-mask (BVM) ventilation. Very few infants require chest compressions, endotracheal intubation, or drugs for successful resuscitation.⁴ It is helpful to remember the inverted pyramid concept when encountering a newborn resuscitation ([Fig. 233.1](#)). Following this stepwise approach, excessive morbidity can be prevented by avoiding unnecessary procedures.

Figure 233.1. The reverse pyramid graphically represents the relative frequency that various modalities are needed to successfully resuscitate a newborn. Note that very few infants actually require the most invasive intervention, and most infants respond to noninvasive procedures. (Adapted from American Heart Association, American Academy of Pediatrics. Neonatal resuscitation. In: *Textbook of pediatric advanced life support*. Dallas: American Heart Association, 1997.)

Although most emergency department resuscitations occur without notice, adequate preparations can be made, specifically in the areas of equipment and personnel assignments that can facilitate the resuscitation process. It cannot be overemphasized that due to the abrupt, unexpected nature of emergency department resuscitations, unless equipment is meticulously organized and readily available, even the most sophisticated personnel will be unable to perform successful newborn resuscitations.

Preparation

Preparation for newborn resuscitation can be divided into two phases: (1) the remote phase (prior to notification of an impending birth) and (2) the immediate phase (after such notification).

Remote Preparation

[Table 233.1](#) outlines equipment that should be maintained in every emergency department and readily accessible at all times. It is convenient to organize certain items in a newborn resuscitation tray. Equipment and drug cards containing correct equipment sizes and drug doses for different-sized newborns (full-term, premature) are also helpful. A radiant warmer should be kept on at all times, and personnel skilled in newborn resuscitation should be available. The American Heart Association and the American Academy of Pediatrics sponsor a neonatal resuscitation course, and the Pediatric Advanced Life Support course includes a newborn lecture and skill station.

Radiant warmer, warm blankets, gowns, infant caps
 Suction, suction catheters (5F, 8F, 10F)
 Resuscitation bags (250 mL for premature only, 450 mL, 750 mL)
 Face masks (premature, newborn, infant sizes)
 Laryngoscope with Miller (straight) blades (no. 0 and 1)
 Medications (epinephrine, naloxone, dextrose, bicarbonate)
 Volume expanders (normal saline, Ringer's lactate, O⁻ blood)
 Gowns, gloves, masks, eye protection (universal precautions)
 The following can be organized into a specific newborn tray:
 Bulb syringe, tape, scissors
 Endotracheal tubes with stylet (2.5, 3.0, and 3.5 mm)
 Umbilical catheter with insertion kit (3.5F and 5.0F)
 Three-way stopcock, syringes (10 cc)
 Obstetric kit/umbilical cord cutting materials
 Meconium aspirator

TABLE 233.1. Neonatal Resuscitation Equipment

Immediate Preparation

The resuscitation of a severely depressed and asphyxiated newborn requires at least two people: one to ventilate (and intubate) and the other to monitor HR (and perform chest compressions). If a prolonged resuscitation is required, the assistance of a third person, to insert intravascular catheters and administer medications, is highly desirable. Assignments must be made quickly, and personnel must adhere to their assigned duties.

Although there is little time for an in-depth history, specific information is useful in preparing for resuscitation. Questions should be addressed concerning multiple gestations, gestational age, and the presence of meconium. A history of maternal drug use and vaginal bleeding may also be helpful. This information will alert personnel to the specific needs of the newborn and allow time for additional preparation, if necessary ([Table 233.2](#)).

History	Newborn Significance
1. Prematurity	Most require intubation
2. Multiple gestations	Multiple resuscitation set-ups; more personnel are needed.
3. Meconium	Suction hypopharynx/trachea before stimulation
4. Maternal drug (opioid) abuse	Avoid naloxone; it may precipitate withdrawal signs (seizures).
5. Maternal opiate administration	Consider naloxone for respiratory depression.
6. Maternal bleeding	May require fluid resuscitation

TABLE 233.2. Significant Maternal History

Assessment

Immediately following birth, all newborn infants should undergo the same initial assessment and basic resuscitation. It should be emphasized that several interventions may occur simultaneously and not in isolated, consecutive steps. For newborns delivered out of hospital who present vigorous and crying, the same initial assessment should be followed. When newborns deliver out of hospital but present intubated or with cardiorespiratory depression, airway management is the immediate priority, followed by the remaining steps of newborn resuscitation.

The initial phase of newborn resuscitation involves preventing heat loss, opening the airway, and evaluating the infant in terms of respiratory effort, HR, and color. ² These steps must be done quickly, so that more advanced resuscitation efforts can be performed if required.

Initial Resuscitation

On delivery, the umbilical cord is clamped and cut, and the newborn is placed under a radiant warmer. Unless meconium is present, the newborn is thoroughly dried with warm blankets to prevent heat loss and stimulate spontaneous respirations. Wet blankets should be removed immediately. The infant is positioned supine, with a rolled towel under the shoulders, and head midline. This will facilitate optimal opening of the airway in the slightly extended neck position. Suctioning of the mouth, then the nose can be accomplished with a bulb syringe or mechanical suction device. If mechanical suction is used, negative pressure should not exceed 100 mm Hg, and is used for only 3 to 5 seconds to prevent vagally mediated apnea and bradycardia. If further stimulation is required, gently rubbing the back or flicking the soles of the feet can be effective. Following this process, evaluation of respiratory effort, HR, and color are performed.

Spontaneous *respiratory effort* is adequate if the infant is able to improve color and maintain HR above 100 beats/min. ⁶ Following delivery, most infants respond to the tactile stimulation of the extrauterine environment by crying and gradually become pink. Some infants, however, require additional brief stimulation and 100% blow-by oxygen. Infants who are outright apneic or have gasping respirations require BVM ventilation with 100% oxygen. Institution of BVM ventilation should not be delayed by providing prolonged stimulation and blow-by oxygen. Once the respiratory effort has been evaluated and appropriately managed, HR can be assessed.

HR is determined by auscultating the chest, feeling the brachial pulse, or, most conveniently, palpating the base of the umbilical cord. In the uncompromised infant, the HR should remain greater than 100 beats/min. HR less than 100 needs to be closely monitored and BVM ventilation initiated (or continued). If the HR remains less than 60 to 100, further interventions with chest compressions or medications may be required.

The *color* of a healthy newborn will remain pink without supplemental oxygen. Acrocyanosis, or peripheral cyanosis, is not an unusual finding at birth. It is thought to occur secondary to cold stress and initially sluggish circulation, not to hypoxemia. ² True cyanosis, or central cyanosis, is determined by examining central structures and mucous membranes. Infants with central cyanosis, regardless of HR and respiratory effort, require supplemental oxygen and, generally, BVM ventilation and endotracheal intubation.

The Distressed Newborn

Following the initial assessment and resuscitation, there are two general outcomes that occur. The newborn is either vigorous and requires no further intervention other than close observation and postresuscitation care, or the newborn is distressed, mandating further resuscitative efforts. One situation that precludes normal resuscitation is that of the infant born with meconium in the amniotic fluid.

Meconium staining of the amniotic fluid generally implies fetal distress. It is found in 8% to 20% of all deliveries, predominantly in small for gestational age (SGA) and postterm stressed newborns. ¹ The clinical concern is to avoid meconium aspiration, with the resultant complications of meconium aspiration syndrome (hypoxemia, acidosis, and persistent fetal circulation). Interventions are aimed at depressed newborns and those born with thick, particulate meconium. Controversy exists over whether a vigorous baby with meconium-stained fluid requires tracheal suctioning. ^{5,6}

Clearing meconium from the airway begins with the delivery of the head, at which time a 10F or greater catheter is used to suction the mouth, pharynx, and nose. Following delivery, the infant is placed on the radiant warmer and care taken to avoid stimulation. The hypopharynx is suctioned under direct visualization on all infants exposed to meconium who are depressed and in any infant passing thick, particulate meconium. The trachea is then intubated and meconium suctioned from

the lower airway. Repeat intubation and suctioning can be performed until meconium is no longer recovered, provided the infant's HR remains above 60 beats/min.⁶ Unless vigorous, most infants will remain intubated, requiring positive-pressure ventilation (PPV). Following tracheal suctioning, the infant should be dried, warmed, and stimulated like other infants.

Distressed newborns require ongoing resuscitation. Following the initial evaluation, any infant who has apnea, gasping respirations, HR less than 100, or persistent central cyanosis requires BVM ventilation with 100% oxygen at 40 to 60 breaths per minute. Initial breaths may require 30 to 40 cm H₂O pressure to establish adequate lung volumes, but all subsequent breaths should be delivered at the lowest possible pressure. Good chest rise should be observed; if not, reposition the infant's head and attempt ventilation again. It is important to ensure a good seal between the mask and the infant's face. Placement of an orogastric tube, to prevent gastric distension, will be necessary if more than 2 minutes of BVM ventilation is required. After 30 seconds of PPV, the HR should be evaluated.

The HR is an internal monitor of ventilation adequacy. If the HR is greater than 100, observe for spontaneous, effective respirations and discontinue PPV. If the HR is 60 to 100 and increasing, continue PPV and reassess the HR in 2 to 3 minutes. A HR that is 60 to 80 and not increasing requires continued PPV and chest compressions. When the HR is less than 60 after the initial 30 seconds of PPV, or if, at any time, the HR is absent, chest compressions should accompany PPV with 100% oxygen.²

There are two acceptable techniques for neonatal chest compressions. Both thumbs may be placed on the lower third of the infant's sternum, just below the nipple line, with hands encircling the infant's chest. Alternatively, the sternum may be compressed, using two fingers (ring and middle or index and middle fingers) at the same location.^{9,10} The sternum should be compressed to a depth of one-half to three-fourths inch and accompanied by PPV at a rate of one ventilation for every three compressions, delivering 120 events per minute (90 chest compressions + 30 ventilations).⁸ Chest compressions should be smooth, with the fingers or thumbs not leaving the infant's sternum between compressions. Care should be taken to avoid applying pressure to the xiphoid process, as this may injure abdominal organs. Compressions may be discontinued if the infant's spontaneous HR exceeds 80 beats/min.

Endotracheal intubation is necessary whenever BVM ventilation is ineffective, prolonged PPV is required, or tracheal suctioning is necessary (e.g., meconium aspiration). It is also recommended when a diaphragmatic hernia is suspected to avoid gastric distension associated with BVM ventilation. Equipment size for intubation can be selected based on the infant's estimated weight and gestational age (Table 233.3). In general, premature newborns require a 2.5-mm endotracheal tube (ETT), while term newborns need a 3.0- to 3.5-mm ETT. A laryngoscope with a straight (Miller) blade is preferred (size 0 to premature, size 1 to term infants) to visualize the newborn's glottis and vocal cords. If a stylet is used, care must be taken to prevent the tip from protruding beyond the end of the ETT and injuring the airway. After intubation, proper ETT placement should be determined by careful physical examination and chest radiograph. Lack of chest rise, asymmetry of chest movement, and the lack of improvement in HR and/or color are signs of inappropriate ETT placement.⁶

Age (wk)	Weight (kg)	ETT (mm)	Insertion Depth (cm)	Blade
<28	<1	2.5	7	0
28-34	1-2	3.0	8	0
34-38	2-3	3.5	9	0-1
>38	>3	3.5-4.0	10	1

TABLE 233.3. Equipment Size Based on Estimated Age and Weight

Medications

Medications are rarely indicated during a newborn resuscitation and are reserved for specific situations.³ Epinephrine is recommended for asystole and bradycardia (HR less than 60 to 80) despite PPV with 100% oxygen and chest compressions for 30 seconds. Volume expansion with 10 mL/kg of crystalloid (normal saline, lactated Ringer's) or colloid (O⁻ blood, 5% albumin) is indicated when acute blood loss is suspected and signs of hypovolemia are present (pallor, poor perfusion, weak pulse). Naloxone is useful when there is severe respiratory depression and a history of maternal narcotic administration within 4 hours of delivery. Naloxone should not delay other resuscitation efforts, such as airway management, and should never be used if chronic maternal narcotic drug use is suspected, as it can precipitate withdrawal signs in the newborn. The use of sodium bicarbonate remains controversial. It is only indicated during a prolonged arrest that does not respond to other therapy after adequate ventilation is established. Glucose should be administered for documented hypoglycemia (less than 30 mg/dL in preterm, less than 40 mg/dL in term infants). A dopamine infusion should be considered when signs of shock continue despite volume expansion. Table 233.4 outlines the recommended doses and routes of administration of resuscitation medications. High-dose epinephrine is not recommended in neonatal resuscitations.

Medication	Concentration	Dose	Route
Epinephrine	1:10,000	0.1-0.3 mL/kg	i.v., ETT*
Volume expanders	Normal saline Ringer's lactate O ⁻ blood, 5% albumin	10 mL/kg	i.v.
Naloxone	1.0 mg/mL	0.1 mL/kg	i.v., ETT i.m., SQ
Sodium bicarbonate	4.2% solution (8.3 mEq/mL)	2-4 mL/kg	i.v. (1-2 mEq/kg)
Glucose	D ₁₀ W	2-4 mL/kg	i.v.
Dopamine	wt (kg) × 5 = µg/kg/min mL/h		
	For example, if kg × 6 × 5, then 1 mL/h = 5 µg/kg/min		
	Continuous i.v. infusion at 5-20 µg/kg/min		

*ETT = endotracheal tube

TABLE 233.4. Medications

The administration of medications can occur via several routes. In general, the quickest route to give epinephrine and naloxone is down the ETT. Medications given down an ETT should be two to three times the intravenous dose, flushed with 1 to 2 mL of normal saline and followed by BVM ventilation. Although intravenous access can be established in newborns, the umbilical vein may be the most rapidly accessible route to give all resuscitation medications, including volume expanders. The use of intraosseous lines in newborn resuscitation is not common because of the fragility of small bones, the small intraosseous space in premature infants, and the easily accessible umbilical vein.⁶ However, when other means of vascular access are not available, the intraosseous route may be attempted.

Vascular Access

When vascular access is needed, the umbilical vein is the most accessible site. Using sterile technique, a tie is placed around the base of the umbilical stump to control bleeding, and a scalpel is used to cut the cord 1.0 cm above the skin. The umbilical vein is easily distinguished from the two smaller arteries, which are usually constricted (Fig. 233.2). Flush a sterile 3.5F (premature) or 5.0F (term) umbilical venous catheter with normal saline and attach it to a three-way stopcock. The catheter is advanced into the umbilical vein until good blood return is obtained (5 to 8 cm). Wedged hepatic positions are recognized by subsequent failure of free blood return after introduction. If this occurs, the catheter should be withdrawn to a position where blood can be easily aspirated. Secure the umbilical venous catheter

to the skin with tape.

Figure 233.2. Insertion of the umbilical venous catheter.

Special Situations

Congenital Airway Obstruction

Newborns with choanal atresia present with cyanosis at rest but become pink with crying. This occurs secondary to membranous or bony obstruction of the nasal passages and is confirmed by the inability to pass a 5F catheter through the nares. An oral airway is useful, but endotracheal intubation may be required for adequate airway management. Infants with large tongues and a small hypopharynx may benefit from an oral airway and prone positioning.

Congenital Diaphragmatic Hernia

Infants suspected of having a diaphragmatic hernia present in respiratory distress immediately after birth, with a scaphoid abdomen and displaced cardiac impulse. Ventilation by BVM should be avoided, because it increases gastric distension and further compromises lung expansion. Infants may require endotracheal intubation and gastric decompression.

Congenital Heart Disease

Infants who remain cyanotic despite adequate resuscitation efforts may have congenital heart disease or persistent fetal circulation. Referral to a pediatric cardiologist for echocardiography is required. Prostaglandin E₁ may be necessary to maintain patency of the ductus arteriosus.

Maternofetal Hemorrhage

Vaginal bleeding may be a sign of placenta previa or abruptio placenta. Infants are at increased risk for hypovolemia and may require volume replacement before they will respond to other forms of resuscitation. Infants placed on the mother's abdomen prior to cord clamping are at risk for hypovolemia as well.

Multiple Births

Additional equipment and personnel will be required to manage multiple births. Resuscitation is frequently required secondary to mechanical complications of delivery and compromised cord blood flow.

Pneumonia/Sepsis

Newborns occasionally present with respiratory distress and signs of sepsis. Common bacterial causes include group B *Streptococcus*, *Escherichia coli*, and *Listeria monocytogenes*. After appropriate cultures and stabilization, treatment with ampicillin and gentamicin (or cefotaxime) is indicated.

Pneumothorax

Pneumothorax is not uncommon in the newborn who receives aggressive resuscitation. Symptomatic pneumothoraces are relieved with needle decompression at the second intercostal space, midclavicular line, or the anterior axillary line at the level of the nipples. Chest tube placement can occur after stabilization.

Prematurity

Premature newborns are prone to respiratory distress secondary to immature lungs and surfactant deficiency. Most will require intubation. They are also at increased risk for hypoglycemia, heat loss, and intraventricular hemorrhage during resuscitation. ⁹ Expedient transfer to a neonatal intensive care unit (NICU) is recommended.

DISPOSITION

All newborns require admission to the hospital nursery or an NICU following resuscitation. Consultation with a pediatrician or neonatologist is necessary at the earliest possible time to facilitate ongoing care and transfer, if necessary. If the newborn requires transfer to another hospital, an advanced cardiac life-support unit should be requested. Often, the accepting hospital will have a neonatal or pediatric transport team available. Newborns remaining in the emergency department for an extended time will need ongoing postresuscitation care.

Postresuscitation Care

Following stabilization of the newborn, special care should be taken to maintain temperature, avoid hypoglycemia, and monitor HR, blood pressure, and oxygen saturation. Infants remaining in the emergency department for any prolonged time should have labs sent, including CBC, arterial blood gas (ABG), and glucose level. A chest x-ray to assess ETT placement and rule out a pneumothorax is recommended. The infant can be ventilated at a rate of 40 to 60 breaths per minute until the ABG results are obtained. Maintenance intravenous fluids can be started with D₁₀W at 80 cc/kg/d, as electrolytes are generally not required in the first 24 hours of life. Lorazepam 0.1 mg/kg is effective to sedate the intubated newborn.

Some emergency departments receive infants who have already been resuscitated. In rural areas, for instance, many children are born at home or in transit, and present to the emergency department after resuscitation. Even in the successfully resuscitated infant, one should assume an airway complication until proven otherwise. It is very easy for an ETT to become dislodged or plugged and for a pneumothorax to be produced by overzealous ventilation. These newborns must be assessed immediately on arrival to the emergency department. Once stabilized, they should be transferred to the NICU as soon as possible.

The Apgar score ([Table 233.5](#)) is assigned at 1 and 5 minutes to all infants born in the delivery room and is helpful in documenting their transition to extrauterine life. It serves as a shorthand notation of an infant's condition and change in status, as well as a general prediction of outcome, although it has limitations. Application of the score to the extremely preterm infant is not standardized, and scoring in the presence of resuscitative interventions is not uniform. The Apgar score, although of prognostic value, should not be used as a guide to resuscitation of the depressed newborn in the emergency department. HR, respiratory effort, and color should serve as the guides to successive steps of resuscitation.

Sign	0	1	2
Heart rate	Absent	Slow (<100)	>100
Respirations	Absent	Slow, irregular	Good; crying
Muscle tone	Limp	Some flexion	Active motion
Reflex irritability	No response	Grimace	Vigorous
Color	Blue, pale	Acrocyanosis	Pink

TABLE 233.5. Apgar Score

SUMMARY

For most newborns, the asphyxial stress of birth is mild and brief and there is no need for sophisticated intervention. When the stress is excessive or the neonate's ability to compensate is decreased, resuscitation may be necessary.

Because newborn resuscitation rarely occurs in the emergency department, skilled emergency physicians and staff accustomed to adult resuscitation may find themselves unprepared or anxious. For this reason, it is important to assign roles in advance and to have appropriate equipment ready and available at all times. It is helpful to have the newborn inverted pyramid posted near or attached to the newborn equipment or tray (see [Fig. 233.1](#)).

After a successful resuscitation, transfer to the newborn nursery or to the NICU should be expedited. In the interim, particular attention should be paid to postresuscitation needs, such as temperature control and airway maintenance.

COMMON PITFALLS

- Failure to have specific neonatal resuscitation equipment set up and readily accessible, including a radiant warmer
- Lack of familiarity with newborn resuscitations in the emergency department; ongoing practice with mock codes is helpful
- Failure to initiate basic resuscitation techniques (dry, warm, position, suction, and stimulate) before invasive procedures
- Failure to adequately clear meconium from the hypopharynx and trachea before stimulating
- Failure to obtain a basic maternal history: twins, gestational age, meconium

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of Ann K. Leahy and Robert C. Luten, who wrote the previous edition of this chapter.

Resuscitation of an infant or child can be one of the most challenging and anxiety-producing experiences any physician will encounter in the emergency department (ED). The ability to recognize and treat life-threatening conditions requires prior preparation, experience, a substantial knowledge base, adequate airway and vascular access skills, and appropriate use of all resources.

The events just before, during, and after a pediatric resuscitation are all critical components to the successful resuscitation of an infant or child. The physician must be able to treat the family, as well as the patient, during and after the resuscitation. He or she must help the parents have some sense of understanding and control as their child is taken to a pediatric intensive care unit or help the parents begin the grieving process if the resuscitation efforts have been unsuccessful.

Annually there are 12.7 to 19.7¹⁴ pediatric arrests in the United States per every 100,000 children.¹³ Approximately half of the arrests are in children less than 1 year old.¹⁴ The survival rate of a child with cardiopulmonary arrest is between 0% and 13%. The most common initial rhythm is asystole.

Because most EDs have very few true pediatric emergencies, preparedness and education are crucial aspects of pediatric resuscitation. Less than 5% to 7% of pediatric ED visits are considered critical, and in less than 1% is cardiac or respiratory resuscitation required.

The pathophysiology of cardiopulmonary arrest and shock in children differs from that of adults in many aspects. Most pediatric cardiopulmonary arrests are caused by progressive deterioration in respiration or circulation due to traumatic or medical illness. Children have a remarkable physiologic compensation mechanism and maximize it just before the cardiopulmonary arrest. For this reason, there is significant intracellular hypoxemia and acidosis that decrease the cardiovascular system's ability to respond to medications and defibrillation.

CLINICAL PRESENTATION

Children who present in emergency conditions usually follow one of two pathways to cardiopulmonary arrest. The most common path leading to cardiopulmonary collapse involves respiratory failure (i.e., inadequate oxygenation–ventilation).

Causes of respiratory arrest can be divided into two categories. First, there is upper airway pathology, which includes anatomic abnormalities, infectious disease, inflammatory reactions, and foreign bodies. The second category is lower airway pathology, which includes interstitial disease, alveolar disease, and bronchus or bronchiole disease.

Shock (inadequate cellular energy supply) is the next most common pathway predisposing the child to cardiopulmonary arrest. Shock has many different etiologies, the most common of which is hypovolemia, either from dehydration or bleeding. Distributive shock is secondary to anaphylaxis, spinal cord injuries, or sepsis. Cardiogenic shock is secondary to an arrhythmia or mechanical abnormality, whether structural or infectious (i.e., myocarditis). Obstructive shock, secondary to cardiac tamponade or tension pneumothorax, and dissociative shock, secondary to hemoglobin abnormalities (carbon monoxide poisoning or methemoglobinemia), complete the list.

Thus, assessment of cardiopulmonary stability is of paramount importance. A rapid survey assessment (known as the Pediatric Assessment Triangle⁹) allows rapid evaluation of the child's appearance, breathing, and circulation status. This assessment can be completed during the first 15 to 30 seconds of the child's initial presentation.

Specifically, the parameters involved include the rapid assessment of the child's airway, breathing, and cardiac status; general appearance,⁹ skin color, and capillary refill; and a general neurologic assessment of the child that includes the child's mental status and best verbal, motor, and eye responses.

Throughout this chapter, fundamental differences, similarities, and intragroup differences related to size and age are highlighted as they affect resuscitation. Management goals of pediatric resuscitation are to correct hypoxemia and ventilation abnormalities, correct metabolic abnormalities (e.g., acidemia), and improve coronary, renal, and cerebral perfusion. A successful outcome depends on adequate alveolar oxygenation and carbon dioxide exchange, maintaining vascular perfusion, and correcting the underlying cause of the cardiopulmonary arrest.

EMERGENCY DEPARTMENT MANAGEMENT

Cardiopulmonary Resuscitation Overview

Single-rescuer cardiopulmonary resuscitation (CPR) should activate EMS after 1 minute of rescue breathing and compressions if the patient is less than 8 years old (more likely respiratory than cardiac).⁵ Infants and children should have a compression rate of 100 per minute and 20 ventilations per minute (5:1). The rescuer's hand should be on the lower half of the sternum and a depth of one-third to one-half the depth of the chest. Foreign-body maneuvers include back blows and chest thrusts for infants and the Heimlich maneuver for children. There are many investigational alternative methods for CPR, but none has been shown to have better outcomes than those described in the American Heart Association (AHA) guidelines for CPR.

Airway

The foundation of all pediatric resuscitative attempts is appropriate airway management. Because the airway in childhood is in dynamic growth, the clinician must deal with variables such as its anatomic location, caliber, and length. Consideration must also be given to variability in head size (occipital prominence), tongue, and mandible size.⁵

As the child grows, the larynx descends from its relatively superior and anterior position in infancy to the adult location, which it reaches by about age 10 years (range, 8 to 12 years). The narrowest portion of the extrathoracic airway in a child younger than 8 years is the cricoid ring, while in older children and adults it is the glottic opening. Head size, equal to or larger than chest circumference in the neonate, grows to adult proportions by adolescence.

Positioning the infant requires careful attention to the tendency of the prominent occiput to cause neck flexion and resultant airway occlusion. Mild extension of the

head (nontraumatic arrest) to achieve the “sniffing” position will provide airway patency in the child with adequate mandibular muscle tone. Overextension may cause airway obstruction by compressing the compliant trachea.

The large tongue may still occlude the airway, even with proper head–neck position. When hypotonia occurs, the mandible will no longer be maintained in a stable open position by the child, so the tongue will fall against the posterior pharyngeal wall, obstructing the airway. Appropriate maneuvers, such as a chin lift or jaw thrust, will move this block of tissue anteriorly and will open the airway. Airway devices, such as nasopharyngeal tubes for conscious children or oropharyngeal airways in unconscious patients, may be helpful once the airway has been opened manually. When the airway cannot be maintained using these maneuvers, or when other indications exist, an endotracheal tube (ETT) may need to be inserted.

There are many physiologic and anatomic differences between adult and pediatric airways. The previous section mentioned many of the anatomic differences in normal children. The physician taking care of children must also be prepared to treat patients with congenital malformations such as webs, tracheolaryngeal malacia, hemangiomas, cranial facial disorders, subglottic stenosis, and extrinsic and intrinsic foreign bodies. Physiologic differences between adults and children include the higher metabolic and oxygen consumption of children (which causes them to become hypoxic sooner), the smaller functional reserve capacity of children, their exaggerated vagal responses, and the higher airway resistance of children.

If the child has inadequate oxygenation or ventilation unresponsive to basic airway treatment, intubation is indicated. Preparations for this procedure should be started while the child is being properly positioned and oxygenated. A bag-valve-mask device with supplemental oxygen and oxygen reservoir can provide a 90% inspired concentration of oxygen, and the child can be ventilated until intubation preparations are complete.

Endotracheal intubation offers the following advantages:

It protects the airway from aspiration.

It provides a conduit for suctioning of secretions and debris.

It permits alveolar ventilation and corrects respiratory acidosis without compromising chest compressions.

It permits 100% oxygen instillation to the trachea with the possibility of applying positive end-expiratory pressure.

Full preparation includes an adequate large-bore suction device for clearing the oral and hypopharynx, a range of ETT sizes, smaller suction catheters for the ETT following insertion, and a laryngoscope with the proper size and shape of blade.

In general, a straight blade is preferable in children 4 years of age and younger. The curved blade should be used for older children. The straight blade is better in the younger child because the epiglottis and larynx are more cephalad and anterior. This anatomic configuration allows the straight blade to be placed in proper position easier than the curved blade. The curved blade must be placed in the vallecula for ideal use, whereas the straight blade is placed posterior to the epiglottis and does not require strict anatomic matching to the curvature of the tongue. The child's anterior and superior anatomy may preclude visualization of the entire anteroposterior dimensions of the glottic opening, even with sufficient help, lighting, positioning, and preparation. In fact, the clinician may be able to visualize only the posterior one-third of that opening.

A rapidly available supply of tubes in a wide range of sizes is needed to accommodate the size- and age-related differences of childhood. In most instances, ETTs without cuffs should be used in children younger than 7 or 8 years of age because the cricoid ring is small enough to produce an air seal. Controversy exists regarding the use of tubes with cuffs in children younger than 8 when a child has ingested a poison, because gastric lavage may potentially lead to aspiration. Theoretically, a cuff could provide better airway protection than could an uncuffed tube. As with any cuffed ETT, cuff pressure must be monitored and maintained at 20 cm H₂O or less to minimize the risk of mucosal ischemia and necrosis. This complication can also be avoided by using an uncuffed tube small enough to allow a minimal leak audible on positive-pressure ventilation.

The appropriate-sized ETT can be found by using a table of approximate sizes. These tables, however, require an accurate age or weight estimation for access of appropriate-sized equipment. Length has been shown to be the most accurate predictor of correct ETT size in children.¹¹ The Broselow Pediatric Emergency Tape (a length-based resuscitation tape) provides accurate equipment selection as well as resuscitation drug doses with a single length measurement. Two additional tubes should be available, one-half size smaller and one-half size larger. The child's small finger can serve as an approximation of his or her tracheal diameter, and an infant's length corresponds to the ETT size.

Because ETTs for children are short and easily dislodged from the trachea, one must be wary of tube movement and carefully secure the tube in position. Holding the tube and the corner of the mouth together until the tube is taped or otherwise held in position usually maintains this security. Once the ETT has passed between the vocal cords, proper position must be determined by auscultating the lung fields in both axillae. An endotracheal vapor cloud may be seen, and apparent breath sounds may be heard, even with esophageal intubation. The latter is especially common in small infants. The *sine qua non* of proper ETT placement is a patient whose vital signs improve, whose chest rises, and whose tissue perfusion improves. If the patient does not improve or if doubt exists, tube position may be checked by direct visualization using a laryngoscope. Alternate airway methods and personnel must be available for the difficult airway that cannot be ventilated or intubated.

Breathing

Once the airway is secured, attention should focus on breathing. The physiologic goals of oxygenation and ventilation require patency of airway and alveoli, normal alveolar capillary membranes, and matching of perfusion with ventilation. Patients with patent airways who require ventilatory support with bag-valve-mask devices must have the proper “bagging” technique employed to avoid complications.

Proper bag-valve-mask use demands a good mask–face seal with an appropriate-sized mask and the use of a bag that allows the provider to supply the necessary tidal volume. The mask must fit over the nose and mouth without compressing the eyes (compression of the eyes may lead to vagal-induced bradycardia) and without extending beyond the chin. A properly sized mask minimizes artificial airway dead space. A self-inflating bag is most commonly used. Overventilation may lead to unilateral or bilateral pneumothoraces; underventilation will lead to carbon dioxide retention and respiratory acidosis.

Whether using a mask or ETT, the clinician should provide a tidal volume that causes the chest to rise. A pop-off valve, if present, allows for a preset maximum inspiratory pressure. Additional tidal volume can be delivered at higher pressures by holding a finger on the valve while delivering the breath with the self-expanding bag. Ideally, an in-line manometer should be used to monitor peak inspiratory pressure.

Resting tidal volume in children and adults is 5 to 7 mL/kg, while ventilatory supported tidal volume may be 10 to 15 mL/kg. Rather than calculating a value, attention should be paid to lung and chest wall compliance while bagging, and the volume should be varied according to chest rise. Resuscitation bags for premature neonates should have a 250-mL capacity; 500-mL bags should be used for term newborns, infants, and small children. Adolescents require 750-mL bags.

Circulation

Adequacy of circulation is a clinical determination based on physical examination. The primary indication for assisting circulation with chest compressions is pulselessness. In neonates, chest compressions are also indicated when the heart rate remains below 60 beats/min despite effective maneuvers to oxygenate and ventilate the patient, or when the heart rate is between 60 and 80 beats/min and not increasing.

Access to the vascular space of infants and small children is required when there is an immediate need to restore circulating blood volume or to infuse medications that can be given by no other route. The most common cause of cardiopulmonary failure in children older than 1 year of age is trauma; most of these children are large enough to allow for rapid intravenous cannulation. Nontraumatic arrests in children younger than 1 year old are most often secondary to respiratory failure. Consequently, appropriate airway management may preclude full arrest, and if cardiac arrest does ensue, the endotracheal cannula provides a route for administration of certain necessary medications.

The most common sites for intravenous cannulation are dorsal hand veins, superficial veins on the dorsum of the foot, antecubital veins of the forearm, superficial scalp veins, the external jugular veins, and the femoral vein in the inguinal canal. Once the airway is patent and maintained, any one or more of these sites may be used. Standard cleansing and cannulation techniques should be used.

Both the external jugular vein and the femoral vein may provide passage to the central venous circulation through guidewire and long-line insertion. These procedures should not be first-line attempts; rather, short, reasonably large-bore cannulas should be placed first. When the patient is stable, these lines can be replaced under more controlled conditions.

An alternate site for access to the vascular space is the bone marrow. Infusion of blood, fluids, and medications into the circulation using the bone marrow has been done for over 50 years.¹⁰ Intraosseous (IO) cannulation can be accomplished using either the distal femur (proximal to the physis) or the proximal tibia (distal to the physis).

The bone marrow can be used to facilitate infusion of all resuscitation drugs and for volume resuscitation with fluids or blood.² These sites are used in the patient in full cardiopulmonary arrest who needs intravenous medications when intravenous access is not obtainable within 90 to 120 seconds.

Pediatric disposable IO infusion needles are available in various sizes for infants and children younger than 7 years of age but can be used in older children. Standard aseptic technique should be used. The IO needle can be removed once one or more intravenous catheters have been placed and are stabilized.

For most resuscitation medications, the intravenous doses are well recognized and standardized. For optimum action, these drugs should be given as close as possible to the heart. In the absence of specific pediatric recommendations, accepted intravenous dosage schedules should be used. Drugs given through the ETT should be delivered well down into the bronchial system for optimum mucosal absorption via a feeding tube (two to three times the dosage for lidocaine, atropine, and naloxone, and ten times the intravenous epinephrine dose). Drugs given through the bone marrow have dosages identical to the intravenous dosage and should be followed with a 2- to 5-mL saline flush to aid delivery to the central circulation. Some authorities also recommend a 2- to 5-mL saline flush after bolus intravenous medication administration.

Equipment selection, medication, and defibrillation dosing errors can be minimized by using standardized charts, forms, tables, and the Broselow Pediatric Emergency Tape. All information should be displayed in large type in an easy-to-read format and be prominently located for reference during critical situations. The AHA publishes resuscitation algorithms and drug dosages in the pocket-sized *Handbook of Emergency Cardio-vascular Care for Healthcare Providers*.

Resuscitation Medications

All of the drugs used during adult CPR can be used for children. For the most part, they function through the same molecular mechanisms. Thus, alpha- and beta-adrenergic receptors must be stimulated by exogenous agonists, as must the dopaminergic receptors. However, children may have fewer available receptors because of underlying maximal endogenous stimulation or incomplete development. The concerns after restoration of cardiovascular function include prolonged tachycardia and potential hypertension.

Oxygen, the mainstay of any resuscitation attempt, is the most important “drug” used during pediatric resuscitation. It has no contraindications, and airway management must be the first therapeutic modality instituted.

Fluids such as normal saline or Ringer's lactate should be used in the hypotensive infant or child. The initial fluid bolus is 20 cc/kg, which may be repeated up to three times, depending on the clinical condition. Packed red blood cells are dosed at 10 cc/kg.

Epinephrine, with both alpha- and beta-receptor action, is a potent medication to help reverse cardiac collapse, treat lethal arrhythmias, treat symptomatic bradyarrhythmias, and treat hypotension not related to hypovolemia. The cardiac beta- receptor action may improve output when heart rate is slow. Thus, epinephrine is often used in neonates and young infants to accelerate heart rate.

The alpha-adrenergic receptor activity that predominates in the doses used for cardiopulmonary arrest has many effects. It increases coronary and cerebral perfusion pressures; increases intravascular resistance of the skin, muscles, and splanchnic vessels; prevents arterial collapse of intrathoracic arteries; increases heart rate, myocardial contractility, and cardiac automaticity; and increases myocardial oxygen demand. All neonatal dosages are 0.01 mg/kg. Higher doses are not used because of the increased incidence of intracranial bleeding in this age group.

The initial intravenous/IO dose of epinephrine for patients outside the neonatal range in pulseless arrest is 0.01 mg/kg (0.1 mL/kg) of the 1:10,000 solution. All endotracheal doses² and subsequent intravenous doses are 0.1 mg (0.1 mL/kg) of the 1:1,000 solution for pulseless arrest. Note that the first dose of epinephrine, subsequent doses of epinephrine, as well as endotracheal epinephrine doses have the same amount of milliliters; only the concentration of the drug changes. These doses may be administered every 3 to 5 minutes during arrest. There is no evidence-based literature to support the use of high-dose epinephrine. High-dose epinephrine may increase return of spontaneous circulation (ROSC) but it does not improve survival to hospital discharge.^{4,8} In addition to increasing myocardial oxygen demand, epinephrine postresuscitation may cause prolonged hypertension and tachycardia after ROSC. For bradycardia, epinephrine may be given intravenously or IO at 0.01 mg/kg of the 1:10,000 solution, or 0.1 mg/kg of the 1:1,000 solution per ETT.

Atropine is a parasympatholytic drug used in cardiorespiratory arrest. It accelerates sinus and atrial pacemakers, reduces cardiac vagal tone, and increases atrioventricular conduction. Atropine increases heart rate and therefore improves cardiac output. In children, an improvement in cardiac output generally relies much more on heart rate than on an increase in stroke volume. Atropine is indicated for symptomatic bradycardia after oxygenation–ventilation and epinephrine have been given. It also attenuates vagolytic effects of infants and children during intubation.

The recommended dose of atropine is 0.02 mg/kg, with a minimum dose of 0.1 mg and a maximum single dose for a child of 0.5 mg and for an adolescent of 1.0 mg. The initial dose may be repeated once. The total of the two doses should not exceed 1.0 mg for the child or 2.0 mg for the adolescent. The endotracheal dosage of atropine is unknown but is generally given at higher than the intravenous dose (two to three times the intravenous dose). Side effects of atropine include paradoxical bradycardia and tachycardia, and increased myocardial oxygen demand.

Glucose is a medication uncommonly used during adult cardiorespiratory arrest. In infants and small children, the small reserve of endogenous glucose in the form of hepatic glycogen is readily exhausted during stress. Rapid bedside glucose testing, with easily usable equipment that provides accurate results, is mandatory in any location that resuscitation of a child may occur. Serum glucose and its anaerobic end product lactate can be monitored during the resuscitation process. If needed, glucose can be given intravenously or intraosseously in a dose of 2 to 4 mL/kg of 25% dextrose in water. Because dextrose concentrations over 12.5% may cause loss of integrity of small peripheral veins, it should be given in as large a vein as possible. The 10% solution should be used in neonates.

Naloxone is a narcotic antagonist and is used for potential narcotic overdose. The dosage is 0.1 mg/kg up to 20 kg, and 2 mg for anyone over 20 kg. There are no adverse side effects, but it does have a short half-life. It needs to be monitored, especially if the child has taken a long-acting narcotic.

Recommended indications for *calcium* are calcium channel blocker toxicity, hypocalcemia, hyperkalemia, and hypermagnesemia. If given, calcium chloride should be used in a dose of 20 mg/kg (0.2 mL/kg).

Respiratory and lactic acidosis are secondary to hypo- ventilation and hypoperfusion. Correction of acidemia is primarily by ventilation–oxygenation and restoration of circulation. *Sodium bicarbonate* is indicated for acidemia after a prolonged arrest when adequate ventilation–oxygen and cardiac compressions are being performed. During CPR, sodium bicarbonate should be given intravenously or intraosseously. The dose of sodium bicarbonate is 1 mEq/kg of the 8.4% solution. In the neonate, the dose is the same, but the solution should be 4.2%. The 8.4% solution can be converted to 4.2% by diluting it 1:1 with sterile water (not sterile saline). Side effects include hypernatremia, hyperosmolarity, alkalemia, and paradoxical cerebrospinal fluid and intracellular acidosis.

Dopamine is used to enhance urine output and treat hypotension not related to hypovolemia. Renal dosages are 2 to 5 µg/kg/min; beta-adrenergic effects, 2 to 10

µg/kg/min; and alpha-adrenergic effects, 15 to 20 µg/kg/min.

Lidocaine is used in ventricular tachycardia (VT) and ventricular fibrillation (VF) or symptomatic ventricular arrhythmias. The initial dosage is a 1-mg/kg bolus, followed by a 20- to 50-µg/kg/min drip.

Electrical Treatment of Rhythm Disturbances

Electrical dysfunction of cardiac muscle in childhood is most often secondary to respiratory failure and/or congenital heart disease. The most common rhythm disturbance after asystole is sinus bradycardia. It will respond to adequate ventilation and oxygenation, if provided early enough, and rarely requires medication. Sinus tachycardia is also seen and may present as the earliest sign of impending cardiopulmonary arrest. Both of these rhythms must be interpreted in light of possible causes, and the underlying cause should be treated. The ventricular arrhythmias in pediatrics are more difficult to treat, because children have a prolonged compensatory stage and therefore are much more acidotic and hypoxic than an adult who has a sudden collapse secondary to a ventricular arrhythmia. Electricity is the immediate treatment for pulseless VT or VF.

Electrical conversion energy levels for supraventricular tachycardia are 0.25 to 1.0 J/kg, while delivered energy for VF or pulseless VT starts at 2 J/kg. [Figure 234.1](#) illustrates current treatment algorithms for potentially lethal arrhythmias.

Figure 234.1. Treatment algorithms for pediatric advanced life support. (A) Bradycardia algorithm. (B) Asystole and pulseless arrest algorithm. (C) Tachycardia with poor perfusion algorithm. (From American Heart Association. *Textbook of pediatric advanced life support*. Dallas: American Heart Association, 1997.)

When electricity is being used to convert an unstable rhythm, appropriate-sized paddles must be placed in an appropriate position. The recommended paddle size for small children (less than 10 kg) is 4.5 cm in diameter, and up to 8 cm in diameter in larger children and adolescents. If only large paddles are available, they should be placed in the anteroposterior position. Regardless of position, a proper conducting medium must be used with full paddle contact on the chest wall.

Paying attention to the underlying ionic, metabolic, or mechanical causes of the unstable rhythm in a child is the mainstay of therapy. The child should be assessed for hypothermia or hyperthermia, hypoglycemia or hyperglycemia, and alterations in oxygen, potassium, calcium, sodium, and magnesium. Acid–base alterations must be corrected. Mechanical causes of pulseless electrical activity (PEA), such as hypovolemia due to dehydration, cardiac tamponade, tension pneumothorax, and ETT obstruction or misplacement should be rapidly addressed.

Implementing Resuscitation Principles

Successful resuscitation requires applying the principles of resuscitation, practicing psychomotor skills, and using proper equipment and drugs. One barrier to optimal results can be the difficulties caused by variations in the size of pediatric patients: It is not uncommon for valuable resuscitation time to be lost calculating drug doses or selecting appropriately sized equipment. This is compounded by the provider's anxiety and the potential for error inherent in this process. ¹² In adults, this problem is virtually nonexistent, because size variations and, therefore, drug and equipment needs do not change significantly from one patient to another. See [Table 234.1](#) for a list of recommended ED equipment and supplies.

The table lists various pieces of equipment and supplies categorized by patient weight (e.g., 0-10 kg, 10-20 kg, 20-30 kg, 30-40 kg, 40-50 kg, 50-60 kg, 60-70 kg, 70-80 kg, 80-90 kg, 90-100 kg). The categories include: Airway Management, Cardiac Monitoring, Cardiac Resuscitation, Circulation, Endotracheal Intubation, Fluids, Medications, Oxygenation, and Other. Each category lists specific items and their required quantities for each weight range.

TABLE 234.1. Guidelines for Minimum Equipment and Supplies for Care of Pediatric Patients in Emergency Departments

A system based on length has been introduced. The Broselow Pediatric Emergency Tape relates the patient's length to his or her weight and, therefore, to the appropriate drug dosage and also to appropriate equipment sizes. The tape provides immediate access to the correct drug dosage, as well as equipment selection, based on a single measurement. It is not enough to have the knowledge and the skills to resuscitate; any barriers to implementation of that knowledge must also be eliminated. Appropriate personnel, training, equipment and medications, and preparedness are the keys to a successful resuscitation.

Postresuscitation Stabilization

Avoiding secondary injury and frequent assessment of the ABCs, neurologic status, urine output, fluid administration, monitors, laboratory results, and vital signs are mandatory for successful postresuscitation stabilization. Sedation and pain management must also be appropriately addressed and monitored. Family members and friends must be continuously updated on the status of the patient.

Outcome Predictors

Respiratory arrests without cardiac arrests have a much higher survival rate. Patients in whom return of spontaneous circulation has occurred with less than 5 minutes of CPR and with fewer than two doses of epinephrine (vs. multiple doses) have a better chance of survival. Those patients who arrested because of VF and are treated rapidly have better outcomes than all other causes of cardiopulmonary arrest. Patients who arrest secondary to sepsis have the lowest rate of survival. Those patients who arrest and have a family member begin CPR have higher survival rates than patients who do not get immediate CPR. ¹³

Family Members' Involvement with Pediatric Resuscitation

Parent surveys have indicated that most parents find being at their child's bedside during a code helps them begin the grieving process if the resuscitation is

unsuccessful. Prewritten protocols and a health-care professional who can be with the family and answer questions as the code proceeds are a must for successful implementation.¹ These health-care providers can help explain procedures and recognize potential problems parents may encounter during the resuscitative effort.

Terminating an Unsuccessful Cardiopulmonary Arrest and Informing the Parents

Patients in cardiopulmonary arrests continuing longer than 30 minutes, unless they are hypothermic, have very little chance of survival. Informing the parents of a child's death is a skill in which very few physicians have any formal training. Most training focuses on interactions with the dying patient, not the bereaved family. Some general guidelines include telling both parents together, knowing the name of the deceased, telling the parents their child has *died* (not that their child is *dead*), looking professional, preparing the patient before the family enters the room, having counselors available, having a private grieving room, and making sure the staff has an adequate debriefing.⁶

PEDIATRIC RESUSCITATION PEARLS

Preparation and competent personnel are mandatory to adequately resuscitate children. Team approaches, with clear identification of individual roles, helps prevent confusion and potential chaos during a pediatric code. Resuscitation rooms in the ED, which are designed to facilitate pediatric resuscitations, help lower the stress of a very stressful situation. They have the appropriate equipment, medications, and room to facilitate the resuscitative efforts. Carts, which are color coded by length, have helped decrease medication errors during these resuscitative efforts.

Neonatal patients are usually not given atropine for bradycardia. The second dose of epinephrine for neonates in VF or pulseless VT is not increased as it is with all other VF and pulseless VT arrests. If the neonatal patient requires sodium bicarbonate, it is given at half strength. The umbilical vein is an excellent vascular access site in neonates. Suction pressure should not exceed 100 mm Hg in neonates and should not last greater than 2 to 3 seconds in any pediatric patient.

All medications given by intravenous, IO, or ETT routes should be followed by a small normal saline bolus. All children in cardiopulmonary arrest should have their glucose immediately checked. A bedside warmer should be used during all pediatric resuscitations. Pediatric patients should be kept in a slight Trendelenburg position during resuscitation efforts, to help prevent aspiration. Airway equipment and alternative airway equipment must be checked every shift to make sure it is always in working condition. The most important medication for any pediatric patient is oxygen.

Appropriate airway management and ventilation of an arrested child can be the difference between a successful and an unsuccessful resuscitation. The rhythm strip should be carefully examined in any pediatric arrest. Cardiopulmonary arrest secondary to sepsis has a very high mortality rate. Always consider child abuse or neglect if there are any inconsistencies in the caregivers' history or the physician's physical examination. Finally, be prepared to help a family begin their grieving process if the resuscitative efforts are unsuccessful.

COMMON PITFALLS

- Failure to have an organized system for stocking appropriate pediatric equipment and supplies
- Failure to perform routine mock codes and assessments of pediatric preparedness in the ED
- All staff should be aware of the anatomic and physiologic differences between pediatric and adult airway management.
- All staff should be knowledgeable about neonatal resuscitations and medications.

- [Paralysis](#)
- [Intubation](#)
- [Summary](#)
- [Common Pitfalls](#)
- [Chapter References](#)

Because all patients requiring emergent intubation, for whatever reason, must be assumed to have a full stomach, they are at risk for aspiration, and intubation must be done with all precautions taken to prevent this complication. Also, manipulating the airway can cause hemodynamic changes, including increases in intracranial pressure (ICP), which, in the head-injured patient, may lead to further central nervous system insult. Using rapid-sequence induction (RSI) with the aid of potent induction agents, muscle relaxants, and cricoid pressure to prevent passive regurgitation, patients can be quickly rendered fully unconscious, facilitating intubation and preventing the side effects of airway manipulation, especially iatrogenic ICP increases. The exposure time to the risk of aspiration can also be reduced. RSI helps facilitate endotracheal intubation in the combative or seizing patient, or in other patients in whom inadequate muscle relaxation prevents endotracheal intubation. The decision to employ the technique of RSI for emergent intubation should be based on a structured assessment of patient stability and the perceived difficulty of obtaining successful endotracheal intubation with the standard oral laryngoscopic technique.^{1,2} [Figure 235.1](#) demonstrates the Universal Emergency Airway Algorithm adapted from the *National Emergency Airway Management Course*.¹² Defined plans or algorithms for crash, difficult, and failed airways must be part of the armamentarium of any practitioner who utilizes RSI, and patients must be selected accordingly. Details of this process are beyond the scope of this chapter, which will focus on standard RSI.

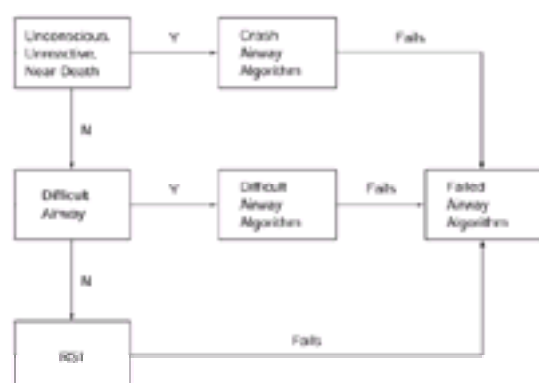

Figure 235.1. The Universal Emergency Airway Algorithm, adapted from the *National Emergency Airway Management Course*.

The steps of RSI are

1. Preparation
2. Preoxygenation
3. Premedication
4. Induction and paralysis
5. Cricoid pressure
6. Intubation

[Figure 235.2](#) presents a timed flowchart of the procedure. [Table 235.1](#), [Table 235.2](#), and [Table 235.3](#) outline the medications used in the scheme.

Figure 235.2. Rapid-sequence induction. This chart reflects details of timed activity of the procedure in the stable patient. All time intervals may be abbreviated by the clinician, if deemed necessary, because of less than optimal or deteriorating clinical status.

Drug	Dose (L.V.)	Action
Lidocaine	1.5 mg/kg	Lowers ICP
Atropine	0.02 mg/kg	Prevents bradycardia associated with airway manipulation and succinylcholine
Pancuronium/ vecuronium (defasciculating dose)	0.02 mg/kg	Prevents fasciculations and ICP elevations from succinylcholine in patients >5 years of age
Fentanyl (optional)	1-3 µg/kg	Attenuates sympathetic discharge and resultant elevations in ICP. Use with caution. May cause respiratory depression or blunt compensatory sympathetic tone

TABLE 235.1. Common Premedications in Rapid-Sequence Induction

Drug	Dose (i.v.)	Onset	Duration
Thiopental	3-5 mg/kg	10-30 s	10-30 min
Ketamine	1-2 mg/kg	1-2 min	15-30 min
Midazolam	0.2 mg/kg (maximum 5 mg)	1-2 min	30-60 min
Etomidate	0.2-0.4 mg/kg	1 min	30-60 min
Propofol	1.0-2.0 mg/kg	30-60 s	10-15 min

TABLE 235.2. Common Agents for Induction of Unconsciousness in RSI

Drug	Dose (i.v.)	Onset	Duration
Succinylcholine	1.0-1.5 mg/kg (>10 kg) 1.5-2.0 mg/kg (<10 kg)	30-40 s	4-10 min
Vecuronium	0.1-0.25 mg/kg (RSI) 0.1 mg/kg (standard dose)	90-90 s 2-3 min	90 min 25-40 min
Pancuronium	0.01 mg/kg (defasciculating dose)	2-5 min	45-90 min
Rocuronium	0.01 mg/kg (defasciculating dose) 1.0-1.2 mg/kg	30-40 s	25-40 min

TABLE 235.3. Common Agents for Muscle Relaxation in RSI

PREPARATION

Without adequate preparation, no amount of skill or expertise can ensure successful intubation. Lack of preparation also increases the likelihood of complications. *Advance preparation* includes equipment, medications, and team function, education, and orientation. *Immediate preparation* includes selecting appropriate equipment, selecting and preparing appropriate medications, and assigning team roles.

Advance Preparation

[Table 235.4](#) lists the equipment needed to perform RSI in children. Most pediatric equipment is age- or size-appropriate. Because the child's age and weight are usually not known in emergencies, using a length measurement such as the Broselow Pediatric Emergency Tape allows for correct selection of equipment and drug dosages.

Oxygen source
Bag-valve masks
Face masks (100% nonrebreather)
Oral airways
Laryngoscope handles
Laryngoscope blades
Suction system
Endotracheal tubes
Stylet
Cardiac monitor
Pulse oximeter
Cricothyrotomy supplies
End-tidal CO ₂ detector

TABLE 235.4. Equipment Required for Rapid-Sequence Induction

Adequate training for team participants is critical. Physicians must be skilled in advanced airway management and RSI, and nursing personnel also need practice with the mechanics of the procedure (e.g., cricoid pressure, the logistics of medication preparation). The Advanced Pediatric Life Support course includes a chapter and skill station on RSI, and there are now several national advanced airway courses available for training. Mock codes and practice sessions help prepare the team and ensure that resources are available.

Immediate Preparation

Early, prehospital length measurement permits timely equipment selection and drug dosage preparation. Team roles (e.g., leader, cricoid pressure designee) are immediately assigned, and the timing of the procedure is monitored by the team leader.

PREOXYGENATION

During RSI, the patient sustains a variable period of complete apnea. To prevent hypoxia by extending the time of adequately saturated blood, the patient must be preoxygenated. The purpose of preoxygenation is to produce nitrogen washout by having the patient breathe 100% oxygen, creating an oxygen reservoir.

In the patient who is spontaneously breathing, 2 to 5 minutes of 100% oxygen delivery by a non-rebreather mask should allow 2 to 4 minutes of apnea without hypoxia. In the apneic or inadequately ventilated patient, preoxygenation with a bag-valve-mask for 1 to 2 minutes should produce the same result. Cricoid pressure is applied during bag-valve-mask ventilation to prevent gastric insufflation.

PREMEDICATION

Certain medications used as adjuncts to RSI are given before the muscle relaxant ([Table 235.5](#)). *Lidocaine* 1.5 mg/kg is of benefit in lowering ICP. *Atropine* 0.2 mg/kg dries secretions and prevents reflex vagal tone and bradycardia due to airway manipulation and succinylcholine administration. It is recommended for all children below 5 years or 20 kg, and any child receiving succinylcholine as the muscle relaxant. An alternative is to give atropine as a premedication to all children, regardless of age or paralyzing agent used. It is a relatively benign drug and can help maintain heart rate—and therefore perfusion—in the face of potential hypoxia- or drug-induced bradycardia.

PREMEDICATIONS
Atropine Lidocaine Defasciculating agent
SEDATION
Ketamine Thiopental Midazolam Propofol Etomidate
MUSCLE RELAXANTS
Succinylcholine Vecuronium Pancuronium Rocuronium

TABLE 235.5. Medications Required for Rapid-Sequence Induction

If succinylcholine is used as a muscle relaxant, a pretreatment dose of a nondepolarizing agent is given to prevent muscle fasciculations and ICP elevations secondary to the succinylcholine. For children less than 5 years old or 20 kg (less muscle mass than older children and adolescents), this additional step is unnecessary. For the sake of simplicity, all premedications can be given 3 minutes prior to the administration of the induction and paralytic agent.

SEDATION/INDUCTION

The choice of induction agent depends on two variables: clinical condition and perfusion status. Advantages and disadvantages of the commonly used sedatives are listed in [Table 235.6](#). [Table 235.7](#) gives examples of the use of thiopental, midazolam, and ketamine, based on the patient's perfusion status and clinical condition.^{4,7} Other agents frequently used include propofol, etomidate, and diazepam, and all have advantages and disadvantages.

Drug	Advantages	Disadvantages
Thiopental	Rapid onset and duration Cerebroprotective effect Decreases ICP	Causes hypotension Histamine release → bronchospasm Increases ICP
Ketamine	Rapid onset Increases BP Bronchodilator	Increases ICP Emergence reactions
Diazepam Midazolam	Antiepileptic Antiepileptic	Long duration
Fentanyl	Short duration Reversible Analgesic effect Atemezates hemodynamic parameters	Possible ICP elevation Chest wall rigidity Variable dose response
Etomidate	Cerebroprotective effect Minimal hemodynamic effect	Cortisol suppression— <i>not</i> usually a problem in acute one-time use Myoclonic jerks
Propofol	Cerebroprotective effect	Causes hypotension

TABLE 235.6. Advantages/Disadvantages of Common Sedation/Induction Agents

Clinical Condition	Perfusion Status		Hemoglobin		Acidosis	
	Normal	Decreased	Normal	Decreased	Normal	Decreased
AGNI	Thiopental	Low-dose thiopental or midazolam	Midazolam	Ketamine	Ketamine or rocuronium	Ketamine
BIODNE	Cerebroprotective	Maximal depressant effect, local anesthetic dose		Increases BP	Ketamine's bronchodilator	Ketamine bronchodilates and raises BP

^aEtomidate preferred in any of these clinical conditions.

TABLE 235.7. Examples of Induction Agent Choices Considering Perfusion and Clinical Condition^a

Of the agents mentioned, etomidate is an agent that can be used in almost any clinical situation, and it has one of the best cardiovascular profiles. It is the agent of choice in RSI for many emergency department physicians.²

CRICOID PRESSURE: THE SELICK MANEUVER

The Sellick maneuver consists of digital cricoid pressure to occlude the esophagus and prevent passive regurgitation. The anatomic structure of the cricoid cartilage—a complete ring—prevents collapse of the airway while occluding the esophagus. If the patient vomits, cricoid pressure is immediately released to avoid esophageal rupture. Pressure is initiated as soon as the patient becomes sedated and is not released until the position of the endotracheal tube is verified. Cricoid pressure is always applied when using a bag-valve-mask to ventilate an apneic patient.

PARALYSIS

Paralytic agents are used to provide total muscle relaxation for optimal intubating conditions. There are two categories of muscle relaxants: the depolarizing agents (succinylcholine is the principal agent) and nondepolarizing agents (e.g., vecuronium, pancuronium, atracurium, and the newer, shorter acting agent rocuronium). The ideal agent acts quickly, thereby reducing the time to intubation. It should have a short duration of action, because if the patient cannot be intubated, he or she will require bag-valve-mask ventilation until the paralysis wears off. The agent should have minimal side effects.^{6,9}

The ideal drug for RSI is succinylcholine. Although it has many side effects, in the acute situation, they are rarely of practical concern. Pretreatment with a defasciculating dose of a nondepolarizing agent prevents rises in ICP. As noted, this is necessary only in the muscular patient (more than 5 years and 20 kg). Atropine pretreatment prevents the bradycardia associated with succinylcholine; such bradycardia is especially common if a second dose of succinylcholine is needed to achieve or prolong paralysis.

Nondepolarizing agents such as vecuronium or rocuronium can also be used as the paralyzing agent and require no pretreatment with defasciculating doses. However, the time to intubation is prolonged with the nondepolarizing agents. They also have a longer duration of action.¹¹ Newer nondepolarizing agents, such as rocuronium, offer the advantage of short onset of action without the potential side effects of succinylcholine or the need for a defasciculating dose for the older child.

INTUBATION

The intubation procedure during RSI is no different from the procedure in other situations. Patience is needed to await complete paralysis (approximately 45 seconds). A stylet is recommended for better control of the endotracheal tube. Tube position should be verified by auscultating the chest and colorimetric CO₂ detection before

releasing cricoid pressure. After succinylcholine administration, a nondepolarizing agent should be given to continue paralysis.

SUMMARY

Table 235.8 summarizes the medications used in the pediatric patient undergoing RSI. The scheme is one approach only and can be modified using alternative induction agents and paralytics if preferred.

0-5 min	Start preoxygenation
0-3 min	Atropine ^a
0	Etomidate + succinylcholine ^b
0 + 45 s	Intubate

^a For elevated ICP, add lidocaine and a defasciculating agent (if >20 kg). Fentanyl may be considered, but caution must be used because of the respiratory-depressant/sympathetic blockade effect in the compromised patient.

^b Substitute rocuronium for patients at risk for hyperkalemia.

TABLE 235.8. Summary of Medications Used in Rapid-Sequence Induction

COMMON PITFALLS

- Failing to have a system in place for RSI that includes all participants (i.e., medical specialists and nursing personnel)
- Lack of preparation of equipment and drugs before initiating the procedure
- Failing to preoxygenate
- Using bag-valve-mask ventilation in the spontaneously breathing patient
- Failing to perform the Sellick maneuver; failing to relax cricoid pressure if active regurgitation occurs
- Attempting intubation before muscle relaxation
- Failing to secure the endotracheal tube adequately after intubation
- Confusing a defasciculating dose with a paralyzing dose of a nondepolarizing agent before using succinylcholine
- Failing to follow succinylcholine with a nondepolarizing agent in patients requiring prolonged mechanical ventilation
- Failing to verify endotracheal tube position both clinically and with an end-tidal CO₂ detector

CHAPTER 236 Shock

Lucian K. DeNicola and James H. McCrory

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Volume Expansion](#)
[Cardiotonic Infusions](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Shock is a complex syndrome resulting from insufficient substrate and oxygen delivery (DO_2) to meet tissue metabolic demands (VO_2) (i.e., DO_2 less than VO_2). Untreated, it leads to metabolic acidosis, organ dysfunction, and death. Recognition, diagnosis, and treatment prior to irreversible organ failure can substantially reduce morbidity and mortality.^{3,6,7}

DO_2 is a direct function of cardiac output (CO) and arterial oxygen content (CaO_2); that is,

$$DO_2 = CO \times CaO_2$$

CO = heart rate (HR) \times stroke volume (SV). SV is the difference between the end diastolic volume (EDV) and the end systolic volume (ESV) and is influenced by preload, afterload, and contractility. CaO_2 is a function of the hemoglobin concentration (Hgb), arterial oxygen saturation (SaO_2) and arterial oxygen tension (PaO_2) (i.e., $CaO_2 = (Hgb \times 1.39 \times SaO_2) + 0.003 \times PaO_2$). Thus, DO_2 can be increased by increasing heart rate, preload, hemoglobin concentration, or arterial oxygenation and by improving the metabolic milieu or, occasionally, by decreasing afterload within certain parameters ([Fig. 236.1](#)).

Figure 236.1. Factors affecting oxygen delivery.

The pathophysiology of shock is far more complex than simple hemodynamics. Decreased DO_2 leads to cellular hypoxia and subsequent alterations in cytochrome oxidation. Reactive oxygen species (oxygen radicals) increase, causing further damage to tissue and initiating inflammatory pathways that lead to release of tumor necrosis factor, interleukin-1, arachidonic acid, complement, and myocardial depressant factors.⁴ In septic shock, endotoxin and lipopolysaccharide also stimulate these highly reactive substances.⁵ Although much has been accomplished in identifying and understanding these complex interrelationships, and specific treatments have been devised to block deleterious pathways,² the successful treatment of shock continues to be based on early hemodynamic improvement to prevent a vicious cycle of cellular destruction.

CLINICAL PRESENTATION

The early diagnosis of shock requires a high index of suspicion based on an understanding of conditions that predispose children to shock. The diagnosis is made by a thorough physical examination that focuses on the adequacy of tissue perfusion, because hypotension is a late and premonitory sign in children due to their ability to sustain pressure by increasing systemic vascular resistance ([Fig. 236.2](#)).

Figure 236.2. Cardiovascular response to hypovolemia from hemorrhage in puppies (based on normative data). (From Schwartzberg SD, Bergman KS, Harris BH. A pediatric trauma model of continuous hemorrhage. *J Pediatr Surg* 1988;23:605.)

The organ systems that are observable include the following:

Neurologic: Fluctuating mental status is a hallmark of poor cerebral perfusion, beginning with lethargy, agitation, and combativeness and progressing to unresponsiveness—even to painful procedures and coma. In infants, in the absence of meningitis, the anterior fontanelle may be sunken.

Skin and Extremities: In order to maintain vital organ perfusion, circulation to the skin and extremities will be diverted. The skin and mucous membranes may be cool, with pallor, cyanosis, and mottling. Rashes may be consistent with classic bacterial, viral, or rickettsial infections. Capillary refill at the nail beds will be greater than 2 seconds, and peripheral pulses at the wrist and ankles may be weak or absent. Poor muscle tone reflects decreased muscle perfusion and, coupled with central nervous system dysfunction, leads to prostration.

Cardiopulmonary: Hyperpnea and tachycardia may be the only cardiopulmonary signs in early, compensated shock, as increases in HR compensate for decreased SV, and hyperpnea compensates for metabolic acidosis. Auscultation of the chest is often normal unless the source of the shock is pulmonary edema or infection,

Volume resuscitation is the mainstay of all forms of shock therapy and is oriented toward restoring intravascular volume relative to the vascular space and optimizing ventricular preload. Even in shock due to myocardial failure, judiciously optimizing left ventricular preload (using aliquots of 5 cc/kg of 0.9% saline) can improve stroke volume. Initially, the resuscitation fluids of choice are either normal saline (0.9% NaCl) or lactated Ringer's solution. Except for shock due to myocardial failure, aliquots of 10 to 20 mL/kg are given rapidly over 2 to 10 minutes. The end point of volume resuscitation is clinical improvement in perfusion as assessed by a decrease in HR and compensatory hyperventilation, an increase in blood pressure, capillary refill, muscle tone and strength of peripheral pulses, and improvement in affect and skin color. These improvements may require from 60 to 100 mL/kg in fluid replacement. If no improvement is seen after 40 to 60 mL/kg of resuscitation fluid has been given, consider ongoing fluid losses or alternative causes of shock, such as adrenal insufficiency, intestinal ischemia, pericardial effusion, or pneumothorax. A chest radiogram may be useful to visualize heart size as a measure of the adequacy of volume resuscitation. When central venous access is obtainable, determination of central venous pressure may be useful in guiding further volume therapy. Early determination of serum glucose, electrolytes, calcium, acid–base status, and hemoglobin concentration will help guide the choice of solutions for definitive therapy.

Cardiotonic Infusions

Lack of unusual fluid losses by history, preexisting heart disease, hepatomegaly, rales, cardiomegaly, and failure to improve perfusion with provision of adequate oxygenation, ventilation, HR, and volume expansion should suggest a cardiogenic or distributive component to the patient's shock state. Cardiotonic and vasoactive drug infusions can further improve cardiac output and tissue perfusion by inotropy, chronotropy, or altering blood flow distribution.

Prior to the administration of cardiotonic–vasoactive drugs, the goals of therapy and the criteria for monitoring the end point must be established. Although a variety of agents are available, only a few drugs are appropriate for the acute resuscitation period in pediatric patients ([Table 236.2](#)) The child's outcome is dependent on both the expeditious reversal of the shock state and the definitive treatment of the underlying cause. Administration of antibiotics, antihistamines, hormones, antidotes or surgical intervention may preclude the need for prolonged cardiotonic treatment.

Drug	Dose	Effect	End Point
Epinephrine	0.05–0.15 µg/kg/min	Increases heart rate, improves contractility and increases systemic vascular resistance	Tachycardia, increased blood pressure
Dopamine	1–20 µg/kg/min Dopamine effects at low dose, beta-1 effects at medium dose, alpha effects at high dose	Increases renal and splanchnic blood flow, increases cardiac contractility and, at high doses, will increase heart rate and vascular resistance	Improved perfusion and urine output may improve blood pressure
Dobutamine	1–5 µg/kg/min	Increases contractility and may reduce systemic resistance	Improved perfusion; may slightly lower blood pressure
Prostaglandin E-1	0.05–0.1 µg/kg/min	Maintains patency of ductus arteriosus in neonates with cardiac lesions that are duct-dependent	Improved perfusion

TABLE 236.2. Suggested Drugs, Dosages, and End Points for Cardioactive Drugs for Pediatric Shock

DISPOSITION

Specific subspecialty referral is dependent on the etiology of the child's shock. In all cases, these children will require admission to an inpatient facility with the trained staff and facilities to care for a critically ill child. The child in shock should be transported by appropriate transport personnel that have pediatric experience and necessary equipment and medications.

COMMON PITFALLS

- The most common pitfall is failure to recognize pediatric shock, either due to the child's ability to maintain blood pressure by increasing HR and systemic resistance or due to early hyperdynamic septic shock where perfusion is maintained. To avoid this pitfall, the physician must have a high index of suspicion and perform a complete physical examination, with emphasis on the shock organs.
- Another common diagnostic error is to assume that all “shocky” children are septic when the true diagnosis may be a neurologic or cardiologic problem or an abdominal vascular crisis (i.e., volvulus or intussusception).
- A major treatment pitfall is inability to obtain adequate vascular access when a child is in shock. If peripheral access cannot be obtained within 3 minutes, alternate routes (intraosseous, central line) should be attempted.
- Another treatment pitfall is failing to rapidly administer the appropriate amount of volume expansion. Children have a higher blood volume relative to weight than do adults, and thus may require substantial volumes of resuscitation fluid. Determining the end point of volume expansion is based on clinical improvement and aided by serial chest radiographs to evaluate heart size. If central access was obtained, a simple bedside central venous pressure can be done by lowering a free-running intravenous line to observe the distance above the heart that backflow occurs. Conversely, excessive volume administration to a child with myocardial failure may lead to overwhelming pulmonary edema and possibly acute respiratory distress syndrome. When an infant less than 1 week of age presents in shock, be sure to consider congenital heart disease as well as sepsis. An initial chest radiograph showing cardiomegaly should preclude overly vigorous volume resuscitation and evoke an immediate pediatric cardiology consultation.
- Shock that is unresponsive to volume resuscitation and cardiotonic administration requires a broadened differential diagnosis that should include adrenal crisis, hypoglycemia, and hypocalcemia, as well as obstructive shock and abdominal crisis. Fingerstick glucose levels can be checked, and prospective treatment with cortisone and calcium is not contraindicated.

[Emergency Alternatives to Intravenous Access](#)
[Chapter References](#)

It is well known that establishing intravenous access in an infant or young child is challenging even under normal circumstances. In an acute setting, intravenous access is needed for the delivery of resuscitative medications, antibiotics, administration of volume expanders, correction of electrolyte abnormalities, and blood sampling for diagnostic tests. In the less emergent scenario, intravenous access allows provision of maintenance fluids for patients unable to maintain adequate oral hydration. Peripheral venous cannulation is the easiest and safest method of access and should be attempted before attempting more invasive methods.

The method selected for intravenous access is determined by the child's age, developmental level, and acuity status. In newborn resuscitation, the umbilical vessels may be used for vascular access. In children younger than 6 years of age who are critically ill or injured, the intraosseous (IO) route is an excellent alternative for intravenous access. Percutaneous central venous access may be attempted in a child of any age in an emergency. Another alternative that is less commonly used in pediatric emergencies is peripheral venous cutdown. Utilizing nonvascular methods for drug administration includes endotracheal, intragastric, intramuscular, subcutaneous, rectal, and inhalation routes. Arterial cannulation provides a direct means of continuously measuring blood pressure and sampling.

This chapter reviews various methods of vascular access and briefly addresses nonvascular routes used for emergency administration of some medications. The role of ultrasonography as an aid in the localization and cannulation of vessels is addressed.

PERIPHERAL INTRAVENOUS LINES

When emergent administration of fluid or medication is indicated, an intravenous catheter must be placed rapidly. The vein that appears easiest to cannulate should be attempted first. The child's developmental level is helpful in determining the best site to be accessed:

Infants: median antecubital basilic, median cephalic veins, scalp veins, and the dorsal veins of the hand

Toddlers: dorsal veins of the hand or foot, antecubital veins

Children greater than 2 years old: hand, forearm, and antecubital veins

The greater saphenous vein is often selected in pediatric patients because of its large size and consistent anatomy, and it may be cannulated successfully without palpation or visualization.¹²

Another useful access site in infants is the external jugular vein, although the infant must often be immobilized and placed in a dependent posture for safe insertion at the site. Unfortunately, external jugular catheters are difficult to stabilize and are easily dislodged.

The use of an arm board to immobilize the site, tourniquets, heat lamps, and transillumination devices can be helpful. It is extremely important to have adequate assistance in immobilizing the site and handling vascular supplies. Caretakers will usually become very emotional or angry if their child requires multiple intravenous sticks secondary to movement or unskilled health-care providers. The skin should be cleansed with alcohol or iodophor before the skin is punctured. A tourniquet should be placed proximal to the intended site of cannulation. A T-connector is often attached from the hub of the catheter to the intravenous tubing to avoid putting tension on the catheter. Sterile dextrose water or saline is then flushed through the catheter to ensure that it infuses freely into the vein.⁴ The catheter is taped securely to the skin, and the extremity is immobilized with a padded arm board. One or both hands may need to be immobilized or "mittened" to prevent the small child from pulling out the intravenous catheter.

PERIPHERALLY INSERTED CENTRAL CATHETER LINES

Peripherally inserted central catheter (PICC) lines are long-term intravenous access devices for peripheral insertion. They can be placed peripherally or advanced into the central circulation. Because the silicone PICCs are especially soft and pliable, they must be inserted with a through-the-needle technique either with or without a guidewire or forceps. Venipuncture is performed in the antecubital fossa. Before insertion, the basilic, median cubital, and cephalic veins need to be thoroughly assessed. A chest x-ray will confirm that the tip is correctly placed.¹³ Complications that may result from peripheral intravenous catheterization include hematoma formation, cellulitis, thrombosis, phlebitis, pulmonary embolism, and air embolism.

CENTRAL VENOUS CATHETERS

The central venous catheter is one of the most commonly used invasive tools in the management of critically ill children. Indications vary from routine access to emergent situations ([Table 237.1](#)).

Inability to establish peripheral venous access and the patient is hemodynamically unstable
Administration of large volumes of potentially caustic or incompatible medications
Delivery of parenteral nutrition
Hemodynamic monitoring in patients not responsive to resuscitative efforts

TABLE 237.1. Indications for Central Venous Access

A central venous catheter should not be inserted in a site where skin is infected or burned or in an extremity that has vascular insufficiency, hematoma, thrombus, or abscess.⁷ Percutaneous central venous catheter kits are available in various sizes. A 3.0F or 4.0F catheter should be used in infants younger than 1 year, while 4.0F to 5.5F catheters can be used in children 1 to 12 years of age. Catheters may be inserted percutaneously into the subclavian, femoral, or internal jugular veins using

the Seldinger technique.¹³

The femoral vein is the easiest and safest central vein to cannulate in emergencies because of its anatomic landmarks and large size, and it can be accessed without interfering with resuscitation.⁸ The leg is abducted and externally rotated. The groin is prepped with iodophor and draped. The femoral vein is located medial to the femoral artery, which can be palpated as a guide.

The area below the inguinal ligament, medial to the femoral artery is infiltrated with 1% lidocaine; be careful not to inject any intravenously or intraarterially. The introducer needle (with syringe attached) is then directed at a 30- to 45-degree angle to the skin, starting about 1 cm below the inguinal ligament and aiming toward the contralateral shoulder. Traction is applied to the plunger of the syringe once the needle has broken the skin. When blood return is noted, the syringe is disconnected from the needle; be careful not to change the angle of the needle in the process. The hub of the needle is covered with a thumb to prevent air embolism during a spontaneous breath.

A guidewire is then threaded through the needle, starting with the J-tip, until at least one-fourth of the wire is in the vein. The needle is removed, leaving the wire in place, and the scalpel is used to enlarge the skin entry site. A dilator is then threaded over the wire and advanced, with a twisting motion, through the skin. The tip of the wire is held in place to prevent its migration into the patient. The dilator is removed, and the catheter (which has been previously flushed with saline) is threaded over the wire through the skin entry site and into the vein. The catheter is not advanced past the skin until it is possible to grasp the tip of the wire at the external end of the catheter. This may require pulling out some of the wire that was previously placed. The catheter then may be inserted to the proper location, determined at the beginning of the procedure. The wire is removed, and a syringe of heparin flush is used to confirm good blood return and to flush the line to prevent clotting. The catheter is sutured in place, and a radiograph is performed to confirm proper position of the catheter.¹

Internal jugular and subclavian venous approaches also can be performed by experienced personnel, but these procedures carry the additional risks of pneumothorax and hemothorax.¹¹

INTRAOSSEOUS ACCESS

The IO route is probably the most useful and versatile of the emergency nonperipheral vascular access sites and should be considered in all children younger than 6 years when emergent access is crucial and attempts at peripheral vascular sites are unsuccessful. In extreme circumstances, the IO technique can be used in older children and adults when other vascular attempts are unsuccessful. The marrow cavity is much smaller in older children. Any drug or fluid that can be administered intravenously can be infused through the IO route. The IO route also provides a means for rapid and effective volume resuscitation using crystalloids, colloids, or blood products.⁹ The bone marrow can also be a source of laboratory studies for diagnostic as well as therapeutic interventions.^{5,14} The preferred site for IO infusion is the flat, anteromedial surface of the proximal tibia 1 cm inferior to and 1 cm medial to the tibial tubercle (Fig. 237.1). Other sites include the distal femur, the distal tibia proximal to the medial or lateral malleoli, and the iliac crests. There are several styles of commercially available IO infusion needles, and Jamshidi-type bone marrow aspiration needles can be used.

Figure 237.1. Intraosseous cannulation technique. (From American Heart Association. *Textbook of pediatric advanced life support*. Dallas: American Heart Association, 1997, with permission.)

The skin over the anterior tibia should be sterilized with iodophor and a towel roll or intravenous fluid bag placed under the knee to stabilize the lower leg. Starting 1 to 3 cm below the tibial tuberosity (to avoid damaging the growth plate), the needle is directed at a 90-degree angle to the medial surface of the tibia. When the needle passes through the cortex of the bone, a decrease in resistance will be apparent. Several signs help to confirm that the needle is in the marrow cavity:

- The needle will stand upright without support.
- When a syringe is attached to the needle, marrow can be aspirated (in approximately 50% of cases).
- Fluid infuses freely without signs of subcutaneous infiltration.

Complications of IO infusions are rare but include osteomyelitis, compartment syndrome, tibial fracture, and skin necrosis.^{1,5,14}

VASCULAR CUTDOWN

Surgical venous cutdown has decreased in popularity since the resurgence of the IO technique, but remains useful in emergency situations when attempts at percutaneous access and IO have failed or cannot be performed. The long saphenous vein that courses anterior to the medial malleolus at the ankle is the preferred site for cutdown.

The lower extremity is immobilized, with the foot turned laterally, exposing the saphenous vein anterior to the medial malleolus. A sterile field is prepared, and 1% lidocaine is injected subcutaneously over the vein. An incision perpendicular to the vein is made, and the vein is gently isolated by blunt dissection with a curved hemostat. Two silk sutures are looped around the vein; the distal one may be used to ligate the vein. With tension applied to the proximal suture loop, a venotomy is made with a no. 11 blade inserted into the lateral wall of the vessel and drawn upward. This avoids complete transection of the vessel. Finally, the cannula is inserted into the vein, advanced, and secured in place by tying a proximal suture loop. The wound is then closed with simple nylon sutures and dressed.

Percutaneously placed peripheral catheters are limited by short-term access, moderate infusion volumes, and solutions that are of low osmolarity. The most important complication in the use of peripheral vascular catheters is their potential to become partially dislodged or occluded, thereby resulting in leakage of nonphysiologic fluids into the extravascular tissue.²

UMBILICAL VASCULAR ACCESS

In neonates, the umbilical vessels may be directly accessed during the first several days of life directly or by intraumbilical cutdown. Both the umbilical vein (UV) and the umbilical artery (UA) may be used for blood sampling and fluid or drug infusion. The UA and the UV may be used for blood pressure and central venous pressure monitoring, respectively. Normally, two UAs and one UV exist. At skin level, the UV is usually in the 12 o'clock position and has a thinner wall and wider lumen than does the UA. The infant must be supine and restrained; maintenance of temperature and sterile technique is mandatory. The umbilicus is scrubbed with a bactericidal solution and draped, and a silk suture is looped around the base of the umbilicus stump. The distal end of the stump is cut off, and the vessels are occluded to prevent blood loss.

A 3.5F to 5.0F catheter is flushed with saline and inserted into the lumen of the desired vessel. Advancement of a UA catheter should place the tip above the celiac axis but below the ductus arteriosus. The UV catheter tip should lie a few centimeters into the UV or inferior vena cava (4 to 5 cm). Plain radiographs should be taken

to confirm placement.³ Complications of umbilical catheters include hemorrhage, infection, air embolism, and perforation of a blood vessel.⁸

ARTERIAL ACCESS

Arterial cannulation for continuous blood pressure and arterial blood gas monitoring is often necessary in critically ill infants and children. Sites available for arterial access include the radial, axillary, femoral, posterior tibial, and dorsalis pedis arteries. Most commonly, the radial artery is used. It lies between the distal radius laterally and the flexor carpi radialis tendon medially. It is important to assess the adequacy of collateral flow to the hand before radial artery cannulation, using a modified Allen test or Doppler flow evaluation.¹

The hand is secured on an arm board, with slight extension of the wrist to avoid excessive median nerve stretching. The fingertips should be left exposed when the hand is taped down so that any peripheral ischemic changes can be observed. Palpate the artery for maximal pulsation and introduce the cannula (22- or 24-gauge catheter) at an angle of 30 degrees. Making a nick into the skin at the point of entry with a larger needle facilitates introduction of the cannula. Blood is aspirated to confirm the intraarterial position of the cannula. Radial arterial cannulation can also be accomplished by the Seldinger technique or cutdown, these techniques being similar to that described for venous access. Similar techniques are used for cannulation of other arteries.³

The most common complications of arterial catheterization include minor skin lesions, localized hematoma, arterial bleeding, and arterial thrombosis with distal ischemia. The catheter should be removed immediately if any evidence of tissue ischemia develops.

ACCESSING PERMANENT INDWELLING CENTRAL VENOUS CATHETERS

Indwelling central catheters are placed in patients who require long-term chemotherapy, parenteral nutrition, antibiotics, and deferoxamine chelation therapy in patients with sickle cell disease. A variety of catheters (e.g., Hickman, Broviac) and implantable venous devices, or "ports" (e.g., Infus-a-port, MediPort), are used in pediatric patients. Familiarity with the technique of accessing indwelling catheters in a child who has one inserted can save multiple painful attempts at venous and arterial punctures, which are not without complication. The most common complications of chronic central catheters are infection, formation of thrombi, and breakage of the catheter.

THE ROLE OF ULTRASONOGRAPHY

In some situations, such as marked hypotension, pulses may not be easily palpable, making arterial catheterization extremely difficult and standard intravenous access difficult or impossible. The use of Doppler ultrasonography has been advocated to aid in the localization and cannulation of both arteries and veins. A recently introduced device incorporates a disposable ultrasound transducer within the lumen of a thin-wall vascular needle (P.D. Access, Advanced Medical Inc., Philadelphia). This allows detection of both arterial and venous sounds, and the intended vessel can be selected for access while avoiding trauma to other structures. The absence of a vessel can also be verified to potentially eliminate further trauma. Another device uses a Doppler transducer with a central orifice that allows passage of the needle through the transducer, once the vessel has been located, using B-mode ultrasonography (Site Rite II, Dymax Corp., Pittsburgh).

EMERGENCY ALTERNATIVES TO INTRAVENOUS ACCESS

A number of other procedures have been used in the past as alternatives to intravenous access when access could not be readily achieved. These included intradermal clysis, rectal clysis, intraperitoneal infusion, sublingual injection, and intracardiac injection.

In the past, intradermal clysis was usually performed with a needle inserted subcutaneously on the back between the scapulae. Clysis was used for volume replacement in dehydration states, but when perfusion is compromised because of hypovolemia or shock, clysis is unreliable and not sufficiently rapid. Rectal clysis involves the infusion of fluid into the rectum for volume replacement. It is also unreliable and erratic and risks rectal perforation, septicemia, and increased volume loss from rectal stimulation and diarrhea.

Intraperitoneal infusion has also been used for volume replacement and, although more effective than clysis, it is clearly not as effective as IO or intravenous fluid administration and risks viscus perforation, injury to other abdominal organs, and the introduction of infection and peritonitis.

Sublingual injection cannot be used for volume infusion, but the sublingual area is a route for the administration, in an emergency, of drugs such as epinephrine, atropine, or lidocaine. Sublingual injection is based on the preferential maintenance of perfusion to the face and brain, even in states of hypovolemia or shock. There is a rich vascular plexus on the underside of the tongue. Unfortunately, studies have demonstrated that the sublingual and intralingual injection of drugs is not very effective in shock or arrest states.

Intracardiac injection was widely practiced in the 1950s and 1960s as a means of administering emergency drugs when an intravenous route was not available, and also of directly administering drugs to the heart when intravenous administration was ineffective. The intracardiac injection of drugs was abandoned by the American Heart Association in the late 1970s, when studies demonstrated that the risks of intracardiac injection exceeded the benefits.¹

CHAPTER 238 Abdominal Pain

Javier I. Escobar II and Steven A. Godwin

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Abdominal pain is a common complaint in children presenting to emergency departments (EDs). It is estimated that abdominal pain alone accounts for approximately 5% of ED visits,³ and that abdominal pain accompanied by vomiting and diarrhea account for nearly 20% of general and pediatric ED visits.¹⁰

Abdominal pain in children is caused by a variety of disorders, and, in each stage of childhood, the common causes of abdominal pain differ. The emergency physician must be able to recognize causes of abdominal pain in children of all ages, from neonatal surgical emergencies to the more typical adult problems of the teen-ager.

Although most etiologies of abdominal pain are benign, it is imperative to identify those that are true emergencies. Prompt recognition of abdominal emergencies, with rapid institution of treatment, can significantly reduce morbidity and mortality in pediatric patients. Unfortunately, early recognition of serious abdominal disorders is often difficult. As an example, one study showed that 28% of pediatric appendicitis cases were initially misdiagnosed.¹² Accurate diagnosis is further complicated by the atypical presentation of abdominal emergencies. It has been reported that the classic triad for intussusception—currant jelly stool, colicky abdominal pain, and vomiting—is noted in as few as 10% to 40% of patients.⁵

A useful method for facilitating the evaluation of children complaining of abdominal pain involves separating the various disorders on an age-related basis ([Table 238.1](#)).

Infants	Toddlers	School-Aged	Teenage
Colic	Acute gastroenteritis	Allograft	Appendicitis
Intussusception	Urinary tract infection	Appendicitis	Pelvic inflammatory disease
Malrotation	Constipation	Acute gastroenteritis	Peptic ulcer disease
Volvulus	Adrenal pain	Constipation	Group pregnancy
Hirschsprung disease	Appendicitis	Urinary tract infection	Mitral regurgitation
Necrotizing enterocolitis		Peptic ulcer disease	
Incarcerated hernia			

TABLE 238.1. Differential Diagnosis of Abdominal Pain in Children

CLINICAL PRESENTATION

The most common condition of infancy, presenting with apparent abdominal pain, is colic.⁶ The predominant symptom is prolonged, continuous crying. The infant may have mild abdominal distention and may pull the knees up against the abdomen, giving the parents the impression that the infant is experiencing abdominal pain. The infant may be inconsolable, although rocking, swinging, or a car ride may calm the baby. The pattern of the pain is predictable, coming on suddenly in the late afternoon or evening. Feeding irregularities, such as excessive air swallowing and gulping, inadequate burping, or bottle propping by the caregiver, may be historic clues.

The physical examination, except for the infant's crying, is often unremarkable. In contrast to the colicky baby, an infant with a serious abdominal disorder often has signs of intestinal obstruction with vomiting and distention. Of particular mention is the infant with bilious vomiting, which should prompt the emergency physician to suspect a mechanical obstruction proximal to the ligament of Treitz. This suspicion should be greatly increased in the absence of rhinitis, sneezing, fever, diarrhea, and other symptoms associated with a systemic viral illness.¹³ Nonsurgical causes of bilious vomiting include sepsis, urinary tract infection, and inborn errors of metabolism. Surgical causes include intussusception and malrotation complicated by midgut volvulus.

Intussusception is the most common cause of intestinal obstruction in children less than 2 years of age, and can be defined as a telescoping of a proximal section of bowel into a more distal segment. It typically has a dramatic, acute onset in a previously thriving baby with an otherwise uncomplicated gastroenteritis. The pain appears to come in waves, with the infant relatively normal between attacks. There may be similarly intermittent waves of extreme pallor and diaphoresis. The triad for intussusception includes abdominal pain, emesis, and the hallmark currant jelly stool that is typically a late finding. Additionally, patients may present with profound lethargy and miosis, presumably from an intussusception-induced endogenous opioid secretion.¹⁵ Naloxone has been successful in the reversal of these symptoms.

Malrotation complicated by midgut volvulus is a surgical emergency. Malrotation is a congenital anomaly in bowel migration and mesentery fixation, which predisposes the bowel to twist on itself, resulting in a volvulus. Bowel injury in patients with malrotation develops rapidly, with bowel necrosis occurring in 1 to 2 hours. These infants often present with an acute onset of pain followed, by distention, obstipation, and, frequently, bilious emesis.

Appendicitis in the infant will present as peritonitis in over 90% of cases.^{11,14} Irritability, crying, refusal of feeding, and vomiting, in conjunction with fever, distention, and shallow, grunting respirations, constitute the clinical presentation. In advanced cases, the infant may present in shock. The physical examination may reveal an indurated and erythematous abdominal wall in these delayed presentations. Older children present with more classic symptoms of appendicitis, such as low-grade fevers, anorexia, and periumbilical pain that localizes to the right lower quadrant. On physical examination, McBurney's point tenderness, Rovsing's sign, and peritonitis may be noted. The diagnosis of appendicitis should be made in a timely manner. This urgency is highlighted by the increased risk of appendiceal perforation with time, as the majority of cases will perforate within 48 hours of symptom onset.²

Gastroesophageal reflux may present with only a vague suggestion of abdominal pain but a perplexing array of symptoms. They include failure to thrive, respiratory disturbances (obstructive apnea, stridor, pneumonia, bronchospasm), or neurobehavioral aberrations (seizure-like episodes, Sandifer syndrome).⁹

Chronic idiopathic constipation, or Hirschsprung disease, may present with crampy, recurrent abdominal pain. A previously unrecognized case of Hirschsprung disease may be complicated by toxic megacolon in 9% to 12% of cases.⁸ Patients with Hirschsprung disease will appear ill and have signs of peritonitis and obstruction.

Carbohydrate intolerance typically presents with cramps, gas, bloating, and diarrhea and is commonly due to lactose intolerance following infectious gastroenteritis.⁴ Other carbohydrates, however, may be involved and hidden in the diet (e.g., sorbitol in fruit juice, candy, or medication).

Recurrent abdominal pain is the most common somatic complaint of school-age children and is usually psychophysiologic in origin.⁷ Subjective pain with associated

pallor, sweaty palms, and anxiety may be present during examination. The child is more likely to be female (2:1), with periumbilical or epigastric pain that lasts less than 3 hours and does not awaken the child from sleep.

Recurrent abdominal pain associated with fever, diarrhea, and growth or sexual maturational arrest may indicate the presence of inflammatory bowel disease.

Cholecystitis may occur as right upper quadrant pain and is uncommon in the younger child unless associated with a chronic hemolytic anemia (sickle cell disease, thalassemia, spherocytosis) or Kawasaki disease.¹ As the teen years approach, cholelithiasis and cholecystitis become more common. They are often associated with female gender, obesity, pregnancy, and previous ileal surgery.

Abdominal pain following trauma may be the chief and only complaint with blunt abdominal contusion. Signs of hemodynamic instability suggest spleen or liver injury. Peritoneal signs suggest a hollow viscus injury or free peritoneal blood. Delayed presentation with recurrent emesis may indicate a mural duodenal hematoma. Handlebar injuries may result in traumatic pancreatitis.

A postpubertal female presenting with abdominal pain should be carefully examined for evidence of reproductive tract sources, such as ectopic pregnancy, pelvic inflammatory disease, tuboovarian abscess, and corpus luteal cyst.

The presentation of abdominal pain and fever in the child with immunodeficiency, nephrotic syndrome, or ascites suggests primary peritonitis.

Sexual abuse may also manifest itself as a vague abdominal complaint in some children. A high degree of suspicion is therefore required by the emergency physician to include this diagnosis as part of the differential that must be thoroughly investigated. Once sexual abuse is suspected, prompt involvement by the appropriate local and state authorities is required.

DIFFERENTIAL DIAGNOSIS

Abdominal pain in children may indicate a primary abdominal process or a condition far removed. Evaluation by the emergency physician should establish first whether there is a surgical emergency (ischemia, obstruction, or peritonitis). Ischemic pain is often of sudden onset and associated with torsion or volvulus. Obstruction is most commonly associated with incarcerated hernia, intussusception, malrotation, Hirschsprung disease, and adhesions from previous surgery. If the evaluation suggests peritonitis, the most frequent etiologies are appendicitis, ruptured viscus from trauma or foreign body, and a complication of bowel obstruction. Nonabdominal conditions such as pyelonephritis or sickle cell disease must also be considered as the underlying cause of peritonitis in some patients.

EMERGENCY DEPARTMENT MANAGEMENT

A detailed history is essential for diagnosis and management of infants and children presenting to the ED with abdominal pain. The history should be obtained from the caregiver most familiar with the child's illness and from the verbal child. Due respect should be given to a parent's intuitive feeling for the child's illness: Such information is essential but difficult to articulate.

The emergency physician should approach the physical examination in a friendly, deliberate manner, with younger children remaining in the parent's lap. Close inspection for distention, asymmetry, or abdominal wall erythema is followed by auscultation with a warm stethoscope. Palpation should then proceed with a soft, warm hand on the abdomen, palpating very slowly for tenderness or masses, initially in the area of the abdomen away from the suspected pathology. The groin should always be examined for hernia or torsion. The anus should be inspected carefully, but rectal examination should be performed only if there is a specific indication (e.g., to rule out impaction or appendicitis or to check for blood in the stool). Percussion of the back evaluates for renal tenderness. The rest of the examination follows, with delay of potentially painful procedures, such as otoscopy, for last. The pelvic examination is reserved for the sexually active or postmenarchal patient.

Laboratory investigations should be tailored by clinical suspicion and may include complete blood count, electrolytes, blood urea nitrogen, glucose, liver enzymes, bilirubin, amylase, blood cultures, urinalysis with culture, and, for the postmenarchal patient, a pregnancy test. In selected cases, the stool may be examined for blood, polymorphonuclear leukocytes, culture, and parasites. Radiographic studies are obtained primarily to rule out an intestinal obstruction or perforation. An occult lower lobe pneumonia causing abdominal pain should not be overlooked and may also be evaluated with chest films. Ultrasound may be helpful in the evaluation of appendicitis, cholecystitis, free peritoneal blood, masses, or the urinary tract. Computed tomographic scanning may be necessary in the trauma patient or to evaluate suspected masses.

If there are signs of hemodynamic instability, vascular access should be obtained promptly. Nasogastric decompression should be performed if there are signs of intestinal obstruction. Prompt pediatric surgical, general pediatric, or urologic consultation is in order whenever obstruction, peritonitis, bleeding, or testicular torsion is suspected. Midgut volvulus is an extreme emergency; rapid detorsion of the mesenteric vessels is necessary to prevent devastating bowel gangrene.

DISPOSITION

Role of the Consultant

If volvulus, intraabdominal bleeding, or torsion is suspected, immediate surgical consultation and attention are mandatory, and a prompt response to the ED should be expected. If there are signs of septic shock or respiratory compromise, pediatric critical care consultation should be obtained.

Indications for Admission

All children with intestinal obstruction, intraabdominal trauma or bleeding, peritonitis, or cardiorespiratory instability should be admitted promptly. Emergency conditions such as volvulus, torsion, or bleeding should be triaged directly to the operating room. In unclear cases, patients should be admitted for observation until the suspected abdominal emergency can be excluded. Parental exhaustion or inability to deal with a fussy child is a legitimate reason to admit a child.

Transfer Considerations

Surgical emergencies in infants require a surgeon with specific expertise; if one is unavailable, the patient may need to be transferred to a pediatric facility.

COMMON PITFALLS

- Beware of a history of previous abdominal surgery; it may predispose the patient to various emergent conditions (obstruction, cholecystitis, intussusception).
- Intussusception is common and easily missed. Early diagnosis requires a high index of suspicion, given the fleeting and intermittent nature of intussusception as a complication of acute gastroenteritis.
- Always err on the conservative side with children in whom the diagnosis is unclear. Admission for observation or recheck in 8 to 12 hours should be the rule.

ACKNOWLEDGMENT

The authors gratefully acknowledge the contribution of Dr. Lowell Clark, who wrote the previous version of this chapter.

A prioritized, disciplined approach to the child with altered mental status (AMS) is critical in order to maximize outcome. The greatest priority is for the physician to ensure that the ABCs of basic and advanced life support are attended to first, before being drawn into lengthy diagnostic considerations. During the initial evaluation, the astute practitioner will often be led to the diagnosis and etiology of the patient's condition by careful observation and the ongoing collection of clinical data.

Because the status of the cervical spine in a child with AMS may be unknown, the possibility of a traumatic injury must be entertained early in the evaluation process. Thus, cervical spine immobilization must be maintained until clinically or radiologically cleared. The airway of the child with AMS may be vulnerable due to the potential loss of laryngospastic and cough reflexes, thus predisposing to aspiration and asphyxiation. Endotracheal intubation may be necessary to continue adequate oxygenation and ventilation, to protect the airway from aspiration, and to decrease elevation of intracranial pressures (ICPs). Supplemental oxygen should be given until adequate oxygenation is verified by pulse oximetry and arterial blood gases. Once hemoglobin dysfunction has been excluded, as in carbon monoxide poisoning and methemoglobinemia, oxygenation may be followed by pulse oximetry. Ventilation can be assessed by venous or capillary blood gas pCO₂ values, or by end-tidal CO₂ monitoring in intubated patients. The status of the circulatory system should be evaluated in terms of cardiac rhythm, pulse rate, blood pressure, and perfusion, with intravenous or intraosseous access obtained to allow for interventions.

Grading the pediatric patient's level of consciousness can be done in a variety of ways.^{9,11,12} However, it is essential that, whichever method one employs, frequent and serial neurologic status examinations continue in order to assess for changes that may dictate modifications in therapy. In the older child and adolescent, the Glasgow Coma Scale may be used. In the infant and nonverbal small child, a modified Glasgow Coma Scale is employed ([Table 239.1](#)). Other methods of assessment include applying standard verbal and painful stimuli and then accurately observing and documenting the child's motor, eye, and verbal responses. Deterioration in a child's neurologic examination at any time should prompt an immediate investigation as to the cause of the decline in status.

TABLE 239.1. Modified Glasgow Coma Scale

DIFFERENTIAL DIAGNOSIS

The acronym AEIOU-TIPS ([Table 239.2](#)) can help remind the physician of key diagnostic considerations.

A—Alcohol
E—Encephalitis/meningitis
I—Insulin
O—Overdose
U—Uremia/metabolic encephalopathy
T—Trauma, tumor
I—Infarction, intracranial hemorrhage
P—Psychiatric
S—Seizures
O—Other

TABLE 239.2. Key Diagnostic Considerations

AMS is often multifactorial, and even though a primary cause may be discovered, it does not exclude the possibility of other contributory factors. As examples, an adolescent who has suffered a closed head injury and cerebral contusion may also have indulged in one or more recreational drugs or alcohol prior to the motor vehicle accident that caused head injury. A dehydrated infant may also be hypoglycemic, hypothermic, septic, or a victim of child abuse. The time course of events leading to the onset of AMS is paramount to making the diagnosis.

A—Alcohol

Alcohol use must be entertained in adolescents, and may be confirmed by assessing breath odor and serum ethanol levels. Alcohol intoxication also may occur in a toddler who has access to alcoholic beverages left out by adults.

E—Encephalitis

There are different types of encephalitis to consider:

1. Encephalitis with positive cerebrospinal fluid (CSF) findings
2. Parainfectious encephalitis: similar in presentation to encephalitis, but the virus (Epstein-Barr) cannot be cultured from the CSF
3. Parainfectious encephalopathy: distinguished from the first two by acellular CSF. Parainfectious encephalopathy may occur with or without increased ICP. When the ICP is increased, Reye syndrome, herpes, or mycoplasma encephalopathy are considerations. Infectious encephalopathy without brain swelling is toxin mediated. The *Shigella* toxin is the most common and should be suspected if there is a history of diarrhea in the patient or contacts or if a rectal examination documents blood or mucus.³ Endotoxin has also been incriminated as a cause of parainfectious encephalopathy.
4. Postinfectious encephalomyelitis: Varicella and other childhood exanthems are the most common causes. A history of preceding rash is helpful in suggesting this diagnosis.
5. Meningitis
6. Brain abscess

The lumbar puncture is key to many of the diagnoses in the encephalitis category. However, several of these diagnoses are complicated by increased ICP, which is a relative contraindication to a lumbar puncture. Therefore, caution should be exercised regarding the timing and performance of a lumbar puncture in a child with AMS. If possible, computed tomography (CT) should be quickly obtained to rule out a severe increase in ICP before a lumbar puncture. Alternatively, a lumbar puncture should be carried out with a small-gauge needle, to withdraw a minimal amount of fluid, and with an intravenous line in place and a bag-mask-valve unit on hand to institute hyperventilation in the event of sudden deterioration.

I—Insulin

Insulin, either too much or too little, represents diagnosis that is easily ruled out with a Chemstrip, quantitative glucose testing, and blood gas analysis. In particular, it is unacceptable to delay the diagnosis of hypoglycemia by relying on a quantitative glucose when a Chemstrip could make or strongly suggest the diagnosis within 2 minutes. If a quick bedside glucose test cannot be performed or is equivocal, a trial dose of 25% dextrose in water, 2 mL/kg, can be given.

O—Overdose

Overdose, a possibility at any age, occurs most commonly in toddlers (accidental) and adolescents (nonaccidental). [Table 239.3](#) is a partial list of substances associated with AMS when taken in overdose by toddlers or adolescents. Those substances for which emergency treatment may be indicated, beyond general support of vital functions, are listed with a superscripted, italic “a,” along with physical and laboratory findings that might lead the physician to the correct diagnosis. Worthy of special mention are the use of a trial dose of naloxone to diagnose narcotic overdose and the routine performance of a 12-lead electrocardiogram to screen for the possibility of tricyclic antidepressant overdose. In most cases, a careful history of specific drug and toxin availability plus rapid comprehensive drug screening of urine and blood will be the keys to diagnosis. Flumazenil is generally reserved for cases of known benzodiazepine ingestion, and is avoided in patients with known seizure disorder, because the reversal of benzodiazepine effect in these patients may induce seizure activity.

Alcohols ^a —osmolar gap
Antihistamines
Barbiturates
Carbon monoxide ^a —carboxyhemoglobin
Narcotics ^a —miosis, response to a naloxone trial dose
Salicylates ^a —hyperpnea, overcompensated metabolic acidosis
Phenothiazines
Tricyclic antidepressants ^a —atropinic signs, widened QRS complex
Atropines
Anticonvulsants
Organophosphate insecticides ^a —increased respiratory secretions, miosis
PCP
Heavy metals (Pb) ^a —basophilic stippling, lead lines, paint chips on kidney-ureter-bladder x-ray, elevated CSF protein

^aSubstances with additional emergency treatments or antidotes beyond the general support of vital functions.

TABLE 239.3. Substances Associated with Altered Mental Status

U—Uremia/Metabolic Encephalopathies

Uremia is one of many metabolic encephalopathies that may result in AMS. Most of these can be remembered by considering various organ system failures ([Table 239.4](#)). Additional considerations include status after anoxia, electrolyte disturbances, hypothermia and hyperthermia, and inborn errors of metabolism. Although this category includes a large number of possibilities, a careful physical examination and a few routine laboratory studies will diagnose most of these conditions. A reasonable initial laboratory evaluation would include electrolytes, with calcium, blood urea nitrogen, and creatinine; arterial blood gas analysis, with carboxyhemoglobin level (and methemoglobin level if the blood appears brown); and liver function studies, including a serum ammonia level. Simple dehydration without frank shock is an entity that may, occasionally, have a deceptively subtle clinical appearance and a normal or near-normal laboratory evaluation. If there is a history of fluid loss or even minimal clinical evidence of dehydration with no evidence of increased ICP, a fluid challenge should be considered.

Lung—hypoxia, hyperpnea
Cardiovascular—shock
Kidney—uremia, hypertensive encephalopathy
Liver—hepatic encephalopathy
Thyroid—hyperthyroidism, hypothyroidism
Adrenal—addisonian crisis

TABLE 239.4. Metabolic Encephalopathies (According to System) That May Cause Altered Mental Status

T—Trauma/Tumor

Trauma (head trauma with cerebral edema or hemorrhage) and tumors are most expeditiously diagnosed by prompt CT scanning. The absence of any external signs of trauma in no way eliminates trauma as a possibility. For example, in the shaken-baby syndrome, the only physical finding, other than AMS, may be retinal hemorrhages. A tumor presenting as acute AMS is unusual; when this does occur, acute hemorrhage into the tumor is the likely explanation.⁸

I—Infarction/Intracranial Hemorrhage

Infarction and intracranial hemorrhage not secondary to trauma include several unusual diagnoses: ⁷

Acute hemiplegia of childhood
Embolism (usually secondary to congenital heart disease)
Intraoral trauma to the carotid artery
Arteriovenous malformation³
Hemorrhage secondary to a bleeding diathesis
Venous thrombosis secondary to severe dehydration
Arterial thrombosis secondary to sickle cell disease

The last of these diagnoses is the most common and demands that any Black child presenting with AMS be promptly screened for sickle cell disease if the sickle cell status is unknown. Most of the remaining diagnoses in this category can be ruled out by contrast medium–enhanced CT scanning and a nontraumatic lumbar puncture, looking for red blood cells in the CSF. This category should also remind the clinician to screen for clotting disorders with a prothrombin time, partial thromboplastin time, and platelet count.

P—Psychiatric

Psychiatric causes of AMS primarily include conversion reaction and hysterical coma. Appropriate challenge tests, used discreetly and with respect for the patient's obvious emotional disturbance, will readily diagnose hysterical coma. Such challenge tests include eye blinking in response to the examiner's hand moving suddenly toward the patient's opened eye, smelling salts, and a calm bedside discussion with the nursing staff regarding the possible need for an nasogastric tube or Foley catheter. A true coma conversion reaction is more difficult to diagnose; fortunately, in the pediatric age group, this diagnosis is exceedingly rare. It is, to a large extent, a diagnosis of exclusion aided by a patient history or a family history of psychiatric disturbance.

S—Seizures

Seizures may be subtle in infants. Typical tonic–clonic movements are often not present. Careful examination of the eyes for rhythmic movements or tonic deviation will often be the only suggestion of seizure activity. Pupillary dilatation, if not caused by medication or ingestion, may also suggest seizure activity. Unequal muscle tone or increased muscle tone greater than that expected for the child's level of consciousness is another clue. Occasionally, a stat electroencephalogram or a cautious trial of an anticonvulsant such as lorazepam will be needed to diagnose seizure activity.

Even more difficult than the diagnosis of subtle seizure activity is the diagnosis of a postictal state in a child who has experienced an unwitnessed seizure. Once again, this becomes a diagnosis of exclusion aided by the finding of steady recovery of mental status. A partial paralysis (Todd paralysis) may also be evidence of a postictal state. However, one must be careful not to ascribe a paralysis too quickly to a postictal state before ruling out head trauma and other central nervous system catastrophes, as described earlier.

O—Other

“Other” is a category that must be included in every diagnostic acronym. In the case of coma in childhood, “other” represents at least three diagnoses: intussusception, hydrocephalus, and vasculitis. Of these, intussusception is the most common and most difficult to diagnose. At least 10% of infants with intussusception will present solely with a depressed level of consciousness. They will not have had the typical prodrome of rhythmic irritability, hematochezia, and vomiting. An abdominal mass may provide a clue to this diagnosis in some infants. However, the key to this diagnosis is the routine performance of a barium or air-contrast enema in any patient between 6 months and 3 years of age with a depressed level of consciousness that remains unexplained after a reasonable workup for other causes.

Hydrocephalus, either spontaneously developing (e.g., after a recent episode of meningitis) or as a result of a blocked shunt, is easily diagnosed by a CT scan of the head.

Vasculitis presenting as a primary alteration in level of consciousness is extremely rare in the pediatric age group. An elevated erythrocyte sedimentation rate in an adolescent girl without other obvious cause for the alteration in level of consciousness should prompt consideration of this diagnosis.

EMERGENCY DEPARTMENT MANAGEMENT

After managing the ABCs, the emergency department focus should be to quickly diagnose and treat those entities discussed earlier that require prompt recognition for successful treatment.

Laboratory and radiographic results will lead to an ongoing revision of the working diagnosis. Often, the patient is admitted or transferred before the definite diagnosis is determined. The patient should be continually reassessed for improvements or deteriorations in the ABCs and mental status.

DISPOSITION

Disposition depends on both specific diagnosis and degree of alteration of level of consciousness. Any persistent alteration in level of consciousness requires admission. Any profound alteration in level of consciousness requires admission to an intensive care unit. If an artificial airway is required, the unit chosen must be experienced in dealing with children. Until admission, the child with an altered level of consciousness requires both continuous electronic monitoring and continuous nursing monitoring. In particular, the child with an altered level of consciousness should not be sent to the radiology department without both forms of monitoring.

COMMON PITFALLS

- Failure to address the ABCs first
- Failure to consider certain diagnoses that uncommonly present as AMS: infectious encephalopathy without CSF pleocytosis, selected poisonings, selected metabolic encephalopathies, cerebral infarction with a negative CT scan, hysterical coma, seizures without tonic–clonic activity, and intussusception
- Failure to prioritize the evaluation of the child with AMS in a fashion that considers both the relative emergent nature of various diagnoses and the potential for iatrogenic complications: lumbar puncture causing cerebral herniation; intubation or uncontrolled fluid therapy, resulting in an exacerbation of increased ICP; positioning for CT scan resulting in exacerbation of an unstable cervical spine injury

[Chapter References](#)

Apnea, one of the many different types of breathing problems presenting to the emergency department, is seen predominantly in the neonate and young infant. In 1987, the Consensus Statement of the National Institutes of Health Consensus Development Conference on Infantile Apnea and Home Monitoring was published in an effort to serve as a guide for future research.² The definitions published in the consensus statement will be used in this chapter ([Table 240.1](#)). The focus of this chapter is on the evaluation, differential diagnosis, and management of the neonate and young infant with apnea and briefly mentions other causes of apnea in older children.

Apnea—Cessation of respiratory motion. The respiratory pause may be central or obstructive in origin. The respiratory effort, chest wall movement, and heart rate usually are normal in obstructive apnea, or absent in central apnea. Apnea is considered pathological if it is associated with any of the following: cyanosis, marked pallor or hyperemia, or tachycardia.

Periodic Breathing—A breathing pattern in which there are three or more respiratory pauses of greater than 3 seconds duration with less than 20 seconds of respiration between pauses. Periodic breathing is not pathological.

Apnea of Prematurity—Periodic breathing with pathological apnea in a premature infant. Apnea of prematurity usually occurs by 37 weeks' gestation, sometimes slightly before or shortly after the normal weeks' gestation.

Apnea of Infancy: Breathing Event (ALTE)—An episode that is frightening to the observer and that is characterized by some combination of apnea, central or obstructive cyanosis, color change (usually pallor or pallor but occasionally hyperemia), or abnormal, marked change in muscle tone (usually marked limpness, arching, or rigidity). In some cases, the observer may not witness the event.

Apnea of Infancy—An unexplained episode of cessation of breathing, the observation of hypoxia, or a shorter respiratory pause associated with bradycardia, cyanosis, pallor, or marked hyperemia. The term apnea of infancy generally refers to infants who are greater than 37 weeks' gestational age at onset of pathologic apnea. Apnea of infancy is usually not reserved for those infants who witness no specific cause of an ALTE and is reserved, in other words, those who witness evidence of a specific diagnosis and are believed to be related to apnea.

From Consensus Statement: National Institutes of Health Consensus Development Conference on Infantile Apnea and Home Monitoring, Pediatrics 1987;79:214.

TABLE 240.1. Definitions of Apnea

EPIDEMIOLOGY

Sudden infant death syndrome (SIDS) occurs in about two per 1,000 live births in the United States. The National Institute of Child Health and Development Cooperative Epidemiological Study of SIDS found that only 2% to 4% of cases had a hospital record of apnea of prematurity, and less than 7% had a history of an acute life-threatening event (ALTE). ALTEs have been reported to occur in up to 3% of all children.¹ The mortality of patients with apnea of infancy varies in the literature from 2% to 6%. Infants presenting with apnea during sleep may have up to 10% mortality, with the risk of death tripling with two or more recurrences. In over 50% of ALTEs, no definitive cause can be found.

PATHOPHYSIOLOGY

In general, apnea is the final common pathway of many pathophysiologic processes, especially in the neonate and young infant. Respiratory function is a complex, precise system regulated in the pons and medulla, which receive afferent stimuli from numerous receptors. These vary from chemoreceptors to stretch receptors found in the bronchioalveolar tree. The efferent impulses from respiratory centers are mainly found in the vagus, phrenic, and intercostal nerves. The neonate has more nerve endings and smooth muscle surrounding the walls of small airways and a thinner pulmonary arterial wall, contributing to the decreased vascular resistance.

These changes, coupled with the immaturity of all the systems, may translate into sudden changes in both pulmonary vascular and distal airway resistance, causing ventilatory–perfusion disturbances, with possible intrapulmonary shunting and hypoxemia. Also, gastroesophageal reflux has been associated with central, obstructive, or mixed apnea due to reflex hypoxic episodes.

CLINICAL PRESENTATION

There is no typical clinical setting or presentation of a child with apnea. Most children are brought to the emergency department in stable condition by the parents, who say the child “stopped breathing.” The child may present, however, in cardiopulmonary arrest or in respiratory distress with an unstable airway ([Fig. 240.1](#)). It is important to determine the child's position, activity, and exact sequence of events before and during the apneic episode.⁸ The child may have a spontaneous inspiratory effort or require stimulation after an apneic episode. The child may also experience a change in color, usually cyanosis, but the color may vary from pallid to erythematous. Associated change in muscle tone can be seen before or during the apneic event. This change in tone may vary from arching or extension of the extremities to marked hypotonia and limpness after the apneic spell.¹⁰ An understanding of the sequence may help guide the diagnosis; for instance, arching with apnea after feeding, with or without formula in the oronasal passages, can be seen in gastroesophageal reflux.⁴

Figure 240.1. Algorithm for emergency department management and evaluation of apnea in an infant/young child.

In general, there are two clinical types of apnea: obstructive and central. An absence of respiratory airflow with effort in respiration and chest wall movement suggests obstructive apnea. The absence of respiratory effort, chest wall movement, and respiratory airflow is consistent with central apnea.

The parents are usually extremely frightened by what they have seen, and frequently believe that their child is dying. In most cases, parents administer some form of

cardiopulmonary resuscitation (CPR) or stimulation. A thorough history is vital in order to determine whether the CPR was actually clinically indicated.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of obstructive, central, and mixed apnea in neonates, infants, and older children is shown in [Table 240.2](#), [Table 240.3](#), and [Table 240.4](#). The most common diagnoses to consider in neonates and infants include sepsis, hypoglycemia, seizures, gastroesophageal reflux, anemia, and electrolyte and acid–base disturbances. In a septic child, there may be associated hypothermia or hyperthermia, thready pulses, prolonged capillary refill, or mottled skin. Apnea may be the only manifestation of a seizure, or a seizure may be precipitated by a hypoxic event. In the toddler and young child, foreign-body ingestion and poisoning should also be considered.

Neonate/Infant	Both	Toddler/Young Child
STRUCTURE		
Vascular ring	Vocal cord paralysis Esophageal atresia Congenital diaphragmatic hernia	
PREMATURITY		
	Positional Laryngomalacia Tracheomalacia	Laryngeal web Tracheomalacia Glossitis Bronchopulmonary dysplasia
ABNORMAL AIRWAY		
Obstructive atresia/ stenosis Tracheoesophageal fistula	Craniocervical junction anomalies	Large tonsils/ adenoids
OTHER		
	Gastroesophageal reflux Hemorrhagic necrotizing enterocolitis Thyroid cystic degeneration Intracranial mass

TABLE 240.4. Differential Diagnosis of Mixed Apnea

The clinician must differentiate between a breath-holding spell and an ALTE: A breath-holding spell is an involuntary event that occurs during an awake state in a healthy toddler or young child during expiration. The most common type is the cyanotic or classic spell, which begins with crying, usually after a known precipitating event. The child then stops breathing in end expiration, with resultant cyanosis and loss of consciousness. The spell usually resolves spontaneously, with resumption of breathing and gradual recovery to the patient's baseline state. There may be associated body jerks and urinary incontinence.³ The clinical sequence and definition of a breath-holding spell does not apply to spells occurring during sleep. The pallid breath-holding spell involves a sudden painful incident, with resultant vagally mediated bradycardia or asystole. The patient turns pale and limp and may experience tonic–clonic seizure activity, but then ultimately resumes normal behavior.

Child abuse should be considered if retinal hemorrhages or signs of increased intracranial pressure are present. Cyanotic congenital heart disease usually presents in the first few weeks of life. The cause of the cyanosis is the right-to-left shunt, and it can vary in degree, depending on the pulmonary blood flow (i.e., the lower the pulmonary blood flow, the greater the degree of cyanosis). These children tend to have difficulty feeding, with associated diaphoresis and poor weight gain. The administration of 100% oxygen can clinically differentiate pulmonary from cardiac causes of cyanosis. The oxygen saturation measurement and PaO₂ increase when the cyanosis is secondary to a pulmonary cause, and they fail to do so in the cardiac patient.

Many infants with known apnea who are on home monitors are brought to the emergency department for “frequent alarms.” False alarms account for greater than 90% of monitor alarm events⁷ and typically are due to shallow breathing or loose lead placement.⁹ A thorough history usually helps to differentiate between a true apneic event and a false alarm. However, if there is any doubt, the child should be admitted for further evaluation.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Most infants who present to the emergency department with a history of apnea are in stable condition and have a normal physical examination. The clinician must ensure a stable airway, because positioning (i.e., excessive neck flexion or extension) may predispose to upper airway obstruction, especially in patients with anatomic anomalies. A thorough physical examination, correlating the vital signs with chest wall movements, respiratory effort, and airflow, helps to differentiate between obstructive and central apnea. All patients presenting with apnea should be placed on a pulse oximeter and cardiac monitor, and an intravenous line should be placed.

The questions in [Fig. 240.1](#) can be used to determine high-risk groups, such as those that meet the criteria for an ALTE, patients with previous events, occurrence during sleep, and events requiring either vigorous stimulation or any form of CPR.⁶ In addition, these questions may help differentiate events that appear similar, such as a breath-holding spell.

After taking a methodical history and performing a complete physical examination, the physician should be able to conclude whether the child has had an ALTE and whether the apneic event was obstructive, central, or mixed (see [Table 240.2](#), [Table 240.3](#), and [Table 240.4](#)). If there is a significant event consistent with ALTE, a

consultant should be notified for further inpatient evaluation and management.

If the patient has an unstable airway, positioning, oxygen, and bag-valve ventilation may be the only necessary immediate support to stabilize the child. If there is no improvement, endotracheal intubation is necessary to secure the airway. Continuous monitoring and intravenous access are necessary.

A common error is failing to obtain an immediate bedside glucose level; hypoglycemia, commonly seen in sepsis, can be treated with 2 to 4 mL/kg of D₂₅ intravenously or intraosseously. Neonates should be treated with 4 to 6 mL/kg of D₁₀, because higher glucose concentrations can cause sclerosis. The laboratory evaluation consists of a complete blood count, renal profile, and pan-cultures. Testing for respiratory syncytial virus should be done in infants who were premature and in patients with congenital heart disease; this virus is associated with an increased risk of apnea in these populations.⁵

A lumbar puncture should be strongly considered in patients less than 2 months of age, regardless of whether they are febrile, to rule out meningitis–encephalitis. Pertussis and chlamydia cultures should be obtained if these diseases are clinically suspected. The radiographic evaluation consists of a chest radiograph and, if upper airway obstruction is suspected, anteroposterior and lateral soft-tissue radiographs of the neck. Many patients are on caffeine or aminophylline; therefore, a theophylline level should be checked, with a therapeutic range of 8 to 12 µg/mL.⁷

An electrocardiogram should be obtained to rule out arrhythmias and prolonged QT syndrome. Head computed tomography should be obtained in patients with an altered level of consciousness, abnormal muscle tone, focal neurologic findings, or retinal hemorrhages. Further inpatient evaluation may include an electroencephalogram, swallowing studies, esophageal pH probe, and polysomnography.¹

DISPOSITION

Any child who meets the criteria for an ALTE, despite a normal workup and physical examination, should have the appropriate consultation and be admitted for further evaluation, observation, and parental education. The stable child can be admitted to a general pediatric ward with an apnea–bradycardia monitor to help determine the frequency and length of the apneic episodes and any associated bradycardia. Children who required any type of resuscitative measures in the prehospital course or in the emergency department should be monitored in a pediatric step-down or pediatric intensive care unit, depending on the severity of the event.

Indications for transfer depend on whether the facility has a pediatric intensive care unit or is capable of the necessary workup. The transfer should be done by personnel trained in pediatric advanced life support.

COMMON PITFALLS

- Failing to believe the caretaker about the event, particularly when the child is happy and alert or if the parents are young
- Failing to obtain an immediate bedside glucose level. It should be repeated within 5 minutes after giving the dextrose bolus. Sepsis can present with respiratory instability, and hypoglycemia must be treated.

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of Manuel Carmona Jr., who wrote the previous version of this chapter.

CHAPTER 241

Chest Pain

Edward J. Bayne and Carissa J. Kostecki*

[Pathophysiology](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation and Management](#)
[Common Pitfalls](#)
[Chapter References](#)

Chest pain is an increasingly common presenting complaint in school-aged children and adolescents. This is particularly the case because there is increasing public awareness of this symptom as a warning sign of myocardial infarction. Cardiac disease, particularly coronary artery disease, is the most important differential consideration in the adult patient with chest pain. In a child who presents with this symptom, however, a systemic approach should be taken. There are many causes of chest pain in a child, most of which are noncardiac.⁴ The clinician should avoid relying on routine laboratory tests for cardiac disease, unless they are specifically indicated by either history or physical examination.

PATHOPHYSIOLOGY

Superficial chest wall pain arises from sensory neurons of the intercostal nerve plexus and travels to the dorsal root ganglia along spinal afferents to the brain.⁷ This type of superficial pain is frequently reproducible on physical examination. Pain also may arise in the dorsal root ganglion (from spinal cord irritation or compression) and may travel along the intercostal neurons.

Visceral pain is less well localized and is usually not reproducible.⁷ The chest wall is covered by dermatomes T1 to T8. Pain presenting in the T1 to T4 distribution may arise from the esophagus, mediastinum, pericardium, aorta, pulmonary arteries, or myocardium. This pain is experienced maximally in the retrosternal or precordial areas. Abdominal organs (the gallbladder, pancreas, stomach, duodenum, liver, or peritoneal surfaces) may produce chest pain in the T5 to T8 distribution, maximal in the xiphoid region with frequent radiation to the back. Diaphragmatic pain may be experienced in the lower chest, the neck, or the shoulder because of more complex innervation. Cardiac pain may also be experienced as deep, visceral pain or as sharp, superficial pain due to crossed innervation.

Hyperventilation is common, either as a primary disorder or accompanying and intensifying other types of chest pain.¹¹ Hyperventilation probably causes pain by producing aerophagia with resultant gastric distention. Hypocapnic alkalosis may produce temporary coronary artery constriction and diaphragmatic muscle spasm, which may also be a part of this mechanism for chest pain.³

DIFFERENTIAL DIAGNOSIS

Causes for chest pain in children and adolescents are listed in [Table 241.1](#), using the mnemonic CHEST PAINS. The differential diagnosis can usually be accomplished through careful history and physical examination. Laboratory testing should not be dictated by strict adherence to established protocol. Although cardiac causes are included in this discussion, noncardiac causes should be considered more frequently in children.

C	Cardiac (mitral valve prolapse, aortic stenosis, cardiomyopathy, arrhythmias, vasodepressor syncope, myocardial infarction ¹⁹)
H	Hematologic/oncologic (sickle cell anemia, acute chest syndrome, ^{15,22} tumor); hyperventilation
E	Esophagitis and other gastrointestinal etiologies; endocrine (breast enlargement)
S	Skeletal/muscular (costochondritis, chest wall syndrome ⁹)
T	Trauma; toxins (cocaine, ^{16,17} marijuana, tobacco)
P	Psychogenic; pneumonia; "precordial catch" ¹⁰ ; pulmonary embolism; pneumothorax
A	Asthma (exercise-induced asthma) ^{18,23}
I	Idiopathic; infectious (pericarditis, pneumonia)
N	Neurologic (scoliosis, radiculopathy, autonomic dysfunction)
S	Sports (with undiagnosed cardiac lesions such as HCM, AS ⁷ ; syndromes (Marfan ⁸)

AS, aortic stenosis; HCM, hypertrophic cardiomyopathy.

TABLE 241.1. Differential Diagnosis for Pediatric Chest Pain (Using the Mnemonic CHEST PAINS)

History of recent trauma, or of recent respiratory infection with excessive coughing, should suggest a musculoskeletal cause, particularly costochondritis. Such chest pain may be intensified by change in position and occurs more commonly on the left side. Costochondritis is usually reproducible on examination.⁵

Psychogenic chest pain is common, particularly in older school-aged children and adolescents. Depressive affect or recent history of chest pain in an older relative should suggest this diagnosis. Psychogenic chest pain is frequently recurrent and may be accompanied by additional history of headache or abdominal pain.¹

History of pleuritic chest pain, dyspnea, fever, and cough should prompt a search for an infectious cause, particularly pneumonia or bronchitis. Constant substernal pain with fever and friction rub should suggest the possibility of pericarditis. Increasingly, bronchial hypersensitivity, especially exercise-induced asthma, is found to be a cause of chest pain. Diagnostic testing and treatment of these entities may be beneficial.^{9,15}

Esophagitis may mimic cardiac chest pain, as in the older patient. There may be an increase in chest pain with change in position or with consumption of certain foods. Atypical peptic ulcer disease also should be considered.

Cardiac causes, although uncommon in children, deserve careful consideration. Chest pain accompanied by a soft systolic ejection murmur on physical examination should not automatically suggest a cardiac cause, because the majority of such murmurs are innocent or functional.

A history of palpitations or of atypical, sharp chest pain in a thin individual with a systolic click on examination should suggest mitral valve prolapse (MVP).^{3,11} MVP is almost always congenital but may not be recognized until adolescence. MVP is more common in females and is frequently associated with Marfan syndrome, straight-back syndrome, pectus excavatum, and scoliosis. Although an electrocardiogram (ECG) is usually normal, it may reveal biphasic T-waves. An echocardiogram is diagnostic.¹¹

Any patient with Marfan syndrome who presents with chest pain or palpitations should be specifically evaluated for MVP. This defect is present in 80% to 100% of Marfan syndrome patients and is the most common cause of morbidity. Aortic root dilation, aortic dissection, and aortic aneurysm are uncommon in the adolescent with Marfan's, but this possibility must be considered, particularly with severe pain and radiation to the back.⁸ Marfanoid patients are more prone to spontaneous pneumothorax, which may present with sharp chest pain. A chest x-ray should be obtained in any patient who presents with chest pain and has marfanoid features on physical examination.⁸ Pneumothorax should be considered in any patient with cough and sudden onset of sharp chest pain, although this is seldom a life-threatening disorder.

Aortic stenosis (AS) accounts for approximately 5% of cardiac malformations in childhood. Rarely, an older child with previously undiagnosed aortic stenosis may present with angina, fatigue, dizziness, or syncope secondary to severe obstruction to left ventricular outflow. Physical findings include an early systolic ejection click, the second heart sound may be split paradoxically (wider upon expiration), and a fourth heart sound may be heard. Typically, the murmur is heard at the upper right

sternal border and radiates to the neck and down the left sternal border. There is usually a thrill in the sternal notch, and an apical thrust with an enlarged left ventricle. The ECG is usually within normal limits, although there may be evidence of left ventricular hypertrophy and strain, with inverted T-waves in the precordial leads. These patients may present following strenuous physical activity and should be kept away from competitive sports pending a complete workup. ^{6,14}

Cardiomyopathies, although uncommon in children, may also manifest with insidious onset of congestive heart failure, chest pain, dyspnea, arrhythmia, or sudden death.

Hypertrophic cardiomyopathy (HCM) has been shown to be a frequent cause of sudden death in adolescents and young adults. Symptoms prior to sudden death may be exertional chest pain, particularly with dizziness or loss of consciousness.

Physical examination reveals a brisk pulse, a systolic ejection murmur along the left sternal border and apex, left ventricular lift, and a double apical impulse. The murmur may increase with exercise and decrease with Valsalva or assuming an erect position. The ECG reveals left ventricular hypertrophy and may or may not show ST-segment depression and T-wave inversion. Any suspicion of cardiomyopathy should warn against the administration of digitalis, diuretics, or inotropic agents, all of which could exacerbate this condition. ¹⁴

Chest pain occurring on exertion and relieved by rest (angina) is unusual in childhood but should suggest a significant cardiac cause, particularly if accompanied by a loud (grade III-IV/VI) murmur.

Chest pain in children and adolescents rarely indicates a life-threatening emergency. ^{6,13} Coronary insufficiency or myocardial infarction must be ruled out if there is a strong suspicion of cocaine abuse. ¹⁰ Significant arrhythmias can occur with abuse of this substance, and such patients deserve careful observation and monitoring.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

A careful history and physical examination, including careful palpation and auscultation of the chest, should suggest the appropriate diagnosis in most cases. Chest radiographs are not routinely indicated in the evaluation of pediatric chest pain but are helpful to rule out intrapulmonary or cardiac disorders if suggested by history or physical examination, or both. An ECG is indicated if there is a history of palpitation, angina, or syncope with chest pain. ECGs should not be routinely ordered, because there may often be confusion in the interpretation of ST-T segments in adolescents, particularly in Black patients. Cardiac enzymes and echocardiograms are seldom helpful in the evaluation of pediatric chest pain, unless directed by specific concerns from history or examination.

Routine reliance on cardiac diagnostic studies may intensify the child's or parent's concerns about the possibility of cardiac disease. Once the unlikely possibility of a significant cardiac problem has been ruled out by history and examination, reassurance is most helpful in the management of pediatric chest pain.

Nonsteroidal antiinflammatory agents such as ibuprofen are helpful for the management of musculoskeletal or inflammatory chest pain. After appropriate reassurance, the patient with idiopathic or psychogenic chest pain should be referred to an appropriate primary caretaker (pediatrician or family physician), because many of these cases may be recurrent. ^{9,20}

COMMON PITFALLS

- The emergency physician can relieve anxiety in the patient and family by not routinely obtaining a battery of studies to rule out heart disease. A thorough history and physical examination are the most important diagnostic tools in the evaluation of pediatric chest pain. ²¹
- The emergency physician should not assume that pediatric chest pain is either cardiac or musculoskeletal. The extended differential diagnosis is often not remembered.
- Chest pain during or after exercise, especially with dizziness or loss of consciousness, merits careful evaluation to rule out a cardiac etiology.
- Acute chest syndrome should be actively considered in all sickle cell anemia patients presenting with fever and chest discomfort.
- Childhood chest pain, particularly in the adolescent with psychogenic pain, can often be a recurrent problem. ¹⁷ It is imperative to arrange appropriate follow-up with a primary physician for such patients.
- ECGs may reveal ST-segment and T-wave "abnormalities" that can often be considered as normal variants (e.g., ST elevation from early repolarization). ² Close clinical correlation, especially with the medical history, is recommended before accepting computerized electrocardiographic readings.
- Chest pain in the child or adolescent with underlying congenital heart disease is an unusual symptom, and additional causes should be considered before attributing the pain to a cardiac disorder in such patients.
- Drugs, especially cocaine, should be considered as an important cause for true angina in an otherwise healthy adolescent. Cocaine abuse has been associated with coronary insufficiency, myocardial infarction, and sudden death during adolescence. ¹²
- Hyperventilation is often an important primary etiology or secondary exacerbating element in pediatric chest pain.

[Common Pitfalls](#)
[Chapter References](#)

Although there are relatively few situations in which disorders of bowel control are truly emergent, concerns about constipation frequently result in emergency room visits. The emergency physician should be able to discern abnormal situations as well as advise concerned parents about the developmental process of bowel control, including normal stooling patterns and normal makeup of stool.

There is a wide variation in “normal” stool patterns. The normal newborn passes a meconium stool in the first 48 hours of life and then passes a mean of four stools per day during the first week, with a range of zero to 12.⁵ Meconium stools are sticky, greenish-black, and odorless. Transitional stools, which are passed within 3 to 5 days, are thinner, greenish-brown, and commonly mixed with milk curds if the newborn is bottle-fed. The stools of breast-fed infants are pale yellow, occasionally slightly green, and are homogeneously mushy. Breast-fed newborns often pass a small stool after each feeding, which may be as frequent as eight to 15 times daily, although an occasional infant may not have a bowel movement for 7 to 10 days.⁷ In contrast, bottle-fed infants tend to have firm, formed, yellow, putty-like stools one to four times daily. Many infants strain, grunt, and turn red in the face during bowel movements, and parents often erroneously interpret this behavior as signaling constipation. When infants are 3 to 4 months of age, stool frequency decreases, with the occasional bottle-fed infant passing only one stool every other day. For children beyond infancy, the normal frequency ranges from passing one stool every other day to passing three daily. Most children develop the adult pattern of having a mean of 1.2 stools per day by age 4 years.⁵

During the first year of life, defecation is a reflex act.⁴ Maturational voluntary control of the external anal sphincter occurs in the second year, and bowel continence then becomes physiologically possible. Between the ages of 2 and 3 years, most American parents begin to toilet train their children, although the techniques and timing vary between cultural and socioeconomic groups. An important pathophysiologic concept relative to bowel control is that of stool retention.⁷ Stool retention usually occurs in boy toddlers, with the common starting point being simple constipation, which leads to painful passage of stool. Parents may describe their children as spending long periods of time straining and trying to have a bowel movement, when, in reality, the children are trying not to have a bowel movement. The association of pain with defecation leads to the cycle of pain, retention to avoid painful defecation, increasing fecal mass, and further retention to avoid pain. Anal fissures are common and may start the process because of their associated pain or may exacerbate the problem by causing pain with the passage of each large stool. The rectum and sigmoid become dilated, the anal canal shortened, and the normal stretch-defecation reflexes blunted. Eventually, the fecal mass may become impacted, and unformed liquid stool leaks around the impaction, resulting in soiled pants. The process becomes established and may continue into the child's school years, at which time, hectic schedules and unsuitable school toilet facilities tend to worsen the situation. Because such fecal soilage occurs beyond the normal training period, the child's emotional or psychological constitution is invariably questioned. If emotional problems are found, they are as likely to be the result of this form of encopresis as the cause. There is also an association between stool retention and recurrent urinary tract infections, enuresis, and urinary incontinence.¹

A single definition of *constipation* has not been agreed on. Although many parents focus on the length of time between bowel movements, any determination of *normal* should encompass stool consistency and the ease with which the stool is passed. A child who defecates twice daily but painfully passes only small, dry pellets is constipated, whereas a child who produces a large, soft stool every other day is probably normal. It is simplest to define *constipation* as the difficult passage of large or hard stools, irrespective of frequency. The epidemiology and clinical scenarios commonly associated with constipation vary with age.⁵ In infants and toddlers, constipation occurs equally in boys and girls. In older, prepubertal children, constipation is more common in boys, with a male-to-female ratio of 3:1. This ratio reverses during adolescence, with constipation being three times more common in postpubertal girls.

CLINICAL PRESENTATION

A newborn infant discharged before 48 hours of age will occasionally present to the emergency department with a history of constipation, progressive abdominal distention, and vomiting, which may become bilious. In relation to constipation, this may be caused by imperforate anus, anal stenosis, meconium plug syndrome, meconium ileus, or Hirschsprung disease.

Constipation in the older infant or child is far less likely to be a serious or life-threatening process, yet is a source of great anxiety and frustration for some parents. Onset of constipation is commonly related to changes in diet, especially from breast milk to prepared formula or baby foods. Inadequate fluid intake is a common predisposing factor, as is any illness that may produce dehydration and inactivity. Constipation may arise with overly zealous efforts at toilet training. The school-aged child may present with constipation simply from reluctance to use the school bathroom.

The child with rectal retention and encopresis has fecal soiling of the underpants and may paradoxically complain of diarrhea. A lower abdominal mass may be found by palpation, and a shortened anal canal with huge fecal impaction may be found on rectal examination.

Older children may present with a clinical picture of acute abdomen.

DIFFERENTIAL DIAGNOSIS

Although there are many primary pediatric diseases with constipation as a symptom, most constipation does not suggest serious underlying disease. Anatomic malformations and congenital intestinal disorders are more likely to present in infancy than at a later age, but nonorganic causes of constipation predominate at all ages.⁵ The more common serious causes of constipation in the newborn are imperforate anus, anal stenosis, meconium plug syndrome, meconium ileus, Hirschsprung disease, volvulus, hypothyroidism, and any of the numerous causes of newborn bowel obstruction. Imperforate anus is easily diagnosed by inspection, which reveals no anal opening. In anal stenosis, the anus appears small, with a central black dot of meconium. In meconium plug syndrome or meconium ileus, there is scanty or no meconium and progressive signs of intestinal obstruction. Meconium plug syndrome is strongly related to Hirschsprung disease. Gentle digital examination produces passage of a dry, hard plug of meconium. Hirschsprung disease is suggested by an empty rectal vault and a long, sleeve-like anal canal around the examining finger. It may be complicated by enterocolitis with paradoxical diarrhea, abdominal distention, and shock. In meconium ileus, there is delayed or no passage of meconium, with progressive intestinal obstruction and, often, serious complications (e.g., volvulus or perforation). Meconium ileus is strongly associated with cystic fibrosis; however, the respiratory symptoms of cystic fibrosis are usually absent in the newborn, and the clinical picture is dominated by the bowel obstruction. In an infant presenting with constipation, inadequate fluid intake should always be considered.

When the infant is beyond the immediate newborn period, constipation tends to be less emergent in nature, with most cases having either an idiopathic or dietary cause.⁶ The more common identifiable causes of constipation include excessive cow's milk intake, lack of dietary roughage, anal fissure, cerebral palsy, anterior displacement of the anus, and dehydration. Less common causes include Hirschsprung disease, drug intake (e.g., phenytoin, methylphenidate, imipramine, codeine), spinal cord lesions, chronic intestinal pseudoobstruction, infant botulism, prune-belly syndrome, presacral teratoma and other tumors, hypocalcemia, hypercalcemia, and hypothyroidism.

Hirschsprung disease is considered whenever there is significant constipation in the pediatric patient. It is caused by the congenital absence of submucosal and myenteric ganglion cells in a segment or all of the colon. It is more common in boys and is occasionally associated with Down syndrome. The cardinal sign is failure to pass meconium within the first 48 hours of life, followed by ongoing constipation and small-diameter (ribbon-like) stools in infants. Hirschsprung disease is the cause of 20% to 25% of neonatal intestinal obstruction. Necrotizing enterocolitis (toxic megacolon) is a complication that may develop in infants. Newborns who are not

diagnosed may present later in childhood with chronic constipation, abdominal distention, and, often, failure to thrive.

A rectal examination of a child should be performed gently and deliberately. The physical examination may reveal well-formed fecal masses suprapubically or in either lower quadrant. Pertinent findings may include an anteriorly displaced anus (anal ectopy), a tight and stenotic anus (anal stenosis), anal fissure, or a sleeve-like anal canal with empty ampulla (Hirschsprung disease). The signs of hypothyroidism (coarse facial features, umbilical hernia, macroglossia) should raise suspicion of that diagnosis.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Evaluation of the constipated patient should include careful history and physical examination, which often provide the diagnosis without requiring further studies in the emergency department. Dietary habits, changes in diet, fluid intake, stooling habits, and associated urinary tract abnormalities should be considered. Physical examination should include abdominal palpation for masses, especially fecal masses in the left lower quadrant; inspection of the anus for fissure, anterior displacement, or stenosis; and inspection of the sacrum for signs of myelodysplasia. Gentle rectal examination with a well-lubricated little finger should be attempted but not forced on an unwilling child. If the history is chronic, a urine culture should be taken to avoid missing the occult urinary tract infection. Exhaustive laboratory and radiographic investigation is not appropriate in the emergency department.

Dietary management of simple constipation includes increasing fluid intake, adding bulk to the diet, and adding fruits such as prunes or plums to the diet. Maltsupex (barley malt extract) or Karo syrup can be safely recommended for infants in a dosage of 1 to 2 teaspoons two to four times daily, added to formula, juice, or food. Cathartics, suppositories (other than small glycerin suppositories), and, especially, enemas should generally be avoided in infants. Hypertonic phosphate enemas have been associated with severe, acute hypocalcemia and cardiac arrest in infants.⁸ Tap water enemas have been associated with acute hyponatremia, seizures, and death.⁹ In the older infant and toddler, milk of magnesia 1 to 3 mL/kg/d, mineral oil 1 to 4 mL/kg/d (contraindicated in children at risk for aspiration), or lactulose 1 to 2 mL/kg/d, all given once or twice per day, can be used. Docusate (Colace) 5 to 10 mg/kg/d or senna extract (Senokot) 5 to 10 mL daily can be safely used in older children.

If an anal fissure is discovered, management includes frequent, gentle, thorough cleansing of the anus and liberal lubrication with petroleum jelly. A stool softener must be used, and a topical anesthetic ointment such as dibucaine may be necessary.³ Aggressive care of the simple fissure is necessary to prevent the pain-retention cycle from becoming established.

DISPOSITION

Role of the Consultant

Consultation for simple constipation is unnecessary. Infants with suspected Hirschsprung disease or bowel obstruction should be expeditiously referred to a pediatrician or pediatric surgeon, and prompt response to the emergency department should be expected, because such conditions may constitute a surgical emergency. Older children with chronic constipation with or without encopresis should be referred to a pediatrician for long-term management. Older children with suspected Hirschsprung disease should be referred to a pediatric gastroenterologist or pediatric surgeon.

Indications for Admission

The following are indications for admission: failure to pass meconium, bowel obstruction, and toxic megacolon complicating Hirschsprung disease. Occasionally, the need for complicated disimpaction and initiation of a therapeutic regimen for chronic constipation with encopresis may require admission, but this is quite rare in the current era of cost containment and emphasis on ambulatory care.

Transfer Considerations

Bowel obstruction or toxic megacolon in the newborn requires specific pediatric expertise on an emergent basis, and transfer to a pediatric facility may be necessary. Before transfer, venous access should be secure, gastric suction and decompression begun, and antibiotics considered. Hypothermia should be vigorously avoided.

COMMON PITFALLS

- The newborn or young infant who presents with constipation should be seriously considered so that Hirschsprung disease is not missed, only to occur later with necrotizing enterocolitis.
- Enemas, especially hypertonic phosphate enemas, should be avoided in infants.

procedures. The initial history and physical examination must focus on ruling out potentially life-threatening causes of crying, such as meningitis, shaken-baby syndrome and other forms of child abuse, acute abdominal catastrophes (e.g., intussusception), incarcerated hernias, metabolic disorders, and intoxications; the less critical causes are collectively more common. A review of the vital signs is essential to rule out cardiac dysrhythmias and respiratory problems. A catheterized or suprapubic urine specimen should be obtained in all infants when the cause is not obvious.

Figure 243.1. Evaluation of the crying infant.

Fluorescein staining and ultraviolet light eye examination is essential to rule out corneal abrasions. Eversion of the eyelids may be needed to visualize a foreign body in the eye. A funduscopic examination should be attempted; if visualization is difficult and the index of suspicion is high for shaken-baby syndrome, this examination should be repeated after dilating the pupils. A careful otoscopic examination may show an unsuspected otitis media.

The head should be examined for any signs of trauma and for a bulging fontanel. The extremities and joints (especially the hips) should be carefully palpated and maneuvered to rule out fractures, osteomyelitis, and septic joint.

An abdominal examination is difficult to perform in a crying infant. It is important to examine the abdomen and chest and listen to the heart before attempting any invasive or painful procedures; if possible, this should be done while the infant is in the mother's lap and sucking on a bottle or pacifier. Flexing the legs at the hip may help relax the abdominal muscles enough to allow a good abdominal examination. Before attempting a rectal examination, the physician should check the anal area for signs of trauma or anal fissures.

If a careful history and physical examination do not reveal or suggest a cause for crying, further studies are indicated. Skeletal roentgenography and cranial computed tomography scanning are indicated in suspected child abuse. If an abnormal cardiac rhythm is auscultated, initial cardiac monitoring and a subsequent 12-lead electrocardiogram may reveal the diagnosis. Suspected gastrointestinal problems should be confirmed with appropriate studies, such as a barium enema or an esophagram. A sepsis workup is indicated if there is any suspicion of an infectious etiology. An elevated anion gap or abnormal urinalysis and electrolyte levels may point toward an inborn error of metabolism or endocrinopathy.

EMERGENCY DEPARTMENT MANAGEMENT

Most infants have a completely normal examination and workup. If the history and physical examination are compatible, a diagnosis of colic should be entertained. Parents who present to the emergency department with a crying infant usually do not readily accept the diagnosis and the inability to treat the cause with medications. Multiple studies have shown the danger of using alcohol-based preparations and Dramamine–Donnatal combinations.¹⁰ About 4% of infants may benefit from changing to a protein hydrolysate formula due to cow's milk allergy.⁵ It is important to empathize with the parents and to take time to counsel them on methods to console the child early; possible intervention techniques include rocking slowly in a quiet room, warm compresses to the abdomen, feeding, frequent burping, and diaper changing.

Other etiologies of crying should be managed as outlined in the appropriate chapters of this book.

DISPOSITION

All children who present to the emergency department with crying need appropriate follow-up to ensure an adequate weight gain and no progression of symptoms, especially if the diagnosis is "colic." Consultation with subspecialists and admission are determined by the diagnosis.

COMMON PITFALLS

- A hurried and superficial history and physical examination on this group of infants will lead to misdiagnosis and inadequate care. On the other hand, doing complete sepsis workups in all infants with crying would subject a large population of colicky infants to unnecessary tests with extremely low yield. A rational approach is to tailor the workup based on a reliable history and physical examination.
- Corneal abrasions are difficult to diagnose without fluorescein staining. Similarly, retinal hemorrhages may not be noted on a cursory ophthalmoscopic examination in a crying, uncooperative patient unless the pupils are dilated.
- Careful attention should be paid to the vital signs, lest the physician miss fever, tachypnea, and supraventricular tachycardia.
- Listen to the parents. Do not underestimate their distress and ability to determine the degree of illness in their infant.
- Avoid terms and diagnoses such as "difficult infant."⁸
- If neglect can be safely ruled out, reassure the parents about their parenting skills.

[Common Pitfalls](#)
[Chapter References](#)

Young infants are especially vulnerable to dehydration because 8% to 10% of their body water is turned over on a daily basis. This turnover represents fluid deficits from the extracellular (mostly intravascular) compartment through insensible losses, urinary losses, and gastrointestinal losses. (Adults, by comparison, turn over less than 5% of body water daily.) It is easy to see, therefore, how hydration, a dynamic state, can be affected through illness. Decreased intake through fasting and vomiting, increased losses through diarrhea, or an increase in insensible losses secondary to fever or respiratory distress can easily upset this balance and leave the infant deficient in total body water. For this reason, any infant who presents with fever, vomiting, diarrhea, or respiratory distress, regardless of etiology, must be assessed for potential dehydration. In addition, dehydration is the single most common initial diagnosis among both children and adults in the early-return and return-admission population in the emergency department.¹

CLINICAL PRESENTATION

History

The physician must obtain an accurate history of the volume and composition of oral intake; the frequency, consistency, and volume of diarrhea; the presence or absence of fever and vomiting; recent body weight; and frequency of urination.

Fulminant diarrhea can rapidly progress to cause dehydration, particularly when associated with vomiting, fever, and decreased intake. The potential for dehydration in this situation is inversely proportional to the child's age. Total body water and the percentage of daily fluid turnover is highest in infants less than 6 months old. In these infants, fulminant rotaviral gastroenteritis, shigellosis, or salmonellosis can easily cause dehydration in minutes to hours. Therefore, even if the infant does not appear clinically dehydrated at the time of examination, continued close observation is necessary to prevent progression.

Physical Evaluation

The diagnosis of dehydration is based on clinical criteria, not on laboratory values.^{2,4,9} However, a low serum bicarbonate (less than or equal to 13 mEq/L) appears to correlate with more severe dehydration and an inability to tolerate oral fluids.^{5,10} Signs and symptoms of dehydration are listed in [Table 244.1](#). Multiple classification schemes exist, none of which has been well validated.² The degree of dehydration is expressed as a percentage of the pre-illness body weight. Less than 5% dehydration is clinically inapparent, but an infant that is more than 15% dehydrated is moribund, cold and clammy, and near death from hypovolemic shock. The physical examination helps to define mild, moderate, and severe dehydration. The diagnosis of dehydration does not require the use of laboratory values; these are only confirmatory in nature. Treatment should never be delayed while awaiting the results of laboratory tests.

	Mild, (5%–8%)	Moderate (9%–12%)	Severe (>12%)
Mucous membranes	Sl. dry	Dry	Parched
Skin turgor	Normal	Decreased	Tenting
Skin	Normal	Cool	Mottled/blue
Fontanel	Normal	Sunken	Markedly sunken
Eyes	Normal	Sunken	Markedly sunken
Mental status	Normal	Normal	Depressed
Pulse rate	Full, normal	Rapid	Weak, rapid
Systolic BP	Normal	Low normal	Shock
Urine output	Decreased	Decreased	Anuria

TABLE 244.1. Clinical Assessment of Hydration Status and Percentage Dehydration

Infants that are 5% to 8% dehydrated typically exhibit an alert and hypoactive affect. They follow the caregiver around with their eyes but appear quiet and listless in bed. With severe dehydration, they exhibit hypotonia, lethargy, mottling, cool skin, and irritability. Before initiating fluid therapy, it is important to feel the liver to assess its size. Cardiogenic shock, although rare, is frequently misdiagnosed as hypovolemic shock. The patient must be reevaluated after every bolus, because it is easy to overshoot and cause congestive cardiac failure with only a few hundred milliliters of extra fluid.

In hypernatremic dehydration, redistribution of fluid out of the intracellular compartment into the extracellular compartment masks the signs of dehydration, even in the face of significant weight loss. The skin consistency is doughy.

In hyponatremic dehydration, the intravascular volume is severely compromised as fluid translocates into the intracellular compartment to maintain osmotic equilibrium. Infants with hyponatremic dehydration exhibit signs of shock in the face of minimal weight loss.

EMERGENCY DEPARTMENT MANAGEMENT

Although most dehydration cases are urgencies, poor management can escalate the problem and lead to shock and a true emergency.

Minimal dehydration (less than 5%) can be managed with an oral fluid challenge (5 to 10 mL/kg every hour).⁷ Frozen oral hydration solutions (Revital-Ice, Pedialyte popsicles) have proven to be particularly effective in the initial management of mild-to-moderate dehydration.⁸ Refusal of oral fluids or failure to tolerate the oral fluids should prompt initiation of intravenous hydration. If dehydration is estimated to be severe, it is prudent to achieve intravenous access and to give a fluid bolus and replacement fluids for a few hours before attempting oral rehydration.^{3,6} If the child is in shock (as evidenced by signs of extreme dehydration, thready pulse, poor end-organ perfusion, capillary refill greater than 3 seconds), vascular access is obtained immediately, and successive fluid boluses of 20 mL/kg of an isotonic solution (lactated Ringer's or normal saline) are given until clinical improvement is noted. After three boluses with crystalloid solution (60 mL/kg), the use of colloids may be appropriate, because only 25% of a bolus of crystalloid remains in the intravascular compartment after equilibration. If the child is not in shock but is clinically dehydrated, the 20-mL/kg fluid bolus may be given more slowly (i.e., over a period of 30 minutes to 1 hour). If two or three attempts at intravenous access fail, obtain intraosseous access.

Blood should be drawn for laboratory studies, which should include electrolyte levels, a bedside screening to rule out hypoglycemia, and venous gas measurements.

Subsequent management consists of calculating the deficit of fluids and evaluating the acid–base and electrolyte disturbances, but this kind of management is not necessarily the responsibility of the emergency physician.

In the consolidation phase, the total volume of fluid needed is determined by calculating deficit fluids, maintenance fluids, and ongoing losses.

To calculate deficit fluids:

1. Determine the patient's admission weight. If the weight is unavailable, the weight in kilograms can be estimated by using a length-based system (Broselow Resuscitation Tape) or by doubling the patient's age in years and adding 10.
2. Calculate the free water deficit. The deficit in milliliters equals 100 divided by the percentage dehydration × weight in kilograms × 10.
3. Calculate the sodium and potassium deficits. First determine whether the dehydration is hypotonic, isotonic, or hypertonic, based on the criteria in [Table 244.2](#). Then determine the electrolyte deficits, based on [Table 244.3](#).

Hypotonic (hyponatremic) dehydration: <130 mEq/L
 Isotonic (isonatremic) dehydration: 130–150 mEq/L
 Hypertonic (hypernatremic) dehydration: >150 mEq/L

TABLE 244.2. Type of Dehydration Based on Serum Sodium Concentration

	Water (mL/kg)	Sodium (mEq/kg)	Potassium (mEq/kg)
Isotonic	100–120	8–10	8–10
Hypertonic	100–120	2–4	0–4
Hypotonic	100–120	10–12	8–10

TABLE 244.3. Free Water and Electrolyte Deficits in Dehydration

4. Calculate the rate of deficit replacement. For isotonic and hypotonic dehydration, the first half of the deficit is replaced in 8 hours, and the second half in 16 hours. For hypertonic dehydration, the total deficit is replaced over 30 to 36 hours. The rate of decline in serum sodium should not exceed 0.5 mEq/L/h.

To calculate maintenance fluids:

1. Free water needs are 100 mL/kg/d for the first 10 kg of body weight, or 4 mL/kg/h; 50 mL/kg for the second 10 kg, or 2 mL/kg/h; and 20 mL/kg for more than 20 kg of body weight, or 1 cc/kg/h.
2. Sodium requirements are 2 to 3 mEq/kg/d.
3. Potassium requirements are 1 to 2 mEq/kg/d.

An alternate method to is to refer to the appropriate kilogram section of the Broselow Resuscitation Tape for maintenance or bolus intravenous therapy.

To calculate ongoing losses, fluid losses from vomiting and diarrhea can be replaced milliliter for milliliter with normal saline every 4 to 6 hours, unless these losses are severe; if so, more frequent replacement may be required. Usually, however, once parenteral fluids are initiated, these losses diminish rapidly to an insignificant level and do not need to be taken into consideration.

Management of Acidosis

Acidosis rarely needs to be corrected by intravenous administration of sodium bicarbonate, because repletion of the intravascular compartment usually corrects this problem. However, if the pH is below 7.20, sodium bicarbonate administration is needed (1 mEq/kg over 30 minutes).

Management of Hyponatremic Seizures

Hyponatremia is a serum sodium level of less than 130 mEq/L. Usually, a rapid fall in serum sodium to less than 120 mEq/L within 24 hours results in nausea, vomiting, muscle twitching, seizures, and coma. Symptoms related to acute hyponatremia are relieved when the serum sodium is raised to 125 mEq/L. The amount of 3% hypertonic saline (513 mEq/L) needed for the correction can be calculated by subtracting the present level of serum sodium from the desired level and multiplying that figure by 0.6 and by the patient's weight in kilograms. Three percent NaCl contains 0.5 mEq NaCl/mL; therefore, the desired increase in mEq/L must be multiplied by a factor of 2 to obtain the milliliters of 3% NaCl needed.

Management of Hypoglycemia

Hypoglycemia can be addressed early by obtaining a bedside measurement and giving intravenous dextrose. The bedside test may then be confirmed by a laboratory serum glucose measurement. The 25% dextrose needed is given at a 2- to 4-mL/kg slow intravenous push.

Vascular Access

Vascular access can be a problem, especially in the dehydrated infant. [Chapter 237](#) discusses the intraosseous infusion procedure that can be effective in hypovolemic shock secondary to dehydration. Otherwise, most infants can be resuscitated effectively with peripheral intravenous cannulation and fluid boluses.

DISPOSITION

In many centers, the clinical diagnosis of dehydration mandates intravenous therapy and, therefore, admission. This is the more classical and accepted management, but some centers advocate intravenous rehydration for selected infants in the emergency department over a period of 3 to 4 hours; the physician then determines the need for admission. Infants requiring more than one fluid bolus of 20 mL/kg or those with acidosis, ongoing losses, electrolyte abnormalities, intolerance to oral fluids,

or social needs should be admitted.

Oral rehydration with specifically designed oral solutions has been tried in certain situations, especially in Third World countries, but is of little use in the routine emergency department management of dehydrated infants. This mode of therapy should be reserved for infants with ongoing losses who present with less than 5% dehydration and have reliable parents and adequate follow-up. Pedialyte is a maintenance fluid and is not adequate replacement therapy for losses secondary to vomiting and diarrhea; Rehydralyte is a more appropriate replacement fluid. Clear liquids should not be continued for longer than 24 hours, and if losses continue, the patient should return for evaluation.

COMMON PITFALLS

- Failing to appreciate the acuity of the ongoing process
- Failing to recognize and treat shock secondary to dehydration. This includes failing to give boluses of 20 mL/kg until end-organ perfusion is improved, or the use of nonisotonic fluids to accomplish this task.
- Failing to monitor ongoing therapy, which may result in overhydration or underhydration
- Failing to address associated abnormalities of electrolyte and acid–base balance
- Failing to address the underlying cause of dehydration (e.g., pyloric stenosis, diabetic ketoacidosis, child abuse or neglect)
- Misdiagnosing cardiogenic shock as hypovolemic shock

Diarrheal illness continues to be a significant cause of pediatric morbidity and mortality. In the United States, approximately 200,000 children less than 5 years of age are hospitalized annually for acute gastroenteritis, which accounts for more than 875,000 inpatient hospital days.² Dehydration secondary to diarrhea is responsible for 300 to 500 pediatric deaths per year. The incidence of diarrhea in children less than 3 years of age is estimated to be 1.3 to 2.5 episodes per child per year, with higher rates in children enrolled in daycare.⁶

Pathophysiologically, the insult most often leading to diarrhea is infectious. Enteroinvasive pathogens cause osmotic diarrhea by invading and destroying enterocytes of the villous tip, resulting in failure of water and electrolyte absorption and damage to the brush border disaccharidase enzymes. Unabsorbed carbohydrates are fermented to organic acids, which impart an acid reaction to the stool (pH less than 5.5), and undigested carbohydrates may appear as reducing substances. In addition, the organic acids increase the osmotic load and result in increased water loss into the stool. In contrast, enterotoxigenic pathogens generally result in secretory diarrhea, in which enterotoxins affect cAMP and cGMP pumps. Secretion of chloride and sodium, followed by water and potassium, results in large-volume diarrhea, usually without acid reaction or reducing substances. Invasion of the mucosa by bacterial pathogens may produce a leukocytic reaction in the stool, demonstrable by staining with methylene blue.

CLINICAL PRESENTATION

The most common presenting condition of children with diarrhea is infectious gastroenteritis, with viral agents accounting for 75% of cases. Acute diarrhea typically lasts less than 2 weeks, and the history is one of a distinct change in stool frequency, volume, and color. The stools may be less well formed and yellowish, loose and green, or watery and voluminous. The presence of bloody, mucoid stools increases the possibility of a bacterial cause. Vomiting is common, especially with viral disorders. However, bilious vomiting demands close attention and raises the possibility of intestinal obstruction. Intussusception may complicate an otherwise mild gastroenteritis. Low-grade fever is common, but if it exceeds 40°C, a bacterial etiology is more likely.

Important history to obtain from the caretaker includes the use of antibiotics; recent travel or other exposures, such as day care; pets; or unsanitary water supply. The patient's prior weight, duration of illness, and associated signs and symptoms, such as fever, abdominal pain, vomiting, rash, seizures, and activity level can aid in determining the degree and severity of dehydration. A vital component of the history is the type of oral intake given to the child. The use of hyperosmolar fluids, such as carbonated soft drinks, apple juice, or excess sodium due to improper formula preparation, can result in hyponatremia, while hypotonic fluid replacement can result in hyponatremia.

Of foremost clinical importance on presentation is the presence of signs of dehydration. Infants may become critically dehydrated over a period of only a few hours and may present with sepsis. The signs and symptoms of progressive dehydration are listed in [Table 245.1](#). As the vascular space contracts, the extremities become cool with decreased distal pulses, and alterations in mental status occur. Gorelick et al.⁵ discovered that the findings of three or fewer of the clinical signs of dehydration correlated with a 5% fluid deficit, three to five signs correlated with 5% to 9% dehydration, and more than six signs, with a fluid deficit of 10% or greater.

Clinical Findings	Mild (<5%)	Moderate (10%)	Severe (≥15%)
Mental status	Alert	Irritable	Lethargic
Tears	Present	Decreased	Absent
Mucous membranes	Moist	Dry	Very dry
Urine output	Normal	Oliguric	Anuric
Systolic blood pressure	Normal	Normal	Decreased
Heart rate	Normal	Normal-rapid	Rapid
Fontanelle	Normal	Flat	Sunken
Eyes	Normal	Sunken	Glassy
Capillary refill	<2s	2-3s	>3s

TABLE 245.1. Signs and Symptoms of Dehydration

Rotaviral gastroenteritis accounts for 30% to 60% of acute diarrheal disease, with a peak incidence in children between the ages of 4 and 23 months.¹⁰ However, up to 25% of severe cases occur in patients over 2 years of age. Rotavirus is responsible for at least 50% of the hospitalizations for gastroenteritis during the peak season of October to May.³ Transmission occurs by the fecal–oral route and by person-to-person transmission. The illness presents with fever and vomiting prior to the onset of diarrhea; bloody stools are uncommon. The patient may have concomitant respiratory disease. A new vaccine has been developed to prevent rotaviral illness and has shown efficacy in preventing severe disease.

Norwalk virus is responsible for up to 40% of gastroenteritis cases in older children. Transmission is via airborne droplets, person-to-person contact, contaminated food, and contaminated water. The incubation period is 12 to 48 hours, with symptoms consisting of nonbloody diarrhea, vomiting, fever, headache, myalgias, and abdominal cramping. Other viruses associated with enteritis include adenovirus, astrovirus, calicivirus and torovirus.¹²

Campylobacter gastroenteritis is the leading cause of bacterial gastroenteritis in the United States. The organism's reservoirs are newborn puppies, chicken, and turkey, with person-to-person transmittal. The incubation period is 2 to 5 days, with symptoms consisting of fever, abdominal pain, bloody stools, vomiting, myalgias, and headache. *Salmonella* gastroenteritis is transmitted by the fecal–oral route, and has an incubation period ranging from 6 to 72 hours. The minimum infective dose is 10 million organisms. The highest attack rate involves those less than 1 year of age. Complications such as pneumonia, bacteremia, septic arthritis, osteomyelitis, meningitis, endocarditis, and urinary tract infections may be seen. *Salmonella typhi* presents with fever, headache, myalgias, organomegaly, and rose spots. Infection with this agent causes a prolonged gastroenteritis. *Shigella* gastroenteritis is extremely virulent in that the minimum infective dose is only 100 organisms, with an incubation period of 1 to 5 days. Typical presenting symptoms include fever, malaise, febrile seizures, and tenesmus, with possible resultant rectal prolapse. *Yersinia* gastroenteritis presents with fever, vomiting, headache, and pharyngitis and may mimic appendicitis, with severe right lower quadrant pain. Erythema multiforme and a reactive arthritis may also be present.

Diarrhea associated with *Escherichia coli* O157:H7 may result in hemolytic–uremic syndrome.¹ The organism has a bovine reservoir and is transmitted by undercooked meat, contaminated water, unpasteurized milk, or person-to-person contact. The illness usually begins as nonbloody diarrhea and may progress to grossly bloody stools. Severe abdominal pain is common, at times mimicking an acute surgical condition. After the gastroenteritic phase of the disease seems to have resolved, the patient may develop irritability, pallor, and oliguria. Laboratory examination reveals anemia with schistocytes and helmet cells, thrombocytopenia, and azotemia.

Peritoneal dialysis may be required.

Profuse sudden-onset diarrhea, especially when associated with vomiting and abdominal cramps but no fever, raises the possibility of bacterial toxin food contamination, such as that caused by *Staphylococcus aureus* or *Clostridium perfringens*. Such illnesses tend to be explosive in onset but brief in duration. Acute-onset diarrhea associated with cranial nerve weaknesses suggests botulism.

Noninfectious diarrhea is less likely to have a febrile and dehydrating onset. Food intolerance as to sorbitol in candy and gum, hyperosmolar juices (pineapple), or, occasionally, even simply overfeeding may precipitate a brief bout of diarrhea. Allergic diarrhea presents, sometimes explosively, soon after exposure to the offending food and may be part of a larger picture of anaphylaxis. Breast milk colitis, caused by sensitivity to maternally ingested proteins, occurs in breast-fed infants and presents as bloody diarrhea with negative microbial studies in an otherwise thriving infant.

A key observation in the child with chronic diarrhea is the presence of failure to thrive, as determined by anthropometric measurements. Such children often lose calories in the stool by malabsorption and do not grow normally. Usually, the malabsorption is accompanied by bulky, malodorous stools that may be oily on close inspection. Disorders with such a presentation include chronic giardiasis, cystic fibrosis, pancreatic diseases, celiac disease, and immunodeficiency disorders, including acquired immunodeficiency syndrome.

The presence of chronic diarrhea without failure to thrive suggests irritable bowel syndrome. These children tend to have frequent, large, occasionally explosive stools early in the day but otherwise appear well. Questioning often reveals a history of colic as an infant and a family history of irritable bowel syndrome.

Acquired disaccharide intolerance is common and presents with flatulence, bloating, cramps, and watery diarrhea. The history often reveals a preceding bowel insult, most commonly infectious. Disaccharide intolerance may also complicate cystic fibrosis, celiac disease, or postoperative states.

In children, especially infants, diarrhea may accompany almost any acute or chronic illness, especially if antibiotics are given. Although fulminant pseudomembranous enterocolitis is uncommon, milder antibiotic-associated diarrhea is often seen. The most frequent drugs that can result in pseudomembranous colitis are clindamycin, third-generation cephalosporins, and anticancer drugs.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis is broad: Diarrhea may accompany almost any pediatric illness at any given point in its course. The differential diagnosis may be categorized as acute or chronic. There may be important diagnostic clues based on age, character of the stool, associated symptoms, and effect on the child's general health.

The most common causes of acute diarrheal disease are listed in [Table 245.2](#). The differential diagnosis of chronic diarrhea includes postinfectious disaccharide intolerance, irritable bowel syndrome, milk or soy protein intolerance, giardiasis, maternal deprivation syndrome, cystic fibrosis, celiac disease, immunodeficiency disorders, short bowel syndrome (postoperative), and, uncommonly, inflammatory bowel disease, tumors (neuroblastoma, carcinoid), stagnant loop syndrome, and acrodermatitis enteropathica.¹⁴ The presence or absence of blood, leukocytes, reducing substances, an acid reaction, or fat in the stool can be helpful in the differential diagnosis. Blood and white cells suggest bacterial gastroenteritis or inflammatory bowel disease. Reducing substances and an acid pH suggest disaccharide intolerance. Fat on Sudan stain suggests malabsorption, most commonly cystic fibrosis, celiac disease, or chronic giardiasis.

BACTERIAL	PARASITIC
<i>Campylobacter</i>	<i>Giardia lamblia</i>
<i>Salmonella</i>	<i>Cryptosporidium</i>
<i>Shigella</i>	<i>Entamoeba histolytica</i>
<i>Yersinia</i>	
<i>Escherichia coli</i>	OTHER
<i>Clostridium perfringens</i>	Medication induced
<i>Clostridium botulinum</i>	Parenteral: otitis media,
<i>Clostridium difficile</i>	upper respiratory
Cholera	infection, urinary tract
<i>Staphylococcus aureus</i>	infection
<i>Aeromonas</i>	Food intolerance
	Psychogenic anxiety
VIRAL	Necrotizing enterocolitis
Rotavirus	Cystic fibrosis
Nonalk virus	Adrenal insufficiency
Adenovirus	Organophosphates
Calicivirus	Heavy metal toxin
Astrovirus	Hirschsprung disease
Torovirus	Intussusception

TABLE 245.2. Common Causes of Acute Diarrheal Illness

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The goals of diarrhea management include prevention of dehydration by early fluid administration, treatment of dehydration with an oral rehydration solution (ORS), continued feeding during the diarrhea, and selective use of antibiotics and avoidance of antidiarrheal medications.^{4,11}

A thorough history should determine acute or chronic status. Preliminary studies that may be indicated for chronic diarrhea include a stool examination for blood, parasites, culture, Sudan fat stain, and alpha-1-antitrypsin. If there is significant failure to thrive or dehydration, the child should be admitted; otherwise, the patient should be referred to a pediatrician for further evaluation.

If the diarrhea is acute, the primary concern is the existence of dehydration, acidosis, electrolyte disturbances, shock, or associated sepsis. The physical examination determines dehydration according to the signs previously described. If dehydration is not present, laboratory studies may be unnecessary. However, the presence of significant dehydration calls for the measurement of electrolytes, blood urea nitrogen, and glucose.⁷ Other than a guaiac test or culture, stool studies such as fecal leukocytes, Rotazyme, pH, reducing substances, and ova and parasites are usually not helpful in the emergency setting. A complete blood count may aid in diagnosis, as patients with *Shigella* typically have a white blood cell count less than 10,000 with a marked left shift. If the ratio of bands to total polymorphonuclear leukocytes (PMNs) is greater than 0.10, a bacterial etiology such as *Shigella*, *Salmonella*, or *Campylobacter* should be suspected.

Dehydration exceeding 5% to 10% or significant electrolyte disturbances are considerations for admission, with rehydration beginning in the emergency department. In patients who are mildly to moderately dehydrated and are refusing oral intake, a nasogastric tube can be placed to initiate replacement therapy. In severely dehydrated children, intravenous fluids should be initiated. Normal saline boluses of 20 cc/kg should be initiated, with repeat boluses, as needed, to restore intravascular volume. It is not uncommon to administer 60 to 100 cc/kg in the initial phase of fluid resuscitation. Close monitoring of the pulmonary status is important in children with underlying cardiac or pulmonary conditions, to avoid iatrogenic pulmonary edema. Once intravascular volume has been restored, dextrose-containing maintenance fluid should be initiated, avoiding potassium replacement until the patient is spontaneously voiding and is known to have normal renal function.

In mild dehydration and in selected cases of moderate dehydration, outpatient oral rehydration therapy should begin with a commercially available ORS.^{8,9} Homemade solutions and electrolyte-glucose beverages for athletes should be avoided; in the former, serious errors may be made in preparation, and the latter contain too little sodium, too much sugar, and almost no potassium. Each liter of a commercial ORS contains about 45 to 75 mEq sodium, 20 to 25 mEq potassium, 2% glucose, and a mixture of chloride and base as anions ([Table 245.3](#)). This ratio of electrolytes and glucose promotes the coupled mucosal transport of sodium and glucose, with water absorption following.

Solution	Na (mEq/L)	K (mEq/L)	Other (mEq/L)	Cl (mEq/L)	Base (mEq/L)	Carbohydrate (g/L)
Pedalyte	45	20		35	30	25
Rehydralyte	75	20		65	30	25
Infalyte	50	25		45	34	30
Resol	50	20	8	50	34	30
WHO solution	90	20		90	30	30

TABLE 245.3. Contents of Commercial Oral Rehydration Solutions

If oral rehydration is chosen, it is best started during an extended period of monitored therapy in the emergency department, and it may be implemented in any child who can drink and is not in shock. A safe program for 5% or less infant rehydration is listed in [Table 245.4](#). After successful oral rehydration, a prompt return to age-appropriate diet is indicated. It should be stressed to parents that the objective is to “feed through” the diarrhea, and that loose stools will persist for a few days but should decrease in volume and frequency. In general, smaller but more frequent feedings should be given so that the total daily intake approaches normal. ⁴

- Estimate daily fluid requirements and degree of dehydration.
- Maintenance: 100 mL/kg for first 10 kg body weight, 50 mL/kg for each additional kg over 11–20 kg, and 20 mL/kg for each kg over 20 kg.
- Deficit requirement for 5% dehydration is 50 mL/kg.
- While patient is being monitored in the ED, give 50 mL/kg ORS over 4 h. ORS is best tolerated as small, frequent volumes rather than larger boluses. If vomiting occurs, give the solution 1–2 teaspoons every 5–10 min.
- Replace ongoing losses with 10 mL/kg ORS for each diarrheal stool.
- If stable and retaining fluids, the child may be discharged after deficit fluid is replaced, with phone contact 4–6 h later.
- The remainder of calculated fluids (deficit plus maintenance) should be given at home as maintenance ORS, such as Pedalyte, Infalyte, or Resol. Any fluid intake desired by the child beyond calculated should be provided as water or dilute juice.
- Infants should be offered breast milk or half-strength formula in increasing amounts. Older infants and children should be offered rice cereal, rice, potatoes, toast, bananas, and smoothies, and rapidly advanced to full caloric intake.

TABLE 245.4. Emergency Department Management of Acute Diarrhea with Mild Dehydration

Subsequent diet depends on the child's dietary status before the illness. If formula was the primary nutrition, a return to half-strength formula for 12 to 24 hours, followed by full-strength formula, is advised. If there is impressive return of diarrhea following refeeding of a standard cow's milk-based formula (Enfamil or Similac), a lactose-free formula (Lactofree, ProSobee, or Isomil) may be tried, again gradually advancing through half- to full-strength formulas. Continued diarrhea on these preparations may require an elemental formula such as Alimentum or Pregestimil. For older children on a mixed diet, a bland diet of rice or rice cereal, bananas, potatoes, noodles, crackers, and toast should be offered in increasing quantities and then advanced to a balanced intake over 24 to 48 hours. Although lactose in milk may cause an osmotic diarrhea, fermented milk products such as yogurt are generally well tolerated. The breast-fed infant with diarrhea generally has a milder illness for which evaluation and reassurance alone may suffice. If significant dehydration exists, oral rehydration should proceed using the previously mentioned guidelines with no or minimal interruption of breast-feeding.

Most episodes of diarrhea do not require antimicrobial therapy. Bloody diarrhea with PMNs probably represents bacterial gastroenteritis, and antibiotic therapy should be considered. Antibiotic selection should be made and adjusted based on stool culture and sensitivity results. For *Shigella*, the episode may be treated with trimethoprim-sulfamethoxazole (TMP/SMX) (TMP 8 mg/kg/d divided b.i.d.) or erythromycin (40 mg/kg/d q.i.d.) for 5 to 7 days. *Campylobacter* enteritis has been shown to be resistant to TMP/SMX, and should be treated with erythromycin for 5 to 7 days. Antibiotics should be avoided in *Salmonella* gastroenteritis, because they prolong the carrier state. Exceptions include certain populations prone to *Salmonella* bacteremia, such as infants less than 4 months old and patients with immunodeficiency or sickle cell disease. These high-risk patients should be admitted and given intravenous antibiotics. If *Giardia* is demonstrated by stool testing, furazolidone (6 mg/kg/d divided q.i.d. for 7 days) or metronidazole (15 mg/kg/d divided t.i.d. for 7 days) is indicated. If *C. difficile* cytotoxin is found in the stool, oral vancomycin (50 mg/kg/d divided q.i.d. for 7 days) or metronidazole is usually effective.

The American Academy of Pediatrics does not recommend the use of antiemetic, antisecretory, or antiperistaltic drugs. ¹¹ The use of narcotic-based agents are specifically contraindicated in bacterial gastroenteritis, because they may induce bowel stasis and promote more aggressive bacterial invasion.

Parents should be instructed on hygienic precautions for diaper handling and good hand-washing practices. The child should be excluded from the daycare center if there is diarrhea not contained by diaper or toilet use, if stools contain mucus or blood, or if there is associated fever.

DISPOSITION

Role of the Consultant

If more than 5% dehydration is present, a pediatrician should be consulted for probable admission, with rehydration efforts beginning in the emergency department. With chronic diarrhea, consultation with a pediatrician or pediatric gastroenterologist is in order. Diarrhea may paradoxically complicate surgical conditions (e.g., Hirschsprung disease), in which case, a pediatric surgeon should be consulted.

Indications for Admission

Patients with the following should be admitted: greater than 5% dehydration, significant electrolyte disturbances, suspected sepsis, intractable vomiting, bilious vomiting, or complicated chronic diarrhea with failure to thrive. Sepsis and serious illness in infants less than 1 month old may be clinically subtle or occult. Even mild dehydration in young infants deserves careful consideration for admission. Poor social situation, parental noncompliance or inability to follow prescribed therapy, and suspected deprivation or neglect are other reasons for admission.

Transfer Considerations

Simple diarrhea with dehydration requires only judicious oral or intravenous rehydration and rarely requires transfer unless there are no inpatient pediatric services. Complicated cases of dehydration (e.g., hypernatremic) or those of chronic duration usually require specific pediatric expertise.

COMMON PITFALLS

- The young infant with diarrhea may initially appear well but develop serious dehydration over a short period.
- Because of renal immaturity, infants less than 3 months old may continue to pass urine even when dehydrated.
- Not relying on the caregiver's history of lack of urine output, lethargy, and the patient's inability to tolerate fluids may lead to inappropriate management and disposition.
- Underestimating the degree of hypovolemia and missing the subtle signs of shock
- Antidiarrheal agents should be avoided. The narcotic-based antidiarrheals may cause apnea in infants or predispose to systemic invasion of certain bacterial

pathogens.

ACKNOWLEDGMENT

The authors gratefully acknowledge the contribution of Lowell Clark, who wrote the previous version of this chapter.

CHAPTER 246 Failure to Thrive

Marc Linares and Bruce J. Quinn

[Diagnosis](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The concept of failure to thrive is commonly used in the pediatric literature but lacks a clear definition.⁸ *Failure to thrive* is frequently defined as a failure to gain weight (weight less than the third percentile for age, or weight for height below the fifth percentile); however, the definition should be more global and should include any decrease of growth velocity leading to a decline of two major percentiles, using the National Center for Health Statistics growth charts. The term *failure to thrive* is used less and less by some experts; terms such as *undernutrition* or *malnutrition* are preferred.³ Measurements of weight, height, and head circumference are necessary to define and classify growth failure. Failure to thrive is common in inner-city emergency departments, with rates from 15% to 30% reported.⁴

DIAGNOSIS

Except for familial short stature and constitutional growth delay, the etiology of failure to thrive is malnutrition.

Failure to thrive can be arbitrarily classified into three groups ([Table 246.1](#)). The most common form is secondary to caloric insufficiency. The child presents with a markedly decreased weight compared with height and head circumference. Decreased caloric intake is usually secondary to parental poverty, maternal disorganization, or neglect. Social history and environmental circumstances are important keys to the diagnosis. Less commonly, caloric intake can be impaired by diseases causing regurgitation (e.g., severe gastroesophageal reflux, pyloric stenosis, rumination syndrome) or malabsorption (e.g., cystic fibrosis, lactase deficiency, renal tubular acidosis). To the fortunate emergency physician, a history of chronic disease may explain the malnutrition.

GROUP I
Most common type. Normal head circumference; weight reduced out of proportion to height. In most cases of failure to thrive, malnutrition is present as a result of either deficient caloric intake or malabsorption.
GROUP II
Normal or enlarged head circumference for age; weight only moderately reduced, usually in proportion to height; structural dystrophies, constitutional dwarfism, endocrinopathies.
GROUP III
Subnormal head circumference; weight reduced in proportion to height; primary CNS deficit; intrauterine growth retardation.
<small>From Kempe CH, Silver RH, O'Brien D, eds. Current pediatric diagnosis and treatment, 6th ed. Los Altos, CA: Lange; 1990:624.</small>

TABLE 246.1. Classification of Failure to Thrive

The second group of children presents with weight and height equally affected. The head circumference is normal or enlarged. Most of these patients have a metabolic disorder (e.g., hypothyroidism, growth hormone deficiency, galactosemia, renal tubular acidosis).

The third group consists of children whose weight, height, and head circumference are all reduced. This category includes patients with genetic disorders (e.g., Turner syndrome, structural dystrophies) or congenital problems (e.g., fetal alcohol syndrome, small for gestational age).

Often a child does not clearly fit into any one particular group, making the differential diagnosis of growth deficiency difficult. Even after hospitalization and a thorough evaluation, 24% of patients will not have a definite etiology for their failure to thrive.⁷

The major challenge for the emergency physician is to recognize growth deficiency. This is more difficult to do when caretakers use the emergency department as their primary care center. When a child is brought to the emergency department with an acute illness, it is not uncommon for both parents and physicians to fail to recognize the insidious and potentially more serious problem of growth failure. Weight measurement should be part of the initial evaluation of any child seen in the emergency department, and it should be routinely charted in the growth chart. When the diagnosis of failure to thrive is suspected, a thorough history, physical examination, and growth pattern evaluation must be done.

EMERGENCY DEPARTMENT MANAGEMENT

The emergency physician's responsibility is to diagnose the condition, *not* to determine its cause. Environmental factors are the leading cause of failure to thrive, principally maternal deprivation. If child abuse or neglect is suspected, proper referral to child protective services should be made. Laboratory tests are of limited value in most cases of failure to thrive, but they can help diagnose some serious conditions that require immediate attention. Tests commonly performed in the emergency department are a complete blood count with differential, a urinalysis with culture, and routine chemistries. More specific tests should be individualized.

DISPOSITION

Traditionally, patients with failure to thrive were admitted and evaluated in the hospital, but over the past few years, outpatient treatment has been advocated.^{5,6} When failure to thrive is mild, with no obvious organic cause, outpatient management is encouraged if private physician follow-up is possible.² A multidisciplinary team approach, involving a social worker, psychiatrist, and nutritionist, is more likely to be successful than the private doctor alone in both inpatient and outpatient treatment. A recent randomized, controlled trial showed that the use of a health visitor significantly improved the growth rate of children, compared with conventional management.⁹ Inpatient evaluation and treatment are reserved for cases in which outpatient management has failed. Also, severe cases of failure to thrive, the presence of an organic etiology, young age, or concerns that the child is at risk for abuse should prompt inpatient management.¹ In all cases of failure to thrive, communication between the emergency physician and the primary physician helps in decision making.

COMMON PITFALLS

- Failing to consider the diagnosis by addressing only the acute illness of presentation
- Failing to look for signs and symptoms of neglect
- Failing to screen for serious disease
- Failing to provide adequate follow-up

[Emergency Department Management and Disposition](#)

[Common Pitfalls](#)

[Chapter References](#)

The combination of fever and petechiae is a common finding in infants and children. Approximately 2 % of febrile children evaluated in an emergency department have a petechial rash.¹⁰ The majority of such children have benign, self-limited illnesses. A rare patient, however, will have a life-threatening infection such as meningococemia or Rocky Mountain spotted fever. Unfortunately, no controlled trials comparing strategies for evaluation and management of children with fever and petechiae have been conducted. In fact, there are only two relatively small, prospective studies of fever and petechiae in children from which conclusions may be drawn.^{3,10}

Petechiae are defined as minute (less than 2 mm in diameter), nonblanching, macular hemorrhagic spots. They result from bleeding into the skin secondary to thrombocytopenia, vasculitis, or abnormal platelet function. In addition, petechiae often develop from purely mechanical causes.

From the limited evidence available, it appears that the child with a benign illness can be differentiated from the child with a life-threatening illness by a careful history and physical examination emphasizing toxicity, distribution of the petechiae, and the presence or absence of purpura. Laboratory tests may also be helpful in certain situations.

CLINICAL PRESENTATION

The typical child with a benign cause of fever and petechiae is 3 to 36 months of age, well-appearing, and smiling, with good tone, color, and eye contact. Onset is usually acute, and the height of the fever is from 38°C to 42°C. Purpura is absent. The findings most helpful in ruling out serious disease are the distribution of the petechiae and the absence of toxicity. In the two prospective studies of fever and petechiae in children, none of the children with petechiae isolated solely above the nipple line had serious disease. Baker et al.³ found no serious invasive disease in children with petechiae above the nipple line, even in the absence of a mechanical explanation for the petechiae. Ill appearance was also found to be 100 % sensitive for serious illness in the largest study to date.¹⁰

Less frequently, one encounters a child with a life-threatening illness as the cause of fever and petechiae. Such children are ill-appearing, typically with acute onset of fever, irritability, tachycardia, lethargy, and signs of meningeal irritation or shock. The petechiae may be tender and lack a characteristic distribution. The petechiae of meningococemia are usually on the extremities and trunk and may appear in “crops.”¹⁶ The presence of purpura in combination with petechiae is an extremely worrisome finding and mandates aggressive evaluation.¹⁰

DIFFERENTIAL DIAGNOSIS

Approximately 40% of children have a clear mechanical explanation for their petechiae.¹⁰ Such petechiae typically develop on the face and upper chest immediately following coughing, vomiting, or vigorous crying. Petechiae that develop in this manner are usually distributed above the nipple line (including the upper arms) and are presumably due to increased intravascular pressure in the superior vena cava. A similar mechanism explains petechiae that develop distal to tourniquets or blood pressure cuffs. Contrary to the common wisdom that mechanically induced petechiae are *limited* to the skin above the nipple line, many patients will also be found to have some petechiae below the nipple line.¹⁰

In another 40% of patients, a benign viral or bacterial illness explains their petechiae.^{3,12} Streptococcal pharyngitis,^{5,10} respiratory syncytial virus,⁵ and otitis media are common identifiable causes. Streptococcal pharyngitis is particularly common in children older than 18 months, accounting for 26% of such cases in one study.¹⁰

Brucellosis, dengue, endocarditis, gonococemia, ehrlichiosis, and illness due to adenovirus, enterovirus,³ and Epstein-Barr virus can all cause fever with a petechial rash. Clues to the diagnosis include contact with farm animals or ingestion of raw milk (brucellosis), recent travel to Central or South America (dengue), history of heart disease (endocarditis), urethritis and polyarthritis (gonococemia), or onset during the summer or fall (enterovirus).³

Finally, a small number of children with fever and petechiae have a potentially serious disease, such as sepsis (usually meningococcal sepsis), leukemia, or idiopathic thrombocytopenic purpura (ITP). In endemic areas, Rocky Mountain spotted fever also should be considered.^{2,6,8,14} Because meningococemia is, by far, the most common serious disease causing fever and petechiae in children, it is described in depth in the following section.

MENINGOCOCCEMIA

Meningococemia is an infectious disease emergency. The disease spectrum ranges from transient bacteremia to fulminant septic shock and death within hours, despite appropriate therapy.^{1,4,5,7,13} Peak incidence occurs in the late winter and early spring; infants younger than age 2 represent 90% of cases.

CLINICAL PRESENTATION

The onset of meningococemia is usually abrupt, with high fever, petechiae, lethargy, and headache. The rash, when present, may be petechial, urticarial, or maculopapular.¹ Maculopapular lesions are often tender. Lesions are sparse and generalized. Purpuric lesions have been described in 60% to 100% of cases and indicate fulminating disease with a high incidence of shock and disseminated intravascular coagulation.^{1,15} Other signs and symptoms include evidence of an upper respiratory tract infection, myalgias, and joint pains. Meningitis occurs in about half of the patients with meningococemia.¹⁵

Approximately 25% of children with meningococcal bacteremia will have neither a petechial rash nor a toxic appearance. They may be initially evaluated in an office or emergency department and sent home.^{5,9} Such children with “occult meningococemia” have, on average, a higher band count than other febrile children. However, because of the rarity of this disease, the predictive value of the band count is almost useless.

EMERGENCY DEPARTMENT EVALUATION

Children with unexplained fever and petechiae should be triaged as urgent or emergent and rapidly assessed. It is useful to divide children into three groups: well-appearing children with a mechanical cause for their petechiae, well-appearing children *without* a clear mechanical cause, and toxic- or ill-appearing children. The evaluation and management of the first and last groups is straightforward, while the evaluation of the middle group is less clear.

In the well-appearing child with a readily apparent mechanical cause, it is reasonable to forego laboratory investigation. A platelet count may be done to rule out thrombocytopenia, although this is extremely unlikely in the child with a typical history and physical examination for mechanical petechiae.

At the opposite end of the spectrum is the septic or toxic-appearing child. Laboratory evaluation should include a chest radiograph; complete blood count (CBC) with differential and platelet cell count; prothrombin time (PT); partial thromboplastin time (PTT); determination of electrolyte levels, including glucose and calcium; blood culture; and urinalysis with urine culture.

A lumbar puncture should be performed in all patients stable enough to tolerate the procedure. Tests to determine the presence of meningococcal antigens in cerebrospinal fluid may be helpful, especially in cases in which prior antibiotic therapy has been given, making culture results unreliable.¹ In contrast, a positive antigen detection test in urine is not helpful, as the sensitivity and specificity in urine are less than 50%.¹

Unfortunately, there is no consensus as to the appropriate management of the child whose petechiae are not clearly mechanical in origin.¹¹ In the absence of purpura or toxicity, the vast majority of these children will have either a benign viral illness or streptococcal pharyngitis.^{3,10} Mandl et al.¹⁰ found that none of 357 "well-appearing" children with fever and petechiae had invasive illness.¹⁰ However, other studies have not found clinical judgment to be as sensitive.^{3,9} Unfortunately, these studies were not designed to look specifically at clinical criteria, as was Mandl's.

The data on using the peripheral white blood cell (WBC) count as a screen for meningococemia are discouraging. At present, it seems that the WBC is too nonspecific to be useful.^{3,9,10} Its sensitivity in meningococemia is also unclear. Mandl et al. found an abnormal WBC count (defined as either greater than 15,000 or less than 5,000) in all patients with invasive bacteremia. All of these children were also assessed as clinically "ill." Thus, it is not clear whether the WBC count adds anything to the sensitivity of clinical assessment in the subgroup of well-appearing children with fever and petechiae.

The patient's age, degree of fever, and identification of a fever source should also be considered. Many emergency department physicians still commonly order a "screening CBC and platelet count" and a blood culture on well-appearing children with fever and petechiae. This is often done for medical-legal reasons.

Perhaps most important in the evaluation of the well-appearing child lacking a mechanical cause for petechiae are careful serial examinations. One should look specifically for the appearance of additional petechiae (showers or crops of petechiae, an acral distribution, or tender petechiae), the appearance of purpura, abnormalities of vital signs (tachycardia, hypotension), or subtle changes in perfusion, mental status, or appearance. Any other workup should be directed toward specific signs and symptoms (throat culture for streptococcal disease, PT/PTT for purpura, etc.).

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

In the well-appearing child with a readily apparent mechanical cause for the petechiae, no specific laboratory evaluation is necessary. These children may be discharged home.

The toxic-appearing child with fever and petechiae should be assumed to have meningococemia, and a complete septic workup should be performed. Children at risk for meningococemia should receive continuous cardiovascular monitoring and frequent examinations, looking for subtle signs of shock. Management includes prompt institution of antibiotics, treatment of coagulopathy if present, and volume expansion and inotropic support for signs of inadequate tissue perfusion. Antibiotics should be administered promptly, even in the child in which lumbar puncture cannot be performed. If you are unable to obtain intravenous access, antibiotics may be administered intramuscularly.

Because hypotension is a late manifestation of shock in children, repeated evaluations of mental status, skin perfusion, urine output, and pulse quality are important. Evidence of inadequate tissue perfusion should initially be treated with volume expansion. Myocardial dysfunction is common in meningococemia and inotropic agents may be required.⁴

Rapid deterioration is well documented in meningococemia. Sudden deterioration within minutes of antibiotic administration has been noted. This phenomenon is likely due to massive endotoxin release from the destruction of organisms, and thus monitoring should be particularly vigilant immediately after the administration of the first dose of antibiotics.

If bacterial meningitis is confirmed, dexamethasone 0.6 mg/kg/d in four divided doses, should be considered in infants and children older than 2 months to reduce hearing loss and/or other neurologic sequelae.¹ Efficacy is currently established only for bacterial meningitis due to *Haemophilus influenzae* type b. If used, it is most effective if administered at the time of or slightly before antibiotics are given. In cases in which there is a strong suspicion of bacterial meningitis (signs of meningitis and cloudy spinal fluid on lumbar puncture), it is reasonable to administer dexamethasone, followed by antibiotics, immediately after obtaining a lumbar puncture.

All patients with suspected meningococemia should be admitted to a facility able to handle children in severe septic shock, usually one in which a pediatric intensivist is available and that has a pediatric intensive care unit. The potential for rapid deterioration during transport should be anticipated. Rapid transport should be done by personnel trained in advanced cardiac life support, preferably a pediatric critical care transport team. Inotropes should be mixed in advance, and infusion rates established. Intubation before transport should be strongly considered in patients in shock. Two secure intravenous lines are desirable.

Antibiotic prophylaxis and careful observation are recommended for all close contacts of persons with invasive meningococcal disease. What constitutes a *close contact* has been meticulously described in the American Academy of Pediatrics 1997 Red Book,¹ and include household contacts and childcare or nursery school contacts in the previous 7 days.

In addition, persons who have had direct exposure to the patient's oral secretions (including kissing, sharing of toothbrushes or eating utensils, mouth-to-mouth resuscitation, unprotected intubation, or suctioning before antibiotic therapy was begun) should receive prophylaxis. The recommended prophylactic regimen is rifampin 10 mg/kg per dose (maximum dose, 600 mg), given every 12 hours for a total of four doses over 2 days. Alternatives include ceftriaxone or ciprofloxacin. Chemoprophylaxis should be done in consultation with local public health authorities.

The most difficult decision is in the management of the well-appearing child with petechiae lacking a clear mechanical cause. Most of these patients do not have serious illnesses. A period of careful observation in the emergency department, although unstudied, is a common approach. The child should be observed for progression of petechiae (looking for showers of new petechiae), development of purpura, and signs or symptoms of meningitis or altered perfusion. Patients who remain stable, smile, have good tone and color, develop no further petechiae, and have no purpura can safely be discharged home with close follow-up by a primary care physician. Well-appearing, febrile children with petechiae, no fever source, and a WBC count greater than 15,000 are often given ceftriaxone intramuscularly or intravenously pending blood culture results.

COMMON PITFALLS

- Failure to detect petechiae in a febrile child often occurs because the patient is not totally undressed.
- Delay in antibiotic administration in a child with meningitis, either due to lack of intravenous access or due to a delay in performing a lumbar puncture, is a frequent but risky occurrence. Remember: Antibiotics may be given intramuscularly if intravenous access is unavailable.
- Failure to diagnose shock in infants and children is common. Once recognized, inadequate fluid resuscitation may occur. Children in septic shock can require massive amounts of volume and potent inotropic agents.
- Mechanically induced petechiae are a common finding in infants and children with or without fever. Although they do not seem to be a risk factor for meningococemia, neither do they "immunize" a child against serious disease. The literature is clear that meningococemia is clinically occult in approximately 25% of children on initial presentation.⁹ Thus, meningococemia and mechanical petechiae may occur simultaneously simply due to chance. All infants with fever, with or without mechanical petechiae, need careful evaluation and close follow-up.

[Common Pitfalls](#)
[Chapter References](#)

Fever is present in 25% of infants and children brought to the emergency department (ED), either as the sole complaint or in conjunction with other symptoms. Fever produces tremendous parental anxiety, often reinforced by health-care personnel. Fever, in and of itself, is usually not harmful, but it may be an early sign of an emergency condition, such as meningitis or other bacterial infections.²¹

The ED evaluation of fever focuses first on identifying life-threatening sepsis syndromes. A source of infection is also sought through a careful history and physical examination. The extent of laboratory testing (to confirm a suspected focus of infection or evaluate the likelihood of occult infection) and the decision to initiate empirical antimicrobial therapy depend on several variables. The patient's age, degree of fever, illness severity, and presence or absence of a clinically suspected source of infection are most important to determine the need for further diagnostic testing. Other factors that must be considered include the patient's history of underlying medical conditions, the examiner's skill, the child's course during a period of observation, laboratory resources, and availability of follow-up.

Both the likelihood and consequences of serious infections are increased in febrile children with immunocompromising diseases, such as sickle cell anemia and leukemia.

Signs of serious illness, such as meningitis, can be subtle. When the examiner's experience is limited, greater laboratory evaluation may be justified. For example, most experts recommend a lumbar puncture for febrile infants less than 1 month old. The ability to determine signs of meningitis in older infants depends on the physician's experience in interpreting infant behavior and clinical examination findings.

Assessing behavior in young children can be difficult, even for experienced examiners. Observation of trends in behavior over time, including alertness, consolability, social interactions, and feeding, is perhaps the most sensitive means to discern the presence or absence of a serious infection in a child with an initially equivocal presentation. Expectant antibiotic therapy for young children with fever without source and presumed occult bacteremia may be justified when a hospital's laboratory requires 48 hours to identify and report on a positive blood culture. But in a hospital that uses radioisotope techniques to identify positive cultures in 12 hours, the justification for empiric antibiotic therapy is less.

AVAILABILITY OF FOLLOW-UP

When follow-up is uncertain, extensive evaluation and cautious disposition are justified. For example, a 3-year-old nontoxic, toilet-trained girl with reliable follow-up might be discharged to return with a voided urine specimen for urinalysis and culture in 12 hours. But if follow-up is uncertain, it might be appropriate to catheterize the child during the ED visit. Children at risk for unreliable follow-up include those with parents who are young, who have no access to transportation, or who believe their child is not ill.²⁵

DEFINITION, MEASUREMENT, AND INTERPRETATION OF FEVER

Traditionally, a rectal temperature (for neonates and young children) or oral temperature (older children and adolescents) at or above 38°C (100.4°F) has been defined as fever. Note that temperature varies diurnally 0.5°C or 1.0°F, and a temperature of 37.0°C (98.6°F) in the early morning hours (e.g., 4 a.m.) may represent a low-grade fever.^{18,26} Rectal temperatures are generally about 0.3°C or 0.5°F higher and less variable than oral temperatures.¹³ Bundling of a nonfebrile child should not cause a fever when the temperature is taken rectally.¹⁷ Axillary temperatures have been shown to be unreliable.²² Although previously not advocated, tympanic thermometers, when used after proper training, may be more reliable than previously thought.²⁸

Recent antipyretic use could interfere with fever identification, although, typically, fever is not eliminated and the antipyretic effect dissipates approximately 2 hours after the last dose.³⁰ It should be noted that the degree of fever response to antipyretic therapy bears no relation to the likelihood of bacterial infection, and thus is irrelevant in clinical decision making.^{4,8} Elevated body temperature is not generally harmful unless the temperature rises above approximately 106.5°F.²¹

INITIAL EVALUATION

All children who are evaluated for fever should receive a thorough physical examination. The initial examination should start with an evaluation of the child's ABCs. Signs of respiratory distress, hypoperfusion, or shock should be treated immediately. The child's mental status and interaction with the environment are especially important to evaluate. A happy and playful infant with a fever of 40.0°C is less concerning than a lethargic child with no eye contact with a fever of 38.5°C. Febrile children should be undressed to look for skin infections and rashes, including petechiae (e.g., meningococemia) and vesicles (e.g., *coxsackie* or *varicella* virus infection). Walking an ambulating child will help evaluate for occult joint infections. [Table 248.1](#) lists other key symptoms and signs that should be pursued as part of the emergency evaluation of febrile infants and children.

HISTORY
Behavior: activity level, consolability, irritability when moved
Onset: time of onset, duration, location
Hydration status: fluid intake, urine output
Respiratory symptoms: cough, difficulty breathing
Constitutional symptoms: vomiting, diarrhea (with blood), stool
Other symptoms: abdominal pain, drowsiness, frequency, urgency, hematuria
Children: focal pain (e.g., limp, sore throat, earache, abdominal pain, rash)
Medical history: immunization status, chronic medical conditions, ID status
PHYSICAL EXAMINATION
General appearance: activity, eye contact, muscle tone, color, consolability
Hydration status: mucous membranes, fontanelle, capillary refill, skin color, turgor
Respiratory: respiratory rate, grunting, nasal flaring, rales, wheezing
Cardiovascular: heart rate, murmurs
Central nervous system: fontanelle, bulging, sunken, CVA* (briskness, rigidity, hyperreflexia, clonus, Babinski's reflex, extensor, clonus, rigidity)
Other: skin (rash, petechiae, vesicles, pustules, ulcers, abscesses, cellulitis, erythema, edema, tenderness, warmth, pain, tenderness, purpura, necrosis)
Musculoskeletal: bone or joint tenderness, swelling, erythema, ability to articulate

TABLE 248.1. Key Historic and Physical Findings Relevant to the Evaluation of the Acutely Febrile Infant or Child

Previously healthy, non-toxic-appearing* term infant
No previous antimicrobial use
No focal infection on examination
WBC count 5,000–15,000/ μ L
Band count < 1,500/ μ L
Stool WBC count \leq 5 WBC/HPF when diarrhea present
 \leq 10 WBCs/HPF in spun urine

*Includes activity, alertness, color, strength of cry, consolability, irritability, eye contact, social responsiveness, and respiratory effort

TABLE 248.5. The Rochester Criteria for Evaluating Young Infants

Fever in Infants and Children Older Than 3 Months by Clinical Findings

In children older than 3 months of age, signs such as mentation and behavior are more reliably present when serious bacterial infections are present. Young infants with meningitis may have a bulging fontanel, and infants older than 12 to 18 months usually have meningeal signs. Careful, repeated assessments of the patients' general appearance, especially just before discharge from the ED, are the key to reasonably excluding meningitis in children 3 to 36 months of age. If the febrile child becomes lethargic or is persistently irritable or inconsolable, then a lumbar puncture is recommended, regardless of other physical findings or laboratory parameters.

Fever and Rash

Vesicles or ulcers isolated to the oropharynx are possibly herpes simplex or Coxsackie virus. If vesicles are also present on the hands or feet, then hand-foot-mouth disease is likely. Diffuse vesicular lesions on an erythematous base suggest the presence of varicella.

A febrile, ill-appearing child with an acute onset of a petechial or purpuric rash should be considered to be meningococemic until proven otherwise. Petechiae may develop on the face or neck area due to severe coughing or vomiting. It is recommended that any child with fever and petechiae not thought to be due to vomiting or coughing should undergo a complete septic workup. If the child remains well-appearing after a period of observation, no new petechiae have developed, and the child has a negative septic workup, then it may be possible to discharge the child with close follow-up.²⁰ Henoch-Schönlein purpura (HSP), a multisystem vasculitis, is suggested by subacute onset of a petechial or purpuric rash of the lower extremities, associated with painful swollen joints and abdominal pain in a slightly older child. As opposed to meningococemia, these children rarely appear acutely ill. If HSP is suspected, stool for occult blood and urine for hematuria should be evaluated.

The pink maculopapular rash of roseola infantum will develop after a high fever has defervesced in an otherwise well-appearing infant. The maculopapular rash of measles will usually be associated with an ill-appearing young child with fever, cough, coryza, conjunctivitis, and Koplik's spots in the mouth. Kawasaki disease is uncommon but has the potential for serious morbidity. Kawasaki disease usually presents in a young child with a several-day history of high fever that progresses to a macular-papular diffuse rash, conjunctivitis, erythematous or fissured lips, strawberry tongue, cervical lymphadenopathy, and edema or desquamation of hands or feet. Children with Kawasaki disease are at risk for developing aneurysms of the coronary arteries. The treatment includes high-dose aspirin, immunoglobulin therapy, and serial echocardiograms.

Fever and a Red Tympanic Membrane

Acute otitis media remains one of the most common discharge diagnoses for young children with fever. Because an erythematous tympanic membrane can result from the fever alone or from crying, this finding alone is not sufficient to diagnose acute otitis media. A bulging membrane or immobility during insufflation is necessary for this diagnosis to be reasonably considered.

Fever and Pharyngitis

Group A beta-hemolytic *Streptococcus* remains a concern as a cause of pharyngitis and fever in children generally older than 5 years of age. This infection is often associated with prominent gastrointestinal symptoms in children. Scarlet fever is likely when a fine, "sandpapery," raised maculopapular rash is also present. A rapid streptococcal antigen test is a relatively specific aid to diagnosis. If it is negative, however, a throat culture is necessary to exclude this diagnosis. Adolescents with exudative pharyngitis accompanied by prominent cervical adenopathy and splenomegaly may have mononucleosis; atypical lymphocytes on a blood smear or a Monospot test help to confirm this diagnosis.

Fever and Cough, Wheezing, or Tachypnea

Upper respiratory symptoms associated with fever in the winter and early spring are often due to respiratory syncytial virus (RSV) bronchiolitis and can range in severity from mild cough and wheezing to severe respiratory distress with tachypnea, retractions, grunting, and nasal flaring. The chest x-ray typically shows hyperinflation with peribronchial cuffing. A nasal wash for rapid RSV antigen testing can quickly be obtained. If the child clinically appears to have bronchiolitis and the RSV antigen test is positive, the yield from blood cultures and urine cultures looking for other sources of fever is low.¹

Pneumonia in pre-school-age children is most often due to viral infection; *Mycoplasma pneumoniae* is more common in older children and adolescents. Toxic-appearing, febrile children of any age may have pneumonia due to pyogenic bacteria such as *Streptococcus pneumoniae*. The signs of pneumonia in young children that are indications to consider a chest radiograph include tachypnea, retractions, nasal flaring, grunting, abnormal auscultatory findings, and a pulse oximeter reading of less than 92%.¹¹

Fever and Vomiting, Diarrhea, or Abdominal Pain

Fever presenting with vomiting, diarrhea, or abdominal pain has a variety of causes, depending on the child's age. Gas- trointestinal causes are the most likely source of the fever and associated symptoms. Acute gastroenteritis is a very common cause of fever with vomiting or diarrhea in young children and can have a viral or bacterial etiology. The most common cause of gastroenteritis in young children is *Rotavirus*. The vomiting frequently precedes the diarrhea by 24 hours. Rehydration is the cornerstone in treating the vomiting and diarrhea. If oral rehydration appears as an option, encourage the parents to try small amounts of fluids (e.g., 5 cc or 1 teaspoon every 2 to 3 minutes for young children). The child's diet should be advanced to a regular diet as soon as possible.

Bacterial causes of enteritis include *Shigella*, *Salmonella*, *Campylobacter*, and enterotoxigenic *E. coli*. Laboratory evaluation of children with fever, hematochezia, and abdominal pain may include a stool culture. A child found to have a bacterial pathogen as the cause of the diarrhea, with the exception of *Salmonella*, should be treated with the appropriate antimicrobial. Treating *Salmonella* may lead to a chronic carrier state and is recommended only for infants less than 3 months of age, patients with immunosuppressive illness, and toxic patients. The fluoroquinolones are relatively contraindicated in young children, due to the potential risk to growth.

Appendicitis also remains a serious cause of fever and abdominal pain in young children. Young children have higher perforation rates compared with older children, due in part to the difficulty in making the diagnosis. Children with appendicitis are often discharged home with diagnoses of gastroenteritis or urinary tract infection (UTI) before the final diagnosis of appendicitis is made. The omentum in young children is less capable of walling off focal areas of infection, such as appendicitis. Peritonitis with diffuse abdominal tenderness is therefore more common. Ultrasound and computed tomography (CT) scan are two modalities that are now used more commonly to diagnose appendicitis in young children.

Streptococcal pharyngitis in older children may present with fever, abdominal pain, and associated dysphagia. Lower lobe pneumonia can sometimes present with abdominal pain and fever. Adolescent girls with fever and abdominal pain should be questioned regarding sexual activity and possibly evaluated for pelvic inflammatory disease. UTIs are also a common cause in girls with fever and abdominal pain. In young children, UTIs may present with fever and vomiting, often

without abdominal pain. UTI should be considered in febrile girls less than 2 years old and in uncircumcised boys less than 1 year old.

Fever and vomiting without diarrhea can be a sign of a neurologic process. Meningitis, particularly bacterial meningitis, is the most serious cause. Children with a central nervous system (CNS) ventricular shunt should be evaluated for the possibility of obstruction and meningitis. This evaluation may include a head CT scan and lumbar puncture or shunt tap for CSF evaluation. Finally, acute otitis media can also present with fever and diarrhea in young children.

Fever and Swollen Joint or Limp

Febrile children who are nonambulatory, walk with a limp, or have local joint symptoms should be evaluated for a joint infection. Toxic synovitis, a benign condition related to coincident viral infection, must be differentiated from septic arthritis, which can rapidly be destructive. Joint effusions should be aspirated and analyzed for cell counts, Gram stain, and culture. If the hip joint is suspected, ultrasound appears to be a reliable test to evaluate the presence of an effusion, and can then be used to guide joint aspiration. Sexually active adolescents may have arthritis or tenosynovitis due to disseminated gonococcal infection.

Fever without Source in Young Children (3 to 36 Months)

After a thorough physical examination, often no identifiable infection source for the fever is found in infants and children younger than 36 months of age. The presence of some clinical diagnoses can reasonably explain fever, including Coxsackie pharyngitis (and hand-foot-mouth disease) and chickenpox. The presence of acute otitis media does not necessarily exclude other diagnoses as the cause of fever.

Fever may be the only indication of a UTI in a young child. Up to 7% of febrile young children without a source found on physical examination have a UTI as a cause of their fever.²⁶ In one study, up to 4% of young febrile children less than 2 years old, with either acute otitis media or gastroenteritis as a source for the fever, also had a UTI.²⁷ A urinalysis and culture are recommended as part of the workup of girls less than 2 years old and of uncircumcised boys less than 12 months old. Urinalysis is insufficiently accurate to be used alone to evaluate the presence of UTI in young children.¹⁸ Therefore, a urine culture should be sent in addition to the urinalysis. Enhanced urinalysis, using Gram stain or hemocytometer, has been shown to improve the capabilities of the urinalysis.¹⁸ Bag urine specimens are also more likely to produce contaminant flora, compared with catheterized specimens. Pneumonia is rarely present without signs of disease (see previous discussion).¹⁴

When no source is found on physical examination, and pneumonia and UTI have been ruled out by either physical examination or laboratory tests, the potential for occult bacteremia should be considered. Previous studies have shown that 3% to 5% of children with no focus of infection and with temperatures above 39.5°C are bacteremic with *S. pneumoniae*, *Haemophilus influenzae*, or *Neisseria meningitidis*.⁵ Previously, up to 25% of these bacteremic children would have seeding of other areas, causing other serious bacterial infections, such as meningitis or septic arthritis.⁵ Due to *H. influenzae* type b vaccine, this virulent bacteria is now almost nonexistent as a cause of occult bacteremia, with *S. pneumoniae* accounting for over 90% of cases. The risk of pneumococcal bacteremia causing meningitis is much lower, at less than 3%.²⁴ Although occult pneumococcal bacteremia ultimately spontaneously resolves in the vast majority of children, both oral and parenteral antimicrobial agents may reduce the risk of focal bacterial infections and possible meningitis in children with occult bacteremia.

The relative benefit of possible averted infectious sequelae, and the risk and cost of unnecessary blood cultures (and consequences of contaminants, etc.) and antimicrobials, compared with careful follow-up alone, is not clear.¹⁶ Currently, no consensus exists as to the need or means to identify and empirically treat children who may be bacteremic among all those with fever without source.

Approaches include blood cultures and empirical antimicrobials for all nontoxic children 3 to 36 months of age with fever without source; for only those at high risk (e.g., temperature greater than 41.0°C, under- or nonimmunized against *H. influenzae*, or a combination of temperature greater than 39.0°C and absolute neutrophil count [ANC] greater than 10,000/μL); and close follow-up without testing or treatment.¹⁶ If empiric antibiotics are to be utilized, intramuscular ceftriaxone (50 mg/kg) is appropriate, especially for the child who is not fully immunized against *H. influenzae*. For other children, oral amoxicillin (60 to 90 mg/kg/d) is a reasonable alternative. A new protein-conjugate pneumococcal vaccine for young children was recently approved and appears to be 80% to 100% effective in preventing bacteremia and meningitis.⁹ Soon, the justification for empiric antimicrobial therapy for presumed occult bacteremia will be significantly less in fully vaccinated children.

EMERGENCY DEPARTMENT DISPOSITION AND INSTRUCTIONS TO PARENTS

Fever control with acetaminophen (15 mg/kg every 4 to 6 hours) or ibuprofen (10 mg/kg every 4 to 6 hours); cool, clear liquids; and light dressing are advised. Sponging may be used but is of questionable value. Body temperature is determined by the temperature regulatory center in the hypothalamus. Acetaminophen resets the regulatory center, but sponging has no effect on it and a minimal effect on lowering the temperature for any significant period of time. Sponging usually results in an irritated, agitated child.¹⁵

Although experimental evidence suggests that fever may be adaptive and stimulate the immune system, fever reduction has not proven to be deleterious, and does lead to increased patient comfort and decreased metabolic demands and fluid loss. Therefore, fever control is recommended.

The second component of discharge instructions consists of the indications for urgent return for reevaluation ([Table 248.6](#)). The most important indications for urgent reevaluation are lethargy and persistent irritability. Even with continued fever, if the child's behavior and disposition improve, urgent reevaluation is not necessary. A child less than 3 months old or a child given empiric antibiotics should generally be followed up in 12 to 24 hours by a primary care physician or clinic. That follow-up may consist of a telephone call to the caretaker or, if there is reason for additional concern, a repeat examination.

AGE OR TREATMENT
Any child less than 3 mo old Any child given antibiotics for fever without a source
BEHAVIOR
Persistent lethargy or irritability
HYDRATION STATUS
Signs of dehydration (decreased urine output, decreased tears)
RESPIRATORY
Worsening cough Difficulty breathing
GASTROINTESTINAL
Persistent vomiting Bilious vomiting Worsening diarrhea
OTHER
New rash Pain

^a Telephone contact may be sufficient in some cases.

TABLE 248.6. Indications for Reevaluation^a

COMMON PITFALLS

- Do not forget to consider noninfectious disease processes as a cause for the fever.
- Remember to account for an infant's age in determining the extent of the fever evaluation.
- Do not forget to carefully evaluate and document the child's general appearance.
- Do not overrely on acute-phase reactants such as the white blood cell or ANC.

- [Chapter References](#)

The causes of bleeding from the gastrointestinal (GI) tract vary with the child's age. The site of bleeding is also important in diagnosis and therapy, and can often be determined by the presenting symptoms. Hematemesis is the vomiting of blood and implies a source proximal to the ligament of Treitz. Vomited blood may have the appearance of coffee grounds or may be bright red, implying ongoing bleeding. Blood from the upper GI tract or proximal small bowel, when passed per rectum, is typically black or tarry, is sticky, has a characteristic aroma, and is called *melen*. Bright red blood per rectum or maroon stools (hematochezia) implies a more distal GI source. Upper GI bleeding, however, may present as gross blood rectally (hematochezia), if the hemorrhage is large and transit time is short.

[Table 249.1](#) and [Table 249.2](#) outline the causes of GI bleeding in children and illustrate the wide, age-related differential diagnosis.

Newborn (0-1 mo)	Infant (1 mo-2 yr)	Preschool (2-5 yr)	School Age (>5 yr)
Anal fissure	Anal fissure	Anal fissure	Anal fissure
Local trauma	Hirschsprung disease	Intussusception	Intussusception
Swallowed maternal blood	Allergic colitis	Infectious colitis	Infectious colitis
Upper GI bleeding	Intussusception	Meckel's diverticulum	Hemorrhoids
Necrotizing enterocolitis	Infectious colitis	Hemolytic-uremic syndrome	Inflammatory bowel disease
Malrotation with volvulus	Meckel's diverticulum	Hemorrhagic purpura	Pseudomembranous colitis
Infectious colitis	Intestinal duplication	Inflammatory bowel disease	Lymphomatous hyperplasia
Hirschsprung disease	Lymphomatous hyperplasia	Intussusception	Hemolytic-uremic syndrome
Allergic colitis	Pseudomembranous colitis	Pseudomembranous colitis	
Celiacopathy		Lymphomatous hyperplasia

Newborn (0-1 mo)	Infant (1 mo-2 yr)	Preschool (2-5 yr)	School Age (>5 yr)
Esophagec	Esophagitis	Esophagitis	Esophagitis
Swallowed maternal blood	Gastritis	Gastritis	Gastritis
Esophagitis	Stress ulcer	Peptic ulcer	Peptic ulcer
Stress ulcer	Mallory-Weiss tear	Varietal esophageal diverticulum	Varietal esophageal diverticulum
Vitamin K deficiency	Vascular anomalies	Mallory-Weiss tear	Mallory-Weiss tear
Blood dyscrasia	Foreign body	Foreign body	Inflammatory bowel disease
Vascular anomalies	Duplication	Blood dyscrasia	
		Vascular anomalies	

TABLE 249.2. Differential Diagnosis of Upper GI Bleeding

CLINICAL PRESENTATION

Bleeding from anal fissures and bleeding from the upper GI tract are the most common reasons children with GI bleeding visit the emergency department. Life-threatening hemorrhage is a rare presentation to the emergency department. More commonly, GI bleeding in the child presents as anemia from chronic upper GI bleeding (typically microcytic) or occult bleeding in the stool (e.g., cow's milk protein sensitivity).⁶ Acute bleeding can be classified as occult, overt, or massive. Massive bleeding (e.g., variceal bleeding) is the most dramatic presentation and is usually accompanied by compromised cardiac output or tissue oxygenation.

DIFFERENTIAL DIAGNOSIS

Reaching the exact diagnosis in a child with GI bleeding is usually unnecessary in the emergency department, because most patients are stable and the differential diagnosis is large (see [Table 249.1](#) and [Table 249.2](#)). A thorough history and clinical examination can usually make the diagnosis. For the emergency physician, it is most important to determine whether the source of bleeding is in the upper or the lower GI tract. The easiest method is to atraumatically pass a small, soft, nasogastric tube and perform a gastric lavage with tap water or normal saline at room temperature. Water appears to be as efficacious as saline, and there does not appear to be any benefit of cold versus room-temperature solution.¹² If blood is not evident on lavage, it is unlikely that the bleeding is above the ligament of Treitz (i.e., bleeding from the nose, esophagus, and stomach).

Measuring the ratio of blood urea nitrogen to creatinine (BUN/Cr), as described by Felber and colleagues,⁴ may also provide supportive evidence of upper GI bleeding. A ratio exceeding 30 suggests bleeding from the upper GI tract; less than 30 might be consistent with either an upper or a lower GI bleeding site. This ratio also provides a useful means of assessing the amount of blood loss and predicting when a significant bleed has ceased.¹⁹

Newborn (0 to 1 Month)

Most causes of bleeding in neonates are never identified, as most bleeding usually stops between 24 and 48 hours of life. Significant upper GI bleeding may result from stress ulcers or hemorrhagic gastritis in the neonate with sepsis, an intracranial lesion, or other major illness. Hematemesis in the neonate may also result from hemorrhagic disease of the newborn (vitamin K deficiency) or congenital bleeding disorders such as hemophilia. The swallowing of a mixture of amniotic fluid and

maternal blood is a frequent cause of hematemesis but may also present as dark red rectal bleeding. Swallowed maternal blood (adult hemoglobin) can be easily differentiated from upper GI bleeding in the fetus (fetal hemoglobin) by adding sodium hydroxide to a blood sample. This test is known as the alum precipitated toxoid test, or the Apt. Fetal hemoglobin resists alkaline degradation and remains pink; adult hemoglobin gives a brownish color.

Anal fissure and local trauma are the most common causes of rectal bleeding in the first month of life. However, both necrotizing enterocolitis and enterocolitis due to Hirschsprung disease may present with occult or overt rectal bleeding. Necrotizing enterocolitis is more common in the preterm infant but is also seen in the stressed term infant. Billious vomiting, abdominal distention, and rectal bleeding are the most common clinical features and may also be due to surgical emergencies such as midgut volvulus. Finding air in the bowel wall (pneumatosis intestinalis) on an abdominal radiograph is pathognomonic for necrotizing enterocolitis.

Infant (1 Month to 2 Years)

Upper GI bleeding is frequently caused by esophagitis, gastritis, or stress ulcers. However, congenital malformations such as duodenal web, although more likely to present in the newborn period, can present after 1 month of life.¹⁴

Lower GI bleeding is most commonly due to anal fissure, but other anorectal lesions, such as juvenile polyps, should also be considered. Intussusception, which classically presents with currant jelly stools, is most common in infants 7 to 12 months old. Infectious colitis is usually secondary to species of *Salmonella* and *Shigella* and to *Campylobacter jejuni*, *Yersinia enterocolitica*, and both enterohemorrhagic and enteroinvasive *Escherichia coli*. Other organisms that should be considered include *Aeromonas hydrophila* and *Entamoeba histolytica*. With the increasing number of children with the acquired immunodeficiency syndrome, cases of GI bleeding secondary to opportunistic infections such as cytomegalovirus will be seen with increased frequency.³

Preschool (2 to 5 Years)

Varices in both the upper and the lower GI tracts can lead to massive, life-threatening hemorrhage in this age group. Two-thirds of patients with portal hypertension sustain bleeds before 5 years of age, and 85% do so by age 10 years. On physical examination, other signs of portal hypertension or liver disease are found, such as splenomegaly, hepatomegaly, and dilated abdominal veins.¹ Foreign-body ingestion, although uncommon, should also be considered as a cause of upper GI bleeding.

Anal fissure and juvenile polyps are the most frequent cause of lower GI bleeding. Polyps are usually solitary and nonmalignant and can be felt on rectal examination. Massive GI bleeding from Meckel's diverticulum is sometimes seen in preschool children. Infectious enterocolitis from infectious agents similar to those described for the infant may also present with bloody stools. Multisystem diseases such as hemolytic-uremic syndrome and Henoch-Schönlein purpura are less common causes of bloody stools.

School Age (Over 5 Years)

Esophagitis, gastritis, and peptic ulcer disease account for most cases of upper GI bleeding. Erosions of the gastric mucosa may occur acutely after any major stress, such as trauma, shock, burns, or sepsis. Peptic ulcer disease may be either primary or secondary to other conditions, such as cystic fibrosis medications (e.g., corticosteroids and nonsteroidal antiinflammatory agents).

Anal fissure and juvenile polyps account for most cases of lower GI bleeding. Intestinal lymphonodular hyperplasia of childhood has a peak incidence between 6 and 10 years; inflammatory bowel diseases (e.g., Crohn disease and ulcerative colitis) have a peak incidence in children over 5 years.⁸ With the increased prevalence of cocaine use, drug intoxication should be considered in cases of unexplained shock and hemorrhagic diarrhea in this age group.¹³

EMERGENCY DEPARTMENT EVALUATION

The emergency physician's initial step is to determine the site and magnitude of bleeding and whether it is ongoing at the time of evaluation. If the patient presents with signs and symptoms of cardiovascular compromise, immediate attention to restoring intravascular volume is necessary. Usually, however, the evaluation can be done in a leisurely manner, beginning with a thorough history and physical examination.

Important elements of the history and physical examination are outlined in [Table 249.3](#). A nasogastric tube should be inserted and fluid aspirated, unless a distal source is obvious. A positive aspirate for blood almost certainly indicates that the site of bleeding is proximal to the ligament of Treitz. However, a negative aspirate does not exclude an upper GI bleeding site beyond the pylorus.

HISTORY	PHYSICAL EXAMINATION
Characteristic bleeding (duration, quantity, color, rectal vs. oral)	Vital signs
Associated pain	Site of bleeding (nose, mouth, outside GI tract)
Vomiting/diarrhea	Acuity or chronicity
Medication history (e.g., aspirin, alcohol)	Anthropometric data
Illicit drugs (e.g., cocaine)	Cutaneous signs (e.g., spider nevi)
Systemic diseases	Abdominal tenderness/mass
Family history	Hepatomegaly
Social history	Splenomegaly
	Anorectal examination

TABLE 249.3. History and Physical Examination for GI Bleeding

In most cases, the cause of bleeding is evident, but sometimes, before beginning an expensive and possibly invasive workup, it may be necessary to confirm that the patient is actually passing blood. Many foods and medications (e.g., tomato or cranberry juice, flavored gelatin, Kool-Aid, red licorice, ampicillin, rifampin, iron, and bismuth preparations [Pepto-Bismol]) can give stools a bloody appearance or test positive for blood. In most hospitals, guaiac benzidine or benzidine derivative test pads (Hemoccult or Hematest) are used to detect blood. These tests use a hydrogen peroxide developer and are based on the peroxidase activity of hemoglobin and its derivatives. In the presence of hydrogen peroxide, these substances catalytically oxidize substrates such as guaiac or benzidine. The oxidation produces a color change in the substrate, indicating a positive test. However, false-negative results can be obtained if the patient has ingested large doses of ascorbic acid or if intestinal bacteria have degraded the hemoglobin to porphyrin. False-positive results can be seen if the patient has eaten rare red meat or peroxidase-containing fruits and vegetables such as broccoli, radishes, cauliflower, cantaloupe, or turnips. A new test, HemoQuant, appears to be more sensitive.^{6,7} Laboratory studies ([Table 249.4](#)) should include a complete blood count with platelet and reticulocyte counts and a coagulation profile. If bleeding is severe, blood should also be sent for a crossmatch. The BUN/Cr ratio is useful in localizing the source of bleeding to the upper GI tract and may provide an estimate of the severity of blood loss from the upper GI tract. Also, an elevated BUN level is more likely to be associated with an upper than a lower GI bleed.¹⁹ Hepatic and renal function tests (to assess liver function and to obtain the BUN/Cr index) should be obtained. If an infective cause is thought likely, stool should be examined promptly for fecal leukocytes, aerobic and anaerobic cultures, and microscopy for ova and parasites.¹⁴

Blood count: CBC with reticulocyte count
 Coagulation profile: platelet count, prothrombin time, partial thromboplastin time, fibrinogen
 Hepatic profile: bilirubin, SGPT, SGOT
 Renal profile: BUN/Cr
 Blood bank: type and crossmatch
 Stools: leukocytes, aerobic and anaerobic stool cultures, microscopy for ova and parasites

TABLE 249.4. Laboratory Studies

Plain radiography and sonography are noninvasive and minimally distressing for a child and may give definitive information, such as a classic appearance of multiple short fluid levels in the abdomen in a neonate with volvulus, or the appearance of an intraluminal mass on sonography, in a case of intussusception.

If the source of bleeding is not obvious after these investigations, more detailed testing, including endoscopy and complex radiographic procedures, is necessary. However, most of these will not be conducted as part of the emergency department workup. In children with a positive nasogastric aspirate, endoscopy within the first 24 hours can determine the source of upper GI bleeding in 90% of cases. Fiberoptic endoscopy in children has shown that the most common causes of bleeding are gastritis, esophagitis, duodenal ulcers, and esophageal varices.⁹ Endoscopy is especially recommended in children with a history of esophageal varices, because the source of bleeding may be from other lesions. Upper GI barium studies are less accurate than endoscopy and may interfere with subsequent endoscopic examination.

Both endoscopy and barium studies fail to determine the source of bleeding in patients with massive bleeding (greater than 0.5 mL/min, making endoscopic examination impossible). In these patients, arteriographic examination of the superior and mesenteric arteries and the celiac axis may reveal some common causes of bleeding, as well as some unusual causes, such as hepatic artery aneurysms, traumatic hematomata, or malformations (e.g., arteriovenous lesions and hemangiomas). Nuclear medicine scans have fewer complications and are preferred by some clinicians.¹⁵

If the nasogastric aspirate is negative, a rectal examination and proctosigmoidoscopy can identify the source of rectal bleeding in 80% of cases. Additional studies are needed to identify the other 20%. Dark blood mixed with stool, in the absence of abdominal pain or diarrhea, may indicate Meckel's diverticulum, intestinal duplication, or right-sided colonic polyps. A bleeding Meckel's diverticulum is the cause in 80% of cases and can often be diagnosed by a nuclear medicine scan. Colonoscopy and, ultimately, an air-contrast barium enema should be performed if the scan is inconclusive.

EMERGENCY DEPARTMENT MANAGEMENT

Management depends on the child's clinical status and the severity and site of bleeding ([Fig. 249.1](#)).

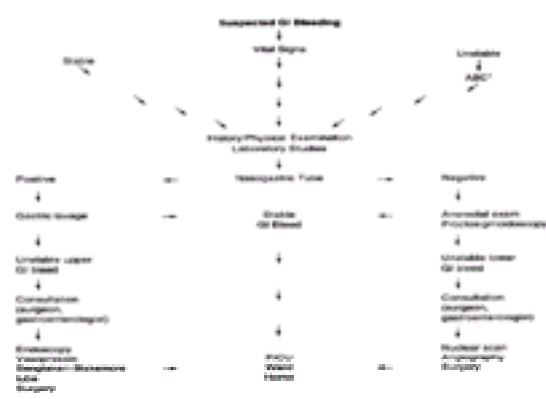

Figure 249.1. Flow diagram of suggested management of GI bleeding in the emergency department. ABC (*) includes attention to respiratory status (may include endotracheal intubation) and cardiovascular support (including vascular access, crystalloid and blood infusions).

Assessment of Cardiovascular Status

Initial management is based on the child's condition, including factors such as age; source, rate, and amount of bleeding; and associated medical illnesses. Assessment of cardiopulmonary status and prompt attention to any derangements are always necessary. Oxygen administration and venous access, followed by fluid boluses of crystalloids (20 mL/kg lactated Ringer's or normal saline), are mandatory, particularly if the patient has signs of volume compromise (anxiety, tachycardia, weak pulses, delayed capillary refill, hypotension, tachypnea). Additional fluid boluses are given as indicated by frequent reevaluations. A nasogastric tube is then placed in the stomach, and lavage with tap water or saline begins.

Occult Bleeding

In the stable child with occult bleeding, management is geared toward making the diagnosis and excluding more serious conditions. Investigations are dictated by the history and physical examination, but most tests, including cultures, radiologic and nuclear medicine scans, and endoscopy, can be performed on an outpatient basis. The cause of occult upper GI bleeding in children is often not from the GI tract. Although anal fissures account for most cases of occult blood in stools, the physician should always consider the possibility of a less benign cause (e.g., necrotizing enterocolitis or intussusception in the ill-looking neonate or infant). Occult bleeding may also presage other serious events, such as Meckel's diverticulum.

Overt Bleeding

Administration of crystalloids (normal saline or Ringer's lactate) to restore intravascular volume is the management priority. Blood is sent for urgent type and crossmatch, or O-negative blood is made immediately available. The child who has lost 10% to 20% of his or her blood volume does not necessarily require blood replacement, provided the bleeding has stopped. If, after 20% of the blood volume has been replaced by crystalloid, the child still has orthostatic hypotension, blood should be given. The child's age and physical condition also dictate the need for blood; for example, children with heart and chronic lung disease may require earlier transfusion. Platelets, fresh-frozen plasma, or vitamin K (1 mg per year of age, up to 10 mg) is given as necessary to correct an identified coagulopathy. In the neonate suspected of vitamin K deficiency, vitamin K (1 mg) is given intramuscularly. Antacid therapy, H₂ blockers, and sucralfate have proven to be efficacious in minimizing or preventing bleeding in patients with stress or peptic ulcer from trauma, shock, or sepsis, if gastric pH levels are kept above 4. H₂ blockers are best given intravenously by continuous infusion. The recommended intravenous dosage is 20 to 30 mg/kg/d for cimetidine or 7.5 mg/kg/d for ranitidine.

Massive Bleeding

Although the incidence of massive GI bleeding in children is low, the emergency physician must be prepared to treat these patients aggressively. Aggressive fluid resuscitation and administration of blood components usually suffice. However, in some cases, endotracheal intubation, to secure the airway and to decrease the work of breathing, is needed in a patient with low cardiac output. Endotracheal intubation allows adequate sedation without the risk of hypoventilation or aspiration, and it also facilitates endoscopy. Continuous monitoring of vital signs, urine output with a Foley catheter, and oxygen saturation with pulse oximetry is essential.

Central venous catheter placement, although not mandatory, may be helpful in monitoring the volume status.

Management of the child with massive variceal bleeding from portal hypertension may include intravenous vasopressin (0.1 to 0.4 U/min), variceal injection, or ligation using endoscopy.¹

Massive bleeding can also occur in children with Meckel's diverticulum; these patients also require aggressive resuscitation initially. Following cardiovascular stabilization, the site of bleeding can be confirmed by a nuclear medicine scan or by arteriography.

If massive bleeding precludes stabilization, immediate laparotomy may be required.

DISPOSITION

Role of the Consultant

Conditions that require urgent surgical evaluation include volvulus, vascular malformations, and necrotizing enterocolitis in the neonate. Some cases of GI bleeding from stress ulcers, variceal bleeding, or intussusception require urgent surgical evaluation. The emergency physician should always be in direct communication with physicians who will assume inpatient care of the child. Consultation with a pediatric gastroenterologist, pediatric surgeon, and/or pediatric intensivist may be necessary early in management. Panendoscopy to establish a specific diagnosis and to assess the rapidity of bleeding, the risk of rebleeding, and, possibly, the administration of definitive therapy may be required.

Transfer Considerations

In the prehospital setting or during interhospital transfer of the child with GI bleeding, attention must be paid to the airway, breathing, and circulation. Oxygenation and vascular access with the administration of crystalloid are priorities if there is evidence of vascular compromise. Continuous monitoring to ensure an adequate airway and stable vital signs is mandatory. Although personnel skilled in advanced pediatric life support should accompany the child, attention to stabilization before transport should minimize the need for interventions during transport.

COMMON PITFALLS

- Assuming the colored material is blood. Many foods and medicines can give secretions or stools a bloody appearance.
- Failing to perform an Apt test on a neonate's stool to rule out swallowed maternal blood.
- Using the wrong-sized nasogastric tube. Smaller bore tubes may be adequate for assessing bleeding, but not for removing clots.
- If the nasogastric aspirate does not sample duodenal contents, or if bleeding is intermittent, a false-negative aspirate may result.
- A carelessly placed nasogastric tube may yield a false-positive aspirate and cause distress to the patient. Iodine, supplemental iron, and ingestion of red meat may cause false-positive results.
- A normal hemoglobin level does not exclude significant, rapid GI bleeding.
- A normal or increased blood pressure in children does not exclude hypovolemia.
- Assuming the blood is from the GI tract
- Performing a barium study before endoscopy
- Not considering sexual abuse as a cause of anal fissures
- Failing to consider nonorganic causes (e.g., Munchausen syndrome by proxy) of GI bleeding

CHAPTER 250

Headache

Laurie Jeanne Burton and Harold K. Simon

[Clinical Presentation and Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Headaches, a common complaint among children presenting to the emergency department, are often associated with other systemic signs and symptoms that can help determine their etiology. Headaches can be acute or chronic, recurrent or of new onset, and often vary in how they progress or resolve. The child's description of the duration, specific location, and intensity is often difficult to elicit and makes classification and treatment a challenge for the physician in the emergency department.

While often a diagnostic and management problem for physicians, headaches in children are equally frustrating and concerning for families. Families confronted with a child who complains of headache are often concerned with severe, life-threatening possibilities such as meningitis or intracranial lesions. For this reason, many families bring their child to an emergency center for evaluation. In addition, for those with chronic headaches, lack of symptomatic relief is a major precipitating factor in bringing a child for evaluation.

Even though most children with acute or chronic headaches do not have life-threatening etiologies or intracranial lesions, these must be of foremost concern for the emergency department physician and must be ruled out by a careful and detailed history and physical examination.^{1,5,6} An in-depth knowledge of the mechanisms and presentations of the various forms of headaches is therefore paramount for the emergency department physician.

Most children presenting to the emergency department are found to have headaches related to minor febrile illnesses, sinusitis, stress, or migraines. Serious neurologic conditions are found in approximately 7% of cases, many of these being viral meningitis.¹ Even so, one cannot be lulled into thinking that all children with the complaint of headache have relatively benign, non-life-threatening concerns.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Headache is often a chief complaint, but it is more often part of a series of concerns. The complaint can be acute or chronic, intermittent or persistent, localized or focal, and mild to extremely intense. The severity of the presentation is related to the general appearance of the child, historic and physical findings, as well as associated signs and symptoms. Most commonly, the concern of headache is associated with viral or self-limited illnesses. Emotional problems and new types of stress (school or home) should be identified.

Certain historic and physical findings raise the suspicion for significant medical conditions. These include historic findings of sudden onset of headache, visual disturbances, weight loss, morning vomiting, neck pain, significant changes in behavior, and persistent and unremitting headache. Physical findings on presentation that would point toward more worrisome conditions include ill appearance of the child, change in mental status, focality on neurologic examination, papilledema, retinal hemorrhages, cranial bruits, nuchal rigidity, fever with petechiae or purpura, café-au-lait spots, hypertension, or signs of nonaccidental trauma.⁵

The two most commonly seen primary headache disorders in the pediatric population are migraine (vascular) and tension (functional) headaches. It may be difficult to distinguish the two types in some pediatric patients, but it is important to do so, because the treatments are somewhat different. Children with migraine headaches usually have a positive family history. Migraines are more commonly unilateral but may present as bilateral throbbing or pulsatile pain located in the regions of the eye, forehead, and temple. The headache may last anywhere from hours to days. It is often associated with nausea and vomiting, and it may be preceded by an aura.

Light, noise, and movement usually aggravate the pain. Motion sickness is prominent in about 45% of children with migraine headaches. Tension headaches, on the other hand, are usually bandlike and nonpulsatile in quality; lack the nausea, vomiting, photophobia, and phonophobia components; and do not have an aura.³ Environmental triggers, anxiety, and depression are often associated with tension headaches.

The differential diagnosis of pediatric headache is outlined in [Fig. 250.1](#).

Figure 250.1. Differential diagnosis of headache in the pediatric patient.

EMERGENCY DEPARTMENT EVALUATION

A complete history often points the clinician toward the correct diagnosis and helps identify concerns for an underlying serious neurologic condition, including central nervous system (CNS) infection or structural pathology. All patients seen in the emergency department with a complaint of headache must have a complete set of vital signs, including measurement of temperature and blood pressure. A complete physical examination is useful diagnostically, and there are several highlights to mention.

The best assessment of CNS "well-being," or perfusion and oxygenation, is the level of consciousness. In the HEENT examination, any signs of trauma, minor infections such as pharyngitis, otitis media, or sinus tenderness could be diagnostic. Given that the frontal sinuses become pneumatized between the ages of 6 to 10 years, there is potential for frontal sinus infection in children aged 6 and older. The patient with frontal sinusitis may have tenderness in the forehead above the inner canthus of the eye. The teeth and gums should be checked carefully for signs of dental caries or abscesses.

Auscultation for a cranial bruit, a very rare finding, can be attempted. The neck should be examined carefully for signs of meningismus, especially for Brudzinski's and Kernig's signs. In the infant, the fontanelle should be checked for bulging, indicative of increased intracranial pressure from such causes as CNS infection or structural pathology. Funduscopy should be attempted on every patient with headache. Although papilledema may not be present early in the patient with increased intracranial pressure, the presence of venous pulsations would effectively rule it out. Retinal hemorrhages are indicative of child abuse until proven otherwise. Performing a complete neurologic examination is fundamental in the evaluation of patients with headache.

Laboratory evaluation is clinically guided and may include a rapid streptococcal throat screen or culture, sinus radiographs, lumbar puncture, toxicology assays in patients with altered consciousness or carbon monoxide exposure, and pregnancy testing. Radiographic evidence of sinusitis includes air–fluid levels, mucosal thickening of greater than 4 to 5 mm, or complete opacification. Indications for a lumbar puncture include any patient with fever and meningismus, bulging fontanelle, or suspicion of subarachnoid hemorrhage.

In the child who has abnormal neurologic findings, controversy exists over whether to perform a lumbar puncture prior to or after a computed tomography (CT) scan. A CT scan confirms there are no signs of increased intracranial pressure that could precipitate herniation. If a lumbar puncture is undertaken prior to CT scan, the risks can best be minimized with the use of a small-bore needle. Obtaining an opening pressure is critical if there is suspicion of intracranial hypertension.

Indications for a CT scan of the head include abnormal neurologic findings without a clear etiology. More specific indications include recurrent morning headaches, persistent emesis without clear etiology, paroxysmal onset of excruciating headache, lethargy, papilledema, retinal hemorrhages, or head trauma with severe headache. The clinician should have a low threshold for obtaining a head CT scan in the following types of pediatric patients: the infant with persistent irritability of unclear etiology, the child under 5 years of age with severe headache, the sickle cell or bleeding diathesis patient with headache, and the ventriculoperitoneal (VP) shunt patient with headache. For the patient with a VP shunt and headache, a shunt series should also be obtained to ensure that there is no shunt disconnection or migration. Lastly, the pediatric patient 6 years of age or older with frontal sinus tenderness and severe persistent headache could have contiguous CNS spread from the sinuses best diagnosed by CT.

In the patient with a migraine headache associated with neurologic deficits, or a “complicated migraine,” CNS imaging is recommended. The preferred imaging test, if available, is a magnetic resonance imaging with angiogram. Otherwise, a head CT, with and without contrast, will suffice.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment should be based on the presumptive diagnosis. Most tension headaches or headaches due to minor illnesses can be treated successfully in the pediatric population simply with analgesics such as acetaminophen or ibuprofen (in patients over 6 months of age). Migraines deserve special mention. Currently, there are no specific practice guidelines for migraine headaches in the pediatric population. Several classes of drugs are used to treat the acute migraine, including various analgesics, vasoconstrictors, serotonin agonists, and antiemetic sedatives. If the patient suffers from chronic migraines, the best approach might be to ask what medications have successfully aborted attacks in the past. Milder migraine pain often responds to acetaminophen; ibuprofen; a dark, quiet room; and rest. More moderate pain often responds to intravenous ketorolac 1 mg/kg (maximum, 60 mg).

Management of a child over 12 years of age is similar to that of an adult, and a serotonin agonist such as sumatriptan can be given to the nonpregnant patient intranasally or orally at a dose of 25 mg.^{2,3} When using these agents, it is important to make a correct diagnosis of migraine, because the serotonin agonists do not work in the patient with tension or other types of headache. Care should be taken not to mix the serotonin agonists with the ergotamines, because side effects can be potentiated. A frequently used ergotamine in the migraine patient aged 12 years and older is dihydroergotamine (DHE) at a dose of 0.5 mg/kg intravenously. For severe pain, opioids such as morphine can be used, as long as serious etiologies of the headache have been carefully excluded. Regarding the younger child, analgesics such as acetaminophen and ibuprofen are first-line therapy. Anecdotally, sumatriptan is effective even in children as young as 6 years of age.⁴ In younger children with more severe migraine pain, inducing sleep is a common therapeutic approach. Antiemetics–sedatives are employed for this purpose, such as Phenergan 0.25 to 0.5 mg/kg per dose PO, PR, intramuscularly or intravenously.

DISPOSITION

There are several scenarios involving the pediatric patient with headache wherein consultation is indicated. Neurosurgical consultation should be sought for any patient with CNS hemorrhage or midline shift. If the etiology of the bleed is from trauma, and no neurosurgical support is available at the site of care, stabilization and transfer should be expedited. Consultation with a neurologist should be considered for a patient with focal neurologic findings or unexplained altered mental status, as well as for patients with papilledema, severe migraine unresponsive to medical management, and a head CT showing a mass lesion that is not felt to be a CNS bleed.

Complicated migraines also warrant consultation with a neurologist. Such migraines, by definition, are associated with abnormal neurologic findings. Examples include migraine with hemiplegia, ataxia, transient blindness or visual field defect, acute confusional state, Alice-in-Wonderland syndrome (visual hallucinations wherein objects appear distorted in size), and olfactory or gustatory hallucinations.⁵ Toxicology consultation with the local poison center should be considered in high-risk populations, such as the adolescent with altered mental status.

Indications for hospital admission include pain control that cannot be maintained in an outpatient setting, altered mental status or focal neurologic findings, suspected increased intracranial pressure, possible bacterial meningitis or encephalitis, severe headache after head trauma, complicated frontal sinusitis, and any CNS pathology.

Patients discharged from the emergency department should be instructed to seek medical attention if the headache worsens, changes, or persists for more than 2 to 3 days. They should also be encouraged to see their primary care provider to ensure proper follow-up and to avoid delays in diagnosis of inapparent or undeclared structural lesions.

COMMON PITFALLS

- All children with headache should have a screening blood pressure. The normal value for the systolic blood pressure in children can be approximated by the formula $2 \times \text{patient's age (in years)} + 90$ mm Hg. Diastolic blood pressure is approximately two-thirds of that value.
- In the setting of head trauma, do not forget about the possibility of occult neck injury.
- Always perform an opening pressure on the patient with headache who is undergoing a lumbar puncture. Many pediatric lumbar puncture kits do not come with manometers. One should be secured in advance, ideally before the first drop of cerebrospinal fluid is obtained.
- Have a low threshold for obtaining a head CT in children with frontal sinusitis and severe, persistent headache. Frontal sinusitis spreading to CNS involvement is not uncommon, particularly in the adolescent population.
- Always palpate the anterior fontanelle in infants under 1 year of age. It may be “full,” especially if the infant is crying, but it should not bulge over the dimensions of the scalp. Life-threatening causes of a bulging fontanelle include not only CNS infection, but also CNS hemorrhage or edema, possibly from abuse.
- In the ambulatory child, the presence of up-going toes is indicative of CNS pathology, whereas the preambulatory child has a Babinski reflex normally.
- Subtle signs of altered mental status can be easy to miss in the “sleepy” patient presenting to the emergency department during the overnight hours. In this scenario, one should have a lower threshold to obtain ancillary testing such as head CT and toxicology screening.
- Meningismus can be a sign not only of CNS infection, but also of occult cervical spine injury or subarachnoid hemorrhage, the latter seen in the pediatric population almost exclusively in the perinatal period.
- CT scanning of the head without contrast more than 7 days posttrauma may miss an intracranial bleed, because the breakdown of blood often causes it to be isodense with surrounding tissue. The use of contrast may be warranted.

CHAPTER 251 Heart Murmurs

Edward J. Bayne

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Heart murmurs are heard frequently in children, particularly in toddlers and school-age children. The incidence of significant congenital heart disease is about 1% (eight per 1,000 live births), but with careful auscultation, heart murmurs can be found in an estimated 40% to 60% of children. Most of these sounds are “normal,” “functional,” or “innocent,” and do not require extensive evaluation, consultation, or diagnostic testing. ^{5,6,7} and ⁸ As Fyler and Nadas⁴ wrote, “The most cost-effective tool for cardiac diagnosis is the stethoscope.”

Murmurs arise from the heart and circulatory system for various reasons. Pathologic murmurs may arise because of valvular stenosis or insufficiency or because of an abnormal communication between chambers or vessels (e.g., ventricular septal defect). The high incidence of normal murmurs in infants and children can be explained by several factors, including

- The relatively thin chest wall in many children, and close proximity between the heart and the stethoscope
- Vigorous circulation through relatively small vessels ⁹
- Conditions under which the child is examined, such as anxiety or fever, both of which increase the intensity of sound

In recent years, echocardiography and Doppler echocardiography have been used to better define the origins of pathologic murmurs and normal murmurs. ⁹

CLINICAL PRESENTATION

Cardiac murmurs can be heard in infants and children at any age. Most cases of symptomatic congenital heart disease manifest before 6 months of age. The infant with a large ventricular septal defect with left-to-right shunt and symptoms and signs of congestive heart failure typically presents at 4 to 8 weeks of age with a loud, long, and harsh systolic murmur at the lower left sternal border, usually with an associated diastolic murmur or gallop and hyperdynamic circulation. The infant with tetralogy of Fallot (ventricular septal defect plus right ventricular or pulmonary artery obstruction) presents with a loud, harsh systolic murmur heard over the precordium and over the anterior and posterior chest. Such an infant shows signs of cyanosis and tachypnea but not of congestive heart failure.

The emergency physician may be the first person to hear a murmur in an older infant or child. High fever and anxiety increase the chances of hearing a cardiac murmur, and, in the absence of symptoms or signs of cardiorespiratory distress, it is unlikely that such a murmur is associated with significant pathology. When children with recognized congenital cardiac pathology are examined in the emergency or acute care setting, factors increasing cardiac output (such as fever) will increase the intensity of heart murmurs, and that increased intensity of sound may not necessarily correlate with worsening condition. Hearing a heart murmur in a child presenting with chest pain should not automatically implicate a cardiac etiology for the source of the pain.

Fever in the child with known congenital heart disease may alert the examiner to the possibility of infectious endocarditis. In such patients, a new or different murmur (e.g., appearance of the high-pitched diastolic murmur of aortic insufficiency in a patient with known aortic stenosis) makes the diagnosis of endocarditis more likely.

DIFFERENTIAL DIAGNOSIS

[Table 251.1](#) lists five common innocent murmurs, along with their differential characteristics. ¹ The second heart sound should split normally with inspiration, although appreciation of normal versus abnormal splitting takes considerable practice. Using the commonly accepted scale of I to VI, innocent murmurs are almost never greater than grade III/VI in intensity, even under conditions of fever. Loud murmurs, especially if associated with high-frequency thrills felt over the chest wall, should raise the index of suspicion for a significant cardiac lesion.

Murmur	Characteristics
Still's	Vibratory, musical quality at ULNB to apex; louder in supine position; disappears with Valsalva
Pulmonary flow	Raspy quality at ULNB; normal S ₂ ; not heard in back
Venous hum	Loudest in seated position; disappears when supine; continuous (systolic-diastolic)
Carotid bruits	Short ejection murmurs over one or both clavicles to carotids
“Physiologic” PPS	Short ejection murmur with quality of breath sounds; heard in axilla and back; age < 6 months

ULNB, lower left sternal border; PPS, peripheral pulmonary stenosis; S₂, second heart sound; ULNB, upper left sternal border.

TABLE 251.1. “Normal” Murmurs in Infants and Children

Diastolic murmurs (with the exception of the venous hum) are more likely to be pathologic. Except for “physiologic” peripheral pulmonary artery stenosis in young infants, it is unusual to hear normal or innocent murmurs radiating to the back. Significant findings, such as failure to thrive, respiratory distress, or cyanosis, make cardiovascular pathology more likely.

EMERGENCY DEPARTMENT MANAGEMENT

[Figure 251.1](#) presents a management scheme for cardiac murmurs. Patients presenting with cardiorespiratory distress require prompt stabilization. Once symptomatic measures have been instituted to relieve respiratory distress or cyanosis, evaluation proceeds with a chest x-ray and electrocardiogram, and consultation is sought.

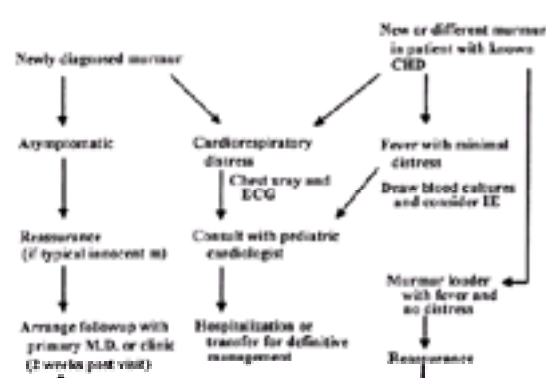

Figure 251.1. Scheme for the emergency department evaluation and management of cardiac murmurs in infants and children. CHD, congenital heart disease; ECG, electrocardiogram; IE, infective endocarditis; m, murmur.

If the examiner discovers a new murmur in an otherwise asymptomatic child, further diagnostic evaluation at the time of the emergency visit is generally inappropriate, and, in most cases, the patient and family can be reassured.¹⁰

The source of fever should be sought for the child with known structural congenital heart disease. If a definite source of fever is identified and the patient is well compensated, he or she is managed like any other patient. If no definite source of fever is identified, blood cultures are obtained, along with other diagnostic studies (e.g., a complete blood count and differential white blood cell count), before starting antibiotics. Close follow-up should be arranged.^{2,3}

DISPOSITION

Emergent consultation is sought for the infant with murmur and cardiorespiratory distress or cyanosis. Young infants with cardiorespiratory distress or cyanosis and murmur generally require hospitalization in a tertiary center with full pediatric cardiovascular services. Prompt communication with specialists at the referral center should include instructions for appropriate stabilization and transport.

For the asymptomatic child with a newly discovered murmur, follow-up with the primary physician or clinic should be arranged. A primary referral to the pediatric cardiology subspecialist is usually not indicated, because, with the resolution of fever, many loud murmurs are considerably less impressive on reexamination. Likewise, it is usually better to delay more involved diagnostic studies, such as echocardiography, until the child can be reexamined at a later time.

COMMON PITFALLS

- Heart murmurs are more commonly identified in infants and children than in adults. The presence of a murmur in an asymptomatic child does not usually imply significant pathology. Other symptoms, such as fever, can greatly exaggerate the intensity of a cardiac murmur.
- Most infants with significant structural congenital heart disease will present with a heart murmur. However, the absence of a murmur in an infant with cardiorespiratory distress or cyanosis should not rule out cardiovascular pathology. Some of the sickest infants with advanced congestive failure or with cyanosis may not present with murmurs.
- Increased intensity of a murmur in a child with known congenital heart disease and fever does not necessarily imply worsening condition.
- Chest pain is a common presenting complaint in the emergency department. Cardiac murmurs are also common findings, and the presence of a murmur in a child with chest pain does not necessarily imply a cardiac etiology.
- On palpation of the chest, transmitted bronchial congestion is often misinterpreted as a cardiac thrill, particularly in infants. A thrill is a well-localized, high-frequency vibration or buzz.

CHAPTER 252

Hematuria

Lina Abujamra and Madeline Matar Joseph

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Hematuria is the presence of blood in the urine, which usually alarms the patient, the parents, and the physician. It can be macroscopic (visible to the naked eye) or microscopic. Microscopic hematuria represents one of the most frequently encountered genitourinary abnormalities in children, occurring in 0.5% to 6.0% of school-age children undergoing routine screening.¹⁰ Currently, the American Academy of Pediatrics recommends performance of a screening urinalysis at school entry (ages 4 to 5 years) and one time during adolescence. The prevalence of hematuria is 0.5% for boys and 1.0% for girls, with an annual new case incidence of 0.4% for both sexes. In the absence of gross hematuria, the primary tool for hematuria screening is a urine dipstick. Greater than 1+ blood is considered positive. The dipsticks used for detection of blood in the urine are very sensitive in detecting red blood cells (RBCs) as well as minute amounts of free hemoglobin and myoglobin. All positive dipstick screens should be confirmed by a microscopic examination of the urine to confirm the presence of RBCs and exclude false-positive and -negative dipstick results. Causes of false-positive dipstick reactions include myoglobinuria (rhabdomyolysis); hemoglobinuria (seen in conditions causing hemolysis); oxidizing contaminants, such as bacterial peroxidases from a urinary tract infection (UTI); delay in reading the dipstick; and interfering compounds, such as beets or aniline dyes. A false-negative dipstick result can occur in urine with high specific gravity and in urine containing large amounts of a reducing agent, such as ascorbic acid.

The definition of *hematuria* is somewhat arbitrary. The presence of five to ten erythrocytes by high power field (HPF) in a centrifuged urine is considered significant by a number of authors.¹¹ Hematuria can originate from any part of the urinary tract. Localizing the source of the bleeding to the kidney or the lower urinary tract can facilitate the workup and assist the emergency physician in developing the most efficient diagnostic plan. A good approach is to classify the origin of hematuria anatomically from the glomeruli, renal tubules–interstitium, or urinary tract. In children, the cause is more often glomerular in origin. Glomerulonephritis is usually accompanied by proteinuria and RBC casts in the urine. This etiology is discussed elsewhere in this text. The nonglomerular causes of hematuria can be further subdivided into renal parenchymal disease and extrarenal disease ([Table 252.1](#)).¹¹

GLOMERULAR	NONGLOMERULAR
Primary Glomerulonephritis Poststreptococcal glomerulonephritis IgA nephropathy (Berger disease) Membranoproliferative glomerulonephritis Focal glomerulosclerosis Secondary Glomerulonephritis Systemic lupus erythematosus Henoch-Schönlein purpura Hemolytic uremic syndrome Familial Alport syndrome Thin basement membrane disease	Renal Parenchymal Anatomic: hydronephrosis, chromogenic infection, obstruction Polycystic kidney disease Vasculitis: ANCA-related Renal vein thrombosis Arteriovenous fistula Sickle cell disease Metabolic Hypercalciuria Hyperoxaluria Infectious Urinary tract infection, pyelonephritis Tuberculosis Foreign Body to Urethra or Bladder
EXTRARENAL Tumors: Wilms', rhabdoid sarcoma Other Drugs and toxins Trauma and exercise Coagulopathy Dehydration Other: menstruation, masturbation, fever	

TABLE 252.1. Causes of Hematuria

CLINICAL PRESENTATION

Once the presence of hematuria is confirmed by microscopic urinalysis, further information regarding the presentation will help guide the investigation. Children with glomerular bleeding will present with cola-colored urine, red cell casts (pathognomonic), renal insufficiency, and proteinuria, whereas lower tract bleeding colors the urine red or pink. Passing blood clots in the urine usually points to the bladder or urethra as the source of bleeding.¹¹ A recent upper respiratory tract infection is often seen with immunoglobulin-A (IgA) nephropathy (Berger disease). Poststreptococcal glomerulonephritis is generally preceded by a sore throat or impetiginous lesion by 7 to 21 days. Dysuria, frequency, or abdominal pain suggests a UTI.

A history of recent trauma, strenuous exercise, menstruation, or bladder catheterization may account for transient hematuria and exclude the need for further workup. An adolescent's history should include certain habits, such as masturbation, excessive bicycle riding, or urethral foreign-body insertions. A recent or earlier history of renal colic or passage of a stone in the urine, as well as a family history of hypercalciuria and renal stones, should be elicited, because hypercalciuria is one of the most common causes of hematuria in children.

Certain medical conditions are commonly associated with hematuria. Children with hemoglobinopathies (sickle cell trait) and coagulopathies should be carefully evaluated. The use of drugs such as furosemide for congenital heart disease can lead to hypercalciuria and, subsequently, hematuria. Antibiotics and over-the-counter medications may cause interstitial nephritis. Chemotherapy and radiation for malignancies can explain isolated hematuria in children. In the neonatal period, hematuria can be caused by thrombosis of the renal vein or artery after use of umbilical catheters. A history of tuberculosis exposure is important to identify children with genitourinary tuberculosis, a rare but reported cause of hematuria.³

A family history can be extremely critical in elucidating the cause of hematuria in the presenting child. Alport syndrome is frequently seen in family members with hearing deficits and renal failure. Other diseases that carry a genetic origin include systemic lupus erythematosus (SLE), sickle cell anemia, hemophilia, and other coagulation factor deficiencies. Nephrolithiasis and IgA nephropathy also have a familial association. The thin basement membrane of the glomerulus is a common cause of benign familial hematuria in children. Family members may not be aware that they have microscopic hematuria and should be screened with a microscopic urinalysis.

The physical examination of the patient with hematuria is not specific, but several elements deserve attention. An accurate blood pressure is essential, because the presence of elevated blood pressure should alert the emergency physician to the possibility of a more severe underlying condition. The height and weight of the child should be plotted carefully to detect failure to thrive associated with long-standing acidosis or chronic renal insufficiency. A funduscopic examination of the retina, looking for evidence of long-standing hypertension or lenticonus as seen in Alport syndrome, should be performed. Periorbital edema is frequently the first site of edema in children. The chest should be examined for signs of fluid overload. Costovertebral angle tenderness may indicate a UTI. Recent trauma can be detected by findings of flank bruises and pain. Examining the abdomen for masses is critical for the identification of malignancies (Wilms' tumor), polycystic kidneys or hydronephrosis. Ascites suggests nephrosis. The examination of the skin can give evidence of pallor or rashes. This may be significant in diseases such as hemoglobinopathies, leukemia, HSP (Henoch-Schönlein purpura; petechial or purpuric lesions on the lower extremities), and SLE (malar rash). The genital examination should be included to identify abuse or trauma, discharge, and meatal stenosis, all of which can cause hematuria.

DIFFERENTIAL DIAGNOSIS

The causes of hematuria are numerous. A careful history and physical examination are essential in guiding the investigation for the correct etiology. It is important to first determine the site of bleeding in the presenting child. In infants, blood on the diaper can originate from the vagina or rectum and be confused with hematuria. In the menstruating girl, vaginal bleeding can be confused with urinary blood (obtain a catheterized urine specimen). The "red diaper syndrome" in infants has two causes: One is a group of healthy infants whose soiled diapers develop a red color after 24 to 36 hours, which is attributed to *Serratia marcescens*; the second is due

hydrochlorothiazide therapy have been shown to decrease urinary calcium excretion; a short course can result in the disappearance of microscopic hematuria. A child with a suspected renal calculus should have a urologic consultation in the emergency department.

When there are no indications for immediate medical intervention, the parents can be reassured that a life-threatening condition does not exist and that most cases of isolated hematuria do not require treatment.

DISPOSITION

Referral to a pediatric nephrologist should take place if the child has gross hematuria, a coexistent significant proteinuria, hypertension, abnormal kidney function tests, persistent hypocomplementemia, or findings suggesting a systemic disease; or if there is a family history of glomerulonephritis, nerve deafness, chronic renal failure, end-stage renal disease, or familial hematuria. If parental anxiety is high, referral to a pediatric nephrologist may help alleviate compounding fears and serve as additional reassurance to the family that dangerous and treatable conditions have been ruled out by the primary physician.

Rarely does a patient with hematuria need to be hospitalized. Patients with newly diagnosed renal disease should be admitted with pediatric nephrologist consultation. A toxic-appearing child with a UTI is admitted for intravenous antibiotics.

For the patient with persistent microscopic hematuria who does not have hypertension, proteinuria, or RBC casts, follow-up urinalysis should be performed every 2 to 4 months for 1 year. This should be done by the primary care or subspecialty physician. Blood pressure and a dipstick test for proteinuria should also be checked periodically. If proteinuria or gross hematuria develops during this follow-up period, the patient should be referred to a nephrologist.

It is important to remember that the most common causes of microscopic hematuria without casts or proteinuria are benign and untreatable. The prognosis for these children is very good. A poor prognosis is associated with proteinuria at presentation, persistent hematuria, and hypertension.

COMMON PITFALLS

- Failure to perform a urine dipstick and urinalysis to confirm the presence of blood in the “red urine” can lead to unnecessary performance of numerous laboratory tests.
- Failure to obtain relevant information in the history (recent pharyngitis, trauma, or a family history of renal stones) can make the determination of the cause of hematuria more cumbersome.
- Although most children with microscopic hematuria have an excellent prognosis, failure to detect proteinuria, hypertension, and the subtle signs of fluid overload can be detrimental to the prognosis of such patients.

The 1997 annual report of the American Association of Poison Control Centers analyzed 2,192,088 human exposures reported to 66 centers.¹⁴ As in the past, the victim's age was one of the major prognostic factors. Of the reported exposures, 52.5% occurred in children under age 6 years, in contrast to the 7.0% and 7.3% that occurred in children ages 6 to 12 years and 13 to 19 years, respectively. Eighty-six percent of the exposures were termed *accidental*, 86.2% involved exposure to a single substance, and the product was orally ingested in 74% of the cases. About 7.5% of the total exposures were suicide attempts. Symptoms related to the exposure developed in only 22.1% of the cases, and almost 74.9% were treated at the site of exposure (home). In short, most of these toxic exposures appear in children, and most of the patients do not develop symptoms.

Management of the poisoned or overdosed patient revolves around certain basic principles: initial stabilization, assessment of history, documentation of findings on physical examination and correlating these symptoms with known toxidromes, institution of techniques aimed at preventing further absorption, use of antidotal and supportive therapies, and modalities to enhance elimination. Age-related factors may warrant modification in some of these techniques. Also, recent changes in some of these procedures have been recommended in the literature and have left us with a seemingly more rational approach to management.

Errors in judgment may occur when the diagnostic, prognostic, and therapeutic management guidelines for adults are directly translated to childhood intoxications. The presence of age-dependent pharmacokinetic variations, the unpredictability and variability in handling of toxins, and differences in sensitivity to the effects of toxic exposures dictate a modified approach to the management of the poisoned child. For example, transit time through the gastrointestinal (GI) tract is shorter and much more variable in the infant, approaching adult values after about 2 to 3 years of age. The importance of this factor is evident, because it may affect the time course of an overdose, especially because GI exposure appears to be the most common route of poisoning in children.¹¹

Decisions on the initiation of therapeutic maneuvers in children should be based on knowledge of the exposure (e.g., what, how, when, where, how much), the potential of the ingested substance(s) to cause toxicity, the prognostic factors relating to the toxin, the risk–benefit ratio when considering the use of invasive therapeutic and diagnostic maneuvers, and patient presentation.

The incidence and etiologic factors behind pediatric exposures differ from those of adult intoxications. History may be more accurate with accidental ingestions in children because they often occur under observation. This is usually not true of ingestions in adolescents and adults, wherein drug abuse, drug experimentation, and suicide come into play. The clinician should be suspicious when assessing the history, as it may be misleading, confusing, or unreliable. The specific product container in question should be produced, if possible. Toxic and nontoxic products may share the same phonetic name, product formulations may be changed over time by the manufacturer, and certain product lines have numerous varieties of the same product with small changes in their ingredients. Prescription bottles should be emptied and the contents counted, specifically identified, then compared with the label information. Patients sometimes use medication bottles to store different, and often multiple, types of medication.

Adult and adolescent suicide attempts often involve polydrug ingestions, and the history obtained is unreliable. In contrast, most accidental ingestions in children involve only a single substance. The accidental ingestion of a bad-tasting household product often results in only one swallow (5 mL) in the child, whereas the suicidal adolescent may ingest much larger quantities. Medications mistaken for candy by children, or those intentionally flavored for pediatric use, are often ingested in multiple quantities.

The following information is obtained to allow accurate assessment of whether the victim is in immediate danger, potential danger, or no danger at all:

- Source of the exposure
- Severity of the symptomatology present
- Nature of the toxin as assessed by the labeled ingredients; place and date purchased; name of the company or person who purchased, obtained, or used the product; and the color, odor, and intended use of the product
- Other medications or products available in the environment
- Time of exposure
- Approximate amount involved
- Actions taken before emergency department presentation
- Reliability of the informant
- Assessment of intent: accidental, therapeutic overdose, or suicide attempt

Accidental ingestions, whether toxic or nontoxic, may warrant investigation into the home situation if

- The ingestion occurs in a child over age 5 years. This usually signals a cry for help.
- More than one episode of “accidental” ingestion occurs. This may signal inadequate parental concern, inadequate poison prevention education, or, possibly, neglect.
- The “accidental” ingestion occurs in a child under 1 year of age. Infants this young often do not possess the physical or mental capabilities required to self-administer a toxin.

The importance of history and an assessment of toxin availability is crucial to the awareness of what type of poisoning, if any, has occurred. GI decontamination may be considered when a potentially toxic amount of a substance has been ingested within a specified period of time.

EMERGENCY DEPARTMENT EVALUATION

Stabilization

Stabilizing vital functions should always precede definitive poison management procedures. The airway is evaluated, as well as ventilatory function, heart rate and rhythm, temperature, and blood pressure, with adequate caution for the cervical spine. Trauma and overdose are not mutually exclusive. Any patient presenting with severe central nervous system (CNS) or respiratory depression is intubated with an endotracheal tube (cuffed in a patient over age 9 years to protect against aspiration). If the patient will not tolerate placement of the endotracheal tube, chances are that he or she does not need it.

If hypotension fails to improve after establishment of adequate ventilation and oxygenation, the patient is placed in the Trendelenburg position to aid venous return. A fluid challenge should be used and will improve the circulatory function if hypovolemia is the problem. If the child does not respond to adequate fluid challenges (20

mL/kg), more invasive critical care monitoring is considered (e.g., central venous pressure, pulmonary capillary wedge pressure measurements) to further guide fluid administration and prevent overload. Cautious use of fluid resuscitation may also be prudent in light of the many drugs and toxins that can alter the permeability of the alveolar capillary beds, increasing the risk for development of pulmonary edema and adult respiratory distress syndrome. Vasopressors or inotropic agents may be required if myocardial depression or vasodilatation is present. The appropriate choice of vasopressor or inotropic agent may depend on the mechanism behind the toxicologic derangement.

The comatose patient should receive the following, either during or soon after the vital functions are stabilized:

1. Oxygen
2. Rapid bedside glucose evaluation or, if unavailable, 0.5 g/kg glucose as 10% to 25% dextrose in water (after a blood specimen for glucose determination is obtained)
3. Naloxone 0.1 mg/kg (up to 2 mg in a child), every 3 to 5 minutes for two doses, unless partial response or high suspicion of opiate intoxication exists, when dosing may proceed up to a total of 10 mg. Given naloxone's short half-life, a naloxone infusion may be considered if adequate response is obtained with bolus dosing. The appropriate dose is calculated as two-thirds of the cumulative initial reversal dose given per hour. Nalmefene is a newer, longer-acting option for opiate antagonism. It may substitute for naloxone infusions using the adult dosing regimen of 0.5 mg/70 kg intravenously.
4. Thiamine (50 to 100 mg intramuscularly or intravenously) may be considered in adolescents and adults if the patient is malnourished or a chronic alcoholic.
5. Flumazenil, a specific benzodiazepine antagonist, can be safely utilized in the pediatric population as long as the signs and symptoms of cyclic antidepressant intoxication are absent. Caution should be exercised in children on benzodiazepines chronically, because a withdrawal reaction may be precipitated. The adult dosing regimen, often used in pediatric overdose, is 0.2 mg administered intravenously over 30 seconds. If no effect is seen within 30 seconds of administration, an additional 0.3 mg is administered; then 0.5 mg. This dose can be readministered until a total of 3 mg has been given. If a partial response has been obtained, dosing in 0.5-mg increments is continued until a total of 5 mg has been administered. Resedation is very common in overdose. Vital sign instability may require an infusion (1 to 5 mg/h) to maintain an adequate reversal.
6. Assessment (if warranted and guided by toxidrome recognition) of arterial blood gases, blood urea nitrogen, creatinine, liver enzyme tests, blood ammonia and electrolytes, blood culture, osmolality, toxicology screen, and an additional tube of blood held in reserve.

Physical Examination

Repeated examinations and clinical assessments, with continuous monitoring of vital signs, are mandatory, because the patient's condition may change with dramatic rapidity. Recognition of a specific toxic syndrome (toxidrome) may help to direct diagnostic, therapeutic, and analytic techniques. The neurologic survey, noting the degree and progression of altered mental status, is particularly important. In children, their behavior and interaction with parents and the examiner are noted. Pupil size, reactivity to bright and dim light, accommodation, shape, equality, presence of nystagmus, irregularities in ocular movements, and presence of fundoscopic changes are also useful in recognizing a toxidrome. Abnormal motor system function and reflexes and the presence of focal neurologic findings are noted. One of the most important diagnostic considerations is the differentiation of a structural CNS disorder, which requires advanced radiologic evaluation (computed tomography scan) and neurosurgical consultation, from a toxic–metabolic or systemic disorder, which requires meticulous supportive and possibly antidotal therapy.

EMERGENCY DEPARTMENT MANAGEMENT

The first priorities are the management and maintenance of vital functions. Next comes an attempt to diagnose the intoxication, although the agent's identity may be unknown. Most ingestions in young children involve nontoxic products or those that cause only minor toxicity.¹⁴ A common error is to treat all ingestions aggressively, even when such treatment is unnecessary.

Ocular and Dermal Exposures

Ocular exposures warrant immediate attention by irrigation with copious water or saline. Wrapping the child in a sheet or blanket, papoose-style, may help control the writhing infant. The parent or guardian may help calm the child and make him or her more amenable to treatment. Dermal exposure requires removal of clothes, followed by complete soap-and-water washing (including the hair, fingernails, and navel) in an attempt to limit further percutaneous absorption. Again, enlisting the parent's help is suggested and may limit the child's fear.

Caustic or Corrosive Exposures

In caustic or corrosive ingestions, dilution with milk or water is warranted. Contraindications include an inability to swallow and signs of upper airway obstruction, esophageal perforation, or shock. Administering more than 15 mL/kg in a child (to a maximum of 250 mL) may result in vomiting, an event to be avoided. Dilutional therapy as a general overdose management procedure has other drawbacks. Ingesting a large volume of water may enhance GI absorption of certain toxins by increasing the solubilization of the product.^{7,8} The use of specific neutralization techniques with caustic or corrosive ingestions is controversial and requires further study. It was believed that neutralization created an exothermic reaction resulting in the release of thermal energy and gas formation, leading to distention. However, several recent studies in animals have questioned this belief.¹²

Gastrointestinal Decontamination

Ipecac

Syrup of ipecac contains two alkaloids that cause local stimulation in addition to central stimulation of the vomiting center in the brain. The administration of ipecac decreased dramatically over the 1990s (10.1 % of exposures in 1987 to 1.5 % in 1997).¹⁴ After review of the available clinical studies, insufficient data were found to support or exclude the administration of ipecac to poisoned patients.³ No evidence was found that demonstrates that this GI decontamination modality improves patient outcome.³ Syrup of ipecac, in the health-care setting, has been found to delay the administration of the more effective decontamination method, activated charcoal, and should therefore be avoided in the emergency department.^{3,11}

Syrup of ipecac may be used in the home setting if an asymptomatic patient has ingested a potentially harmful amount of a toxin, but it must be within 1 hour of the ingestion.³ Because emesis carries its own dangers, the unnecessary and routine administration of ipecac should be avoided. The following are contraindications to the use of ipecac³:

1. Relative contraindications
 - a. The ingestion of a high-viscosity petroleum distillate, a very low viscosity hydrocarbon, and certain other hydrocarbons in small quantities
 - b. The ingestion of an agent likely to produce rapid depression of consciousness or to induce convulsions
 - c. A child under 6 months of age, who may have immature protective airway reflexes
 - d. The ingestion of a foreign body; emesis is usually ineffective in removing the object and increases the risk of creating or worsening airway obstruction.
2. Absolute contraindications
 - a. The ingestion of a caustic or corrosive product
 - b. A comatose or seizing patient
 - c. The presence of hematemesis
 - d. Lack of or depression of upper airway protective reflexes

Some clinicians argue that ipecac is safe to administer at home in children aged 6 months or older.¹¹ The appropriate dose should be based on the child's age: less than 1 year old, 5 to 10 mL; 1 to 12 years old, 15 mL; 12 years old to adult, 30 mL.³ This dose of ipecac may be repeated once if the child does not vomit within 15 to 20 minutes. Water (120 mL in infants and small children, 240 mL in older children) should accompany the ipecac.³ Expiration of the ipecac should not preclude its administration.

Although normal ipecac doses pose little threat of toxicity, ipecac has reportedly produced mild adverse effects, with the most common being protracted vomiting, diarrhea, and lethargy. Symptoms, if noted, should not be mistaken for part of a toxic syndrome.

Gastric Lavage

The use of gastric lavage as a decontamination method has decreased from 3.4% to 2.4% of exposures reported to the American Association of Poison Control Centers during the past 4 years.¹⁴ Lavage is indicated if a patient has ingested a life-threatening amount and presents to the emergency department within 1 hour of the ingestion.² However, gastric lavage has not been shown to improve patient outcome and, in fact, may increase morbidity by increasing the chance of aspiration.^{2,17} Complications can be minimized by respecting these contraindications²:

- Caustic or corrosive ingestions without previous assessment of esophageal damage
- Absence of protective upper airway reflexes without previous insertion of an endotracheal tube
- Ingestion of certain petroleum distillates or hydrocarbons

The best results are obtained from gastric lavage when the largest bore tube that can be reasonably and safely inserted is used. Although many argue that children cannot tolerate large orogastric tubes, others say that a 36F orogastric hose can be safely passed in children as young as 1 year of age. Most commonly, a 24F to 28F orogastric tube is utilized after lubrication. Once the tube is placed, aspiration of gastric contents is followed by positive identification of tube placement, which precedes instillation of any lavage fluid.

If the child is to be endotracheally intubated before lavage, a cuffed endotracheal tube should not be used in a child less than 9 years old for fear of tracheal damage. If a cuffed tube is used in the older child, it is deflated immediately after lavage.⁷

Without elective endotracheal intubation, the patient is placed in the left lateral decubitus position, with the head 15 to 20 cm lower than the hips (Trendelenburg position). This will help to prevent aspiration if vomiting does occur without physical airway protection.¹⁵

Although the standard lavage fluid in adults is either water or saline, children should be lavaged with normal saline.¹⁵ The use of an alternative fluid composition in children may lead to hyponatremia or other severe electrolyte imbalances.² Although adults may tolerate up to 250 to 350 mL, only 10 to 15 mL/kg should be used in children.² If this volume is exceeded, the stomach contents may be forced through the pylorus into the intestine, or vomiting may result. Lavage is continued until there is a consistently clear fluid return. Activated charcoal is given after the lavage procedure is completed.

Concretions

The physician should remember that specific ingestants are known to cause gastric concretions (e.g., ferrous sulfate, meprobamate, glutethimide, and salicylates), as do large amounts of dry tablets. A concretion may require prolonged, forceful, whole bowel irrigation to dissolve, break up, or otherwise remove the bolus of material. This may be an indication for the use of multiple-dose activated charcoal in combination with whole bowel irrigation. As a last resort, endoscopic or surgical removal may be required. Clues to the presence of concretions include failure to respond to appropriate treatment, continued deterioration despite therapy, or measured blood concentrations that do not decrease with adequate GI decontamination.

Activated Charcoal

Despite previous practices, activated charcoal should no longer be administered to every overdose patient presenting to the emergency department.⁴ With few exceptions, administration of activated charcoal should be considered in patients who ingest a potentially toxic amount of a substance less than 1 hour prior to their arrival in the emergency department.⁴ Insufficient data are available to support or exclude the use of activated charcoal more than 1 hour postingestion.⁴

Activated charcoal, with its ultrasmall particle size and very large surface area, is known to adsorb a number of chemical agents. The standard-grade activated charcoals commonly used have a surface area of over 1,000 to 1,500 square meters per gram. Even though activated charcoal has been shown to produce a mean decrease in bioavailability of approximately 69% if given within 1 hour of the ingestion, it has not been proven to improve patient outcome.⁴ Charcoal should not be given with ingestions involving a caustic or corrosive product because it does not effectively adsorb these compounds, may cause vomiting, and will most probably hinder any endoscopic attempts to evaluate the esophageal or gastric mucosa.

Activated charcoal cannot adsorb all known toxins. It has limited usefulness with boric acid, caustics, corrosives, cyanide, ethylene glycol, iron, iodides, lithium, and other elemental metal ingestions.¹⁸ Certain pesticides and other poorly water-soluble compounds also may not be effectively captured by the charcoal complex. The alcohols may be adsorbed to a limited extent by charcoal, but this appears to have little clinical significance because the systemic absorption of the alcohols is so rapid.

The dose of standard-grade activated charcoal is usually 1 to 2 g/kg in children. The charcoal is given as a slurry in at least 100 mL of water solution, and is given orally or through a gastric tube.

Charcoal administration in children is more easily discussed than performed. Using a firm approach will make the child more likely to comply. The charcoal slurry is placed in an opaque container with a fitted lid to mask its color. The suspension is sipped through one or two straws, alternating with sips of a clear fluid such as water. If attempts to get the child to drink this antidote within 15 to 20 minutes have failed, a nasogastric tube is placed and the charcoal slurry administered through it.⁴ Activated charcoal may be used in smaller and more frequent doses, making administration easier in the child by virtue of the absolute volume given per dose. In fact, this may be more efficacious in small children, because it is more likely that the slurry will be retained when smaller volumes are given.

The role of multiple doses of activated charcoal, given every 2 to 6 hours to enhance elimination, is not very clear, despite its common usage. Multiple-dose therapy appears useful in cases of long-acting or sustained-release agents, preparations resulting in concretions, and agents undergoing enterohepatic or enterogastric recirculation. Activated charcoal can produce a "gastric dialysis" in addition to serving as a stool marker, indicating that no further compound is available for absorption.^{6,13} This dialysis concept has proven useful for agents administered both orally and parenterally, for such ingestions as phenobarbital, salicylate, theophylline, digoxin, cyclic antidepressants, phenytoin, and carbamazepine.^{6,13} The efficacy of this procedure is reportedly due to the creation of a concentration gradient out of the systemic circulation, with the charcoal acting as an adsorbent sink. This enhances the rate of back-diffusion from the central compartment into the GI tract.

Nonetheless, multiple-dose charcoal should not be given indiscriminately without evaluating the risks, the clinical symptomatology, and its reported usefulness for a particular compound. Multiple doses of charcoal should not be given to a patient who has absent bowel sounds or any evidence of ileus.

For multiple dosing in children, give 0.5 to 1.0 g/kg of activated charcoal every 2 to 4 hours with water.

Cathartics

Cathartics are used to shorten the transit time of the toxin or toxin-charcoal mixture through the GI tract and prevent the formation of "charcoal briquets" in the GI tract when multiple-dose activated charcoal is administered. Despite their previously common use in the management of poisoning, there is no scientific or clinical proof to support the efficacy of cathartics when administered alone.^{1,15} Likewise, there are no data to support the use of cathartics with single doses of activated charcoal, because constipation has not been seen after a single dose.¹ Adverse effects of cathartic administration, such as fluid loss and moderate-to-severe electrolyte imbalances, appear to be more common in children. Fleet's Phospho-Soda should never be used in children, due to the risk of severe electrolyte complications.

Sorbitol is used most commonly because it improves the palatability of charcoal and is a better cathartic than magnesium or sodium salts. The use of sorbitol in children is not without concern, because it may induce significant diarrhea and electrolyte imbalances.⁹ For this reason, prepared charcoal-sorbitol mixtures should not be used, especially in multiple-dose therapy. Children should receive no more than a 35% concentration and must be monitored carefully for dehydration and electrolyte disturbances.¹ Sorbitol is not recommended for children under 1 year of age and should be used cautiously in those under 3 years of age.

Sorbitol can be given in doses of 1 to 2 g/kg of no greater than a 35% solution, once every 12 hours.¹⁸ With multiple-dose regimens, standard commercially prepared

charcoal-sorbitol slurries should not be used, because they lock the clinician into giving sorbitol every 2 to 4 hours, which is far too often. It is safer and more rational to stock the aqueous charcoal slurry and to add a specific dose of sorbitol when, and if, necessary.

Whole Bowel Irrigation

Although whole bowel irrigation has been shown to decrease the bioavailability of ingested substances, it has not yet been shown to improve patient outcome.⁵ Whole bowel irrigation may be considered for ingestions of iron, lithium, and other toxins not effectively bound by charcoal, as well as ingestion of massive quantities and sustained-release products, and ingestions of illicit drugs by body packers and stuffers.^{5,20} This procedure may pose a significant risk of fluid and electrolyte imbalance in children unless a balanced solution (polyethylene glycol-electrolyte) is used.²⁰

A nasogastric tube is placed and secured in the patient, who is seated on a commode. The room-temperature polyethylene glycol-electrolyte solution is given by gravity into the stomach at a rate of 25 mL/kg/h up to a maximum of 500 mL/h in toddlers and preschoolers.²⁰ Adolescents and adults will tolerate up to 2 L/h. If vomiting occurs, the rate should be slowed and then gradually increased back to full rate.²⁰ The end of the procedure comes with clear return from the rectum.

Whole bowel irrigation is contraindicated if an ileus, bowel obstruction or perforation, unprotected airway, or persistent vomiting is present.⁵

Enhancing Elimination

Other methods of enhancing the elimination of certain toxins, besides multiple doses of activated charcoal, include ion trapping to enhance the renal clearance of certain compounds and the use of extracorporeal methods of removal.

Alkalinizing the urine, by virtue of its ability to produce an ion-trapping effect, can significantly increase the elimination of phenobarbital, barbitol, and salicylates. However, a volunteer study found that multiple-dose activated charcoal was superior to urinary alkalinization to enhance the elimination of phenobarbital.¹⁰ Urinary alkalinization is accomplished by raising the urine pH to 7.5 to 8.0, without allowing the blood pH to go beyond 7.55. This goal is attained by giving intravenous sodium bicarbonate (1- to 2-mEq/kg bolus, followed by an infusion); this, in itself, requires close monitoring of the urinary and plasma pH. This procedure may also place the patient at risk for hypokalemia or hypocalcemia.

The use of forced diuresis, where fluid and possibly a diuretic is given to stimulate urine flow three to six times that of normal, has been abandoned due to the associated risks. The use of fluid administration to induce a high urine flow rate may result in cerebral edema, pulmonary edema, disturbances in acid-base and electrolyte balance, and drug-induced SIADH (e.g., barbiturates, opioids, salicylates, cyclic antidepressants, sulfonyleureas, biguanides, carbamazepine), placing the patient at a higher risk for morbidity.¹⁶ This is especially true in children, in which administration of large fluid loads and sodium bicarbonate presents a more pronounced problem than in adults. This problem is compounded when, by virtue of the specific toxicologic action, certain exposures actually produce cerebral or pulmonary edema or renal failure. Likewise, acid diuresis accomplished with the use of intravenous ammonium chloride has been abandoned in amphetamine, quinine, strychnine, and phencyclidine poisoning, because it may cause severe metabolic acidosis, precipitation of myoglobin in the renal tubules, and severe electrolyte shifts.¹⁶

Although fairly useful with certain adult poisonings, extracorporeal means of removing toxic substances may have limited utility in children and small infants, depending on the patient's age and the clinical characteristics of the exposure. These modalities are rarely first-line choices; they are reserved for severe, life-threatening poisonings that are amenable to dialysis or hemoperfusion. These measures are also useful if maintenance of appropriate acid-base balance becomes difficult or refractory, severe electrolyte imbalances arise, overhydration due to acute renal failure is evident, or the patient develops uremia and its related syndromes. Consultation with the nephrologist should be sought when

- Progressive deterioration occurs despite intensive supportive care
- Severe intoxication results in refractory hypoventilation, hypothermia, or hypotension
- Complications arise that depict catastrophic deterioration
- Impairment of normal drug excretory pathways is evident

Even though peritoneal dialysis is reportedly only one-twentieth as effective as hemodialysis, it is easier and less hazardous to perform. It is particularly useful in small children, whose blood vessel size and small blood volume make hemodialysis difficult.¹⁶ Peritoneal dialysis has been successful in ingestions of barbiturate, bromide, phenytoin, ethanol, ethchlorvynol, ethylene glycol, inorganic mercury, isopropyl alcohol, lithium, methyprylon, quinidine, salicylate, and theophylline.¹⁶ Peritoneal dialysis is contraindicated if the patient has had recent abdominal surgery or if there is evidence of an intraabdominal infection.

Exchange transfusions, primarily used in young infants and children, are effective with highly protein-bound drugs exhibiting a low volume of distribution. They have limited use in older children.

Antidotal Therapy

Table 253.1 summarizes the indications, dosages, and considerations for the use of specific antidotes.¹⁹

TABLE 253.1. Pediatric Dosages of Selected Antidotes

DISPOSITION

If adequate facilities are available, emergency department observation for 4 to 8 hours, depending on the toxic potential, is usually long enough to unmask most of the delayed-onset toxic reactions. Children under 1 year of age are at a higher risk for toxicity. Because children often do not show the classic adult symptomatology, caution should be used in their early discharge.

Appropriate indications for admission, other than a patient who is already manifesting signs and symptoms, include exposure to an agent known to be highly toxic, a dose or exposure to a toxin sufficient to anticipate the development of toxicity, or a history of an intentional ingestion. The adequacy of the home environment is assessed before discharge. Older children with suicidal ideation are evaluated before release.

Prevention

Treatment is incomplete until the existing problem is addressed, whether it is inadequate poison-proofing in the home, undersupervision of the child, a cry for help, or

even child abuse. If warranted, the proper social service authorities should be contacted. If it was truly an accidental ingestion, poison prevention should be emphasized to avoid a repeat of the episode. This important modality is often overlooked. Each training session should be tailored to the patient and family situation.

1. Safety packaging has contributed significantly to the decline in pediatric accidental ingestions. Urge members of households with children to use these packages.
2. Instruct parents to keep products in their original containers and to discard containers safely.
3. Medicine should never be called "candy" and should never be taken in front of children, who are great imitators.
4. Old and out-of-date medications and those no longer used should be discarded.
5. Medications and household products should be kept out of reach of children.
6. Children must be taught never to eat anything without checking with a parent or caretaker.
7. Stress the appropriate storage and use of ipecac syrup, and provide information about the poison control center.

COMMON PITFALLS

- Failing to appreciate a difference in historic factors may lead to a misinterpretation of the event's actual toxic potential. This may lead to underly or overly aggressive management.
- The variation in pharmacokinetic handling of a toxin in children should always be considered. If not, a serious error may be incurred when predicting the time course and toxic potential of an exposure.
- Directly translating poisoning management procedures for adults to children, without regard to the differences between adult and pediatric protocols, may be harmful.
- Assuming that all overdose patients require GI decontamination. This may place the patient at risk for unnecessary complications.

[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Locomotion is accomplished by a graceful succession from a stance phase to a swing phase. The stance phase is initiated by the heel striking the ground and terminates with toeing-off. The swing phase begins with flexion of the knee and hip, followed by extension of the knee, and ends with dorsiflexion of the foot, which permits heel contact. Altered locomotion and gait disturbance are generic terms for any deviation from this rhythmic movement. Paralysis implies loss or impairment of neuromuscular mechanisms. Pseudoparalysis is a physiologically intact neuromuscular apparatus but with a refusal to walk or an inability to support weight. ^{4,20} A child who limps has faulted cadence of the swing and stance phase. When pain is the cause of acute loss of rhythm, the gait is described as antalgic. ¹⁸

When a previously healthy child has either an acute or insidious onset of gait disturbance, it may benefit the emergency physician to consider anatomic units that may be functionally deranged. Lesions of the central nervous system, spine, peripheral nervous system, intraabdominal contents, hip, knee, ankle joints, feet, or any of the weight-bearing long bones can lead to distinct patterns of altered locomotion. By organizing the characteristic history and demonstrating the accompanying physical findings, the emergency physician may readily establish the affected organ system. ¹⁷

Unfortunately, because of the close proximity of these structures, many disease states that alter locomotion are likely to involve a combination of them. This fact may make it more difficult to draw a prompt conclusion as to the pathogenesis of the altered gait, but, often, historic, physical, and adjunctive laboratory features may help in characterizing its probable origin. ¹⁶

CLINICAL PRESENTATION

Take the history in a setting comfortable for both the parent and the child. The physician should attempt to remain as inconspicuous as possible, and the historian should be encouraged to distract the child's attention from the physician. The physician should inquire about the length of time the child has been symptomatic. With gait disturbance, symptoms may be acute, constant, of a brief duration, or insidious with inconstant manifestations.

Are there temporal relationships or patterns related to physical activity? Ask the parent what part of the body appears to be the source of the child's problem. Determine whether there is pain associated with the gait disturbance. Attempt to identify the site, if pain is present. Focus on posture during sleep and rest, avoidance of a particular position, and discomfort with handling a specific body part.

Seek the history of an acute traumatic event, such as a fall, a twisting injury, a direct blow, or penetration by a foreign body. Inquire about the presence of fever, which may accompany an inflammatory or infectious problem. Is there exposure to contagion? Is there an antecedent infectious process? Is the child currently being treated with antibiotics for an intercurrent infection? The review of symptoms should emphasize cutaneous lesions such as a scarlatiniform erythroderma, erythema marginatum, erythema migrans, erythema nodosum, urticaria, or purpura. Make inquiry regarding weight loss, morning stiffness, decreased motor strength and agility, a change in bladder or bowel control, altered mental status, headache, rhinorrhea, cough, anorexia, nausea, vomiting, and abdominal pain. Exclude exposures to animals, ticks, and potential intoxicants, such as heavy metals, insecticides, alcohol, or various medications, such as hydantoin, isoniazid, antimetabolites, and steroids.

Determine whether there have been recent intramuscular injections, including immunizations. Is there a history of previous joint disease, prior lumbar puncture, or underlying disease state, such as endocrinopathy, sickle hemoglobinopathy, diabetes mellitus, or immunocompromised state? Is there a family history of inflammatory bowel or joint disease? Is there any suggestion of physical abuse, sexual assault, or psychosocial disturbances that would predispose to a conversion reaction? Has there been acquisition of any new footwear? ^{6,18}

In the preschool-aged child, first carry out the physical examination with the child on a parent's lap. Begin with inspection. Observe the position of the patient at rest, and look at the child's passive movements. Focus on the skin, looking for evidence of hemorrhagic diathesis, occult trauma, and penetrating wounds. Look for soft-tissue swelling and skin changes that suggest pyoderma, varicella, cellulitis, or a deeper plane infection. Look for asymmetry of gluteal, thigh, and popliteal creases. Determine whether there is effusion or distension of the joint capsules of the hip, knee, or ankle.

Only after inspection should the physician palpate for localized induration, warmth, or tenderness over the bones, particularly metaphyseal regions of long bones. Gently examine the joints for motion, avoiding the probable area of pathology until last. Handle the limb systematically and delicately, providing anxiolytic, distracting speech. Determine the degree of restriction of flexion, extension, abduction, and rotation. Palpate the spine in the midline, looking for paraspinal muscle spasm or scoliosis. Determine whether there is any sensory disturbance, asymmetry of deep tendon reflexes, loss of motor strength, cranial nerve abnormalities, or nuchal rigidity. Finally, examine the feet and footwear for embedded foreign objects.

Transfer the patient onto an examining table. Readdress positive physical findings. With the patient recumbent, look for abdominal guarding or palpable mass in the iliac fossa. Perform a pelvic rock. With a rectal examination, exclude a mass in the pelvic floor. Perform a Valsalva maneuver, heel strike, and straight leg raise. ^{10,18} Remove the patient from the examining table, and place him or her on the floor in a sitting position. Observe the method chosen to achieve the erect position. If the child refuses to arise, stand the child on the floor at a distance from the parent. Determine whether the child refuses to bear weight on one of the limbs or simply walks with an antalgic gait.

DIFFERENTIAL DIAGNOSIS

A wide variety of problems have a presenting complaint of limp. The ones most common in the emergency department are listed in [Table 254.1](#). Because of their frequency, overt or occult trauma and infectious diseases should be part of the differential diagnosis for any child with an acute gait disturbance. ^{4,17}

Overt and occult trauma
Cellulitis
Osteomyelitis
Pyarthrosis
Sickle cell, vasoocclusive crisis
Drug intoxication
Transient synovitis
Legg-Perthes disease
Appendicitis
Juvenile rheumatoid arthritis

Modified and reproduced with permission from Singer J. The cause of gait disturbance in 425 pediatric patients. In: Ludwig S, Fleisher G, eds. *Pediatric emergency care*, vol 1. Baltimore: Williams & Wilkins, 1985:7.

TABLE 254.1. Principal Causes for Altered Childhood Locomotion

Trauma to the lower extremities is the principal cause of gait disturbance, especially in early childhood. In children less than 5 years old, multiple obstacles may impede this diagnosis. A fracture of the tibia or fibula should be considered the probable diagnosis in an afebrile child less than 5 years old who suddenly refuses to walk or place any weight on a single lower extremity. The absence of direct trauma should not rule out the diagnosis, because these fractures may occur as the result of trivial, indirect injury associated with the child's daily activity. ¹⁹

Older children may limp from stress fractures of the femoral head, tibial tubercle, and tibial or fibular shaft. They also may limp from avulsion of the ischial apophysis, lesser trochanter, or navicular tuberosity, or from lacerations and compression of cartilage plates, fracture of the epiphyseal ossification centers, shaft fractures, and infractions at various levels of the long-bone metaphyses. These traumatic lesions may present singly or in various combinations. They may appear acutely or insidiously, caused by repeated injury during sports. Trauma and repeated stress may be important factors in the genesis of slipped capital femoral epiphysis, transient synovitis, and Legg-Calvé-Perthes disease, three of the most common hip afflictions associated with antalgic gait. ^{8,9}

Among the nontraumatic conditions that can cause altered locomotion, potentially serious infectious diseases predominate. A history of an antecedent infectious process with or without fever in the preceding 2 weeks should heighten concern for a serious infectious disease in the child with a gait disturbance. Similarly, current treatment with antibiotics for a recognized infection, especially of the skin or respiratory tract, in a child with gait disturbance should raise suspicion for a more serious infection.

The most common infectious conditions associated with gait disturbance are focal cellulitis of the lower extremity, unifocal pyarthrosis of a weight-bearing joint, and osteomyelitis of the femoral or tibial metaphyses. On clinical grounds alone, it may be difficult to differentiate these three conditions. The final diagnosis rests with isolation of an offending organism from either the skin and soft tissues, synovial fluid, or subperiosteal space. ¹⁶

Patients with sickle hemoglobinopathy may present acutely with a gait disturbance from dactylitis, stasis of blood in tendons and periarticular and synovial tissues, bone infarction, osteomyelitis of the long bones, and avascular necrosis of a femoral head. ¹⁶

Dose-dependent toxic reactions from alcohol or diphenylhydantoin and prolonged exposure to heavy metals, insecticides, and toluene-containing compounds may produce clumsiness, incoordination, and unsteady gait with overt ataxia or inability to walk. This diagnosis depends on the medication history and potential exposure to toxins. ¹⁶

In acute synovitis, there is a transient, unilateral inflammatory reaction in the hip. There may be antecedent minor trauma or recent upper respiratory tract symptoms, possibly associated with low-grade fever. An affected child presents with either acute or progressive discomfort in the hip, anteromedial thigh, or ipsilateral knee, eventually leading to an antalgic gait. Clinically, this condition is indistinguishable from Legg-Calvé-Perthes disease. In both cases, children do not appear systemically ill. They will choose a position with the thigh flexed, abducted, and externally rotated. They guard the hip during examination and have pain with internal rotation of the hip and, to a lesser extent, with hip extension. ⁹

Patients with uncomplicated appendicitis, or a perforated or abscessed appendix, exhibit a gait disturbance manifested by a cautious, slow gait, often accompanied by flexion of the trunk. An outright right-sided limp is seen occasionally. The gait resembles that seen with cervicitis or any pelvic inflammatory disease. ¹⁶

The clinical manifestations of juvenile rheumatoid arthritis are so varied that it may be difficult to distinguish this disease when first encountering a patient. The mode of onset varies considerably, from involvement of a single joint with no constitutional reactions, to a more widespread polyarthritis of varying severity, to a generalized systemic onset with extraarticular manifestations. ¹⁶

Major Emergency Entities

An early presumptive diagnosis for the cause of gait disturbance must be established for a few conditions ([Table 254.2](#)). Failing to consider these conditions at the initial encounter may lead to deformity, functional disability, or death. ¹⁶

Osteomyelitis
Long bone, spine, pelvis
Pyarthrosis
Hip, knee, ankle
Sacroiliac infection
Psoas abscess
Deep-plane infection
Epidural abscess
Slipped capital femoral epiphysis
Cord tumor
Cuillain-Barré syndrome
Tick paralysis
Meningitis
Encephalitis
Cerebral abscess
Appendicitis

Modified and reproduced with permission from Singer J. Evaluation of acute and insidious gait disturbance in children less than 5 years of age. In: Barncroft LA, et al., eds. *Advances in pediatrics*, vol 26. Chicago: Year Book, 1979.

TABLE 254.2. Disease States Associated with Limp That Require Prompt Recognition

Pain associated with osteomyelitis of the long bones is primarily located over the affected metaphysis. Direct pressure over the affected metaphysis produces extreme discomfort. Swelling is limited to the immediate metaphyseal area initially, but it can spread rapidly to involve an entire extremity or adjacent periarticular tissue. Joints adjacent to the infected metaphysis may have some limitation of motion caused by voluntary guarding or sympathetic effusion. If the joints are handled gently, slowly, and persistently, motion is not as restricted as in septic arthritis, and full range may be possible. Neck pain, back pain, and refusal to walk may signal the presence of osteomyelitis of the spine. Fever associated with back, buttock, or hip pain with gait disturbance may be the initial expression of osteomyelitis of the pelvis. ¹⁶

Patients with pyarthrosis are readily diagnosed because of the protective posturing imposed by joint capsule distention. When there is hip involvement, children assume a position of comfort, with the thigh on the affected side in moderate flexion, abduction, and external rotation. Children place the affected limb on the ground in the same position as when it is supine, and often hold the foot in plantar flexion. ¹² If the knee or ankle is involved, it is erythematous, warm, swollen, and painful to palpate, with limited range of motion. Minimal active motion, extreme muscle spasm, and pain with passive movement are distinguishing features of pyarthrosis in weight-bearing regions. ¹⁶

Suppuration may be limited to the sacroiliac joint and causes gait disturbance in rare cases. Patients have pain in the buttocks and lower back that radiates to the hip, lateral thigh, lower leg, or abdomen. They may hold a single hip guarded, abducted, and externally rotated, but flexion, abduction, external rotation, and hip extension are permitted. Another differentiating feature is pain caused by direct compression of the sacroiliac joint or pain in the sacroiliac joint during rectal examination or from compression of the iliac wings. Often, the straight leg-raising test is positive. ⁵

Hip, groin, abdomen, lower back, buttock, or upper thigh pain associated with fever and limping may occur with a psoas abscess. Like patients with septic arthritis of the hip, those with psoas abscess may assume the position of hip flexion, abduction, and external rotation. Hip extension and internal rotation that stretches the iliopsoas muscle may cause increased pain. Rotation of the fully flexed hip is typically pain-free. When they attempt to walk, patients keep the affected extremity advanced in relation to the unaffected side, with the trunk deviated toward the affected side, the pelvis tilted down, and the knee and hip flexed slightly. Several findings may differentiate psoas abscess from septic arthritis or osteomyelitis: the presence of abdominal guarding with tenderness in both lower quadrants, or a palpable mass in the iliac fossa or pelvic floor that may be detectable by rectal examination. Patients also may have bulging of the flank with or without cutaneous edema, scoliosis, immobility of the spine with spasm of the paravertebral muscles, or decreased excursions of the diaphragm. ¹⁴

Deep-plane infection refers to suppuration that extends to the depth of fascia or muscle. In necrotizing fasciitis, fat and fascia are destroyed. Muscle is typically

uninvolved, and skin, on occasion, may be spared.⁷ In bacterial myositis, the striated muscle is involved, and there may be localized abscess formation within the muscle (pyomyositis).³

Clinical features of fasciitis and myositis overlap. Neither is common in immunologically intact children. Predisposing conditions including diabetes mellitus, chronic cardiac or pulmonary disease, collagen vascular disease, varicella complicated by pyoderma, and antecedent blunt trauma. There is a predilection for involvement of the lower extremities, especially the groin and thigh. Symptoms are often insidious, starting with poorly localized extremity pain that impairs gait. Fever may be absent or only of low grade. Pain that is out of proportion to the degree of physical findings may be the only clue to the correct diagnosis at the initial encounter.¹

With varicella, a violaceous hue about a cluster of pox lesions may be the clue to deep-plane infection. In those without varicella, rapidly developing skin changes suggest the diagnosis. These include a localized soft-tissue swelling, erythema, and either darker discoloration of the skin (pyomyositis) or bullae formation, and spontaneous sloughing (necrotizing fasciitis). If misdiagnosed at the time there is painful gait without skin changes, children may return in extremis within 24 to 48 hours in septic shock.^{1,3}

Hip pain and limp may be the presenting complaints with epidural abscess, but most patients seek medical attention because of unremitting back pain. At the onset, most patients exhibit fever, headache, malaise, and aching midline back pain. Patients may have tenderness on palpation of the spinous processes at the level of the subjective back pain. Neck stiffness is present in more than one-third of patients, and when altered sensorium is an accompanying feature, the disease may mimic meningitis. Overt cord involvement may be heralded by weakness of voluntary muscles and bowel and bladder sphincters, or by sensory abnormalities, most often characterized as ascending anesthesia.¹⁴

Deep groin pain and hip, distal medial thigh, or knee pain may be of sudden onset or progressive over weeks as result of acute or chronic slipped capital femoral epiphysis. Classically, pain is vague, dull at rest, and exacerbated by ambulation. Children seek comfort by externally rotating the leg when walking. They limp, and there is often a truncal shift with ambulation to accommodate hip abductor weakness. Examination demonstrates a partially flexed, irritable hip maintained in external rotation. Maximal hip flexion is restricted, and complete internal rotation is not possible. Delay in recognition of an acute slip may result in further displacement or may increase the risk for avascular necrosis.⁶

A diagnosis of cord tumor must be considered in any child with a gait disturbance who also has a recent history of altered bowel pattern or an insidious onset of motor weakness of the lower extremities, subjective sensory disturbance (including leg and neck pain), or back pain that is usually progressive. The back pain associated with a cord tumor is classically increased in the supine position and increased in intensity by the Valsalva maneuver. Physical examination may reveal weakness of the lower extremities, paraspinal or hamstring muscle spasm, nuchal rigidity, scoliosis, back stiffness, spine tenderness, relaxed sphincter tone, and absence of fever. Even when cord tumors present precipitously, the absence of systemic manifestations helps to discriminate them from acute epidural abscess.¹⁶

Alterations in gait seen with Guillain-Barré syndrome can be secondary to subjective complaints of foot or leg pain, impairment of position sense, or profound leg weakness with loss of voluntary movement. The clinical hallmark of Guillain-Barré syndrome is rapidly progressive, relatively symmetric motor impairment. The motor deficit may range from isolated lower limb weakness to total paralysis of the muscles of all four extremities and the trunk. Mild sensory symptoms or signs strongly support the diagnosis. Severe sensory dysfunction with pain as a dominant expression is a clinical variant. Such patients may experience bilateral pain in the large proximal muscles, including the lower back, buttocks, and anterior and posterior aspects of the thighs. Such sensory disturbances can precede the onset of clinically demonstrable weakness.¹⁶

The prognosis for full functional recovery from tick paralysis depends on establishment of the diagnosis. After a brief period with nonspecific symptoms, patients experience a progressive weakness of the lower extremities, usually without pain or paresthesias. The weakness or attendant ataxia can lead to inability to walk, and the patient may seek medical attention before the development of a generalized flaccid paresis.¹⁶

Children may be reluctant to assume an upright position or to walk because of cephalalgia, myalgia, electrolyte imbalance, compromised circulatory status, and altered sensorium from encephalitis or meningitis. The cardinal symptoms of cerebral abscess include severe and intractable headache, altered sensorium, vomiting, fever, and neurologic abnormalities that include seizure, paresthesias, incoordination, unsteady gait, or hemiparesis.¹⁶ Early recognition of these intracranial infections can prevent significant morbidity and mortality.

EMERGENCY DEPARTMENT EVALUATION

Among the benign and potentially life- or limb-threatening causes of gait disturbance, several have a classic profile. By recognizing the characteristic history and subsequently demonstrating the accompanying physical findings, the physician may establish a diagnosis. Where the pathogenesis is clear, no diagnostic investigation is an option. When the provisional diagnosis is elusive, ancillary tests from phlebotomy or imaging may be helpful.

A complete blood count may facilitate the diagnosis of systemic infection, hemoglobinopathy, or blood dyscrasia. The erythrocyte sedimentation rate (ESR) correctly identifies over 75% of all patients with limb pain who have an inflammatory or infectious disease.¹¹ About 70% of patients with an ESR of more than 30 mm/h have arthralgia or arthritis of infectious or inflammatory origin. Those with an ESR of 40 mm/h or more have bacterial infections as the cause of their refusal to walk.⁴

When the area of pain has been localized, radiographs limited to the area of interest have proven diagnostic efficacy. Plain radiographs may aid in the diagnosis of periostitides, osteochondroses, benign and malignant tumors, mechanical disturbances, metabolic derangements, and infectious diseases. Films that appear negative should never hinder therapeutic strategies. Several noteworthy conditions that present with gait disturbance, such as tibial fracture in the toddler, septic hip in the child over 1 year old, osteomyelitis of the long bone or pelvis, sacroiliac joint infection, and intervertebral disk infection, may be associated with normal radiographs. Radiographs are often insensitive and unreliable, especially in the early course of these disorders.^{2,13}

Ultrasonography may be helpful in the investigation of hip irritability. Sonography may demonstrate intraarticular effusion when plain films are normal.

Radionuclide scans rarely establish an unexpected diagnosis, but they do provide important positive and negative information central to inpatient management. A positive technetium scan reflects any condition that results in increased bone formation or blood flow. A negative technetium scan does not rule out an infectious process and should be followed by a gallium scan. Gallium accumulates in leukocytes independent of blood supply. A positive gallium scan supports a provisional diagnosis of infection, and negative technetium and gallium scans refute it. The diagnostic accuracy of these procedures is augmented only when both scans are performed sequentially.

Computed tomography (CT) scanning is useful for the study of tumors and inflammatory and infectious problems of the musculoskeletal system in children. Magnetic resonance imaging (MRI) is superior to both plain films and CT scans for soft-tissue detail. MRI may be the most sensitive means of establishing an early diagnosis of Legg-Calvé-Perthes disease, differentiating bone infarction from osteomyelitis in the sickle cell patient and benign from malignant bone tumors. MRI may be useful in certain anatomic regions that are difficult to evaluate with plain films (e.g., region of the sacroiliac joint, vertebral bodies, and intervertebral disks).¹² All of these imaging modalities, however, are of limited assistance to the emergency physician, who must make a prompt diagnosis.^{15,16 and 17}

EMERGENCY DEPARTMENT MANAGEMENT

The intensity of the emergency department management of patients with gait disturbances rests with the physiologic derangement at the time of presentation. Rarely, a patient with limp, pseudoparalysis, or paresis requires establishment of an airway or ventilatory support. Cardiovascular instability, which can occur with a few of the infectious diseases (notably deep-plane infection, meningitis, and appendiceal abscess), requires fluid resuscitation. Neurologic deficits may be rapidly progressive in a few conditions associated with gait disturbance. Continuous monitoring of neurologic status is warranted for patients suspected of having Guillain-Barré syndrome, poliomyelitis, acute transverse myelitis, tick paralysis, brain abscess, meningitis, and cerebral vascular accident. A few conditions associated with gait disturbance require specific emergency department treatment to forestall functional disability. Various therapeutic modalities include splinting of fractures, antibiotic administration, arthrocentesis to reduce intraarticular pressure, and removal of a tick to definitively treat tick paralysis.

DISPOSITION

When presented with a child who has a gait disturbance, the physician has a major responsibility to distinguish between those children who require emergency department intervention and immediate hospitalization and those who have self-limited conditions. The following features, when present, may be helpful in characterizing patients who require greater scrutiny. Be more cautious when the gait disturbance is more likely to be from illness rather than from injury. In nontraumatic states, have a heightened awareness for adverse outcome when a gait disturbance is associated with a rapid progression of signs and symptoms or when there is an indolent illness with sudden change.

Admission is warranted for children with gait disturbance in certain circumstances. Admit all patients who appear to have a serious bacterial infection. History and physical examination are more likely to uncover serious bacterial infection than are ancillary laboratory investigations. Maintain a high index of suspicion for serious bacterial diseases in those patients who have recently been febrile or are currently being treated with antibiotics for benign intercurrent illness.

Certain clinical findings suggest that serious bacterial illness is present. They include fever, even if of low grade; nuchal rigidity; limitation of joint motion; lower limb direct metaphyseal pain; compression tenderness over a spinal process; pain in the sacroiliac joint, with pelvic rock; and back pain enhanced with Valsalva movement, heel strike, or straight leg raising. Additional features that suggest serious bacterial infection include pain that is disproportionate to physical findings or neurologic abnormalities. In the context of a likely infectious disease, do not be dissuaded by a normal white blood cell count or normal ESR. Conversely, do not admit a child who has no historic or clinical findings to suggest serious bacterial infection when there is an isolated finding of leukocytosis or elevated sedimentation rate.

Admission is warranted for all patients with neurologic abnormalities, such as altered consciousness, cranial nerve involvement, subjective or objective sensory disturbance, ataxia, alteration of sphincter tone, urinary retention, altered deep tendon reflexes, or loss of voluntary movement. Admit patients with gait disturbance who might have been physically abused.

COMMON PITFALLS

- Think of trauma when there is an abrupt onset of gait disturbance without prodromal events in a previously healthy child.
- Deemphasize the history of trauma, even if witnessed, when there is an antecedent or current infectious process; this scenario suggests serious bacterial infection.
- Fever, leukocytosis, and elevated ESR may not uniformly accompany infectious diseases associated with gait disturbance.

CHAPTER 255

Respiratory Distress

Bruce Quinn and Marc Linares

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Respiratory distress is a compensatory state in response to impaired oxygen delivery to the tissues, with or without decreased carbon dioxide elimination. When the patient's capacity for compensation is overwhelmed, respiratory failure occurs.

The respiratory system can be divided into two anatomic categories: the lungs, or gas-exchange portion; and the "respiratory pump," consisting of the nervous system, respiratory muscles, and thorax.¹² Pathology involving any of these areas can potentially lead to the signs and symptoms of respiratory distress. Depending on the etiology of the respiratory compromise and the time until presentation in the emergency department, these signs and symptoms may be subtle.

A number of differences exist between the pediatric and the adult patient that place the child at greater risk for respiratory compromise. Infants and young children have a subglottic airway that is smaller and has less supporting cartilage than that found in adults, therefore making it easier for obstruction to occur secondary to edema, secretions, constriction, or compression.⁴ The smaller the airway, the greater the resistance for a given decrease in luminal diameter. Dynamic collapse of a partially obstructed airway, as can be seen in croup during inspiratory, is a direct consequence of the high compliance of the pediatric airway.⁴ Children less than 1 to 2 years of age may not have the anatomic pathways or "collateral ventilation" that allow aeration distal to an obstructed airway, thereby increasing the risk of atelectasis and ventilation-perfusion mismatching.¹² Due to the increased chest wall compliance of the pediatric patients, some of the diaphragmatic contractions force is wasted distorting the rib cage rather than expanding the lungs.¹² The younger the child, the greater the pliability of the chest wall, placing the neonate at greatest risk for fatigue, respiratory failure, and cardiopulmonary arrest.

In addition to anatomic differences, the higher metabolic rate in children, compared with that in adults, places them at a further disadvantage by increasing their oxygen demand. With the onset of hypoventilation, hypoxemia will occur more rapidly in the child.⁴

CLINICAL PRESENTATION

The presentation of a child in respiratory distress varies, depending on a number of factors, including the specific etiology, duration of illness, age, underlying medical conditions, and interventions prior to arrival in the emergency department. Any degree of respiratory compromise needs to be quickly detected and appropriate therapy instituted, in order to avoid potential deterioration to respiratory failure and cardiopulmonary arrest.

Signs of respiratory distress can be separated into two categories: visual and audible ([Table 255.1](#)). Initially, simply looking at a child and listening, avoiding prolonged eye contact and use of a stethoscope, can provide a great deal of information with minimal, if any, anxiety being produced in the patient.

VISUAL	AUDIBLE
Chest retractions	Cough
Abnormal behavior	Stridor
Altered mental status	Wheezing
Tachypnea/bradypnea	Grunting
Shallow/deep respirations	Abnormal voice or cry
Nasal flaring	
Head bobbing	
"See-saw" respirations	
Cyanosis	

TABLE 255.1. Indicators of Actual or Possible Respiratory Compromise

Visual inspection begins with the child's behavior. Normal behavior in a child does not rule out underlying pathology, but it does inform the clinician that the child is comfortable and in no need of urgent intervention. However, a quiet, serious child, who prefers sitting upright in a sniffing position, is a cause for concern and requires immediate assessment. Behavior changes such as restlessness or irritability can be subtle clues of hypoxemia. Any alteration in mental status can represent either generalized central nervous system (CNS) disease or hypercarbia, with or without hypoxemia.

The presence of either tachypnea or bradypnea is taken as evidence of respiratory compromise. It is important, therefore, to be aware of the normal range of respiratory rates in the pediatric population. Hooker et al.¹⁴ found normal respiratory rates to be higher than in previously published studies with a wide range of "normal." In addition, fever, pain, and anxiety increase the respiratory rate in the absence of pulmonary disease. In Hooker's study, patients younger than 1 year of age had a mean respiratory rate of 39 ± 11 with a minimum of 22 breaths per minute to a maximum of 65.¹⁴ Patients 2 to 3 years of age had a mean rate of 28 ± 4 , with rates at 8 years of age falling into the adult range (20 ± 4).¹⁴

Rather than an absolute respiratory rate, a better marker of respiratory distress may be a change in the respiratory rate for a particular child, as well as an assessment of the depth of respirations. Shallow respirations are often seen in diseases causing lower airway obstruction, while deep respirations are often associated with diseases causing metabolic acidosis and represent a central compensatory mechanism.²² The presence of chest retractions indicates respiratory distress. They begin subcostally with mild disease, and progress upward as the disease process worsens.³⁴ Nasal flaring can be a subtle sign, more commonly present in the infant and younger child, and is usually associated with lower tract disease. Head bobbing with each breath and "see-saw" or "rocky" respirations, in which the chest pulls in while the abdomen thrusts out, are signs of severe distress; the latter is an inefficient means of ventilation that can quickly lead to respiratory failure.⁴ Cyanosis is not apparent until at least 5 g of desaturated hemoglobin per deciliter of capillary blood is present; this usually correlates with a PO_2 below 40 and an arterial oxyhemoglobin saturation of 85% or less.^{5,20} Because anemic patients can be acyanotic and profoundly hypoxic, cyanosis should not be considered a dependable or an early indicator of hypoxemia.⁴

Certain indicators of respiratory distress can be heard without the use of a stethoscope. Persistent, forceful, nonproductive coughing may indicate a foreign body lodged in the upper airway, with the potential for complete obstruction. Stridor is a harsh, crowing sound, occurring during inspiration²⁸ and commonly seen in the pediatric population. It signifies upper airway pathology being produced by rapid, turbulent air flow through a narrowed area.³⁴ Wheezing represents expiratory obstruction of the lower airways.²² If heard without chest auscultation, it clearly indicates serious disease and the need for urgent intervention. Grunting, an end-expiratory sound, is produced by glottic closure during exhalation in an attempt to provide physiologic positive end-expiratory pressure (PEEP).²² When detected, it indicates a disease process causing alveolar and/or interstitial fluid.²² An abnormal voice or cry, particularly if muffled in quality, should alert the clinician to possible upper airway disease and the need for prompt, nonthreatening evaluation.

In the absence of visual and audible signs of respiratory distress, the likelihood of an infant or child having serious respiratory pathology requiring emergent

intervention is small.

DIFFERENTIAL DIAGNOSIS

Determining the precise etiology of respiratory distress in the pediatric patient can be challenging; the differential diagnosis is substantial ([Table 255.2](#)). The clinician needs to recognize the signs and symptoms of respiratory distress in a child and determine the degree of severity. In moderate-to-severe degrees of distress, a rapid assessment of the likely etiology is needed so that proper therapy can be initiated.

INFECTIOUS	TRAUMA/MECHANICAL
Respiratory Tract	Hemothorax
Etiology	Pneumothorax
Croup	Pulmonary contusion
Epiglottitis	Flail chest
URI	Spinal cord injury
Bacterial tracheitis	Intracranial hemorrhage
Peritonsillar abscess	Abdominal distension
Retropharyngeal abscess	
Lower	ENVIRONMENTAL
Pneumonia	Foreign body
Bronchiolitis	Smoke inhalation
Central Nervous System	Near drowning
Meningitis	Ingestions
Encephalitis	
Brain abscess	OTHER
	Seizures
HYPERACTIVE AIRWAY	Cardiac failure
Asthma	Cystic fibrosis
Anaphylaxis	Metabolic acidosis
	Vocal cord dysfunction
	Congenital anomalies
	Hypocalcemia

TABLE 255.2. Etiologies of Respiratory Distress

The presence of stridor indicates some degree of upper airway obstruction and, when associated with fever, one should suspect an infectious etiology. Croup classically presents between 6 months and 3 years of age, with a history of a low-grade fever and upper respiratory infection (URI) symptoms for a few days, followed by the sudden onset of a barking cough, hoarseness, and stridor, with or without chest retractions.

In any child thought to have croup, the diagnosis of epiglottitis must be considered and ruled out. Although the incidence of epiglottitis has declined dramatically since the introduction of the *Haemophilus influenzae* type b conjugate vaccine,^{13,35} the physician must remain vigilant for this potentially life-threatening disease. Epiglottitis usually occurs between 3 and 8 years of age, although it can be seen as early as 6 months and as late as adulthood.³³ Sudden onset of high fever is often the earliest manifestation.⁵ Losek et al.²¹ reported that among children with epiglottitis, 95% of those aged 2 years and older had a history of sore throat, and that 92% of all children had a change in voice or cry. At physical examination, the most common signs of epiglottitis were found to be stridor (88%), retractions (81%), and temperature 38°C or higher (85%); drooling (66%) and a preference for sitting (58%) were less common.²¹ The time course from first clinical sign to respiratory distress can be rapid, usually occurring within 12 hours.⁵

In distinguishing between epiglottitis and croup in a child presenting with fever, stridor, and retractions, the importance of the history cannot be overemphasized. Drooling in the absence of spontaneous cough is the most specific indicator of acute epiglottitis.²⁴ It is important to note, though, that cough can be seen in epiglottitis, and that its presence in no way eliminates it from the differential diagnosis.^{5,21}

Not infrequently, a URI alone will cause signs of mild-to-moderate respiratory distress in the very young infant. Simply suctioning the nares, using several drops of normal saline and a bulb syringe, is usually all that is required.

Other, less common etiologies to consider in a child with fever and stridor include bacterial tracheitis and peritonsillar or retropharyngeal abscesses. Patients with bacterial tracheitis typically have symptoms of croup initially and then go on to develop high fever, toxicity, and purulent tracheal secretions, resulting in airway compromise.⁵ Peritonsillar abscesses are most common in older adolescents and young adults in their early 20s.¹¹ There is sudden elevation of temperature, toxicity, and unilateral throat pain following an earlier tonsillitis.⁵ The patient complains of trismus and has drooling, difficulty speaking, and a muffled voice.⁷ Examination may reveal bilateral tonsillar hypertrophy, but one tonsil will be more enlarged and possibly cause deviation of the uvula.⁷ Unlike peritonsillar abscesses, retropharyngeal abscesses usually present in young children, from infancy to 3 years of age.⁵ The clinical picture is similar to that seen with epiglottitis, but with a less sudden onset.⁷ If the child is stable, a diagnostic lateral neck x-ray should be done.

Infectious etiologies of the lower respiratory tract that may cause respiratory distress include bronchiolitis and pneumonia. Bronchiolitis is any wheezing-associated illness in the first years of life that is preceded by a URI.³⁵ Differentiation from acute attacks of asthma, often triggered by viral infections, may be difficult.

In those patients presenting in respiratory distress not obviously associated with infection, the history and physical examination should quickly solve the mystery. Most commonly, a diagnosis of asthma will be made. An important etiology to include in the differential diagnosis is anaphylaxis, a multisystem syndrome involving the cutaneous, respiratory, cardiovascular, and gastrointestinal systems; involvement of two or more systems is required for the diagnosis.⁶ Both the upper and lower airways can be involved, leading to hoarseness, stridor, wheezing, and cough. Early diagnosis and distinction of anaphylaxis from more benign conditions is essential, as these patients can progress rapidly to anaphylactic shock.⁶

Environmental causes of respiratory distress, such as smoke inhalation and near drowning, will usually be evident from the history. Others, particularly foreign-body aspirations, may be difficult to determine. An infant or young child found in the midst of peanuts or similar sized objects, who subsequently develops a persistent cough with stridor, should obviously be evaluated for foreign-body aspiration. Often, however, the history of a foreign-body aspiration is less apparent, with the parents reporting only that their previously well child suddenly “began coughing out of the blue.” Stridor or wheezing not responsive to appropriate therapy requires further evaluation, beginning with lateral and anteroposterior x-rays of the neck and chest.

Etiologies of respiratory distress associated with trauma should be evident from clinical examination. Tension pneumothorax and hemothorax need to be rapidly diagnosed and treated. Respiratory depression in the trauma patient without obvious respiratory tract pathology should raise the possibility of injury to the CNS.

Other important causes of respiratory compromise in the child include seizures, congestive heart failure, cystic fibrosis, and metabolic acidosis due to sepsis, diabetic ketoacidosis, renal disease, and certain ingestions (e.g., salicylate, methanol). Neuromuscular diseases, including Guillain-Barré, botulism, and myasthenia gravis, also need to be considered. Vocal cord dysfunction, believed to represent a conversion disorder, results in either inspiratory or expiratory stridor that may be confused with wheezing.³⁶ Congenital anomalies should be considered in infants less than 6 months old who present with stridor; such anomalies include vascular rings, laryngeal webs, vocal cord paralysis, and laryngomalacia.²⁰ Hypocalcemia, in addition to having neurologic, cardiovascular, and psychiatric manifestations, can also result in apnea, laryngeal spasm, bronchospasm, or biphasic respiratory noises and needs to be included in the differential diagnosis of any patient with respiratory distress.¹

EMERGENCY DEPARTMENT EVALUATION

The goals of the emergency department evaluation are to reach a diagnosis quickly, with minimal stress on the patient, and to promptly begin appropriate therapy and monitoring. Assessing the degree of respiratory distress is important, but mild distress must not be underestimated, as some diseases or conditions can progress rapidly (e.g., epiglottitis). The initial evaluation begins when the physician enters the room, noting any visual and audible indicators of actual or possible respiratory compromise. The child in respiratory distress must be approached in a gentle, reassuring manner and allowed to find the most comfortable position, whether it be on the examining table or on a parent's lap. In the child who is alert and behaving normally, the evaluation can proceed with the history and physical examination. However, any child who has an altered mental status, or one who is irritable or restless, with other signs of distress, needs to have an immediate assessment of airway, breathing pattern, and circulatory status, the ABCs of resuscitation. Further assessment or therapeutic intervention follows this initial evaluation.

Important historic points include underlying medical problems (e.g., asthma, cystic fibrosis, or seizure disorder), the onset and type of current symptoms, and the

possibility of a foreign-body aspiration or ingestion or poisoning. If epiglottitis is suspected, forced visualization of the pharynx should be avoided in the emergency department.³³ Although such attempts by Mauro and colleagues²⁴ in six patients did not lead to complications, forced visualization may result in a vasovagal response, causing cardiopulmonary collapse, respiratory obstruction, and death.⁸ We recommend the traditional approach of taking the child with suspected epiglottitis to the operating room for direct visualization of the airway in the presence of personnel skilled in establishing the airway.

After the history and physical examination, the etiology of the respiratory distress is usually clear. Noninvasive monitoring can be used to help with clinical assessment. Pulse oximetry provides a continuous, generally valid measure of the arterial hemoglobin oxygenation status and arterial pulse. Obtaining blood gas measurements stress an already distressed child, and should therefore generally be avoided early in the evaluation.

Sometimes, the diagnosis may not be obvious from the history and examination, and further evaluation may be needed. In situations in which aspiration of a foreign body is suspected, lateral and anteroposterior neck and/or chest x-rays should be obtained; if normal, either an assisted expiratory film, bilateral decubitus x-rays, or fluoroscopy should be done.³ If the distinction between croup and epiglottitis is not obvious, and the child is stable and only mildly ill, a lateral neck radiograph with close monitoring has been traditionally viewed as appropriate. However, Ragosta and colleagues³⁰ found lateral neck films to be of limited value in the initial evaluation of suspected epiglottitis and recommend against their use.

Repeated evaluations at regular intervals, as well as noninvasive monitoring, are essential in any child presenting to the emergency department in respiratory distress. Once the diagnosis is determined and appropriate therapy instituted, the response to therapy must be constantly reassessed. Often, the best way to determine whether an adult or older child is improving is simply to ask, "Are you feeling better?" In the nonverbal or frightened child, however, the response to therapy must be assessed by using changes in clinical parameters. Repeated examinations, although difficult in busy emergency departments, can be lifesaving for the child in respiratory distress.

EMERGENCY DEPARTMENT MANAGEMENT

The importance of a gentle, nonthreatening approach cannot be overemphasized. Interventions of any sort are usually poorly tolerated by young children and, at least temporarily, may result in a worsening of their condition. The benefit of any intervention must always be weighed against its potential for adversely affecting the child.

Management of the child in respiratory distress generally involves two goals: keeping the patient as calm and comfortable as possible, and providing appropriate therapy. Therapy begins with humidified oxygen. Infants and some children often do not tolerate masks well, and depending on their oxygen requirement, may best be served with blow-by oxygen administered by the parent. In addition to the physical examination, pulse oximetry is useful in following the oxygenation status. Normal pulse oximetry readings have been reported as 91.5% to 100% in awake infants 6 months and younger,²⁵ and 96% to 100% (median, 99.5%) in asleep children 2 to 16 years of age.²⁷ If the anxiety produced by the administration of oxygen to children in mild distress worsens their condition, then the oxygen is clearly doing more harm than good and should be avoided. However, the anxiety elicited by the administration of oxygen is usually transient. An attempt at oxygen delivery should be made for all children in respiratory distress, except, perhaps, for the rare patient with chronic obstructive pulmonary disease (COPD). For severely distressed or cyanotic patients, 100% humidified oxygen must be provided quickly, irrespective of their acceptance.

The next step in management is to provide disease-specific therapy. Common diagnoses that respond to specific medical therapy include croup, asthma, and bronchiolitis. Children presenting with croup and stridor at rest can be provided a trial of humidified air. However, a beneficial effect of mist therapy on the upper airway edema found with croup has not been established.^{9,23} Steroids, given orally, parenterally, or via nebulizer, have been shown to be effective in the management of croup.^{9,23} A single oral dose of dexamethasone (0.15 mg/kg) significantly reduced the need for follow-up in children discharged from an emergency department with mild croup; 16.7% of the placebo group required additional medical care versus 0% of the steroid group.¹⁰ In patients with moderately severe croup, parenteral dexamethasone and, to a lesser extent, nebulized budesonide were shown to provide clinical improvement; both significantly reduced hospital admissions.¹⁵ For severe croup, nebulized epinephrine can rapidly relieve distress, but its effect lasts only 1 to 3 hours.³² Either racemic epinephrine or L-epinephrine can be used, the latter having been shown to be as safe and effective as the more commonly prescribed racemic form.³⁸ Although nebulized epinephrine's activity is short lived, studies indicate that when it is used with steroids (e.g., dexamethasone, 0.6 mg/kg, intramuscularly or orally), patients can be safely discharged home after 2 to 4 hours if clinically well (e.g., without retractions and stridor at rest).^{16,18,19,29,32} Caution should be used when employing nebulized epinephrine if epiglottitis is suspected, as it may precipitate airway obstruction.¹⁷

The mainstays of therapy for acute asthma are inhaled beta-adrenergic bronchodilators and corticosteroids, either orally or parenterally.³⁷ Anticholinergic agents, widely recognized as important therapy for chronic asthma and COPD, have been shown to be effective for asthma exacerbations as well.² Combining a nebulized anticholinergic agent with a beta-adrenergic agent appears to provide better bronchodilation than either drug alone.²⁶

Although the effectiveness of inhaled bronchodilators in the management of bronchiolitis is controversial, an initial trial of inhaled beta-adrenergic agents is recommended.^{37,39} In addition, Reijonen and colleagues³¹ found nebulized racemic epinephrine to be safe and useful.

DISPOSITION

The disposition of the child in moderate-to-severe distress depends on the hospital's capacity to accommodate the patient's needs. Often, an inpatient pediatric floor or a pediatric intensive care unit (PICU) is required.

For the stable child in moderate distress, admission to an inpatient pediatric floor is appropriate. When there is a concern that the patient may deteriorate due to the particular disease process (e.g., anaphylaxis) or medical history (e.g., an asthmatic previously requiring intubation), admission to a PICU should be considered. If necessary, transfer to the nearest hospital having a PICU should be arranged in accordance with federal guidelines. The transfer should be done by personnel skilled in airway management (i.e., an advanced cardiac life-support unit or the pediatric transfer team of the receiving hospital). Ground transport is adequate for the stable child in only moderate distress.

Any child in severe distress should be admitted to a PICU. If transfer is necessary, consideration should be given to intubating and stabilizing the airway before departure, rather than risk deterioration and the need for a potentially difficult intubation en route. Transfer by ground units with personnel skilled in airway management is adequate for most patients in severe distress. However, the need for ground versus air transport must always be individualized.

COMMON PITFALLS

- Taking a blood pressure before giving therapy to the well-perfused patient
- Starting an intravenous line not needed for initial therapy²²
- Forcing oxygen on the child in mild distress who will not tolerate it
- Obtaining blood for blood gas analysis in a severely distressed patient before providing therapy
- Doing a detailed history and physical examination before intervening in the severely distressed child²²
- Not allowing the patient to assume a comfortable position²²
- Misinterpreting decompensation for improvement
- During pulse oximetry monitoring, determining a sleeping infant to be hypoxic without further evaluating him or her in an awake state

A seizure in a child can be a dramatic event, provoking fear and panic in parents and caregivers. The majority of parents will bring their child to the emergency department (ED) for evaluation, even if the child has seemed to fully recover. The initial step in this process requires determining whether the seizure has stopped and whether the child has returned to his or her prior neurologic baseline. If the child is continuing to have seizure activity on arrival to the ED, stopping the seizure is the first priority.

A seizure is a series of excessive, abnormal electrical discharges from cerebral neurons that produce transient involuntary alterations in functioning, including consciousness, motor activity, behavior, and/or autonomic regulation. Affecting 4% to 6% of children by age 16, seizures are the most common childhood neurologic disorder. The incidence is highest in newborns, and higher in childhood than in later life.

During seizure activity, consumption of oxygen and glucose is increased in cerebral tissues. Early physiologic changes include hypertension, hyperglycemia, and hypoxemia. With subsequent or prolonged seizure activity, progressive lactic acidosis, rhabdomyolysis, hyperkalemia, hyperthermia, and hypoglycemia may develop, leading to possible permanent neurologic damage.

Most childhood seizures are brief and isolated, and they have a good outcome. In some children, seizures are prolonged and recurrent. *Status epilepticus*, defined as recurrent or continuous seizure activity that lasts longer than 30 minutes without recovery of baseline mental functioning, is one of the most common neurologic emergencies encountered in children. Because seizures are one of the more common pediatric symptoms that lead to an ED visit, and stopping the seizure and its complications is time dependent to prevent sequelae, the ED physician should be familiar with all aspects of seizure management. These aspects include initial stabilization, primary investigation of cause, acute management, and disposition.

CLINICAL PRESENTATION

The single most important clinical finding when a child presents with a seizure is whether there is ongoing seizure activity. Seizures are classified as either generalized or partial. Generalized seizures may be convulsive or nonconvulsive and may manifest with an altered level of consciousness and with or without bilateral motor activity. Partial seizures may be simple, without affecting consciousness; or complex, with impaired mental status. In the ED, ongoing seizures may manifest with a wide array of clinical presentations, from tonic, clonic, tonic-clonic, or myoclonic activity; or by clouding of, or loss of, consciousness; eye deviations; repetitive, stereotyped movements; or by isolated behavioral changes, such as continuous crying or bicycling movements seen in infants. Whether the child responds to a caregiver's presence or voice can also be a useful clinical clue.

If the seizure has already stopped, additional related clinical findings include presence of a postictal phase, loss of bowel and/or bladder control, or focal neurologic deficit. A hemiparesis or other focal neurologic deficit (without signs of increased intracranial pressure [ICP]), also called a Todd's paralysis, is an important localizing sign and suggests that the seizure had a focal onset. If it is new and persists, a structural cause for the seizure should be sought. Fever is the most common cause of seizures in childhood; discussion of febrile seizures follows in a subsequent section. Clinical signs of neurologic disease or remote neurologic events that predispose a child to seizures include skin findings associated with neurocutaneous disorders (such as ash leaf spots or adenoma sebaceum, suggesting tuberous sclerosis; café-au-lait spots, suggesting neurofibromatosis; or port-wine staining of the face, suggesting Sturge-Weber syndrome), microcephaly, dysmorphic features, spasticity, hemiplegia, or quadriplegia. Stroke, increased ICP, or meningitis may be associated with acute clinical findings such as hemiparesis, papilledema and bulging fontanelle, or stiff neck. Unexplained superficial bruising should raise the suspicion of a bleeding disorder or child abuse.

DIFFERENTIAL DIAGNOSIS

A seizure is not a diagnosis but a clinical symptom of an underlying disease or process with many potential causes, which vary with age ([Table 256.1](#)). Other entities that may be confused with seizures include underlying neurologic disease, such as spasticity, and acute dystonic reactions, neither of which has associated loss of consciousness. A detailed history of the seizure event from a witness is the single most important feature for accurate diagnosis. It is important to determine whether the child has actually had a seizure, because many childhood conditions can easily be mistaken for a seizure. These disorders can be classified by one of three presentations: sudden loss of consciousness, paroxysmal movements, or sudden change in behavior.

NEONATAL
• Birth injury, such as hypoxic-ischemic encephalopathy
• Infection: meningitis, encephalitis, toxoplasmosis
• Metabolic: hypocalcemia, hypoglycemia
• Drug toxicity: maternal medications
• Genetic: phenylketonuria, galactosemia
INFANT
• Febrile convulsions
• Infection: meningitis, encephalitis
• Metabolic: hypocalcemia, hypoglycemia
• Structural: congenital anomalies
• Trauma
• Stroke
CHILDREN AND ADOLESCENTS
• Febrile convulsions
• Infection: meningitis, encephalitis
• Metabolic: hypocalcemia, hypoglycemia
• Structural: congenital anomalies
• Trauma
• Stroke
ADULT
• Infection: meningitis, encephalitis
• Metabolic: hypocalcemia, hypoglycemia
• Structural: congenital anomalies
• Trauma
• Stroke

TABLE 256.1. Acute Causes of Seizures by Age

Disorders with sudden loss of consciousness include breath-holding spells, syncope, cardiac dysrhythmias, and complicated migraines, and each is differentiated from a seizure because a postictal state is rare. Breath-holding spells occur in two forms, cyanotic and pallid, usually in children between 6 months and 4 years of age. Cyanotic spells begin with vigorous crying, followed by apnea, cyanosis, and, occasionally, myoclonus. Pallid spells begin with a painful stimulus (even fear), followed by pallor and loss of consciousness. Vasovagal syncope, the most common cause of syncope in childhood, may be preceded by light-headedness and dizziness, followed by loss of consciousness. The loss of consciousness is brief, and recovery is rapid. Syncopal events from cardiac dysrhythmias are usually associated with a positive family history; they are characterized by a brief loss of consciousness, with myoclonic movements, and rapid recovery. Electrocardiographic (ECG) or Holter monitoring as an outpatient may be needed for confirmation. With complicated migraines, loss of consciousness may be associated with or preceded by blurred vision, blindness, dizziness, or loss of postural tone.

Disorders with paroxysmal movements include tics, shuddering attacks, benign sleep myoclonus, and pseudoseizures. These are differentiated from seizures because a loss of consciousness is rare. Tics are brief, stereotyped, nonrhythmic movements that may be precipitated by stress; usually, some voluntary control is exhibited. Shuddering attacks are characterized by rapid tremors of the entire body, which may occur up to 100 times a day. They are usually inherited, are self-limited, may be precipitated by stress, and may require an electroencephalogram (EEG) (which is normal) to convince the family that they are seizures. Benign sleep myoclonus usually presents in infancy with benign, self-limited, sudden, jerky movements of one or more extremity. Although more common when the child is falling asleep, they may occur throughout sleep. Pseudoseizures may be difficult to distinguish from seizures in the ED and may require video EEG monitoring for diagnosis. They present with paroxysmal movements, lack of coordination, and moaning or talking during the episode, and can even be seen in patients with a seizure disorder.

Disorders with sudden behavioral changes include night terrors. These are differentiated from seizures by their characteristic findings. Night terrors, a form of parasomnia, occurs in preschoolers, with sudden awakening from sleep with fits of crying, sweating, and rapid breathing, and there may be associated stereotyped movements.

EMERGENCY DEPARTMENT EVALUATION

History and physical examination are the most useful tools in ED evaluation. History should focus on a detailed description of the seizure and finding an acute cause of it, such as trauma, infection, recent immunization, or intoxication, and history of seizures and anticonvulsant use. Physical examination should search for signs of trauma, increased ICP, and meningeal irritation. Laboratory testing should be guided by the history and examination. Useful studies may include a rapid bedside glucose, serum electrolytes, calcium, magnesium and ammonia, a complete blood count (CBC), and a urine toxicology screen.

A lumbar puncture is not indicated for the nonfebrile child with a seizure, but should be considered in a neonate. Magnetic resonance imaging has become the imaging modality of choice for new-onset seizure in children, but it usually is not required on an emergent basis. Brain imaging studies for the ED patient at most institutions consist of a cranial computed tomography (CT) scan. Indications for CT in the ED include a focal deficit on neurologic examination, signs of increased ICP, an infant less than 12 months old (possible child abuse), patients with ventriculoperitoneal shunts, and suspected head trauma. EEG monitoring is rarely used emergently, except for refractory status or if a diagnosis of nonconvulsive status is considered (EEG may be the only way to accurately diagnose this disorder).

EMERGENCY DEPARTMENT MANAGEMENT

Seizure activity in the ED should be considered status epilepticus until further history can be obtained, and the main priorities should be resuscitation of the child and stopping the seizure. A brief history should focus on finding an acute cause of the seizure, such as trauma, infection, or intoxication, and history of seizures and anticonvulsant use. A rapid physical examination should search for signs of trauma, increased ICP, and meningeal irritation. If meningitis is a concern, appropriate antibiotics should be given.

Management of Status Epilepticus

The following protocol is suggested to manage status epilepticus.

0 to 5 minutes

Maintain airway, give oxygen, support ventilation, and consider cervical spine immobilization for trauma patients.
Obtain intravenous access, check bedside glucose, and send blood samples for electrolytes, CBC, glucose, and anticonvulsant levels.
Monitor vital signs, pulse oximetry, and ECG.
Consider intravenous glucose 2 mL/kg of D₂₅, and/or pyridoxine 100 mg for neonates (or isoniazid overdose).

At 5 to 15 minutes, if seizure continues

Lorazepam 0.05 to 0.1 mg/kg intravenously, or diazepam 0.2 to 0.4 mg/kg intravenously; if no intravenous access, consider diazepam 0.5 to 1.0 mg/kg PR, or midazolam 0.2 mg/kg intramuscularly.
Repeat up to two times every 5 minutes.

At 15 to 30 minutes, if seizure continues

Fosphenytoin 15 to 20 mg phenytoin equivalents (PE)/kg intravenously or intramuscularly, not to exceed 150 mg PE/min; or phenytoin 15 to 20 mg/kg intravenously, not to exceed 1 mg/kg/min.
Consider phenobarbital 15 to 20 mg/kg intravenously.
Reevaluate airway and consider need for intubation.
Check electrolyte results; consider need for intravenous hypertonic saline.

At beyond 30 minutes, if seizure continues

Consider additional fosphenytoin 5 mg PE/kg or phenytoin.
Consider consultation with neurologist. Discuss need for EEG monitoring.
Contact pediatric intensivist to arrange transport and need for pentobarbital, midazolam, or propofol coma. Consider general anesthesia in consultation with an anesthesiologist.

At beyond 60 minutes, if seizure continues

Begin alternative (coma) regimen and consider transfer to appropriate facility or location.

Brief Overview of Pharmacotherapy

First-line drugs for the management of status include benzodiazepines, fosphenytoin or phenytoin, and phenobarbital. Benzodiazepines are the current drugs of choice for initial management of status epilepticus, and should be used only in patients with active seizures. Lorazepam, diazepam, and midazolam may be used to manage status. Lorazepam is preferred for its longer half-life (24 hours). If diazepam is used initially, consideration should be given to an additional longer acting agent, such as fosphenytoin or phenytoin. Benzodiazepines cause respiratory depression and, in higher doses, may cause hypotension. Diazepam can be given rectally if intravenous access is not available. The rectal dose is 0.5 mg/kg, to a maximum dose of 20 mg, and is given via a short no. 8 feeding tube or a needleless 1-mL Tb syringe. Recently developed Diastat, a viscous solution for rectal administration, is available in prefilled, rectal-tipped syringes in a variety of doses.

Fosphenytoin or phenytoin is utilized if a seizure continues after benzodiazepine use. Fosphenytoin, a newly developed prodrug of phenytoin, is often preferred for use in children because it causes fewer side effects, such as respiratory depression and cardiac and tissue necrosis. Fosphenytoin can also be given intramuscularly if vascular access has not been established.

Phenobarbital is the drug of choice for neonatal seizures and for complex febrile seizures that are unresponsive to benzodiazepines. Noteworthy is the increased risk of respiratory depression when phenobarbital is given concomitantly with benzodiazepines.

DISPOSITION

Children with first-time seizure can be followed as outpatients if they appear well, the parents are comfortable with outpatient management, and follow-up can be

assured. These children frequently do not require maintenance anticonvulsant therapy, but the decision to start therapy, and which agent to use, should be done in consultation with a pediatric neurologist and the primary care physician. Hospital admission is reserved for children with a prolonged seizure or status epilepticus, even if successfully treated in the ED. Children requiring intubation and ventilatory support or those with prolonged refractory status should be transported to a tertiary care facility with pediatric subspecialists.

FEBRILE SEIZURES

Febrile convulsions are the most common form of seizures in childhood, occurring in 2% to 5% of children. Generally, febrile seizures are defined by a seizure in association with a febrile illness, without central nervous system infection or electrolyte imbalance. They usually occur between the ages of 6 months and 6 years; peak incidence is approximately 18 months of age. Febrile seizures are classified as simple or complex. A febrile seizure is complex if it is focal, prolonged more than 15 minutes, or multiple (more than one seizure during the febrile illness). The majority of febrile seizures are simple febrile seizures that are brief, isolated, and generalized. Although the pathophysiology of febrile seizures remains unclear, it appears that the absolute peak temperature plays a key role. Mortality is extremely rare, and there are no differences in cognitive abilities after a febrile seizure, even when prolonged.

EVALUATION, MANAGEMENT AND DISPOSITION

To diagnose a febrile seizure, meningitis, encephalitis, electrolyte imbalances, and other acute neurologic disease must be ruled out. Most of these can be eliminated by a careful history or physical examination. In 1996, the American Academy of Pediatrics issued guidelines for the evaluation of children with simple febrile seizures who are between the ages of 6 months and 5 years. According to these guidelines, a lumbar puncture should strongly be considered in all infants less than 12 months of age, should be carefully considered in all children between 12 and 18 months, and should not be considered necessary in well-appearing children over 18 months, without symptoms of meningitis. Neuroimaging of any kind is not routinely required, and additional routine blood studies are of limited value. If the child arrives in the ED in apparent status from a febrile seizure, it should be treated as such. Benzodiazepines are the drugs of choice, but the most studied agent is diazepam, as discussed.

Other than evaluation and treatment of the underlying cause of the fever, the majority of cases will require only reassurance and education of parents about febrile seizures. Anticonvulsant prophylaxis is not routinely recommended.

COMMON PITFALLS

- Failure to address airway, breathing, and circulation as the first priority in status epilepticus management
- Failure to recognize and treat the underlying disease causing the seizure
- Failure to consider shaking or child abuse in young children
- Failure to diagnose meningitis in infants with a febrile seizure

[Three Months to Two Years](#)

[Older Child and Adolescent](#)

[Emergency Department Management](#)

[Disposition](#)

[Common Pitfalls](#)

[Chapter References](#)

Vomiting is a common nonspecific complaint of children presenting to the emergency department. It can be a presenting finding in a variety of medical and surgical diagnoses. In determining a cause, a complete history and physical examination may be all that is required. Laboratory and radiologic studies may become useful to confirm a suspected diagnosis.

Vomiting in children is usually associated with a transient illness and has little clinical significance. However, it may also be a response to a serious or potentially life-threatening illness.¹ Initial treatment is usually directed at stabilization while the diagnosis is being made.

EMERGENCY DEPARTMENT EVALUATION AND DIFFERENTIAL DIAGNOSIS

Factors important in evaluating the patient with vomiting are age, appearance at presentation, and presence of associated symptoms. The majority of cases of vomiting are due to self-limiting infectious illness and can be diagnosed based on associated symptoms and physical findings. The patient's age is important when considering the differential diagnoses (see [Table 257.1](#)).

TABLE 257.1. Life-Threatening Causes of Vomiting

Birth to Three Months

In infants, the history should focus on the time of onset, the duration of vomiting, the description of the emesis, and any associated gastrointestinal or other complaints. Most commonly, gastroesophageal reflux (GER) presents during this time. Excess vomiting secondary to GER is a common cause of failure to thrive.⁵ A majority of these infants present with regurgitation of formula or breast milk after feeds, clinically are in no distress, and are well appearing. As a result, they can be managed conservatively with cereal-thickened feedings and antireflux precautions.

This condition must be distinguished from hypertrophic pyloric stenosis (HPS). HPS usually presents with projectile vomiting of formula shortly after feeding and is typically well described by the parents (see [Chapter 289](#)). The classic presentation of the 3- to 6-week-old infant presenting with hypochloremic metabolic alkalosis and severe dehydration is no longer common. Earlier diagnosis with ultrasound results in earlier surgical repair and decreased morbidity.³

Other obstructive lesions to consider include duodenal and jejunal atresia as well as malrotation with midgut volvulus. These entities were typically seen in the newborn nursery but now are seen in the emergency department secondary to early hospital discharge. Infants with these conditions are typically ill appearing, have bilious vomiting, and have abdominal tenderness and various degrees of abdominal distention.² Plain radiographs may reveal a gasless abdomen. Rapid stabilization and surgical intervention are required.

Medical illness and metabolic disorders may also present with vomiting as an associated finding. Infectious illness such as pneumonia, sepsis, meningitis, and inborn errors of metabolism are examples. These diagnoses are usually suspected because of other associated symptoms and are confirmed with laboratory and radiologic evaluation.

Three Months to Two Years

The most common cause of vomiting in children 3 months to 2 years old is infectious gastroenteritis, most commonly of viral etiology. Fever and diarrhea typically accompany the vomiting. Presentation can vary from a well-appearing child (early) to a severely dehydrated one (late). Laboratory evaluation may direct therapy, especially when hyponatremia, hypernatremia, or hypoglycemia is present. Other medical conditions to consider, especially in the absence of diarrhea, include pneumonia, meningitis, and increased intracranial pressure.

Surgical causes in this age group include intussusception, incarcerated hernia, and volvulus. Intussusception is the most common surgical condition in this age group. This typically involves the child less than 1 year of age with paroxysmal, cramping abdominal pain, followed by vomiting and periods of lethargy. The classic triad of vomiting, currant jelly stools, and right-sided mass may be present in only 20% of cases. Physical examination may reveal a right-sided mass (85%) and various degrees of distention.² Plain films may be nonspecific and, early in the illness, may be normal.⁶ Because of this, a high index of suspicion, not laboratory findings or plain radiography, should direct the management. A contrast enema or air is commonly both diagnostic and therapeutic. Once the intussusception is reduced, admission for observation is indicated.

Older Child and Adolescent

The most common cause of vomiting in this age group is infectious gastroenteritis. A viral etiology is the most common of these cases. Fever and diarrhea typically accompany the vomiting. Dehydration as a complication of acute viral gastroenteritis is far less common in the older child and adolescent and, if present, should alert the physician to consider other diagnoses.

The most common surgical etiology of vomiting is acute appendicitis. Associated symptoms include migrating pain to the right lower quadrant, associated anorexia, and low-grade fever. In addition, diarrhea has been noted to be present in 16% of patients.⁴ However, especially in the child less than 6 years old, the typical findings are not always present and the physical examination is often difficult. Consequently, the diagnosis is often missed in the child less than 6 years of age.⁴ The physical examination may prove more reliable in the older child. A high index of suspicion is based on the history and physical examination. Laboratory or radiographic

evidence may be used to support the diagnosis, but normal studies are common. Surgical consultation is indicated with positive physical findings.

Other causes of vomiting in the adolescent include pregnancy, pelvic inflammatory disease, undiagnosed diabetic ketoacidosis, and self-induced vomiting (bulimia). These entities can usually be confirmed with history, examination, and supportive laboratory evaluation.

EMERGENCY DEPARTMENT MANAGEMENT

Regardless of the etiology of the vomiting, the initial management of the patient should include a rapid cardiopulmonary assessment and a determination of the stability of the patient. The management is then guided by these findings. The unstable patient may require fluid resuscitation while a diagnostic evaluation is being completed. Certain rapid diagnostic tests may be indicated, based on suspicion of illness. For example, in a lethargic vomiting child less than 3 months of age, a rapid determination of serum glucose is indicated. In a child with moderate-to-severe dehydration, an infusion of 20 mL/kg of crystalloid solution is given and the patient is reassessed. Dextrose-containing fluids should not be used in the initial fluid resuscitation. If hypoglycemia is present, a separate infusion of dextrose should be administered. If the patient's clinical appearance and physical examination are suspicious for an obstructive lesion, surgical consultation should proceed prior to return of laboratory values or radiologic studies.

Antiemetics are contraindicated, except when used for predictable, limited causes (e.g., chemotherapy, motion sickness). Most antiemetics have variable, unpredictable side effects, and, more importantly, the cessation of vomiting may lead to a delay in diagnosis of a life-threatening condition (e.g., meningitis).

DISPOSITION

Admission to the hospital should be considered for children with vomiting and dehydration who require intravenous fluid boluses and for children with suspected but unproven surgical etiologies. Patients admitted for observation should be made NPO if a surgical diagnosis is being ruled out. Children that are discharged home should have explicit instructions regarding when to return for reevaluation.

COMMON PITFALLS

- Vomiting in the infant may be due to overfeeding.
- Plain radiographs of the abdomen may be normal in early intussusception.
- Diarrhea can be present with acute appendicitis.
- Antiemetics should be used with caution, especially in young children.

CHAPTER 258

Abuse: Sexual

J. M. Whitworth

[Clinical Presentation](#)
[Emergency Department Evaluation](#)
[History](#)
[Physical Examination](#)
[Laboratory Evaluation](#)
[Emergency Department Management](#)
[Common Pitfalls](#)
[Chapter References](#)

Until recent years, sexual abuse in children was considered an uncommon problem. It is now clear that sexual abuse or sexual molestation affects at least one in four girls and one in seven boys before age 18.⁷ The short- and long-term physical and psychological effects of sexual abuse depend on many factors, including the severity of the abuse, the length of time of involvement, the relationship of the abuser to the child, and the sensitivity of intervening professionals and family members after the problem has come to light.

The needs of sexually abused children differ from the needs of sexually assaulted adults. Although children are sometimes raped, the usual case is characterized by a long-term process perpetrated by an older person who is well known to the child, and results in totally different evidentiary, evaluation, and treatment approaches. The “child sexual abuse accommodation syndrome” describes characteristics seen in these children and points out the challenges in approaching child victimization, as compared with adults. Children are gradually entrapped in a secret arrangement with a trusted adult or adolescent and feel helpless. They accommodate to the abuse and often display delayed and conflicting disclosure, followed by retraction of the allegation.²⁵ A specially trained professional interviewer is needed to begin addressing these specific issues often seen in children.

The emergency department response to sexual abuse of children must address the child's medical needs and must be equally considerate of his or her psychological needs. The emergency department visit can serve as the first step in a therapeutic process. The forensic examination is a small part of a multidisciplinary effort to evaluate and protect the child; the examiner must have the time, effort, and skill to minimize the traumatic aspects of the encounter. If such a commitment cannot be ensured, the emergency department should consider referring cases to another facility for evaluation.

CLINICAL PRESENTATION

A few child sexual abuse cases present to the emergency department as a medical emergency, usually with a history of genital bleeding or clinical suggestions of acute abdominal trauma or peritoneal irritation. In these cases, matters of evidence collection, forensic evaluation, and reporting are secondary to the need for immediate intervention to stabilize the child's condition. Resuscitation takes precedence.

More typically, patients present in one of two ways. First, the child may present with a chief complaint of sexual abuse by personal report or because of a caretaker's suspicion. Second, the child may present with a seemingly unrelated chief complaint, and the examiner suspects sexual abuse because of findings in the history or physical examination.

The approach to these presentations may be different, but the examiner's immediate reaction should always be the same. After an assessment to determine whether there are immediate medical needs, a team of professionals must become involved to obtain a detailed interview, to recommend and perform necessary interventions, and to ensure the child's safety. Psychosocial assessment and treatment plans must be addressed early in case development. This requires the involvement of the local child protection agency, law enforcement, and, ideally, a multidisciplinary child protection team in the community.^{2,3}

Whenever sexual abuse is suspected, the health-care professional must make a report to child protective services or to a law enforcement agency in the community.²³ Local and state laws determine the physician's responsibility for reporting.

EMERGENCY DEPARTMENT EVALUATION

History

In the sexually abused child, the medical history is separate from the detailed interview. The medical history focuses on the information necessary to make a diagnosis, determine assessment needs, determine public health issues, and plan treatment. Taking a medical history should not be seen as an opportunity to do a detailed interview, unless there is no other resource available in the community.

The exact history and source of the information should be clearly recorded in the chart. If possible, the history should come from the child to ensure greatest reliability. It should be taken in the least threatening environment possible; adequate time must be taken to develop rapport with the child. Generally, the child should be interviewed alone. The examiner must spend enough time with the child to ascertain his or her names for body parts and bodily functions. If the child volunteers specific information, it is recorded as direct quotes. Information gathered from others is considered hearsay. Questions must be presented in a format that does not lead the child; if a question can be answered “yes” or “no,” it is probably leading. If the child says nothing, this fact should be recorded in the chart, documenting that the child was asked to give information about the case.

The history should also include an assessment of evidence for other kinds of abuse, family violence, and any other significant medical problems.

The decision as to the type and extent of medical intervention should be made by a health-care professional. It should not be based on the supposed needs of the legal system or a child protection agency. This medical responsibility for protecting the child cannot be abrogated to others who may not understand the potential trauma of a forensic examination in a child.

Physical Examination

Before the examination, the child should be told what to expect, and he or she should receive constant reassurance during the procedure.

The examination of the genitalia of a sexually abused child should always be done in the context of a complete standard pediatric physical examination. This approach is necessary to ensure that other significant problems are documented and addressed, and it is also necessary to reassure the child that he or she has been completely examined by a health professional and is intact. Abused children generally perceive themselves as “damaged goods.”

Abnormal findings should never be reported in the child's presence. Likewise, assurances by the physician that the child is not at fault and is believed are remembered by the child long after the minor trauma of the examination has faded. The physician should approach the child in a warm, friendly, age-appropriate manner and should not engage in extensive play or subterfuge to accomplish the examination, because playing games and subterfuges are often approaches used by an abuser.

If the child will not or cannot cooperate, the examination can be done at another time or in another place. With adequate preparation and patience, examination under anesthesia or with sedation is rarely necessary.

In a busy emergency department, an examination for sexual abuse of a child may have unanticipated negative effects. Other patients and the procedures performed on them may frighten the child. The examination should be done in a quiet environment. A support figure—never the suspected abuser—should be present and

should be selected by the child. Blood samples, if necessary, can be obtained shortly after the examination.

The examination of the genitalia of a prepubertal child is primarily a process of description and observation based on a knowledge of normal structures and deviations from normal. A child's genitalia differ in appearance from adult structures, so review of a standard pediatric gynecology reference is essential. ²⁴

Proper positioning of the child for a genital examination varies depending on the child's age, comfort, and degree of cooperation. An adequate examination can be performed with a small child on the mother's lap. Preferable positions, from the examiner's viewpoint, are the knee–chest and frog-leg positions. In the frog-leg position, direct inspection and moderate downward and outward pressure on the labia majora allow adequate visualization of all structures germane to the examination. In the knee–chest position, structures can usually be visualized directly without pressure or traction on the labia, but this position is often difficult to accomplish because it makes the child feel more vulnerable.

There are significant differences in the appearance of normal anatomic structures in different positions, as well as with different degrees of relaxation in the same child. For this reason, only findings that clearly indicate scarring from trauma, consistent changes in reflex response, or active infection should be considered definitive.

Invasion with a speculum or digit is seldom necessary or helpful, except in much older children or children who are sexually active. Cultures or specimen collection should be done with the smallest swab available. Inspection of the labia and introitus should include attention to evidence of old or new lacerations or abrasions.

Hymenal configuration should be noted and may be described as annular, crescentic, cribriform, septate, or imperforate. ¹³ Congenital absence of the hymen does not occur. ¹⁵ Thickness of the membrane should be described, along with any scarring located, and recorded as related to the face of a clock. The hymenal opening diameter in lateral and anteroposterior aspects is carefully measured and recorded. In the past, the lateral hymenal diameter was considered extremely important in making the diagnosis of sexual abuse or molestation, but currently, this measurement seems less important than evidence of chronic scarring or acute injury.

If the vaginal canal can be visualized, a description of general appearance, rugous folds, and any scars may be important.

Abnormalities in the prepubertal child fall into several categories ^{1,6,13,14,18,19,20} and ²¹:

1. Findings diagnostic of sexual abuse
 - a. Presence of sperm or semen in a prepubertal child
 - b. Presence of a sexually transmitted disease with no reasonable possibility of nonsexual transmission (i.e., gonorrhea, syphilis)
 - c. Witnessed or photographically documented sexual abuse with or without physical findings
2. Findings diagnostic of penetration and consistent with a history of sexual abuse
 - a. Healed or fresh vaginal tear
 - b. Healed or fresh hymenal tear
 - c. Missing section(s) of hymen in the posterior half
 - d. Fresh or healed rectal tears
 - e. Immediate reflex anal dilatation (greater than 20 mm) in the absence of stool in the ampulla
3. Findings diagnostic of genital trauma (insult) and consistent with a history of sexual abuse
 - a. Microlacerations of the posterior fourchette
 - b. Abrasions of the fossa navicularis or perihymenal tissues
 - c. Bruises of genital tissues
 - d. Presence of other sexually transmitted diseases (a disease not exclusively sexually transmitted, such as chlamydia or herpes)
 - e. Rectal fissures
4. Findings that neither support nor negate an allegation of sexual abuse
 - a. Redness or irritation of the genital area
 - b. Agglutination of the labia minora
 - c. Variations in the vascular pattern seen without attendant scars
 - d. Enlargement of the hymenal opening
 - e. Attenuated hymen without scarring
 - f. Vaginitis (other than sexually transmitted diseases)

In cases of documented sexual abuse, definite physical findings are present in only about 50% to 60%; this is also true in many cases of known penetration. ²² The physical examination, therefore, can never be used to negate an allegation of sexual abuse.

Findings should be recorded, for future reference, on a standard anatomic chart. Color photography is strongly recommended but is not always readily available in the emergency department.

When reaching a conclusion, external pressures always suggest that a definitive “yes” or “no” answer is necessary. This is not always possible, and the examiner should not be tempted to make definitive statements if the history and physical examination are not definitive. The physician may conclude that the examination is diagnostic of sexual abuse, consistent with sexual abuse, or neither confirms nor negates a history of sexual abuse. The examiner will probably be asked to support his or her conclusions at a later date.

Laboratory Evaluation

Useful forensic evidence is almost never found beyond 72 hours after an assault. If forensic evidence collection is needed, an evidence collection packet must be sought from local law enforcement sources, and the physician must be knowledgeable about the use of the kit before doing the examination. Thorough training in maintaining the chain of evidence and evidence collection techniques is mandatory and varies from jurisdiction to jurisdiction. Training is available from adult sexual assault centers or from police departments.

Sexual abuse victims must always be assessed for sexually transmitted diseases, but the extent of the search is a matter of clinical judgment. Cultures for *Neisseria gonorrhoeae* should be obtained from all prepubertal patients from the vagina, rectum, and throat, assuming a reasonable history or finding that suggests potential transmission. Cultures for *Chlamydia trachomatis* are useful if facilities are available. The use of screening or presumptive tests for chlamydia or gonorrhea is not recommended. ¹²

Wet mounts are done with anogenital discharges, and dark-field examinations are done on genital ulcers. Viral cultures for herpes simplex are indicated with vesicular lesions, and routine bacteriologic cultures should be done in all patients with a demonstrable discharge. The utility of cultures for herpes and human papillomavirus in determining sexual transmission is limited. Routine serologic tests for syphilis should not be done unless there are clinical indications.

Human immunodeficiency virus transmission can occur with sexual abuse but is uncommon. Routine testing is not recommended but should be available for any patient with high-risk exposure, or on request. ⁹ There are compelling clinical reasons for testing only in a setting where adequate preparation and follow-up with counseling services are provided.

EMERGENCY DEPARTMENT MANAGEMENT

The first priority is to alleviate any urgent or life-threatening medical needs. Subsequent treatment should be responsive to time-sensitive evidence collection and the treatment of sexually transmitted diseases. Presumptive treatment is never advisable; treatment should be undertaken only after definitive culture evidence exists or when there are life-threatening infectious disease issues.

In selecting treatment choices, the physician should always seek a history of drug sensitivity and should be familiar with the expected sensitivity of organisms in the

community. Treatment recommendations are shown in [Table 258.1](#).^{5,8,10}

Agent	Drug	Dosage
<i>Neisseria gonorrhoeae</i>	Ceftriaxone or Azithromycin	125 mg i.m. 1 g PO if >45 kg
<i>Herpes genitalis</i>	Acyclovir	400 mg PO t.i.d. for 7–10 d
<i>Chlamydia trachomatis</i>	Erythromycin ethylsuccinate or Azithromycin	50 mg/kg/d for 10 d 1 g PO if >45 kg
<i>Treponema pallidum</i>	Benzathine penicillin G	50,000 U/kg i.m. (max, 2.4 million units)
<i>Trichomonas vaginalis</i>	Metronidazole	15 mg/kg/d divided t.i.d. for 7 d, or 40 mg/kg (max, 2 g) as a single dose

Data from Barone⁵ and Committee on Infectious Diseases, American Academy of Pediatrics.⁸

TABLE 258.1. Treatment Recommendations for Children Who Have Contracted a Sexually Transmitted Disease through Sexual Abuse

COMMON PITFALLS

- The examiner should not become confused when a child recants a history of sexual abuse. This phenomenon is common and often results from fear, parental coaching, the observed response of authority figures, or the realization that intervention may result in jail for a family member or family separation. Recantation is so common that it does not necessarily interfere with prosecution or with therapy for the patient. Documentation of the emergency department visit assumes greater importance in these cases.
- Investigators may think that the absence of physical findings means that sexual abuse did not occur or that a case cannot be prosecuted. This is contrary to current knowledge and experience with sexually abused children and can actually lead to further victimization. Because a child's disclosure of sexual abuse is generally accurate, and because serious sexual abuse can occur without physical findings, the history is the critical piece of evidence. The absence of physical findings does not hinder the ability to obtain a conviction.^{9,16,22}
- The examiner must record all data, because he or she may need to recall the information in detail months or years later in a courtroom. Meticulous attention to detail in the examination and in the recording of the history and examination findings is essential to minimize this problem.

An awareness of child abuse and neglect is of particular importance in the emergency department setting. Any visit by a child may afford the health-care professional an opportunity to protect a child from further harm. The visit may also provide a rare window into a family that may desperately need intervention and supportive services.

The problem of child abuse affects about 2 million children yearly in the United States and results in the deaths of 2,000 to 5,000 children. Because many of these children receive only episodic medical care or care at a time of medical crisis, the emergency department or acute care clinic plays a special role in identification and reporting of child abuse and neglect. Although the physician is legally required to report suspected child abuse and is protected from liability for making a report in all states, the more important responsibility of the physician is to protect the child from further harm, and, therefore, cause an investigation to be done by the appropriate agency.² More detailed information as to state reporting requirements and procedures should be sought from local law enforcement or child protection agencies.

PHYSICAL ABUSE

Physical abuse occurs in all cultural, ethnic, socioeconomic, and racial groups. There are some geographic and regional differences in the prevalence of given types of abuse, but not in overall incidence. The incidence of abuse in a socioeconomic subgroup is most closely related to the presence of significant stresses in that population (i.e., joblessness, homelessness, drug and alcohol abuse). In any parent dyad, the parent with care-taking responsibilities is more likely to abuse a child. Abusive parents are usually not psychotic and generally respond to their children in a pattern similar to that experienced in their own childhood. They fairly consistently have unrealistic expectations of their children, with limited knowledge of developmental norms, and are unable to cope with the failure of the child to meet expectations. Triggering behaviors in the child, such as excessive crying or colic, are frequently seen.

EMERGENCY DEPARTMENT EVALUATION

Presentation

The history from an abused child or an abusive parent remains the most important evaluative tool for the physician. The veracity of a child's history must be assumed until there is good reason to assume otherwise. If children lie, they usually do so to hide the abuse rather than to bring it to light. The history from an abusive parent usually reflects a significant delay in seeking medical attention, and if a primary physician exists, parents have usually not sought his or her advice. There is almost always a history disparate from the severity or type of injury. If repeated questions are used to elicit the history, there is usually considerable variation in detail. Injury may be attributed to a sibling or to someone not present to verify the occurrences. Parents often simply cannot relate any explanation for the injuries sustained. A brief interview of witnesses to trauma can often quickly obviate a need for investigation of a case.

Physical Assessment

The initial physical assessment of the child may show findings that are strong indicators that further evaluation for abuse is necessary:

1. Bruises in unusual locations or where an accidental etiology is implausible due to the age or developmental status of the child (e.g., nonambulatory infant with multiple bruises)
2. Bruises that have a characteristic pattern, suggesting an object used to inflict the injury (e.g., hand print, belt mark)
3. Second-degree burns without bullae that show a characteristic pattern (e.g., the sole plate of an iron)
4. Second-degree burns with bullae and no evidence of splash marks and an unusually sharp line of demarcation (e.g., glove or stocking burns of an extremity)
5. Burns limited to the perineum
6. Swelling of any part of the body out of proportion to the severity of described injury (e.g., may indicate underlying fracture)
7. Unexplained or implausibly explained sudden changes in neurologic status
8. Retinal hemorrhages
9. Failure to thrive without a history suggestive of chronic or debilitating disease

The physical finding most commonly present in abused children is a bruise. Bruises are also the most commonly found accidental injury in children. Accidental bruises are located in areas most frequently exposed to injury in play or other normal childhood activities. These areas include the elbows, knees, and skin over the anterior tibia. The occasional bruise in less usual locations is of little concern and generally occurs over a bony prominence. The only commonly occurring lesion that may be mistaken for a bruise is the Mongolian spot. Mongolian spots are most common in darker skinned infants and are characteristically shiny and blue-black and limited to the back.

Bruises that occur in clusters and in unusual locations, such as on the abdomen, the back, or buttocks, and that show unusual severity or varying stages of resolution should cause concern, because they are rarely accidental. Resolution of bruises takes place in a sequence related to the severity and location of the injury. While there are findings that indicate an acute injury, such as swelling and tenderness, the color of a bruise cannot be used to date the injury accurately. A bruise has usually resolved after about 2 to 4 weeks.¹² Much more specific sequencing can be accomplished by experience in observing many bruises. Photographic documentation of these findings may become critically important to those pursuing the investigation of abuse, and this must be anticipated in completing the medical record.

Children who have been injured in falls from a height often present challenges in assessment for abuse versus an accidental cause. Although there have been poorly designed papers in the literature that would suggest otherwise, a significant head injury requires a fall from a distance of 4 feet or higher. Falls from a bed or sofa never result in serious injury beyond an uncomplicated fracture or bruise.⁴

Laboratory Evaluation

Laboratory evaluation in suspected physical abuse cases should include bleeding and clotting studies when bruises are present and when there is any suggestion of easy bruisability. At a minimum, these studies should include a prothrombin time, partial thromboplastin time, and platelet count. In addition, a photographic record of any finding is always preferable to a written or schematic description alone. Radiographic studies are indicated when evidence of trauma is noted and in children for which abuse is identified by some other means. These studies should include the chest, skull, and long bones in addition to the area of suspected injury. Films should be reviewed for fractures as well as evidence of osteopenia, increased trabeculation, and presence of excessive numbers of wormian bones in the skull. These findings, along with an appropriate family history, might suggest the presence of osteogenesis imperfecta. If fractures are seen, they should be related to the history of the type of injury. For example, spiral fractures occur in response to a torsional force, and chip fractures of the metaphysis occur with traction of the extremity or with a

shearing force across the end of the bone. Metaphyseal chip fractures are rarely accidental.⁸

In addition, it is often necessary to estimate the age of fractures in comparison to the history. Fractures of differing ages without good evidence of multiple accidental trauma are virtually diagnostic of physical abuse. Healing of a fracture takes place in a predictable sequence. Periosteal new bone is formed as early as 4 to 10 days after the fracture, and soft callus formation may be seen as early as 10 to 14 days. Hard callus formation may occur as early as 14 days, and remodeling may begin by 3 months after the acute fracture.⁹

Computed axial tomography of the head is indicated in those children with retinal hemorrhages or evidence of acute neurologic deterioration. The presence of intracranial hemorrhage with or without skull fracture and in the absence of a history of major trauma is diagnostic of child abuse until proven otherwise.⁶ Magnetic resonance imaging is a useful tool in identifying small areas of bleeding and to more carefully determine areas of bleeding that have occurred at different times.¹ The use of bone scans is usually not indicated, except under special circumstances in which abuse is clearly a likely possibility and in which fractures may be suspected that are not yet visible on routine films.

With abdominal trauma, one might expect to see evidence of acute anemia associated with intraabdominal bleeding or an elevated amylase with trauma to the pancreas. Hematuria is not an uncommon occurrence with paddling or spanking, in which one or more blows has strayed cephalad.

ASSOCIATED SYNDROMES

Shaken-Baby Syndrome (Acceleration–Deceleration Injury)

Shaken infants rarely present with a history of shaking. The most common presentation is that of respiratory difficulty, apnea, or unexplained seizures. The basic insult is the presence of intracranial bleeding, which may be characterized as subdural, epidural, interhemispheric, or intraparenchymal. Symptoms are usually a result of increased intracranial pressure. Retinal hemorrhages are the single most common physical finding and, outside the newborn period, provide presumptive evidence of intracranial bleeding due to trauma. Although retinal hemorrhages may be seen with other head trauma, they should be considered the hallmark of the shaken-baby syndrome until another plausible explanation is found. The hemorrhages seen are usually superficial and diffuse, as compared with the deeper flame-type hemorrhages seen in hypertension. The diagnosis is made by a careful history after documentation of intracranial bleeding by computed tomography or magnetic resonance imaging. The mechanism of injury was once believed to be totally due to rotational and shear forces created by the to-and-fro motion of the head in shaking. Later studies strongly suggest that similar lesions can be caused by significant increased venous pressure transmitted from squeezing of the chest as part of shaking or in any type of injury in which significant increases in intraabdominal or intrathoracic pressure are sustained.⁶ The latest studies suggest that impact of the head is necessary to produce the full clinical picture and that acceleration–deceleration forces are important.⁵

As might be expected, other skeletal injuries can be seen with shaking. The child is commonly held by the thorax or the extremities with enough force to cause fractures at those sites. The combination of intracranial bleeding, as described here, and metaphyseal chip fractures of the distal tibiae is indicative of the child being held by the feet and cracked like a whip. The clinical outcome in this syndrome is dismal, in that approximately 65% of children will die or have significant neurologic sequelae as a result. Milder forms of this syndrome undoubtedly exist with milder neurologic sequelae but are yet to be carefully documented. This syndrome is frequently missed or misdiagnosed in the clinical setting.

Failure to Thrive

Failure to thrive is often categorized as organic and nonorganic, although there are often some elements of both types in most individual cases. The child presents with the weight being greater than two standard deviations below the mean expected for age, and there may be associated growth failure as well. In most cases of organic failure to thrive, a strong suggestion of the underlying etiology will be evident from the history or physical examination. Suggestions of a nonorganic etiology may be evident in observing the interactions between the mother and child. The mother and child often show little interaction, and nonnurturing behavior is evident on the part of the mother. The child often shows little eye contact and is generally withdrawn from the environment.³ Most commonly, nonorganic failure to thrive requires a period of observation in a hospital setting for accurate diagnosis.

Munchausen Syndrome by Proxy

This unusual type of child abuse occurs when a caretaker describes or produces factitious illness in a child as a response to their own psychiatric pathology. This is a diagnosis of which the emergency physician should be aware but is not a diagnosis to be made in the emergency department. This diagnosis requires intense record review and, usually, inpatient evaluation.¹⁰

EMERGENCY DEPARTMENT MANAGEMENT

After a decision to report has been made, the next dilemma is to decide whether to tell the parents about the report. Under most circumstances, the physician should calmly inform the parents that a report is being made because he or she is required to do so by state law and therefore has no choice in the matter. It is generally good to relieve some of the mystery of what will happen after the report is made by informing the parents about the steps in the investigation process. The circumstance when it is better not to inform the parents is one in which the physician feels the parents are likely to flee with the child and further endanger the child's health and welfare.

Meticulous attention to the chart is essential in all abuse cases. The examiner is often called on to recall the encounter with the patient and parents in great detail months or years later. The use of direct quotes from the child is helpful in avoiding questions of hearsay information. The use of detailed body charts to delineate injuries and findings, including careful measurements, is important. Even better is the inclusion of photographs of findings as part of the medical record.

The emergency department physician should be aware of community agencies that provide investigative and intervention services to abusive families and abused children, so that he or she has immediate access to information and consultation on individual cases. If the services of a multidisciplinary team are available, participation in the activities of the team is often very valuable in receiving feedback as to case outcome and progress.

COMMON PITFALLS

The most common pitfall in the diagnosis of child abuse is the failure of the physician to seriously consider this etiology in the differential diagnosis of trauma to children. The presence of documented findings of trauma with an implausible history should provide more than adequate impetus for further evaluation and careful documentation.

Appendicitis is the most common surgical emergency in childhood, with an estimated 80,000 children affected annually.² Despite the decline in mortality since the introduction of antibiotics, morbidity has remained unchanged over the past 40 years, due primarily to perforation because of delays in diagnosis. Perforation rates are higher in children, occurring in 50% to 70% of preschoolers with appendicitis, versus 10% to 20% in an adult population.^{10,14} This highlights the importance of early diagnosis and treatment in the prevention of significant morbidity.

Obstruction of the appendiceal lumen, caused most commonly by a fecalith (calcified fecal material), is the primary cause of appendicitis. Other less common causes of obstruction include inflamed lymphoid tissue; vegetable and fruit seeds; intestinal worms (especially *Ascaridae*); bacterial infection with *Yersinia*, *Salmonella*, or *Shigella*; and, rarely, retained barium from previous radiographic studies, or anomalies of mucus-secreting glands, as in cystic fibrosis.^{13,20}

Luminal obstruction of the appendix causes distention and increased intraluminal pressure, resulting in obstruction of the blood supply. Bacterial invasion occurs, and, ultimately, the ischemic appendix becomes gangrenous and perforates. Bacteriologic cultures of perforated appendices have revealed polymicrobial organisms, including *Escherichia coli*, *Bacteroides fragilis*, and enteric streptococci.⁸

The progression from appendiceal obstruction to perforation is more rapid in children. What starts as vague abdominal complaints can quickly progress to ileus, nausea, vomiting, fever, tachycardia, localized pain, and, finally, peritonitis. The inability of omentum in young children to wall-off localized infections contributes to the development of diffuse peritonitis. Therefore, appendicitis must be recognized early and proper management instituted without delay.¹⁴

CLINICAL PRESENTATION

The symptoms of acute appendicitis correlate with the pathophysiology of the disease. Obstruction and distention of the appendix stimulates stretch receptors, relaying pain through visceral nerve fibers to the tenth thoracic ganglion, resulting in the perception of periumbilical pain. Bacterial invasion and inflammation then lead to fever, nausea, or vomiting in up to 80% of children. As the inflammation extends to surrounding tissues, localized pain depends on the location of the appendix. Up to one-third of appendices are located in areas other than the usual intraperitoneal location. This results in up to 30% of children with appendicitis having localized pain in areas other than the right lower quadrant. A retrocecal location of the appendix may cause back or flank pain, a pelvic appendix may cause suprapubic pain, and a retroileal location may cause referred pain to the testicle.

If appendicitis is allowed to progress without surgical intervention, appendiceal rupture will occur. The diagnosis of perforation is easier to make. The child is usually ill appearing, toxic, and dehydrated. Particularly in younger children, the incompletely developed greater omentum is incapable of walling off the inflammatory process. Therefore, the abdominal pain is more diffuse and may decrease in intensity just after perforation, becoming much more severe as peritonitis develops.

Examining a young child with abdominal pain is often fraught with difficulty. Because young children are often frightened of doctors and “white coats,” observing the child from the doorway or across the room can be revealing. A young child who is ambulating easily around the room, interested in his or her surroundings, is less concerning than a child who is ill appearing and lying very quietly. A slight limp in the child's gait, hesitation to climb onto the examination table, and inability to stretch the right leg may suggest appendicitis even before the full evaluation. The child usually prefers to lie still in the supine position with the thighs, particularly the right, drawn up, because any motion increases pain. Vital signs are essentially normal, but a child with simple appendicitis may show a mild temperature elevation. Tachycardia may be present if the child is dehydrated, febrile, or in pain.

Examination of the abdomen for bowel sounds and tenderness can often frighten young children. Distraction of the young child, using a hand puppet or other toy, may help achieve a better examination. Bowel sounds are usually normal in early appendicitis. Advanced inflammation, perforation, or both, usually result in an ileus and a quiet abdomen.

Abdominal palpation should start away from the painful area. Muscular resistance to palpation of the abdomen parallels the severity of the inflammatory process. Early in the disease process, resistance, if present, consists of voluntary guarding. With the progression of peritoneal irritation, muscle spasm increases and becomes involuntary. The classic physical finding is point tenderness at McBurney's point (3 to 5 cm from the anterior–superior iliac spine on a straight line drawn from that process to the umbilicus).²⁰

Physical signs usually associated with acute appendicitis are as follows:²⁴

1. Rovsing's sign. This may be found if local peritoneal inflammation is present. By testing for tenderness in the left lower quadrant, referred tenderness can be elicited in the right lower quadrant.
2. Psoas sign. The child lies on the left side, then stretches the psoas muscle by slowly extending the right thigh. Alternatively, the child lies supine and flexes the right hip against a hand placed just above the knee. Pain elicited by either maneuver can indicate an irritating focus in proximity to the psoas muscle.
3. Obturator sign. A positive obturator sign occurs when passive internal rotation of the flexed thigh with the patient supine produces right-sided abdominal pain. This sign indicates irritation around the obturator internus muscle.

A positive psoas or obturator sign suggests retrocecal or retrocolic inflammation. Although these signs (Rovsing, psoas, and obturator) are often quoted as associated with appendicitis, there have been few studies published evaluating the accuracy of the clinical examination for appendicitis.²⁴ A metaanalysis regarding the clinical signs most likely to identify patients (both children and adults) at increased likelihood for appendicitis was published. The clinical signs with the highest positive likelihood ratios were right lower quadrant pain, rigidity, and migration of initial periumbilical pain to the right lower quadrant. Clinical signs with the highest negative likelihood ratios for ruling out appendicitis were absence of right lower quadrant pain and presence of similar previous pain.²⁴ The diagnostic value of the rectal examination in children is limited; rectal tenderness is present in 50% of all children with or without appendicitis.³

DIFFERENTIAL DIAGNOSIS

The differential diagnosis in children depends on three major factors: the anatomic location of the inflamed appendix, the stage of the process (simple or ruptured),

and the age and sex of the patient. The five main groups of differential diagnoses are as follows: [13,19,20,23](#)

1. Intestinal diseases: mesenteric adenitis, viral and bacterial enteritis, Meckel's diverticulitis, intussusception, enteric duplication
2. Uterine or tuboovarian pathology: ovarian or testicular torsion, acute epididymitis, pelvic inflammatory disease, ectopic pregnancy, endometriosis, mittelschmerz
3. Urinary tract pathology: acute pyelonephritis, cystitis, renal stones
4. Respiratory and systemic diseases: basal pneumonia, Henoch-Schönlein purpura, sickle cell crisis, diabetic ketoacidosis
5. Trauma: accidental or nonaccidental injury

Acute Mesenteric Lymphadenitis

Mesenteric adenitis is most often confused with acute appendicitis in children. A careful history almost invariably reveals the presence of upper respiratory symptoms in these patients. Laboratory procedures are usually of limited value in differentiation, although a relative lymphocytosis may suggest mesenteric adenitis or a generalized viral syndrome. The abdominal pain is usually more diffuse and less severe, and generalized lymphadenopathy may be noted on physical examination.

Pelvic Inflammatory Disease

A history of vaginal discharge in a sexually active adolescent can often be elicited. Interviewing adolescents alone, without parental presence, may offer a more revealing and true history regarding sexual activity. Pain is most often bilateral and lower in location. Physical examination reveals Chandelier's sign (pain with motion of the cervix).

Acute Gastroenteritis

Acute gastroenteritis usually can be differentiated from appendicitis. Often, there is a history of other ill contacts. These patients have nausea, vomiting, watery diarrhea, and intermittent, crampy abdominal pain. Often, the vomiting precedes the diarrhea by 24 hours. Localizing signs on the abdominal examination are usually absent.

Meckel's Diverticulitis

Preoperative differentiation is unnecessary, because the signs and symptoms of Meckel's diverticulitis are similar to those of acute appendicitis, and surgical treatment is indicated for both.

Intussusception

Differentiating between intussusception and acute appendicitis is important and relatively straightforward. Appendicitis is rare in children younger than 2 years of age, whereas nearly all intussusceptions occur in children younger than age 2 years. Intussusception typically occurs suddenly in an otherwise healthy infant. The infant "doubles up" with apparent colicky pain, but is usually without pain between attacks. A bloody mucoid stool is usually passed several hours after the onset of pain. Physical examination may reveal a sausage-shaped mass in the right lower quadrant. Occasionally, infants with intussusception present with an altered mental status. Treatment of intussusception is reduction by barium or air enema (see [Chapter 277](#)).

Henoch-Schönlein Purpura

Henoch-Schönlein purpura, a diffuse vasculitis, classically presents with joint pain and swelling and purpura. Abdominal pain may also be a prominent symptom. Rectal examination should be performed for occult blood. Urinalysis to evaluate for hematuria due to nephritis should also be performed.

Mittelschmerz

These patients are at the midpoint of their menstrual cycle. The pain of mittelschmerz is usually sudden in nature and may be localized to one side of the lower abdomen, or diffuse in nature.

Ovarian or Testicular Torsion

A number of nonspecific symptoms may exist, including anorexia, nausea, and vomiting. The correct diagnosis can be made by always including the genitalia in the physical examination, which usually reveals the subtle findings of asymmetry in gonadal size or position. A normal examination of the ovarian or testicular size or position does not completely rule out the diagnosis of torsion, however.

Urinary Tract Infection

Bacteria or white blood cells may be present in the urine specimen of approximately 17% of children with acute appendicitis. ¹ This occurs if the appendix lies near the ureter or bladder. With the exception of an elevated specific gravity due to dehydration, the urinalysis is normal in more than 80% of children with acute appendicitis.

EMERGENCY DEPARTMENT EVALUATION

The most important steps in making a correct diagnosis of appendicitis are eliciting a complete history and performing a complete physical examination, including examining the external genitalia in boys and performing an internal pelvic examination in adolescent girls. However, because the sensitivity of the clinical examination has been reported to be as low as 63%, other modalities have been utilized to improve diagnostic capabilities. ⁷

Indicated laboratory studies include a complete blood count with differential and urinalysis. Moderate leukocytosis (10,000 to 18,000 white blood cells/mL) with a predominance of polymorphonuclear cells is classically seen but does not necessarily correlate with the severity of the disease. ⁴ A left shift in the differential may precede a total leukocytosis in children. It must be noted that a normal white blood cell count does not rule out the diagnosis of appendicitis.

Abdominal radiographs are not particularly helpful, as the presence of a fecalith is shown in only 10% to 20% of children with appendicitis. ¹³ Nonspecific findings on plain abdominal films include isolated distended loops of bowel in the right lower quadrant and obliteration of the psoas shadow. Because lesions that irritate nerves at the T10 to T12 level may simulate the referred pain distribution of appendicitis, a chest film may be required to rule out right lower lobe pneumonia, especially if signs or symptoms of lower respiratory tract disease exist.

Other noninvasive imaging studies, such as ultrasonography or computed tomography, may help make the diagnosis and have gained popularity. Ultrasound in children has been shown to have a sensitivity and specificity of 90% and 97%, respectively, with an overall accuracy of 96%. ¹¹ The classic finding of appendicitis, when viewed by ultrasound, is a thickened, noncompressible, nonperistaltic appendix. Ultrasonography in adolescent girls is especially useful to differentiate appendicitis from tuboovarian disease (e.g., a tuboovarian abscess or ovarian cyst). A normal appendix should be visualized to rule out the diagnosis of appendicitis. ^{11,17,21} Computed tomography of the abdomen, with rectal contrast, has been shown to have sensitivity and specificity of 94% and negative predictive value of 97%. ⁶ Computed tomography also has been shown to reduce the number of inpatient prediagnosis observation days, operations, and negative laparotomies. ⁷

It has been shown that 20% to 40% of children with acute appendicitis are given the wrong diagnosis on the first visit to a physician. ^{7,14,18} The most common erroneous preoperative diagnoses, in descending order of frequency, are acute mesenteric lymphadenitis, no organic pathologic condition, acute pelvic inflammatory disease, ovarian cyst, mittelschmerz, and acute gastroenteritis. These account for more than 75% of all missed diagnoses. A thorough history and physical examination should result in a higher degree of accuracy. ¹⁹

There is a higher incidence of perforation in younger children and in children with a history of prolonged symptoms. Symptoms suggestive of perforation are as

follows:²³

- Duration of symptoms more than 36 hours
- Temperature greater than 102°F
- White blood cell count of more than 15,000/mL
- Physical findings of peritonitis

The surgical consultant should be contacted as soon as the diagnosis of acute appendicitis is entertained, to avoid the complication of late diagnosis and perforation. Perforated appendicitis has a mortality rate of 5% and a morbidity rate of up to 46% in some series, compared with a mortality rate of 0.1% for nonperforated appendicitis.^{5,12,19}

EMERGENCY DEPARTMENT MANAGEMENT

Appendicitis is a surgical emergency. All children thought to have an abdominal surgical emergency should be seen by a surgeon as soon as possible. The initial emergency department management of simple and perforated appendicitis is essentially the same. Once the diagnosis is made, the child must be fluid-resuscitated intravenously and kept NPO. In a child who has been vomiting, obtaining serum electrolyte levels should be considered while intravenous fluid therapy is begun. Those children who have clinical signs or symptoms of dehydration should receive 0.9 NaCl or Ringer's lactate boluses at 10 to 20 mL/kg to maintain urine output at 1 to 2 mL/kg/h. Once the child is considered fluid-resuscitated, dextrose 5% in 0.45 or 0.225 normal saline and 20 mEq/L KCl at 1.5 times maintenance should be given, as long as the child is not oliguric. If the patient has eaten or vomited within a few hours of the operation, insertion of a nasogastric tube to empty the stomach may be requested by the surgeon. If the child is febrile, an acetaminophen suppository may be given.

The use of routine antibiotic coverage in children with uncomplicated appendicitis continues to be debated. It appears that short-term perioperative antibiotic prophylaxis in children with acute nonperforated appendicitis may decrease the rate of postoperative infectious complications.²² Absolute indications for extended therapy and a broader spectrum of antibiotic coverage are systemic signs of toxicity, sepsis, suspected perforation, and the presence of underlying conditions that predispose the patient to complications of bacteremia (i.e., infants younger than 6 months of age and children with congenital or acquired cardiac anomalies, sickle cell disease, diabetes mellitus, chronic renal failure, or other states of immune suppression).¹⁵ One commonly used regimen includes ampicillin (100 mg/kg/24 h in four doses), gentamicin (5 mg/kg/24 h in three doses), and clindamycin (40 mg/kg/24 h in four doses). This particular regimen ensures coverage of aminoglycoside-resistant enterococci, gram-negative bacilli, and anaerobes, respectively.^{5,16} Other antibiotic combinations or single-drug therapy can be used as long as the same microbial coverage is obtained in the setting of acute noncomplicated disease.

DISPOSITION

All children with appendicitis should be admitted to the hospital for surgical exploration. In certain cases of appendiceal abscess, a surgeon may opt for admission to the hospital for intravenous antibiotics or percutaneous drainage, with an interval appendectomy several weeks later.¹⁵

If there is doubt about the correct diagnosis, but the suspicion for appendicitis is still high, the child should be admitted to the hospital for serial physical examinations. If the suspicion is low but still a consideration, the child may be discharged with clear instructions to return in 6 to 8 hours for a reexamination of the abdomen. If there is any doubt about the ability of the child to return for a revisit, the child should be admitted to the hospital for serial physical examinations.

The child may require transfer to another facility if appropriate surgical staff is unavailable at the initial hospital. This should be done expediently after resuscitation has been started.

COMMON PITFALLS

- Immediate diagnosis of acute appendicitis in children is essential. Rapid progression of disease in this age group necessitates early suspicion, diagnosis, and operation if perforation is to be avoided. Late diagnosis results in significantly higher morbidity and mortality.
- The evaluating physician must be thorough in obtaining the history and performing the physical examination. In some cases, children or adolescents have been admitted to the hospital for observation with a diagnosis of "rule out appendicitis," when the actual, unrecognized diagnosis was testicular torsion or pelvic inflammatory disease, which could have been recognized if a complete physical examination had been performed.

Asthma is the most prevalent chronic disease in children.¹ In 1995, it accounted for almost 3% of all children's visits to the emergency department (ED) in the United States. Visit rates were almost four times higher among Black children than among White children (2.8 and 0.7 visits, respectively, per 100 children).⁷

Asthma can simply be defined as recurrent reversible bronchospasm due to a trigger ([Table 261.1](#)). There are underlying inflammatory and neural mechanisms that make the airways more sensitive to the triggers and result in bronchial hyperresponsiveness. A number of preformed and generated mediators cause the airway epithelium to become fragile and denuded and the epithelial subbasement membranes to thicken. Also, mucus production and consistency increase, and endothelial leakage results in mucosal edema.³ Mediator-induced abnormalities in the parasympathetic and nonadrenergic noncholinergic nervous systems may also lead to increased bronchial hyperresponsiveness.

TABLE 261.1. Triggers of Asthma Symptoms in Various Age Groups

CLINICAL PRESENTATION

Acute asthma exacerbations vary in severity and duration. They can resolve without any intervention. The patient or family may not even have realized there was a problem. An asthma attack can be divided into two phases: early and late asthmatic responses. The early asthmatic response (EAR) occurs soon after trigger exposure, producing bronchospasm, and usually lasts 1 to 2 hours. About 50% of patients go on to develop a late asthmatic response (LAR), with reoccurrence of bronchospasm about 4 hours after the initial trigger exposure. The LAR episode usually lasts 12 to 24 hours but may persist up to several days in some children.

Clinical events such as symptoms, spirometry, and ventilation–perfusion measurements poorly correlate with each other.¹⁰ Spirometry tends to reflect the degree of bronchoconstriction in large and medium airways. Ventilation–perfusion mismatch is more related to obstructive changes in the peripheral airways. Patients who are admitted to a hospital tend to have more severe airway obstruction.⁵

Classically, with an acute asthma attack, the child presents with wheezing and respiratory distress. Bronchospasm, however, can also present as cough, chest pain, shortness of breath, and fatigue with exertion. This can make the diagnosis and appropriate management more difficult. Acute asthma attacks can be divided into mild, moderate, severe, and impending respiratory failure¹² ([Table 261.2](#)).

Classification	Signs and Symptoms	Respiratory Rate	PEFR/FEV ₁	Oxygen Saturation (SaO ₂)
Mild	Wheezing, cough, chest tightness	< 20	> 80% predicted or personal best	> 95%
Moderate	Wheezing, cough, chest tightness, tachypnea	20–30	60–80% predicted or personal best	92–95%
Severe	Wheezing, cough, chest tightness, tachypnea, retractions	> 30	< 60% predicted or personal best	< 92%
Impending respiratory failure	Wheezing, cough, chest tightness, tachypnea, retractions, cyanosis	> 30	< 60% predicted or personal best	< 92%

PEFR, Peak expiratory flow rate; FEV₁, forced expiratory volume in one second.

TABLE 261.2. Classification of Severity of Asthma Exacerbation

With a mild attack, the child usually has been symptomatic for a short period of time and may still be in the EAR. There may be some increase in the respiratory rate, with a tight, hacking cough or end-expiratory wheezing. There is good air exchange, with minimal breathlessness and no accessory muscle use. Room air oxygen saturation (SaO₂) is greater than 95%, and peak expiratory flow rate (PEFR) or forced expiratory volume in one second (FEV₁) greater than 80% predicted or personal best.

In a more moderate attack, symptoms may have been ongoing for several hours to days, indicating LAR. There is an increase in the work of breathing, with tachypnea and accessory muscle use. Expiratory wheezing may be audible on entering the examination room, and inspiratory–expiratory wheezing may be present. The child may become breathless while talking and be somewhat agitated. An infant may have a less vigorous but more irritable cry and pull away from an offered bottle. Oxygen saturation will be in the low normal range, and PEFR/FEV₁ less than 80% predicted or personal best.

Severe attacks are similar to moderate in their time of onset and duration. There is marked respiratory distress, work of breathing, and tachypnea. Accessory muscle use is associated with intercostal and tracheosternal retractions and nasal flaring. Breath sounds can range from inspiratory–expiratory wheezing to a somewhat quiet

chest. The child will be breathless at rest. Neurologically, the child may range from anxious and agitated to somnolent and difficult to arouse. Infants will range from very agitated to unusually quiet and will refuse to take a bottle. Hypoxia is present, and the PaCO₂ may rise above 40 mm Hg. PEF₁/FEV₁ will be less than 50% predicted or personal best.

While type I respiratory failure (hypoxia without CO₂ retention) can develop with a moderate-to-severe asthma attack, type II failure (hypoxia with CO₂ retention) develops as the child becomes fatigued from the increased work of breathing. Respiratory efforts are labored to the point of paradoxical respiratory movement. The chest may be quiet because of the inability to move any air. The level of consciousness will be depressed. Bradycardia may develop because of hypoxia. Oxygenation may remain significantly low (SaO₂ less than 92% and PaO₂ less than 60 mm Hg) despite adequate supplementation (greater than or equal to 40% O₂).

It is important to remember that a child may present with symptoms from any and all of the mentioned categories, and symptoms thus do not always lend themselves to easy classification.

DIFFERENTIAL DIAGNOSIS

The clinician's careful history and physical examination can help locate from which part of the respiratory tract the symptoms originate. It is important to note that the term *reactive airways disease* refers to a group of conditions that affect the lower airways. Generally, the diagnosis of asthma can be made after documentation of three or more episodes of bronchodilator responsive bronchospasm.¹⁹

Cough or rattling chest sounds that could mimic asthma are most commonly heard with upper airway pathology. These sounds can occur in children with an upper respiratory infection and in older children and adolescents with allergic rhinitis and sinusitis. These conditions also can contribute to an asthma exacerbation. Similar sounds can be produced in infants with choanal atresia and in children with hypertrophy of the tonsils or adenoids. The examiner should especially be aware of the potential of foreign bodies in toddlers and young children.

Middle-airway pathology can not only cause cough, but also result in wheezing and chest sensations that a young or preverbal child may indicate to be chest pain. Stridor, which is an inspiratory sound, should not be confused with wheezing. Examples of conditions that produce stridor include croup, epiglottitis, and pharyngeal foreign bodies. Fortunately, epiglottitis in the post-*Haemophilus influenzae* vaccination era has become rare in children. Unfortunately, laryngotracheobronchitis ("wheezy croup") and tracheal foreign bodies can produce wheezing.

In infants, anatomic conditions that can cause cough and wheeze include laryngomalacia, tracheomalacia, tracheoesophageal fistula, and hemangiomas. Laryngeal webs, vascular rings, and slings are seen in older infants and toddlers. Vocal cord dysfunction is rare and usually seen in older children and adolescents. In all of these conditions, there is minimal, if any, improvement in symptoms with asthma therapy.

The lower airway causes of asthma-like symptoms are more difficult to differentiate from asthma. Cystic fibrosis can present with symptoms that initially respond well to asthma therapy. Children with cystic fibrosis can go on to develop digital clubbing, which is rarely seen with asthma. Now less common due to surfactant therapy, bronchopulmonary dysplasia can occur in ex-premature infants who required prolonged ventilatory support. Chronic aspiration and gastroesophageal reflux, which can exacerbate underlying asthma, can produce cough and wheezing on their own. Inhalation of chemical and toxic substances and foreign bodies must also be considered.

Viral bronchiolitis is a common cause of wheezing in children under 2 years of age, although viral infections can trigger wheezing in any age group. Bronchitis should be considered an adult or adolescent disease. *Chlamydia trachomatis* (infants under 3 months), pertussis (especially in infants under 6 months of age), pneumonia, and chronic *Chlamydia pneumoniae* in asthmatics can present like or worsen asthma.

Rare lower airway conditions to consider include complications of congenital cardiac conditions, alpha₁-antitrypsin deficiency, pulmonary hemosiderosis, and pulmonary eosinophilia (Löffler syndrome).

EMERGENCY DEPARTMENT EVALUATION

Determination of the severity of the attack is based on a rapid initial assessment that includes a brief history, directed physical examination, and baseline SaO₂ measurement, which should be done in a calm and reassuring manner. PEF₁ or FEV₁ should be obtained in all children 6 years of age and older ([Fig. 261.1](#)).

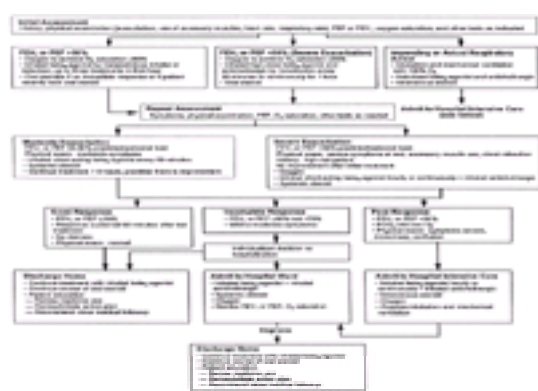

Figure 261.1. NHLBI ED/Hospital Care management algorithm. (Modified from National Heart, Lung, and Blood Institute, National Institutes of Health. *Expert panel report 2: guidelines for the diagnosis and management of asthma*. NIH Publication No. 97-4051, Bethesda, MD, 1997:112.)

The presentation and duration of symptoms and response to any therapy prior to arrival in the ED help determine whether the child is in LAR. Identifying contributing factors (e.g., fever, choking) assists in determining the need for ancillary tests or other therapy. The number and timing of similar episodes, prior ED visits and hospitalization (including intensive care unit admissions and the need for bilevel positive airway pressure [BiPAP] nasal mask ventilation and/or intubation), and medication history (including last exposure to systemic steroids) will reveal the severity and risk of the child's disease.

The physical examination should rapidly determine the child's work of breathing by evaluating the degree of breathlessness, use of accessory muscles and nasal flaring, and listening to breath sounds. Neurologic status is reflected by the degree of irritability and interaction with the examiner. Measurement of PEF₁ or FEV₁ allows objective monitoring of lung function. It should be expressed as a percentage of a predicted value based on height, age, and sex from any of several available tables. A better comparison is the child's own personal best value that was obtained during a symptom-free period.

Routine radiographs are not needed for the straightforward asthma attack that improves with ED treatment. Plain chest films should be considered if there is a fever or suspicion of pneumothorax or pneumomediastinum. Care should be taken not to "overread" the x-ray. Hilar prominence and patchy atelectasis are common findings and sometimes misinterpreted as pneumonic infiltrates. Inspiratory–expiratory (or left and right lateral decubitus in infants and toddlers) chest views showing unilateral hyperinflation are useful in evaluation for possible inhaled foreign bodies. Portable chest films are appropriate for any child who has a worsening of symptoms in the ED or is in impending respiratory failure. Children with chronic reoccurring exacerbations may benefit from sinus films to determine the presence of sinusitis. An untreated or undertreated sinusitis may be causing the reoccurrences. Upper airway radiographs should be obtained if middle airway pathology is suspected.

The use of pulse oximetry and noninvasive end-tidal CO₂ monitors has diminished the need for arterial and capillary blood gases. Blood gases are indicated for patients who have persistent hypoxia on greater than 40% O₂, elevated end-tidal CO₂ trends, or impending respiratory failure or arrest. A serum level should be obtained for all patients taking theophylline. Routine complete blood counts or electrolyte determinations generally do not provide useful information in uncomplicated

asthma attacks.

Clinical asthma scores (CAS) are an additional method of monitoring the child's progress in the ED. Many CAS have been developed over the years and are variations and improvements of the Wood-Downes-Lecks respiratory failure score.²⁰ An ED can develop and validate a simple scoring system based on the current National Heart, Lung, and Blood Institute (NHLBI) guidelines.

EMERGENCY DEPARTMENT MANAGEMENT

Beta-Agonists

Inhaled, intermediate-acting beta-agonists (albuterol, terbutaline, biosterol, pirbuterol) are the mainstay of acute asthma therapy. The inhaled medications are preferred because they have been shown to be more effective and have fewer side effects than their oral or parenteral counterparts.^{2,11,15} Children respond better to aggressive high-dose albuterol therapy than do adults. There is a significant relationship between albuterol dosing and improvement in pulmonary function.¹³ Higher and more frequent administration also leads to greater bronchodilatation.¹⁸

The initial dosage of albuterol is 0.15 mg/kg (2.5 mg minimum) by oxygen-powered nebulizer. This dose may be repeated at 20-minute intervals during the first hour, as indicated by the patient's response. Subsequent doses at 0.15 to 0.3 mg/kg (10 mg maximum) may be given every 1 to 4 hours, depending on the child's response. Children with moderate-to-severe exacerbations may benefit from continuously nebulized albuterol.¹⁴ The dosage is 0.5 mg/kg/h (7.5 mg minimum) or the equivalent of three intermittent treatments over 1 hour. This may be repeated in severe attacks or impending respiratory failure.

A metered-dose inhaler (MDI) with spacer has been shown to be equivalent to nebulized albuterol in mild-to-moderate exacerbations.⁹ Four to eight puffs (each puff taken at 30- to 60-second intervals) of albuterol, pirbuterol, or biosterol are taken every 20 minutes, as needed, in the first hour. The dose may then be repeated every 1 to 4 hours, as needed, while the patient is in the ED.

Subcutaneous injections of epinephrine or terbutaline have no advantage over the inhaled beta-agonists. Their use should be limited to those patients with very poor air exchange. The dose for terbutaline (1 mg/mL) and epinephrine (1:1000 solution) is the same: 0.01 mL/kg (0.1 mL minimum, 0.3 mL maximum). This may be repeated at 15- to 20-minute intervals to a maximum of three doses.

There is no intravenous beta-agonist approved in the United States. The injectable preparation of terbutaline has been used for children with impending respiratory failure.⁸ A loading dose of 10 µg/kg is given over 10 minutes, followed by a maintenance infusion of 0.4 µg/kg/min. The dose is titrated in increments of 0.2 µg/kg/min until desired respiratory effects are achieved or unacceptable tachycardia occurs. The usual effective dose is 3 to 6 µg/kg/min. The most common side effects of beta-agonists, tremors and tachycardia, are dose related.

Ipratropium

Ipratropium bromide is a quaternary ammonium derivative of atropine. This greatly diminishes its systemic absorption and side effects. By itself, ipratropium has a relatively long onset but a prolonged duration of action when compared with the beta-agonists. Its anticholinergic activity does provide an additional mechanism of bronchodilation. When given with albuterol, there appears to be greater improvement in pulmonary function than when the same medications are given individually.¹⁶ This appears to be especially true for children with moderate-to-severe attacks.¹⁷ Also, because cough is more a large-airway (rich in cholinergic innervation) function, this medication may be of benefit when there is a significant cough component.

The dose for ipratropium is 0.25 mg for infants and 0.5 mg for older children and adolescents. It may be repeated at 20-minute intervals during the first hour and is mixed in the same nebulizer with the albuterol. Repeated doses are given every 2 to 4 hours. Add 0.5 to 1.0 mg to any continuous albuterol treatment.

Corticosteroids

Systemic corticosteroids are important in controlling LAR. They also decrease the relapse rate during the first week after an asthma exacerbation. Oral and parenteral forms appear equally effective. The onset of antiinflammatory activity is approximately 4 to 8 hours;^{16e} however, corticosteroids appear to upregulate the beta receptors in about 1 hour.⁴

Oral prednisone, prednisolone, or methylprednisolone, 1 to 2 mg/kg (60 mg maximum), should be given within the first hour of ED arrival to children with moderate-to-severe attacks. If the child is unable to tolerate oral medications, then 1 to 2 mg/kg (120 mg maximum) of methylprednisolone intravenously, or 0.15 to 0.6 mg/kg (30 mg maximum) of dexamethasone intramuscularly, may be given. There may be no benefit in using corticosteroids in children with EAR. The oral and intravenous doses may be repeated every 6 hours, up to 48 hours. The higher dose of intramuscular dexamethasone will provide 2 to 3 days of corticosteroid coverage.

Oxygen

Any child with significant respiratory distress will benefit from oxygen, even with a normal SaO₂. Low-flow oxygen (1 to 2 L/m) by nasal cannula is usually sufficient. Warm, humidified oxygen is preferable because dry oxygen can irritate the respiratory tree. High-flow oxygen should be administered via a non-rebreather mask whenever the child is hypoxic.

Alternative Therapies

For the child with a severe asthma attack or impending respiratory failure who is not responding to conventional treatment, there are limited alternatives. BiPAP has been shown to be of benefit in children with moderate hypoxia as an alternative to intubation.⁶ The use of Heliox, Ketamine (1 mg/kg IV loading dose and a maintenance drip at 0.5–.75 mg/kg/hr.), and magnesium sulfate (25 mg/kg intravenously; max, 2 g) remains controversial. There are some subgroups of patients who may benefit from these alternatives. Theophylline is no longer considered first-line therapy for an acute asthma attack.

Antibiotics

There is no benefit to the routine use of antibiotics in the management of an acute asthma attack. They should be used when findings are consistent with pneumonia or other clinical bacterial infection. Therapy is directed to the most likely organism (see [Chapter 288](#)).

DISPOSITION

Patient disposition depends on the severity of the attack, response to treatment, and contributing risk factors. It is important that the patient be reassessed after initial therapy and observed for an appropriate period of time for relapse while in the ED.

A child who has had a mild attack, required no more than one or two albuterol treatments, and whose PEF_r or FEV₁ was not less than 70% may be sent home after a short (30-minute) observation period. All other patients should be observed for at least 1 hour for signs of relapse. Patients with an incomplete or poor response to therapy should be considered for admission. The decision to watch a patient in an observation unit or an inpatient ward is dependent on local policy and capabilities. Children presenting in impending or actual respiratory failure or who have deteriorated in the ED should be admitted to a pediatric intensive care unit.

Discharged children should be sent home with inhaled beta-agonists (albuterol, pirbuterol, biosterol) if they do not already have the medication. Normal oxygen saturation and a respiratory assessment should be documented at time of discharge. An MDI and appropriate spacer (with or without a mask) can be used in children as young as 1 month of age. Older children and adolescents can use an MDI with autoactuator or dry powder inhaler. The initial MDI dose is two to six puffs (separated by 1 minute) every 3 to 4 hours for the first 24 to 48 hours following ED treatment. For patients with a home nebulizer, the dose is 2.5 mg per treatment. The patient should be weaned as rapidly as possible to four times a day, with rescue use up to every 3 to 4 hours, as needed. A good rule of thumb is to use this

intensive course of beta-agonist for as long as the patient is taking corticosteroids (3 to 14 days).

Children respond well to short courses ("bursts") of corticosteroids and generally do not need to be "weaned" from the systemic steroid effects. The dose of prednisone, prednisolone, or methylprednisolone is 1 to 2 mg/kg (60 mg maximum) in one or two divided doses. The length of treatment is a 3- to 7-day course, depending on patient's severity and rapidity of response. Use a tapering dose if the child has taken systemic corticosteroids in the previous 30 to 60 days, has had three bursts in the past 6 months, or has had four bursts in the past 12 months. The taper should be over 7 to 14 days. Because of the potential risk of disseminated disease and death, the risks of using systemic (not inhaled) steroids in children with active varicella must be carefully weighed against the benefits. In some cases, it is appropriate to start preventative therapy with inhaled corticosteroids on discharge from the ED.

Children should be sent home with an asthma plan that details what treatment the patient received and how they should manage continuing problems at home. Children 6 years old and older should be sent home with a PEFR meter. The PEFR is done two to four times a day, and the results used to trigger part of the action plan (Fig. 261.2).

Figure 261.2. NHLBI ED/Hospital Care asthma action plan form. (Modified from National Heart, Lung, and Blood Institute, National Institutes of Health. *Practical guide for the diagnosis and management of asthma*. NIH Publication No. 97-4053, Bethesda, MD, 1997:45.)

All children who have an ED visit for asthma exacerbation should be referred back to their primary care physician or specialist for follow-up. At a minimum, the parent should make phone contact within 24 hours of discharge to advise the physician of the child's progress.

COMMON PITFALLS

- Failure to provide early, aggressive treatment can lead to unnecessarily prolonged ED care or hospitalization.
- Failure to educate parents and children about potential triggers and how to avoid them. Smoking is a significant environmental trigger and is potentially harmful to the child, even if the parent "smokes outside."
- Do not use the term *reactive airway disease* or *bronchitis* if the child has asthma. They are different entities. If the child has not been diagnosed with asthma, then use symptom- and complaint-based terminology (e.g., wheezing, shortness of breath, respiratory distress).
- Asthma is an inflammatory disease. Viral infections are an important trigger. There is no need to routinely use antibiotics unless there is a bacterial focus of infection.
- Corticosteroids are like any other medication with appropriate and inappropriate uses. Not every child who comes to the ED with an asthma attack needs corticosteroids.
- Send the patient home with a written action plan. It can provide guidance and help avoid an unnecessary ED visit.

[Chapter References](#)

Bleeding disorders in children arise from defects in either the cellular (platelet) or humoral components of the coagulation system. These defects, congenital or acquired, may be either qualitative or quantitative in nature. The most common bleeding disorders in children are immune thrombocytopenic purpura, von Willebrand disease, and the hemophilias.

IMMUNE THROMBOCYTOPENIC PURPURA

Immune thrombocytopenic purpura (ITP) is an acquired syndrome characterized by thrombocytopenia, without abnormality in other cell lines, caused by the immune-mediated destruction of circulating platelets, primarily in the spleen. About 85% of cases in children are acute, lasting less than 9 months; the rest are chronic, lasting variable periods. Patients with ITP soon exhibit rapid clearance of circulating platelets, resulting in severe thrombocytopenia, despite increased platelet production in the bone marrow.

ITP may occur at any age, but the typical child is 2 to 6 years old. Prepubertal children are more likely to have the acute form than are postpubertal children.

CLINICAL PRESENTATION

The classic presentation is that of an otherwise healthy child with a recent viral syndrome noted to have an acute onset of petechiae and ecchymoses. Apart from the bleeding diathesis, the history and physical examination are normal; in particular, there is no history of significant fever, weight loss, bone or joint pain, or anorexia. The physical examination reveals no significant adenopathy, hepatosplenomegaly, or masses. Bruising can range from rare scattered petechiae to severe, diffuse ecchymoses. Bleeding in the oral mucosa and other mucous membranes is also seen.

Occasionally, gastrointestinal (GI) or renal bleeding or, rarely, intracranial bleeding is seen. The key element in the laboratory evaluation of ITP is the lack of any hematologic abnormality other than severe thrombocytopenia. Anemia secondary to bleeding (e.g., GI or renal) is occasionally seen.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a child who, on a physical examination, is normal, except for the presence of petechiae and ecchymoses, should include child abuse; bone marrow failure (aplastic anemia); bone marrow replacement, as in acute lymphoblastic leukemia or metastatic neuroblastoma; sepsis; and disseminated intravascular coagulation. Children with organomegaly or involvement of more than one hematologic cell line must be more extensively evaluated.

EMERGENCY DEPARTMENT EVALUATION

Evaluation should include a thorough physical examination, with close attention to detecting hepatosplenomegaly, significant lymphadenopathy, or soft-tissue or intraarticular bleeding. Any of these findings warrants a complete hematologic evaluation. Laboratory evaluation should include a complete blood count with manual differential, platelet count, reticulocyte count, and careful morphologic review of the Wright-stained smear. Most children with ITP have profoundly low platelet counts (usually less than 20,000/ μ L). Large (young) platelets are often observed on the peripheral smear. Any evidence of abnormality in another hematologic cell line (red or white cell) without obvious explanation necessitates a hematologic consultation.

The optimal evaluation of the child with ITP remains controversial. Anything in the history, physical examination, or laboratory studies inconsistent with ITP necessitates a full evaluation, including bone marrow aspiration or biopsy. Many hematologists perform these tests on all patients to confirm the diagnosis and to allay fears of a misdiagnosis.

EMERGENCY DEPARTMENT MANAGEMENT

ITP may be treated expectantly or with intravenous gamma globulin (IVIG), prednisone, or, in rare refractory cases (life-threatening emergencies), splenectomy. Because most children do not experience severe or life-threatening bleeding despite nearly undetectable platelet counts, a growing number of hematologists are treating these children expectantly. Most hematologists recommend treatment with immunosuppression, either IVIG or corticosteroids, for children with platelet counts below 10,000/ μ L, associated with moderate-to-severe bruising.

IVIG has the advantage of rapid onset, relatively few side effects, and minimal effect on other hematologic cell lines. The major disadvantage of IVIG is its expense. It may be given as a single dose (1 g/kg intravenously over 4 to 6 hours) or given over several days (250 mg/kg/dose intravenously over 4 to 6 hours daily for 4 days).^{1,2,7,9} IVIG is preferred if the bone marrow cannot be examined before beginning therapy.

Corticosteroids (prednisone, methylprednisolone) are also effective in producing a prompt rise in the platelet count. They should be avoided if a definitive diagnosis has not been made. Patients with acute lymphoblastic leukemia may be placed in a temporary remission with prednisone alone. A typical course of prednisone is 2 to 4 mg/kg/d orally, in two or three divided doses for 4 days, followed by 1 to 2 mg/kg/d, in divided doses, to complete a 14-day course.

Intraoral bleeding is usually not a significant problem in children with ITP, but in the case of a child with thrombocytopenia and gingival hemorrhage, the use of topical collagen (INSTAT) is reportedly an effective means of control.^{8,10} Splenectomy is reserved for refractory chronic ITP and rare life-threatening bleeding, particularly intracranial hemorrhages. Clamping the splenic pedicle is associated with an almost immediate increase in the platelet count.

DISPOSITION

Role of the Consultant

In the initial management of the child with suspected ITP, the physician's role is to rule out other etiologies, such as marrow failure or replacement. A pediatric hematologist should promptly evaluate any child with abnormalities of the history, physical examination, or laboratory studies inconsistent with a diagnosis of ITP.

Indications for Admission

Once a diagnosis is established, the patient may be managed by the primary care physician and hematologist in either a clinic or an inpatient setting. Most patients can be managed primarily on an outpatient basis. Admission is indicated if there are clinical features suspicious for child abuse or suggestive of another hematologic disorder. Admission is also indicated if there is evidence of severe bleeding, or if reliable outpatient follow-up is problematic. In general, these patients may be managed on general pediatric floors.

Transfer Considerations

The rare patient with severe bleeding may require more intensive monitoring. The patient should be transferred if the initial center does not have pediatric hematology support. The skill level of the transport should be dictated by the severity of the bleeding, which is usually minor.

VON WILLEBRAND DISEASE

Von Willebrand disease (vWD) is a relatively common (1% of population) congenital coagulation defect. Inherited, most commonly, in an autosomal dominant fashion, it is caused by deficient, defective, or absent von Willebrand factor (vWF). vWF is a high-molecular-weight multimeric coagulation factor with a primary role in platelet adhesion to vascular surfaces.

There are several variants of vWD. Type I vWD, the most common form, is caused by deficient production of normal vWF. Type 2 vWD is associated with production of an abnormal vWF, resulting in impaired function. Type 2A is associated with an abnormal isotype that has decreased platelet adhesion. Type 2B is associated with an abnormal vWF that tightly binds to platelets and may produce thrombocytopenia. Type 2N (type 2 Normandy) is a rare form of vWD in which the binding site for factor VIII is dysfunctional, with a resulting phenotype similar to classical hemophilia. Type 3 vWD is the complete absence of circulating vWF in a patient with homozygous disease (from two affected parents), and is clinically most severe.

CLINICAL PRESENTATION

vWD causes an abnormality of platelet adhesion to vessel walls, producing a delay in the formation of the hemostatic platelet plug. The clinical presentation is prolonged mucocutaneous bleeding (e.g., nosebleeds, excessive bleeding from sites of dental extractions, prolonged menstrual bleeding, petechiae, excessive bruising). vWF also stabilizes the factor VIII molecule; therefore, a severe (homozygous) deficiency of circulating vWF may result in a deficiency of factor VIII procoagulant, producing soft-tissue and joint bleeding similar to that seen in hemophilia. Symptoms of this disease are variable in any given patient.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes platelet defects, either qualitative or quantitative in nature, and abnormalities of the humoral coagulation system, such as hemophilia. A history of a variable bleeding tendency suggests vWD. Because the inheritance of vWD is autosomal dominant, women are also clinically affected.

EMERGENCY DEPARTMENT EVALUATION

The initial evaluation of a patient with known vWD who is actively bleeding should focus on determining, from the patient or records, the type of vWD present in order to plan appropriate therapy. Laboratory evaluation of a newly diagnosed patient would include a platelet count, prothrombin time (PT) and partial thromboplastin time (PTT), factor VIII level, factor VIII-related antigen ([FVIII Rag, von Willebrand antigen] the antigenic measure of the vWF), and a ristocetin cofactor ([RcoF] a measure of vWF activity). Studies of vWF multimers may be needed to further classify the type of vWD, and will almost certainly necessitate consultation with a hematologist.

EMERGENCY DEPARTMENT MANAGEMENT

The management of the bleeding patient with vWD centers on raising the circulating level of vWF to hemostatic levels. Depending on the type and severity of the patient's vWD, several options are useful. For patients with mild-to-moderate type I vWD, DDAVP (0.3 µg/kg) infused over 30 minutes is often effective in controlling bleeding. Intranasal DDAVP (Stimate) may be used to treat minor bleeding in those patients known to respond to this preparation. For patients with severe type I, type 2B, or type 3, DDAVP should be avoided, and factor replacement using cryoprecipitate (0.2 U/kg) or intermediate purity FVIII concentrates (such as Humate-P or Koate-HP) should be pursued. These factor concentrates are dosed according to guidelines for hemophilia A ([Table 262.1](#)). If the type of vWD is unknown, the patient should be managed using factor replacement therapy. If the diagnosis of the factor deficiency is uncertain, consultation with a hematologist is indicated for proper planning of factor replacement.

Site	Factor VIII (U/kg)	Factor IX (U/kg)
EXTREMITY		
Muscle	20-30	30
Joint	30	30
ABDOMEN		
Bladder	30	30-40
Intrabdominal	40	50
CHEST		
Chest wall	30	30
Intrathoracic	50	50-70
HEAD/NECK		
Intracranial	50	50-70
Artery	50	50-70
Mucous/mucosa	30	30

Note: Subsequent therapy should be coordinated with the patient's hematologist. Bleeding in soft tissues that occurs on a major intramuscular site/arm of the arm should be treated with 50 U/kg of the appropriate factor.

TABLE 262.1. Emergency Factor Dosages for Bleeding Episodes in Hemophiliacs

DISPOSITION

The role of the emergency physician in the treatment of acute bleeding in patients with vWD is principally limited to ongoing therapy and the treatment of patients who develop soft-tissue or joint bleeding. Patients who develop such a bleed should be referred to an experienced center for follow-up. Patients with type 2B vWD may develop thrombocytopenia if given DDAVP. These patients have a more complicated course and should be referred to an experienced hematologist.

HEMOPHILIA

Hemophilia A (factor VIII) and hemophilia B (factor IX) are X-linked recessive congenital deficiencies of circulating coagulant factors. The incidence of factor VIII deficiency is one in 100,000 White males and accounts for 85% of hemophilia cases; factor IX deficiency accounts for most of the rest. Factor VIII deficiency has a

high incidence of spontaneous mutation, with about 30% of cases arising *de novo*. Both diseases are classified into three severity groupings according to the circulating level of factor. Severe disease is defined as less than 1% of normal activity (normal range, 50% to 150%); moderate disease, 1% to 5%; and mild disease, 5% to 30%.

CLINICAL PRESENTATION

The clinical presentation varies with the severity of the deficiency. Severe hemophilia may be diagnosed soon after birth, with intracranial bleeding associated with difficult labor or excessive bleeding from circumcision or other bleeding sites.

After the neonatal period, the typical patient is spared significant bleeding problems until toddler age, when the child begins walking (and falling). Even at this age, the diagnosis may not be obvious. Patients with a severe deficiency of either factor are prone to spontaneous bleeding in muscles and joints, body cavities, and the head and neck. Moderate hemophiliacs may experience excessive bleeding due to trauma or surgery, but they experience spontaneous bleeding episodes less frequently.^{3,5,10} Mild hemophiliacs may often go undiagnosed until they require surgery or suffer major trauma, at which time they will have excessive bleeding.

EMERGENCY DEPARTMENT MANAGEMENT

The two principal goals are stabilization and protection of normal function, and prompt hemostasis. A patient with a life-threatening bleed is treated promptly with factor concentrates to restore normal hemostasis.

Bleeding may occur at any site, but some sites are of greater concern. Bleeding in the head and neck area is emergent if it encroaches on either the intracranial space or the airway. Intracranial bleeding is most often manifested by headache and vomiting, and it occurs spontaneously in 60% of cases. Intracranial bleeding is most common in children, with 50% of all bleeding episodes occurring in boys less than 10 years old, and 75% in boys less than 20 years old. The mortality rate may reach 30%, depending of the site of bleeding.¹² Human immunodeficiency virus (HIV) infection should not be blamed for any mental status changes seen in an HIV-infected hemophiliac until a hematoma or other space-occupying lesion has been ruled out.¹

Other areas of the head and neck region may be the site of an emergent bleed, especially if the bleed may encroach on the airway. Areas of particular concern are the posterior half of the oropharynx, the tongue, the soft tissues of the anterior triangle of the neck, and the retropharyngeal space. Any bleeding or mass in these areas must be considered as potentially life-threatening and treated aggressively. After initial treatment with factor VIII or IX at 50 U/kg, to achieve levels approaching 100% activity, and the patient is stabilized, he should be transferred to a center experienced in the care of hemophilia.

Less emergent sites of bleeding in the head and neck include lip lacerations and dental extraction sites. Usually, these are successfully treated with 20 to 30 U/kg of clotting factor, with additional antifibrinolytic therapy to combat the fibrinolytic effect of saliva and to stabilize the clot. Tranexamic acid (4.8% aqueous solution) may be used as a mouth rinse. Epsilon-aminocaproic acid (Amicar) is also useful (100 U/kg orally every 6 hours for 7 days). These bleeding episodes generally resolve without incident, but close follow-up should be arranged, as blood may dissect between soft-tissue planes to cause compartment compression if bleeding is not well controlled.

Abdominal bleeding usually presents as vague abdominal discomfort, although if presentation is delayed, a palpable mass may be noted. Bleeding in the abdomen requires a high level of factor replacement and is generally treated with 40 U/kg of factor VIII replacement product or 50 U/kg of factor IX replacement product. Factor replacement is required for several days, and subsequent therapy should be coordinated with the patient's hematologist. Occasionally, patients develop painless hematuria not related to trauma, inflammation of the kidney, or renal calculus. Once other causes are ruled out, hydration and observation are generally sufficient treatment.⁹

Bleeding in the retroperitoneum is most commonly located in the iliopsoas muscle. The classic clinical presentation is a combination of severe acute back pain and the inability to extend the hip on the affected side due to pressure on the muscle body from the evolving hematoma. This is generally treated with 30 U/kg of either factor VIII or IX. Unlike other sites of bleeding in the musculoskeletal system, these bleeding episodes frequently require several days of factor replacement, as well as narcotic analgesia.

Bleeding into the joints (hemarthrosis) is the most common bleeding problem seen in hemophilia. Early treatment with clotting factor and local measures, such as ice packs, rest, and immobilization, typically result in resolution within a couple of days. Delay in factor replacement results in more bleeding into the joint space and the potential development of a so-called target joint. Leukocytes produce greater damage to the synovium, resulting in synovial hypertrophy. The resulting spongy synovium is more prone to additional bleeding. Hemophiliacs may thus develop target joints that bleed more frequently than others. The clinical presentation of a hemarthrosis is warm, painful swelling of the joint, with limited range of motion. Erythema may accompany the swelling if considerable inflammation is present, although erythema is generally not prominent. These bleeding episodes are treated with 20 U/kg of factor VIII (same dose for factor IX). Subsequent factor replacement may be needed to control severe bleeds. Factor VIII is usually given at 20 U/kg every 12 hours for 2 to 3 days, and factor IX at 20 U/kg daily for 2 or 3 days. Ice, compression, elevation, and rest are also important in treatment.

Intramuscular bleeding is the second leading cause of long-term disability, after hemarthrosis. Delayed or insufficient replacement therapy may result in a hematoma with compartment compression and subsequent injury. The usual clinical presentation is swelling and pain over a muscle body. These bleeds are most common in the large muscles of the extremities, but they may occur in any muscle. They are treated with 30 U/kg of either factor VIII or IX. Subsequent therapy should be coordinated by a hemophilia center, and, generally, several days of factor replacement is required. Following hemarthrosis and hematoma formation, an aggressive physical therapy program should be encouraged, once the bleeding has resolved.

In patients with a mild deficiency of factor VIII, DDAVP (0.3 µg/kg intravenously over 30 minutes) is effective in controlling minor bleeds. It should not be used for life- or limb-threatening bleeding. Another contraindication is a bleed likely to require more than 3 days to resolve. The response to DDAVP diminishes over time. By 48 to 72 hours, many patients develop significant tachyphylaxis.¹² Intranasal DDAVP has also been found to be effective in patients with mild factor VIII deficiency.

Severe hemophiliacs have little or no circulating factor, and thus fail to develop immune tolerance to the factor in which they are deficient. About 15% of patients with severe hemophilia A develop an antibody to infused factor VIII, an inhibitor that negates the function of subsequently infused factor VIII. Inhibitors vary in titer and in affinity. Clinically, they may complicate therapy for bleeding episodes by neutralizing the replacement factor before hemostasis can be achieved. Patients with a previously undiagnosed inhibitor often present with a bleed unresponsive to the usual therapy. The diagnosis is made by measuring the titer of the inhibitor. Therapy for these patients, particularly those with high-titer inhibitors, is complex and requires an experienced center.⁴

COMMON PITFALLS

Bleeding disorders in children are a relatively uncommon problem in the emergency department. Failing to recognize some of the nuances of these diseases can lead to misdiagnosis and mistreatment. Knowledge of the following facts can help avoid errors.

- Children with significant adenopathy, organomegaly, or other abnormalities apart from their bleeding diathesis probably do not have ITP.
- ITP produces isolated thrombocytopenia; an unexplained abnormality of another cell line is inconsistent with the diagnosis of ITP.
- Half of all children with acute lymphoblastic leukemia have normal white cell counts, indistinguishable from a child with ITP.
- ITP produces a systemic decrease in platelet numbers. Bruises and petechiae occur in a widespread, symmetric, and random fashion. Child abuse usually results in bruises that are asymmetric and nonrandom and may form patterns, such as a belt mark.
- vWD patients often have a variable coagulopathy and may have an episodic bleeding history.
- Sixty percent of all intracranial hemorrhages in hemophilic boys occur spontaneously. Headache and vomiting are the most common symptoms.
- HIV infection may complicate bleeding in hemophilia due to HIV-induced thrombocytopenia.
- Mild hemophilia commonly is asymptomatic until excessive bleeding from an injury occurs. It should be considered in any boy who develops excessive or prolonged bleeding after an injury. Hemophiliacs with potentially life- or limb-threatening bleeds should receive factor concentrates before any imaging studies are done.
- Recombinant human factor VIII concentrates should be used preferentially in boys with hemophilia A, and ultrapure factor IX concentrates in boys with hemophilia B.

- If the specific factor deficiency is not known, fresh-frozen plasma (10 mL/kg, if tolerated) is the product of choice for factor replacement. Fresh-frozen plasma is also the product of choice for the treatment of rare clotting-factor deficiencies.
- DDAVP (0.3 µg/kg) is effective for the treatment of mild hemophilia A and mild type I vWD. It is not useful in severe deficiencies or in factor IX deficiency.
- DDAVP may be helpful in controlling excessive bleeding in patients with uremia and qualitative platelet disorders, but it is not helpful in treating bleeding due to thrombocytopenia.
- Intranasal DDAVP (Stimate) may be useful in controlling minor bleeding in suitable patients, but it should not be relied on for treatment of patients that have not been shown to respond to it previously, as the response rates differ for intravenous versus intranasal DDAVP.

[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Indications for Admission](#)
[Role of the Consultant](#)
[Transfer Considerations](#)
[Common Pitfalls](#)
[Chapter References](#)

Each epidemic season, the emergency physician is faced with evaluating and treating infants and young children with bronchiolitis and determining their disposition. Unlike children with reactive airway disease, their lower respiratory tract symptoms are caused by inflammation of the bronchiolar epithelium by an acute infection. The resultant necrosis of epithelium and plugging of the 75- to 300- μ m airways by cellular debris may result in air trapping or atelectasis distal to the obstruction. ¹ This lower airway pathology may manifest as tachypnea, wheezing, rales, increased work of breathing, and/or hypoxemia.

Respiratory syncytial virus (RSV) is probably the most important respiratory pathogen among young children and may cause serious morbidity and mortality. Over 50% of infants will acquire RSV infection during the first epidemic that they experience, and 40% will progress from upper to lower respiratory tract illness. One in ten infants will require hospitalization. The peak incidence of lower airway disease occurs in infants 2 to 5 months of age. ^{8,9,13} Two major subtypes of the virus, strains A and B, circulate concomitantly, with one predominating during a given season. Subtype A is more commonly associated with more severe disease. ¹⁶ Children in the first few months of life, those with a history of prematurity, children with congenital heart disease (CHD), especially uncorrected pulmonary hypertension, and those who are immunosuppressed or have chronic lung disease are most at risk for severe disease and death. ^{6,11,15,22} Although RSV is the most common pathogen, other viruses, such as parainfluenza, influenza, adenovirus, and rhinoviruses, may cause bronchiolitis. ^{9,13}

CLINICAL PRESENTATION

The presentation of the infant or young child with bronchiolitis ranges from the smiling, interactive child with mild tachypnea and end-expiratory wheezing to the child who presents with severe respiratory distress or failure. Typically, there is a several-day history of upper respiratory tract symptoms of coryza and congestion before the onset of lower respiratory tract symptoms. The parent may have noted that the child started with a cold and now is not as active, is breathing faster, and has difficulty feeding. Although most have tachypnea, cough, wheezing, and increased work of breathing, the young infant may present with lethargy or irritability, apnea or tachypnea, and have few lower respiratory findings. ^{10,22} Fever is often present early in the course of the illness, but may be absent or low grade at the time that lower respiratory tract symptoms manifest. Once lower respiratory tract involvement occurs, it usually progresses and peaks within 3 to 5 days. However, resolution of symptoms, including cough, wheezing, and some degree of hypoxemia, may take days to weeks.

DIFFERENTIAL DIAGNOSIS

Because bronchiolitis is so endemic during the winter months, the emergency physician must remember to consider other causes of acute onset of lower respiratory tract distress in infants. Congestive heart failure in the infant is often thought initially to be bronchiolitis during epidemics, as the infant may present with a history of poor feeding and tachypnea, rales, and wheezing on examination. Congenital lesions compromising the airway, such as vascular rings, slings, or teratomas, may appear to have acute onset. Aspiration from gastroesophageal reflux or tracheoesophageal "H-type" fistulas should cause symptoms around feeding. Congenital infections such as chlamydia pneumonia are prevalent throughout the year. Community-acquired bacterial pneumonia should also be considered in children of all ages. Foreign-body aspiration should also be suspected in young children.

In older infants and children, it is often difficult to distinguish bronchiolitis from asthma or reactive airway disease. The first episode of wheezing with upper respiratory tract symptoms in the young child should be considered bronchiolitis. Children with prior episodes of wheezing responsive to bronchodilator therapy, atopy, and a family history of asthma may have reactive airway disease. Repeat episodes of bronchiolitis are not uncommon, even with RSV. Additionally, infants who have had RSV bronchiolitis may be more prone to have repeated episodes of wheezing. ²³ Whether the viral infection causes pulmonary damage or immunologic changes or the child who develops lower respiratory tract illness has a predisposition to reactive airway disease is the subject of debate.

EMERGENCY DEPARTMENT EVALUATION

No single fact or finding during emergency department (ED) evaluation is sensitive enough to predict which child will develop severe disease. ^{18,22} A combination of historic, physical examination, and laboratory measures must be considered when determining risk for significant morbidity and mortality ([Table 263.1](#)). In taking a history, it is important to determine the gestational age at birth and whether there were any perinatal complications, such as bronchopulmonary dysplasia (BPD). Underlying diseases or anomalies such as congenital heart disease, cystic fibrosis, or immunodeficiencies may put the infant at increased risk. It is also important to determine whether the child is in the first few days of illness, in which the disease will continue to progress, or beyond the 3- to 5-day peak of illness. Social issues, such as the mother's ability to care for a sick infant or return if the disease progresses, are also important to evaluate.

Moderate Risk	High Risk
HISTORIC FACTORS	
Prematurity 34–37 wk Age < 3 mo First 3 d of illness	Prematurity < 34 wk History of cyanosis or apnea Underlying condition Pulmonary disease Congenital heart disease Immunodeficiency
PHYSICAL EXAMINATION FINDINGS	
General appearance: ill, not toxic Moderate accessory muscle use Respiratory rate: 60–70/min	General appearance: toxic Marked accessory muscle use Respiratory rate: >70/min
TESTING	
Oxygen saturation: 95%–96% Atelectasis on chest radiograph RSV infection, subtype A	Oxygen saturation: <95%
<small>Data from Fiksson et al.,²⁴ Green et al.,²⁵ Heller et al.,²⁶ McConachie et al.,²⁷ Quinlan et al.,²⁸ and Shaw et al.²⁹</small>	

TABLE 263.1. Risk Factors Associated with More Severe Disease

The overall appearance of the child is a sensitive indicator of disease severity. The child's respiratory rate, accessory muscle use for breathing, and air exchange are important to evaluate at presentation and after therapeutic trials. The infant's oxygen saturation, as determined by pulse oximetry, is the single most objective predictor of more severe disease and should be measured on all infants and children presenting to the ED with bronchiolitis. ²² Assessment of the child's hydration status by physical examination (moistness of mucous membranes, capillary refill at the fingertip, presence or absence of tears) should also be done, as many have a history of poor oral intake.

Radiographs are indicated in infants or young children with their first episode of wheezing or in children with high fever or severe disease. The majority of radiographs will show some degree of hyperaeration (flattening of the diaphragms on lateral view or increased radiolucency with small heart size on the anterior view) or

peribronchial thickening. Atelectasis or infiltrates occur in less than 10% of children presenting for outpatient evaluation. ²² Most areas of opacity represent atelectasis, but pneumonia cannot be excluded as a cause.

Evaluation of fever in infants less than 2 or 3 months of age should be done as per usual practice. For infants over 2 months of age with classic bronchiolitis, fever is unlikely to indicate serious bacterial illness and more likely to indicate early viral illness, pneumonia, or otitis media. ^{3,14} Therefore, routine culture of the blood or urine may be unnecessary. Complete blood cell counts are rarely useful. Microbiologic testing to determine viral etiology is indicated only for those with or at great risk for severe disease (BPD, CHD) or for cohorting purposes for hospital admission.

EMERGENCY DEPARTMENT MANAGEMENT

Children with moderate or severe respiratory distress should be allowed to assume a position of comfort, and 100% oxygen should be delivered. Suctioning of copious nasopharyngeal secretions may relieve some distress caused by airway obstruction. A trial of bronchodilators and/or racemic epinephrine should be delivered. Intubation is required for the child with severe respiratory distress not responding to these measures.

[Table 263.2](#) lists current treatment options for children with bronchiolitis. Most children presenting to the ED with bronchiolitis have mild or moderate severity of illness. Those with very mild disease require supportive therapy only. The use and effectiveness of bronchodilators such as nebulized albuterol is controversial. ^{5,12,17,21} A trial of two nebulized treatments of albuterol (0.15 mg/kg per dose) given 20 to 30 minutes apart is usually given to infants and young children with moderate-to-severe symptoms. Assessment for objective improvement in oxygen saturation, lowering of the respiratory rate, or improved aeration indicates response. For those without improvement, there is no need or benefit to continue further treatments. ⁵ Nebulized racemic epinephrine has been more effective than β_2 agonists in several clinical trials and may be tried for those who do not respond and will require hospitalization. ^{17,21} Cromolyn sodium and immunoglobulin therapies are used for preventive care and have no role in the ED. ^{2,20} Ribavirin, an expensive antiviral agent, is probably not effective and also has no role in the ED. ¹⁹ Steroids, either inhaled or oral, have not been proven to be effective. ⁴ They should be reserved for children who have reactive airway disease. Antibiotics are indicated only when a specific bacterial infection has been diagnosed or for neonates with fever. ⁷ Many children with bronchiolitis have or develop bacterial ear infections. ³

Therapy	Indications	Efficacy
Supportive nursing, fluid	Mildness of illness for mild or moderate bronchiolitis; suctioning prior to feeding helps infant to feed better.	Success of support therapy for a beneficial effect is unclear. ²²
Oxygen	Oxygen saturation < 95%.	Proven against hypoxia.
Antibiotics	Not indicated empirically or for treatment of bronchiolitis.	Use only for specific diagnosed bacterial infections, such as otitis media or pneumonia. ^{7,23}
steroids (oral or inhaled)	Not indicated for bronchiolitis.	Not proven to be helpful. ⁴
Bronchodilators	Not an exchange.	Undetermined; probably helps some children for a time, but not for all. ^{5,12,17,21}
β_2 agonists, anticholinergics	Respiratory rate > 60/min; marked work of breathing; Oxygen saturation < 95%.	Multiple clinical trials have shown effectiveness for moderate to severe disease. ^{5,12}
Racemic epinephrine	No response to trial of β_2 agonists and persistent or severe symptoms requiring admission.	Undetermined; not indicated in the ED. ^{17,21}
Cromolyn sodium	Not useful in the ED.	Probably not effective, even for those hospitalized for severe disease. ¹⁹
Immunoglobulin (IGIV) or palivizumab	For prevention only.	Proven to be beneficial in reducing hospitalization and severity of disease for infants who were premature or have bronchopulmonary dysplasia, not indicated for congenital heart disease. ²⁴

TABLE 263.2. Treatment Options

DISPOSITION

Indications for Admission

Most infants and children with bronchiolitis do not require admission. Clearly, those in respiratory distress or with hypoxia require intervention and admission. Among those with mild or moderate disease, no single factor can predict necessity for admission. ^{18,22} Children at high risk for developing more severe disease (see [Table 263.1](#)) should be considered for admission or close outpatient observation. Any child who is early in the course of the illness or has moderate severity of illness, not requiring admission, should have follow-up arranged in 24 hours.

Role of the Consultant

Children with underlying medical conditions should have their subspecialist physicians consulted about treatment and indications for admission. For example, the pediatric cardiologist can determine whether the child with congenital heart disease has significant uncorrected pathology putting them at higher risk. If the diagnosis of bronchiolitis is not clear, a pediatrician may offer further help with the differential diagnosis or workup.

Transfer Considerations

Children with respiratory failure requiring intubation should be transferred to a facility with a pediatric intensive care unit. Children with underlying medical conditions or at high risk for severe disease or mortality should also be transferred to a facility with pediatric subspecialists and a pediatric intensive care unit.

COMMON PITFALLS

- Failure to identify that the child is in the first few days of illness and may get progressively worse. These children who appear to have mild illness may progress over the next hours or days and require close outpatient follow-up. The caregiver should be given specific instructions of what to look for and when to return.
- Failure to identify that the child has an underlying condition or history of prematurity. It is important to ask and document whether the child has risk factors that put him or her at high risk for morbidity and mortality.
- Persistence in using bronchodilators despite no evidence of response. Less than half of infants with bronchiolitis will respond to bronchodilators. If they have mild disease, they should be sent home with symptomatic care instructions and follow-up arrangements.
- Failure to use pulse oximetry to identify children with hypoxemia. This is the most specific and objective indicator of more severe disease. Cyanosis detectable on physical examination does not occur until the oxygen saturation is less than 85%!
- Use of routine laboratory tests or radiographs. Evaluation of infants and young children with bronchiolitis should be tailored to the individual patient.

CHAPTER 264

Cellulitis

Christopher S. Kennedy and Madhumita Sinha

[Epidemiology](#)
[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Cellulitis is an acute inflammation of the skin and subcutaneous soft tissue that is commonly caused by bacterial infection. The age of the child, the history, and the location of the infection serve as important determinants of the most likely bacterial agent. Cellulitis may occur by local tissue invasion following minor skin breaks, by puncture wounds by an object or tooth, or from hematogenous dissemination of a pathogenic organism. More common in the pediatric population, periorbital and facial cellulitis occurs in children less than 5 years of age, and may be accompanied by fever and ill appearance. Unique to the newborn period is neonatal omphalitis (infection of the umbilicus and surrounding tissues).

In most instances, children with cellulitis recover uneventfully. However, the recent resurgence of invasive group A *Streptococcus* (GABHS) infection, characterized by necrotizing fasciitis, bacteremia, and toxic shock, reminds us that the potential for serious complications exists, and emphasizes the need for accurate diagnosis and appropriate management.

EPIDEMIOLOGY

During the course of normal play, children incur minor injuries with breaks of the skin. Any injury or skin opening that disrupts the protective barrier of the skin can serve as portal of entry for pathogens, most commonly GABHS or *Staphylococcus aureus*. Puncture wounds by a contaminated object such as a cat claw or a nail penetrating a tennis shoe may predispose to other causative pathogens, such as *Pasteurella* sp. and *Pseudomonas* sp., respectively. Likewise, animal and human bites result in an increased likelihood of *Pasteurella multocida* and *Eikenella corrodens* infections.

Omphalitis, or infection of the umbilicus, with accompanying erythema of the abdomen, is a diagnosis unique to the newborn period, usually occurring in the first few weeks of life. The cord stump may serve as a portal of bacterial entry for *S. aureus*, GABHS, group B streptococci, and gram-negative enterics.

The epidemiology of childhood facial cellulitis has changed dramatically since the introduction of *Haemophilus influenzae* type B (HIB) vaccine. HIB had been the cause of more than 50% of cases of facial cellulitis, but, in the postvaccine era, it has become a rare agent. Now, common organisms include GABHS, *S. aureus*, and *Streptococcus pneumoniae*. Facial and periorbital infections caused by HIB and *S. pneumoniae* usually spread by a hematogenous route, and hence can be isolated by blood culture.

Primary dental infection may lead to bacterial seeding of adjacent facial soft tissues by a variety of aerobic and anaerobic bacteria, such as *Bacteroides* and *Fusobacterium*.

Important preexisting conditions that may predispose to infections include other traumatic injuries, particularly crush injuries, preexisting vascular or lymphatic compromise, chronic cutaneous conditions such as eczema, and immunocompromised states. More recently, case reports of necrotizing fasciitis due to GABHS infection have indicated a predisposition for severe varicella infection.

CLINICAL PRESENTATION

The most reliable way to diagnose cellulitis is to recognize the characteristic clinical features: localized erythema, warmth, edema, and pain. Most often, cellulitis involves the extremities, usually the lower extremities in children. Demarcation between involved and adjacent normal skin may be indistinct. There may be associated lymphangitis, appearing as red streaks radiating from the margin of the lesion, and also enlargement and tenderness of regional lymph nodes. The white blood cell (WBC) count is usually normal. Children with cellulitis of an extremity may exhibit limitation of movement of the affected limb due to pain from the infection. In 10% to 20% of cases, cellulitis may be associated with fever and other systemic symptoms, such as chills, myalgias, malaise, and even emesis. When fever is present, a concomitant bacteremia should be presumed and leukocytosis expected.

Distinct clinical entities include erysipelas, periorbital cellulitis, omphalitis, and necrotizing fasciitis. Erysipelas, a more superficial cellulitis most often associated with GABHS infection, typically has very sharp, elevated margins that rapidly spread outward, with central clearing and tenderness to palpation.

Periorbital cellulitis, a form of facial cellulitis usually seen in children less than 5 years old, presents with swelling of the eyelids, erythema of a violaceous hue, normal eye movements, and absence of proptosis. Bacteremia and leukocytosis may be associated particularly with infection by *H. influenzae* or *S. pneumoniae* in as many as 90% of cases.

Omphalitis presents in the newborn as purulent, foul-smelling discharge from the umbilical stump and erythema of the abdominal wall. Associated fever, hypothermia, lethargy, and irritability may be seen late in the course. Laboratory studies such as a WBC count will be normal in early localized infections. The diagnosis of omphalitis can be challenging, because drainage and small areas of erythema may be present without true infection, and there are no definitive criteria. Suggestive findings include anterior abdominal erythema and circumferential erythema of the umbilicus. Infection is clearly indicated when induration and erythema of the anterior abdominal wall are present.

Deeper infections of the skin and soft tissues may include fasciitis, myonecrosis, and gas gangrene. Necrotizing fasciitis initially presents as a cellulitis, but the subsequent development of purpura, blistering, necrosis (manifested clinically by pain out of proportion to the cutaneous findings), and severe systemic toxicity with tachycardia, and even hypotension, suggest a more serious infection. The child may be lethargic, disoriented, and in profound shock.

DIFFERENTIAL DIAGNOSIS

Any tender, erythematous swelling of the skin and subcutaneous soft tissue may resemble cellulitis. Trauma, insect bites or stings, localized urticarial eruptions, swelling overlying a sprain or fracture, or a joint with septic arthritis may be mistaken for cellulitis. Mosquito bites may induce significant lymphedema surrounding the bite site, which develops over hours. The bites are usually described as itching rather than painful. Bee stings and spider bites may also cause significant lymphedema, warmth, and even tenderness, and they may be more difficult to distinguish from cellulitis.

“Popsicle panniculitis” can also mimic facial cellulitis. Thought to be a cold-induced histamine response from eating water ice, typically the skin involvement begins at the labial crease and spreads outward with a warm, mildly tender cheek. Insect bites and stings, panniculitis, and contusions all lack fever, a relatively common symptom of cellulitis. Localized, specific soft-tissue infections, such as folliculitis (infection of a pilosebaceous follicle), furuncles and carbuncles (deep follicular abscess, either solitary or multiple), impetigo (vesiculopustular lesion), ecthyma (ulcerated impetigo), and others, should be differentiated from cellulitis by their characteristic clinical appearances.

Extremity cellulitis, as mentioned earlier, may cause limitation of movement of the affected limb; for that reason, it may be difficult to distinguish from deeper tissue infection such as osteomyelitis or septic arthritis.

EMERGENCY DEPARTMENT EVALUATION

In most situations, diagnosis of cellulitis is made on clinical grounds. Blood culture and WBC count should be reserved for patients presenting with fever or associated systemic toxicity or for those who are immunocompromised. Certain clinical features are specific enough to make a reasonable etiologic assumption. Erysipelas, with its characteristic rapidly advancing, raised, sharply demarcated margin, is usually caused by GABHS. A bluish or violaceous discoloration of the area involved by cellulitis suggests infection by *H. influenzae* or *S. pneumoniae*.

With the reemergence of suppurative GABHS infections, it is important to distinguish early streptococcal necrotizing fasciitis from cellulitis, as fasciitis may require surgical debridement. Necrotizing fasciitis is characterized by diffuse swelling with extreme tenderness at the local site, followed by bulla formation with rapid purplish discoloration and extension into deeper fascial planes. Streptococcal toxic shock syndrome may be associated with necrotizing fasciitis in as many as 50% of cases.¹

Cellulitis in the buccal or perineal area that develops after a human or animal bite, or cellulitis in an area involving devitalized or necrotic tissue, should raise the concern for the anaerobic organisms *Bacteroides*, *Fusobacterium*, and *Clostridium*. Cellulitis caused by pet bites is often associated with *Pasteurella*. Cellulitis due to water-contaminated wounds is often caused by *Aeromonas* and *Vibrio* species. Severe systemic symptoms in any patients with cellulitis should suggest the possibility of concurrent bacteremia. Presence of immunocompromised states should alert the clinician to the possibility of atypical infectious agents as the etiologic agents of cellulitis.

In any patient with periorbital cellulitis, it is particularly important to rule out orbital cellulitis, a much more severe infection that may need surgical intervention. In a patient with orbital cellulitis, unlike periorbital cellulitis, the ocular movements are restricted and painful, and proptosis is usually present.

Although the combination of clinical features and epidemiologic considerations may suggest the etiology of cellulitis, definitive bacteriologic diagnosis requires isolation of the causative organism. In the past, because of the high prevalence of bacteremia with *H. influenzae*, blood cultures were routinely done in children with cellulitis. In the post-HIB vaccine era, however, the association of bacteremia with cellulitis in children has reduced dramatically, and recent studies indicate that the practice of obtaining blood cultures routinely may not be cost effective.^{5,6} Of note, positive blood cultures are most commonly associated with younger age, active varicella, and soft-tissue infections such as osteomyelitis or septic arthritis.

Needle aspiration of the cutaneous inflammatory lesion, accompanied by prompt Gram stain and culture, is a rapid and specific tool to establish a bacteriologic diagnosis. Aspiration is performed by inserting a 22-gauge needle attached to a 1-cc syringe into the advancing edge of the cellulitis. If no material is aspirated, 0.1 mL of normal saline may be injected in to the area, followed by immediate aspiration. The yield of needle aspiration, however, is modest; a positive aspiration rate in different studies varies from 5% to 50%.⁴

If underlying deeper trauma or infection is suspected, appropriate imaging should be done. In a patient with severe periorbital cellulitis, a computed tomography scan is recommended if orbital involvement is suspected or cannot be excluded by examination of the eye, and if inflammation progresses despite optimal antibiotic treatment.³

EMERGENCY DEPARTMENT MANAGEMENT

Application of warm compresses to the affected area, elevation of the affected limb, and bed rest are often useful. Analgesics may be needed for control of pain. Antibiotic therapy, in most cases, except in the mildest form of cellulitis, is warranted. Given the low yield of microbiologic workup, in most situations antibiotic therapy is empirical but should be based on sound clinical judgment.

Hospital admission and parenteral antibiotic therapy should be strongly considered in any febrile child with cellulitis. All neonates with suspected omphalitis should be promptly admitted and started on parenteral antibiotics. In infants less than 3 months of age, cellulitis is commonly caused by group B streptococcus and should be treated with parenteral penicillin along with an aminoglycoside and hospital admission. Between 3 months and 3 years of age, *H. influenzae* and *S. pneumoniae* are the likely organisms, and third-generation cephalosporins (ceftriaxone or cefotaxime) should be administered. Some 10% to 40% of *H. influenzae* isolates are resistant to ampicillin, which should not be used alone. Ampicillin with a beta-lactamase inhibitor such as clavulanic acid may be used instead.

Erythromycin also is not appropriate for treatment of cellulitis. Beyond age 3 years, patients with well-localized cellulitis and without fever or systemic toxicity may be treated on an outpatient basis with an antistaphylococcal oral antibiotic, including penicillinase-resistant penicillin or newer cephalosporins such as cefuroxime. Ceftriaxone, with its once-a-day intramuscular dosing, may also be used in appropriate patients.

Any patient with cellulitis who shows severe systemic toxicity or does not improve within 48 hours of oral antibiotic therapy should receive high-dose intravenous broad-spectrum antibiotic therapy covering both streptococci and staphylococci. Patients suspected of a severe infection with GABHS, such as fasciitis, may need parenteral clindamycin in addition to penicillin, a surgical consultation, and close monitoring for signs of shock.

Patients who respond promptly to parenteral antibiotics may be changed over to oral antibiotics, but, in most cases of cellulitis, total duration of therapy should be at least 7 days. Patients with immunosuppressed conditions often develop cellulitis caused by atypical organisms, *Corynebacterium*, *Pseudomonas*, atypical mycobacteria, and even fungi. A microbiologic diagnosis should be vigorously pursued in these patients, particularly when initial empirical therapy fails to show any response.

Complications of cellulitis usually develop from extension of infection to deeper underlying tissue, often resulting in osteomyelitis or arthritis. Septicemia may develop in patients with severe, suboptimally treated infections, and meningitis, arthritis, endocarditis, or other metastatic complications may develop. Immunocompromised patients and younger patients are at the greatest risk for such complications. Patients with cellulitis involving the dangerous area of the face are susceptible to the complication of cavernous sinus thrombosis.

DISPOSITION

All infants younger than 6 months old who have cellulitis should be admitted, as should patients who appear to be toxic and have severe systemic symptoms and those who are immunosuppressed. Patients with facial cellulitis and a fever of more than 38.5°C and patients with extremity cellulitis and a fever of more than 38.5°C and a WBC count of more than 15,000/mL should be admitted. All other patients with cellulitis may be started on antibiotics on an outpatient basis, with follow-up arranged at 48-hour intervals. The recommendations for hospital admission are essentially based on the risk of bacteremia associated with cellulitis and the consequent need for intravenous antibiotics. However, with the decreasing incidence of *H. influenzae* cellulitis and associated bacteremia and the availability of potent oral antibiotics, more and more patients with cellulitis will probably be managed as outpatients in this age of managed care and cost containment.

COMMON PITFALLS

- With the recent increase in invasive GABHS infections, early recognition is important, as it may drastically change management.
- Orbital cellulitis should always be considered in the differential diagnosis of periorbital cellulitis.
- In immunocompromised patients with cellulitis, atypical and opportunistic infections are common, and microbiologic diagnosis should be actively pursued.
- Patients with cellulitis who are treated as outpatients should have follow-up within 48 hours.

Emergency care required by the child with cardiac disease may be quite variable, with symptoms from a variety of etiologies (congenital heart defects, arrhythmias, cardiomyopathies). This potentially broad range of presentations makes definitive diagnosis and treatment a complex topic.⁴ In general, the symptomatic child or infant with heart disease will present with low cardiac output, congestive heart failure, or cyanosis. Unfortunately, the diagnostic tools available to the emergency physician are often limited to the chest radiograph, the electrocardiogram (ECG), and, of course, the physical examination. Appropriate management of the cardiac patient requires a timely response by the emergency physician, coordinated with the primary care physician and the pediatric cardiologist or cardiovascular surgeon. Herein, we discuss the clinical presentation, initial evaluation, and management of these patients in the emergency department.

LOW CARDIAC OUTPUT

The discerning emergency physician should easily recognize the child with low cardiac output. These children usually present with tachypnea with or without distress, pallor or mottling of the extremities, peripheral cyanosis, diminished or asymmetric pulses, and oliguria and/or acidosis.⁹ Because of decreased peripheral perfusion, venous or arterial access may be difficult to obtain, although necessary for resuscitation. They may present with hemodynamic instability or may initially appear stable hemodynamically and then quickly deteriorate. Depending on the degree of distress at presentation, a specific congenital heart defect may not be characterized until the patient's postmortem study.

The pathophysiology of low cardiac output in the pediatric cardiology patient generally falls into three categories: left-sided obstructive lesions, poor myocardial function, and poor ventricular filling ([Table 265.1](#)).

LEFT-SIDED OBSTRUCTION
Aortic stenosis
Hypoplastic left heart
Coarctation of the aorta
Interrupted aortic arch
POOR MYOCARDIAL FUNCTION
Cardiomyopathy
Myocarditis
Glycogen storage diseases
Coronary artery anomaly
POOR VENTRICULAR FILLING
Congenital mitral stenosis
Tachyarrhythmias
Pulmonary venous obstruction

TABLE 265.1. Etiology and Pathophysiology of Low Cardiac Output

Left-Sided Obstructive Lesions

The timing of presentation of a left-sided obstructive lesion is variable and is dependent on the degree of obstruction. The most common lesions that present in the emergency setting are aortic valve stenosis, hypoplastic left heart syndrome (HLHS), coarctation of the aorta and interrupted aortic arch (IAA). The patient with mild aortic stenosis due to a bicuspid aortic valve may present in late childhood when a murmur is noted during an otherwise normal physical examination. The patient with severe aortic stenosis may present in early infancy and have very little murmur due to the small orifice of a unicuspid aortic valve and associated diminished cardiac output. These patients may appear cyanotic due to right-to-left shunting across a patent ductus arteriosus (PDA), their main source of systemic blood flow. Alternatively, they may present obtunded with severe acidosis following spontaneous ductal closure. Likewise, infants with HLHS and IAA may present in an obtunded state following ductal closure. Patients with coarctation of the aorta may have a progressive course, depending on the degree of obstruction. Symptomatic infants generally present at 2 weeks of age due to progressive ductal closure, while older children with less severe coarctations may present with hypertension and multiple collateral vessels. Unlike patients with aortic stenosis and HLHS, who present with diminished pulses throughout, patients with coarctation of the aorta and IAA have asymmetric upper and lower extremity pulses.

The radiographic findings in patients with left-sided obstructive lesions may vary, depending on the lesion. With chronic aortic stenosis, there may be evidence of cardiomegaly with poststenotic dilatation of the ascending aorta. However, infants with HLHS may, surprisingly, have normal radiographic findings. Infants with coarctation of the aorta who present in failure may have cardiac dilatation; however, older children may have a normal heart size with visible indentation at the coarctation site and evidence for collateral blood vessels, characterized by rib notching. Infants with IAA in general have cardiac dilatation and pulmonary congestion at the time of presentation. A narrowed mediastinum on chest radiograph suggests the absence of a thymus. This finding, along with hypocalcemia, suggests the presence of DiGeorge syndrome.

Electrocardiographic findings vary considerably. In most of these lesions, the ECG may be normal. As the patient develops evidence of ventricular failure, evidence of LV hypertrophy and lateral T-wave inversion may arise. Patients with coarctation often have evidence of right ventricular hypertrophy, characterized by a Q wave in the anterior precordial leads. The hypocalcemia accompanying IAA with DiGeorge syndrome can result in QTc prolongation.

If cyanotic, a patient with low cardiac output due to left-sided obstruction will increase their PaO₂ greater than 20 mm Hg when challenged with oxygen.

The appropriate treatment of low cardiac output in a child depends on the etiology. If there is concern regarding a *left-sided obstructive lesion*, initiation of prostaglandin E₁ (PGE₁) with inotropic support is indicated to maintain systemic blood flow via a PDA. In some congenital heart defects (e.g., HLHS), it is acceptable to decrease the F_iO₂ less than 21% to increase pulmonary vascular resistance and promote systemic blood flow across the PDA. A prompt referral to a pediatric cardiologist or pediatric cardiovascular surgeon is indicated for evaluation and treatment.

Poor Myocardial Function

Clinical signs of diminished cardiac output may occur in patients with poor myocardial function due to a cardiomyopathy or myocarditis. A cardiomyopathy may occur as a result of ischemia due to a coronary anomaly, a glycogen storage disease, a previous viral infection, a muscular dystrophy, or an inherited or idiopathic

myopathy. The degree of symptomatology is usually related to the degree of cardiac dysfunction. The patient with mild dysfunction may present with only mild cardiomegaly on a routine chest radiograph, while the patient with an end-stage cardiomyopathy may present in florid congestive heart failure requiring emergent resuscitation. Likewise, the child with acute myocarditis may present with severe cardiac dysfunction and an associated tachyarrhythmia (e.g., polymorphic ventricular tachycardia) or bradyarrhythmia (e.g., complete atrioventricular [AV] block).

The radiographic findings in these patients are cardiomegaly and, frequently, pulmonary edema. Depending on the etiology, the cardiomegaly is usually LV in origin.

Patients with a “dilated,” poorly functioning hypertrophic cardiomyopathy may have evidence of increased voltages throughout the precordium, with evidence of ST-segment or T-wave changes. Children with glycogen storage diseases, such as Pompe disease, may have evidence of a short PR interval with very large precordial QRS voltages. Decreased amplitudes, manifested as a *low-voltage QRS* (less than 5 mm total in each frontal lead), suggest the presence of myocarditis. Patients with an anomalous left coronary arising from the pulmonary artery will have evidence of an LV infarct with an abnormal Q wave in leads aVL and I, as well as T-wave and ST-segment changes laterally.⁵

If cyanotic, a patient with low cardiac output due to poor ventricular function will increase the PaO₂ greater than 20 mmHg when challenged with oxygen.

If the etiology of the low cardiac output appears to be due to poor myocardial function, then oxygen is indicated with inotropic support, including afterload reduction. These measures are used to reduce cardiac work in an attempt to improve cardiac output. The use of steroids in myocarditis is controversial.

Poor Ventricular Filling

Diminished cardiac output may occur in children with poor ventricular filling as a result of congenital or rheumatic mitral valve stenosis, pulmonary venous obstruction, and tachyarrhythmias. These children may not only present with evidence of poor systemic blood flow, but also, in the most severe cases, often have evidence of pulmonary edema and right heart failure, manifested by hepatomegaly and peripheral edema.

Radiographically, these patients will have electrocardiographic evidence of cardiac enlargement and pulmonary edema. Patients with mitral stenosis have the classic radiographic findings of left atrial enlargement, with pulmonary edema and dilation of the pulmonary vasculature. In patients with pulmonary venous obstruction, the left atrium is usually small, with pulmonary edema and right heart enlargement. In particular, the pulmonary blood vessels may be massively dilated due to chronic pulmonary hypertension. Patients with sustained tachyarrhythmias usually have cardiac enlargement as a result of LV failure and, as such, demonstrate LV enlargement on the chest radiograph.

Patients with congenital mitral stenosis have electrocardiographic evidence of left atrial enlargement and LV voltages, while patients with tachyarrhythmias tend to have retrograde P waves while in supraventricular tachycardia (SVT) or V-A dissociation if in ventricular tachycardia.

If cyanotic, a patient with low cardiac output due to poor ventricular filling will increase their PaO₂ greater than 20 mmHg when challenged with oxygen.

In patients with poor ventricular filling as their etiology of poor cardiac output, oxygen administration and diuresis are usually indicated. If symptomatic, many patients may also require correction of a severe metabolic acidosis. If obstruction is significant, these patients can become severely ill in a short period of time. Although administration of PGE₁, in some cases, can promote systemic blood flow via a patent ductus, prompt referral to a pediatric cardiovascular surgeon is required for surgical repair or palliation.

If the patient has a tachyarrhythmia, conversion either by adenosine (0.1 to 0.3 mg/kg per dose) or, if hemodynamically compromised, DC cardioversion (0.5 to 2.0 J/kg) is indicated.⁸ Calcium channel blockers in children, particularly in infants, are contraindicated. They are negative inotropes as well as a peripheral vasodilators and, as such, can produce dramatic hemodynamic compromise and, in some cases, cardiac arrest.

CONGESTIVE HEART FAILURE

Children with congestive heart failure generally present with symptoms similar to adults: tachypnea, tachycardia, and diaphoresis.¹ Because the majority of work performed by infants and small children occurs during feeding, many of these children will also have feeding intolerance and failure to thrive. Uncommonly, they may have peripheral edema. Most infants with a significant left-to-right shunt will present at 6 to 8 weeks of life as their pulmonary vascular resistance naturally drops to permit pulmonary overcirculation.

The pathophysiology of congestive heart failure in these children is increased pulmonary blood flow, pulmonary interstitial edema, and volume overload. The congenital heart defects most commonly associated with congestive heart failure are those that result in pulmonary recirculation via a large left-to-right shunt. They include ventricular septal defects, AV canal, PDA, atrial septal defects, aortopulmonary windows, and truncus arteriosus ([Table 265.2](#)).

PATHOPHYSIOLOGY
Increased pulmonary blood flow
Pulmonary interstitial edema
Volume overload (dilation)
CONGENITAL DEFECTS
Ventricular septal defects
Atrioventricular canal
Patent ductus arteriosus
Atrial septal defects
Aortopulmonary window
Truncus arteriosus

^a Stiff lungs, large heart, and increased pulmonary vascular markings.

TABLE 265.2. Etiology and Pathophysiology of Congestive Heart Failure ^a

The clinical findings of “stiff, wet lungs” and a large heart correlate with the radiographic findings. Typically, there is cardiac enlargement and increased pulmonary vascular markings, with pulmonary edema.

The electrocardiographic findings may be nonspecific, depending on the level of the shunt; however, a QRS axis of –30 degrees to –120 degrees in an infant, particularly one with trisomy 21, is consistent with an AV canal.

If cyanotic, these children will increase their PaO₂ by greater than 20 mm Hg in response to oxygen.

The treatment, in general, is respiratory support and inotropic support. Afterload reduction and intravenous diuretics are often indicated; however, those patients who have feeding intolerance may present with dehydration, in which case initiation of intravenous diuretics should be withheld until the patient is appropriately rehydrated.

CYANOSIS

The cyanotic child is usually diagnosed in infancy; however, due to multiple factors, including (1) the ratio of fetal-to-adult hemoglobin, (2) the concentration of deoxyhemoglobin, and (3) the total hemoglobin, cyanosis may go undetected. Also, it is not uncommon for a child to have unrecognized cyanosis while at rest, only to become hypercyanotic when agitated. Interestingly, as these patients become more cyanotic, their murmur gets softer as blood is shunted right to left, away from the

area of obstruction. In general, pediatric patients with cyanosis have one of three presentations: (1) a normal heart size with decreased pulmonary vascular markings (2) a small heart with pulmonary edema, and (3) a large heart with increased pulmonary vascular markings ([Table 265.3](#)).

NORMAL/LARGE HEART WITH DECREASED PVMS
Tetralogy of Fallot
Double-outlet right ventricle with pulmonary stenosis
Pulmonary atresia, severe pulmonary stenosis
Transposition of great arteries with VSD and PS
Tricuspid atresia
Ebstein's anomaly of the tricuspid valve
SMALL HEART WITH PULMONARY EDEMA
Total anomalous pulmonary venous returns with obstruction, often below the diaphragm to the portal system
LARGE HEART WITH INCREASED PVMS
Transposition of the great arteries
Total anomalous pulmonary venous returns
Truncus arteriosus
Double-outlet right ventricle
Single ventricle
<small>PVMS, pulmonary vascular markings; PS, pulmonary stenosis; VSD, ventricular septal defect.</small>

TABLE 265.3. Etiology of Cyanosis Based on Radiographic and Clinical Findings

Normal or Large Heart with Decreased Pulmonary Vascular Markings

Patients with a normal or large heart size with decreased pulmonary vascular markings typically have some degree of obstruction of pulmonary blood flow. Because of an atrial or ventricular right-to-left shunt, they have mixing of desaturated blood with systemic blood, resulting in cyanosis. Their degree of cyanosis is variable, depending on the degree of obstruction and the degree of shunt at the time of presentation. The congenital heart defect most associated with these symptoms is tetralogy of Fallot but may also include double-outlet right ventricle with pulmonary stenosis, pulmonary atresia or severe pulmonary stenosis, transposition of the great arteries with a ventricular septal defect and pulmonary stenosis, tricuspid atresia, and Ebstein's anomaly of the tricuspid valve.

These patients typically present with central cyanosis but may also have a history of hypercyanotic spells. At the time of cyanosis, they are often hyperpneic. Occasionally, they may present with acidosis due to a low cardiac output as a result of closure of a ductus arteriosus.

Radiographically, these patients may present with an increased heart size. Classically, Ebstein's anomaly is the congenital heart defect with a “wall-to-wall heart.” Also, transposition of the great arteries and tricuspid atresia may demonstrate cardiac enlargement on chest radiograph. If there is a narrowed mediastinum with an “egg on a string” appearance, transposition of the great arteries should be considered. Patients with tetralogy of Fallot and a right aortic arch or patients with pulmonary atresia may have an absent pulmonary artery segment, thereby giving the heart a “boot-shaped” appearance.

Electrocardiographically, these patients may have right ventricular hypertrophy (tetralogy of Fallot, double-outlet right ventricle, pulmonary stenosis, transposition of the great arteries, or Ebstein's anomaly) or decreased right ventricular forces (tricuspid atresia and pulmonary atresia). If the QRS axis is negative with right atrial enlargement, then tricuspid atresia should be considered.

Because these patients have an obligatory shunt or a fixed obstruction to pulmonary blood flow, then their PaO₂ would increase less than 20 mm Hg in response to oxygen. Because oxygen can be an effective pulmonary vasodilator, in some cases, a decrease in pulmonary vascular resistance may diminish right-to-left shunting, resulting in a significant increase in PaO₂ in response to oxygen. In patients with hypercyanosis, the treatment of choice includes oxygen and sedation. Often, the mother is allowed to hold the child, and all attempts at intravenous access are withheld until the patient is adequately sedated with low-dose morphine (0.05 to 0.1 mg/kg intravenously or intramuscularly) or, in some cases, ketamine (1 mg/kg intravenously or 2 mg/kg intramuscularly). In addition, maneuvers such as “knee-to-chest” positioning and volume administration are performed to increase systemic vascular resistance. In refractory cases, alpha agonists (e.g., phenylephrine) should be considered to increase systemic vascular resistance and promote pulmonary blood flow by diminishing the right-to-left shunt. Referral to a pediatric cardiologist or pediatric cardiovascular surgeon is indicated for balloon palliation or surgical palliation or repair.

Small Heart with Pulmonary Edema

These patients may present in severe distress, with tachypnea, metabolic acidosis, low cardiac output, and central cyanosis. The pathophysiology of these findings is obstruction of pulmonary venous return. Typically, this is due to a total anomalous pulmonary venous return (TAPVR) with obstruction. Often, this occurs below the diaphragm at the portal but may also occur supradiaphragmatically.

The chest radiograph generally demonstrates a heart that is either normal or small in appearance, with pulmonary edema. Patients with supracardiac TAPVR may demonstrate a “snowman sign,” due to the ascending vertical vein. These patients are much less commonly obstructed.

Electrocardiographic findings may be normal or demonstrate right ventricular hypertrophy.

The response to oxygen may be variable. In general, the PaO₂ increases less than 20 mm Hg when challenged with oxygen; however, in the presence of a PDA that shunts right to left and secondary pulmonary hypertension, oxygen may result in improved PaO₂.

Treatment generally requires aggressive inotropic support and immediate intervention, which may include balloon atrial septostomy, balloon dilation at the site of obstruction, or surgical repair or palliation.

Large Heart with Increased Pulmonary Vascular Markings

The pathophysiology of cyanosis in children with a large heart and increased pulmonary vascular markings includes pulmonary recirculation and “stiff lungs.” These congenital heart defects include transposition of the great arteries, TAPVR (unobstructed), truncus arteriosus, double-outlet right ventricle, and single ventricle. In general, these patients present with central cyanosis, tachypnea, tachycardia, feeding intolerance, failure to thrive, and, occasionally, acidosis.

Radiographic findings may demonstrate a narrowed mediastinum in patients with transposition of the great arteries and, occasionally, double-outlet right ventricle (“egg on a string”), or “snowman sign” in those patients with supracardiac TAPVR. Electrocardiographically, there may be right ventricular or LV hypertrophy.

Response to oxygen depends on the congenital heart defect. Patients with transposition of the great arteries and TAPVR increase their PaO₂ less than 20 mm Hg. Patients with truncus arteriosus, double-outlet right ventricle, and single ventricle may increase their PaO₂ by greater than 20 mm Hg.

Treating these patients may or may not include oxygen therapy, depending on the congenital heart defect. In general, however, oxygen is not detrimental, as many of these patients are not dependent on the PDA as their means of systemic blood flow. Diuretics are indicated with inotropic support and, occasionally, afterload reduction. Balloon atrial septostomy or surgical palliation or repair is indicated.

SUPRAVENTRICULAR TACHYCARDIA

SVT may present in an emergency department setting at almost any age.² Typically, SVT is diagnosed between 2 and 4 months of age. These patients may demonstrate symptoms of tachypnea and feeding intolerance. If SVT is sustained for several hours, the patient may present with decreased cardiac output and metabolic acidosis. In general, however, SVT is well tolerated.

The majority of SVTs are reentrant and therefore respond to intravenous adenosine.⁸ The initial recommended dose for adenosine is 0.1 mg/kg as a rapid bolus,

followed by a rapid push of 5 to 10 mL of normal saline. Following adenosine therapy, the patient may have a short break in tachycardia, with early recurrence requiring additional doses. The infant may require up to 0.3 mg/kg by intravenous push in a peripheral intravenous line. Usually, the adenosine dose required is lower if central venous access is obtained. In general, calcium channel blockers are contraindicated in infants and children.⁶ An ECG should be obtained prior to and at the time of conversion to document the underlying rhythm. If preexcitation is present, digoxin and calcium channel blockers are contraindicated for chronic therapy. Additionally, intravenous beta blockers are almost never required in infants and children for conversion from a reentrant arrhythmia. In all cases, chronic therapy in an infant should be decided after consultation with a pediatric cardiologist.

Although reentrant SVT is often well tolerated, without evidence of clinical compromise, certain “chronic” tachycardias may present with evidence of a tachycardia-induced cardiomyopathy. These patients may have evidence of severe metabolic acidosis and diminished cardiac output requiring resuscitation. In general, these “chronic” tachycardias are automatic in nature, such as atrial ectopic tachycardia (AET) or junctional ectopic tachycardia. However, an incessant reentrant arrhythmia, such as a permanent junctional form of reciprocating tachycardia (PJRT), may also present with this clinical scenario.

In automatic tachycardias, the arrhythmia is due to an abnormal focus located in the atrial, AV nodal, or ventricular myocardium. AET ([Fig. 265.1](#)) is, by far, the more common of these arrhythmias. Administration of adenosine will only block the AV node but will not terminate the tachycardia. In this case, you will see P waves continue to march through at their tachycardia rate until AV nodal conduction returns, at which time, SVT will resume. In general, this tachycardia is not as rapid as a reentrant arrhythmia; however, due to its chronic nature, it may result in a cardiomyopathy. Usually, support of the circulation is beneficial until appropriate referral to a pediatric cardiologist is obtained. Administration of intravenous sympathomimetic agents to improve cardiac output may only exacerbate the tachyarrhythmia, resulting in further clinical compromise. In these patients, administration of intravenous digoxin in the emergency setting may result in either reduction in the tachycardia rate or decreased AV nodal conduction. Occasionally, a calcium channel blocker or a beta blocker is required in the treatment of this arrhythmia; however, given their negative inotropic effects, they are less desirable. Intravenous amiodarone or procainamide is usually better tolerated and more effective in the treatment of this arrhythmia acutely. The therapy of choice in the older child is radiofrequency ablation.

Figure 265.1. Atrial ectopic tachycardia. P waves with abnormal morphology and variable AV conduction in a 1-month-old that presented with feeding intolerance, tachypnea, and poor peripheral perfusion. This infant required amiodarone infusion before his tachycardia converted to normal sinus rhythm.

PJRT is a special type of reentrant tachycardia that is usually incessant in nature, thereby resulting in a cardiomyopathy. Like AET, the heart rate is generally less than 200 beats per minute, even in the smallest infants. Unlike AET, PJRT can be terminated with adenosine; however, it is not uncommon that there is immediate recurrence once adenosine is metabolized. Furthermore, the hypotension that can accompany adenosine often results in a release of endogenous catecholamines that may increase the tachycardia rate. Like patients with AET, these patients may be treated with intravenous antiarrhythmics (e.g., digoxin, amiodarone, or procainamide) or nodal blocking agents. However, the treatment of choice for both PJRT and AET is radiofrequency ablation.

Although uncommon, hemodynamically unstable arrhythmias require immediate and aggressive therapy. The two most common arrhythmias of this type include ventricular tachycardia and rapid conduction of atrial fibrillation in a patient with Wolff-Parkinson-White syndrome. Patients with ventricular tachycardia who are hemodynamically compromised require immediate DC cardioversion. Electrolyte abnormalities should be considered in patients who are refractory to cardioversion. Patients with a history of intoxication (e.g., with cocaine) may require pharmacologic therapy in addition to cardioversion, such as with lidocaine or beta blockers. In patients with a history of digoxin toxicity, DC cardioversion should be avoided, and treatment with digoxin-specific Fab fragments initiated. These patients require cardiopulmonary resuscitation while managing their malignant arrhythmia in order to avoid permanent central nervous system injury.

In patients with atrial fibrillation and Wolff-Parkinson-White syndrome, there may be rapid conduction to the ventricles.³ Electrocardiographically, this may mimic rapid ventricular tachycardia ([Fig. 265.2](#)). However, these patients may be surprisingly hemodynamically stable initially and then deteriorate rapidly if they remain in this arrhythmia. Again, DC cardioversion is the treatment of choice; however, if the patient appears stable, infusion with intravenous procainamide or ibutilide may be tolerated. In general, treatment with adenosine will not result in any arrhythmia change. Because digoxin and calcium channel blockers may increase accessory pathway conduction, resulting in ventricular fibrillation, these medications are contraindicated whenever this arrhythmia is suspected.

Figure 265.2. Atrial fibrillation with rapid conduction via an accessory pathway in a patient with Wolff-Parkinson-White syndrome. This patient presented without hemodynamic compromise. There was no response to adenosine.

SYNCOPE

The evaluation of the child with syncope in the emergency department can be difficult.^{7,10} Most of these children will have normal findings indicative of a neurocardiogenic mechanism. The confounding factor is that most children who die of sudden cardiac death have a history of syncope. Therefore, the child who presents with syncope cannot be taken lightly. It is important to obtain a good clinical and family history, as well as perform a thorough physical examination. The family history should ensure that there is no familial sudden death, arrhythmia, or early cardiac disease. The clinical history should ensure that syncope is not exercise- or catecholamine-induced, which is suggestive of an arrhythmic etiology or coronary anomaly. An ECG should be performed in all children with their first syncopal episode or nonfebrile seizure to ensure that there is a normal corrected QT interval. If the ECG is normal, along with the physical examination and clinical and family histories, the patient can be safely discharged from the emergency department, with appropriate follow-up by their primary care physician or pediatric cardiologist.

COMMON PITFALLS

- Infants with cardiogenic shock and septic shock can present similarly with cardiomegaly and metabolic acidosis. However, it is an important distinction to make,

because septic shock requires fluid resuscitation and cardiogenic shock often requires diuresis.

- All “first-time wheezers” require a chest x-ray to rule out cardiomegaly. Hyperinflation from bronchiolitis should result in a normal or small cardiac silhouette. Cardiomegaly in a child with wheezing suggests “cardiac asthma” due to myocarditis, anomalous left coronary from the pulmonary artery, or other cardiac etiologies.
- All patients should undergo electrocardiography after an initial syncopal episode or nonfebrile seizure to rule out an arrhythmic cause (e.g., long QT syndrome).
- Intravenous calcium channel blockers are almost always contraindicated in infants and small children.

CHAPTER 266

Croup and Epiglottitis

Timothy G. Givens

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Croup is a clinical syndrome characterized by a barklike cough, hoarseness, inspiratory stridor, and respiratory distress of variable severity. The two most common forms are viral (laryngotracheobronchitis [LTB]) and spasmodic croup. The former is due to infection with parainfluenza viruses types 1, 2, and 3; respiratory syncytial virus; influenza virus type A; or adenovirus.^{7,9} The virus causes inflammation of the subglottic tissues and sometimes of the tracheal mucosa. The supraglottic structures are normal.

Spasmodic croup is of uncertain etiology, although seen more commonly in patients with a family history of asthma, allergies, or recurrent episodes of croup. The peak incidence of LTB is during late fall and early winter. It can occur in all age groups but is most often seen during the second year of life. There is a 2:1 male-to-female ratio, with a recurrence rate of 5%.⁷ Most cases of croup are mild to moderate in severity and are self-limited.

Epiglottitis, in contrast, is an acute bacterial process that is life-threatening. While the epiglottis and the aryepiglottic folds become inflamed and swollen, the glottis and subglottis remain normal. Epiglottitis is usually caused by *Haemophilus influenzae* type B (HIB).^{7,9,18} Its incidence has fallen dramatically since the introduction of HIB vaccination.^{1,6,17,21} Epiglottitis occurs throughout the year. It traditionally afflicts preschool children (2 to 6 years old) but can present in almost any age group, including adults. Because of widespread HIB vaccination, cases are now more often seen in older children and adolescents. Epiglottitis does not recur after the first infection.⁷ The onset of epiglottitis is usually rapid, with a fulminant course that leads to respiratory arrest from either complete airway obstruction or fatigue associated with a partial airway obstruction. If properly managed, the signs and symptoms of the acute infection resolve within 24 to 72 hours.

CLINICAL PRESENTATION

Inspiratory stridor, a barking cough, and hoarse voice with mild-to-moderate respiratory distress are the common presenting symptoms of LTB. One to 2 days of coryza with a low-grade fever is the usual prodrome. The symptoms peak by 2 to 3 days, with improvement and resolution noted by 5 to 7 days.^{7,9} Respiratory distress worsens when the patient cries or becomes agitated. Some patients may present with wheezing, tachypnea, and stridor. These patients have a combined illness of bronchiolitis and croup. A clinical scoring system may assist the physician in assessing the degree and progression of respiratory distress.³ In spasmodic croup, the same barking cough, stridor, and labored breathing are observed, but the patient is afebrile and does not have the upper respiratory symptoms that precede LTB. Patients with spasmodic croup are usually responsive to cool, humidified air and often improve by time they reach the emergency department.

Patients with epiglottitis usually have the abrupt onset of sore throat, high fever, and one or more of the four D's: dysphagia, dysphonia, drooling, and distress. Inspiratory stridor may be audible, but there is usually no cough. Secretions, laryngospasm, and fatigue can further compromise breathing.⁷ Classically, patients assume a tripod sitting position, with the mandible extended forward in an effort to maintain airway patency. Patients appear very apprehensive and often toxic because of sepsis.¹⁸

DIFFERENTIAL DIAGNOSIS

With a typical presentation of croup, the diagnosis is clinical, and laboratory and radiographic studies are unnecessary.⁹ Atypical clinical features should prompt other considerations. Occasionally, a child with LTB caused by parainfluenza or influenza virus will present with stridor and wheezing and is diagnosed as having bronchiolitis. Epiglottitis is differentiated by its more acute and fulminant presentation ([Table 266.1](#)). A history of HIB vaccination does not rule out epiglottitis. Ludwig's angina (a rapidly spreading inflammation of the sublingual, submandibular, and submaxillary spaces) and retropharyngeal and peritonsillar abscesses are suspected based on inspection of the oral cavity. If membranes are noted in the oropharynx, diphtheria and infectious mononucleosis must also be considered. Bacterial tracheitis may be suspected when there is no response to the standard management for LTB, or when the patient's symptoms worsen. If the patient is afebrile or has a history of choking, the possibility of aspiration of a foreign object should be investigated, using noninvasive techniques such as inspiratory and expiratory chest radiographs, fluoroscopy, or computed tomography scanning. Direct visualization by laryngobronchoscopy may be required.^{7,18} For recurrent or persistent stridor or a clinical presentation of LTB during an atypical time of year, the following also should be considered: congenital airway anomalies, acquired tracheal stenosis secondary to previous intubations, congenital heart disease with associated vascular anomalies, tracheal hemangiomas, or recurrent angioneurotic edema.⁷

Characteristic	LTB	Supraglottitis
Age	6 mo-3 yr	2-6 yr
Onset	Gradual	Rapid
Etiology	Viral	Bacterial
Swelling site	Subglottic	Supraglottic
Symptoms		
Cough/voice	Hoarse cough	No cough Muffled voice
Posture	Any position	Sitting
Mouth	Closed; nasal flaring	Open; chin forward, drooling
Fever	Absent to high	High
Appearance	Often not acutely ill	Anxious, acutely ill
Radiograph	Narrow subglottic area	Swollen epiglottis and supraglottic structures
Palpation larynx	Nontender	Tender
Recurrence	May recur	Rarely recurs
Seasonal incidence	Winter	None

TABLE 266.1. Comparison between Epiglottitis and Laryngotracheobronchitis

EMERGENCY DEPARTMENT EVALUATION

The child in respiratory distress should not be separated from parental comfort unless respiratory arrest is imminent.^{7,9} Minimal manipulation is necessary so as not to increase the child's work of breathing and worsen the respiratory distress. The physical examination consists of inspection and observation at a comfortable distance from the patient. Oxygen can be delivered in a manner tolerable to the child. Venipuncture should be deferred to avoid distressing the patient. When epiglottitis is highly suspected, immediate arrangements must be made to transport the patient to an operating room in order to secure placement of an artificial airway. Further evaluation of the airway by direct visualization can then be done with the patient anesthetized. A physician experienced in airway management must accompany the child during transport to the operating room.

If the history and physical examination suggest LTB, the physician may apply a clinical scoring system to assess the patient's degree of compromise ([Table 266.2](#)).³ Sequential scoring is done after each intervention. If the diagnosis is in doubt and the child is stable, an inspiratory soft-tissue lateral neck radiograph and chest radiograph may be helpful (see [Fig. 266.1](#), [Fig. 266.2](#) and [Fig. 266.3](#)).⁷ Classic radiographic signs of epiglottitis include the thumb sign (enlarged epiglottis), swelling of the aryepiglottic folds, blunting of the vallecula, and obliteration of the piriform sinuses. In LTB, the steeple sign (a gradual narrowing at the subglottic area) may be

observed, but all supraglottic structures should appear normal. Radiographic widening of the soft tissue between the air column and cervical vertebrae points to retropharyngeal abscess or cellulitis.

	0	1	2
Inspiratory breath sounds	Normal	Harsh with rhonchi	Delayed
Stridor	None	Inspiratory	Inspiratory and expiratory
Cough	None	Hoarse cry	Barking cough
Retractions/Flaring	None	Flaring, suprasternal retractions	As in 1 plus subcostal/intercostal retractions
Cyanosis or PaO_2 (mm Hg)	None	In room air	In 4% O_2
CNS function	Normal	Depressed/dilated	Coma

EMERGENCY DEPARTMENT MANAGEMENT

Maintenance or provision of an adequate airway is the first priority in any illness in which airway obstruction is possible. Each institution must establish an epiglottitis protocol that can be rapidly activated.⁷ Once the diagnosis of suspected epiglottitis is made, appropriate personnel must be mobilized. The patient must be taken to the operating room immediately, where inhalation anesthesia is given with the patient in a sitting position. The hypopharynx is then visualized, and rapid intubation is performed with an endotracheal tube 0.5 to 1.0 mm smaller in diameter than that predicted for the patient's age and weight. A surgeon skilled in pediatric tracheostomy should be prepared to perform an emergency tracheostomy, if necessary. Intravenous access and laboratory studies are obtained at the discretion of the anesthesiologist, usually after induction of anesthesia.

Patients with LTB who have a clinical score of 7 or greater and who do not respond quickly to initial therapeutic maneuvers may also be candidates for endotracheal intubation. Continuous pulse oximetry monitoring will reveal any deterioration in the patient's oxygenation status in a noninvasive fashion.¹⁸ Ventilatory failure should be suspected if the patient loses head control or becomes lethargic. Because of airway narrowing, an endotracheal tube size smaller in diameter than that predicted for the child's age and weight should be used if intubation becomes a necessity.

For patients who present to the emergency department with impending or complete respiratory arrest, the airway must be addressed immediately. Bag-valve-mask ventilation with 100% oxygen should be initiated. Higher positive pressures are sometimes necessary, requiring a two-handed technique to obtain an adequate chest rise. If these measures are unsuccessful within 15 to 30 seconds, a rapid oral intubation should be attempted. Tips for intubating children with epiglottitis include using a smaller size endotracheal tube, using a stylet, and looking for an air bubble at the glottic opening while someone compresses the chest.

If intubation is impossible, emergency cricothyrotomy must be done. A large-bore (14-gauge) angiocatheter is inserted through the cricothyroid membrane at a caudad angle and attached to a 3.0 endotracheal tube. This maneuver may provide a temporary open airway for bag ventilation or direct connection to a pressurized continuous-flow oxygen source.¹⁸ A pediatric surgeon or otolaryngologist should be consulted for emergency tracheostomy. Complications associated with the disease, as well as the artificial airway placement, include pulmonary edema, tension pneumothorax, subcutaneous emphysema, pneumomediastinum, bleeding,

endotracheal tube plugging, accidental extubation, and bronchospasm.^{7,18}

In LTB, therapy is provided commensurate with the patient's level of respiratory distress. In mild cases (croup score less than 4), a trial of cool mist therapy may be offered. Cool, humidified air is thought to work by moistening secretions to facilitate clearance, activating mechanoreceptors in the larynx to produce reflex slowing of the respiratory rate, or by reducing patient anxiety and associated hyperventilation as the parent holds the child close to administer the mist.⁹ Despite empirical experience, no significant benefit to cool mist therapy has ever been proven. Because croup tents may actually interfere with observation of the patient or increase anxiety, their use to administer mist therapy has become passé.⁹

Patients with LTB who have a clinical score of 4 or greater or inspiratory stridor at rest should receive oxygen and nebulized epinephrine (0.05 mL/kg per dose [max dose, 0.5 mL] of a 2.25% solution diluted in 3 mL of saline, repeated as necessary).^{7,9,15,18} Equivalent doses of either racemic epinephrine or L-epinephrine, which is more readily available and less expensive, have been shown to be equally efficacious.²³ There should be almost immediate clinical improvement due to reduction of the edema and vasoconstriction of the inflamed mucosa through the stimulation of the α -adrenergic receptors. Parents should be encouraged to deliver the nebulized treatment in a nonthreatening manner. Heart rate should be monitored during treatment with nebulized sympathomimetics. The treatment should be stopped when the heart rate exceeds 200 beats per minute or if dysrhythmias occur.

Previously, all patients who received nebulized epinephrine were admitted to the hospital because of a possible rebound effect, a clinical worsening due to vasodilation, and increased mucosal edema as the adrenergic effects abate. This phenomenon usually occurs within 2 to 4 hours after epinephrine treatment.⁷ Recently, the need for hospitalization has been reassessed. Several studies suggest that discharge from the emergency department is safe following epinephrine therapy if, after 3 to 4 hours of observation, the patient has no stridor at rest and has normal air entry, normal color, and normal level of consciousness.^{9,13,14,16}

There is now ample evidence to suggest that corticosteroids are of benefit to patients with croup. Steroids promote resolution of laryngeal edema through antiinflammatory activity. Dexamethasone (Decadron), 0.3 to 0.6 mg/kg, administered either orally or as a single intramuscular injection, has been shown to reduce the severity of symptoms,^{2,4,10,20} rate of hospital admissions,⁴ need for subsequent nebulized epinephrine treatments,²⁰ and duration of hospital stay or observation in the emergency department.^{4,5} Dexamethasone has a half-life of 54 hours, so one dose is sufficient. A smaller 0.15-mg/kg oral dose of dexamethasone, compared with placebo, has been shown to reduce the number of return visits to the emergency department in children with mild croup that were discharged home.⁵ Both oral and intramuscular routes have been shown to be effective compared with placebo, but to date there have been no data directly comparing the two routes.⁹ As effects from corticosteroid treatment take 6 hours, early use is most beneficial.²² All patients who require epinephrine therapy should also receive steroids. Inhaled corticosteroids (budesonide) have a rapid onset (within 2 to 4 hours) and are effective in mild-to-moderate croup.^{3,8,11,12} More studies are needed, however, before steroids can be recommended routinely.

Antibiotics are unnecessary for patients with LTB. Patients with epiglottitis should receive intravenous antibiotics beginning in the operating room. Options include ceftriaxone (100 mg/kg/d at 12-hour intervals), cefuroxime (150 mg/kg/d at 8-hour intervals), cefotaxime (150 mg/kg/d at 8-hour intervals), or chloramphenicol (100 mg/kg/d at 6-hour intervals). Bronchospasm secondary to secretions can be treated with β_2 -agonist nebulization (e.g., albuterol) and suctioning. Additional supportive treatment includes antipyretics and intravenous fluids for patients with compromised oral intake.

DISPOSITION

Intubated patients (including all epiglottitis patients) must be admitted to a pediatric intensive care unit, accompanied by personnel skilled in pediatric airway placement. LTB patients with a clinical score of 4 or greater (significant respiratory distress), those with persistent stridor at rest, and those with minimal to no response to nebulized adrenergic treatment should be admitted. Instructions to parents whose children are sent home include monitoring the child's work of breathing (respiratory rate, retractions, and agitation), implementing a method of rapid and easy communication access between physician and family, placing a humidifier at the child's bedside, and ensuring minimal stimulation.

COMMON PITFALLS

- Separating children from parents during initial assessment or during administration of nebulized medications or oxygen
- Underestimating the degree of respiratory distress
- Increasing agitation and respiratory distress by performing medical procedures (vital signs, laboratory and x-ray studies)
- Obtaining radiographic studies when the diagnosis by history and clinical presentation is clear
- Delaying the establishment of an artificial airway or not having the appropriate equipment readily available
- Failure to have a physician skilled in establishing artificial airways accompany the child during transport
- Using too large an endotracheal tube during intubation

CHAPTER 267

Diabetic Ketoacidosis

Timothy G. Givens

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Diabetic ketoacidosis (DKA) is caused by either an absolute or a relative insulin deficiency accompanied by increased action of four counterregulatory hormones: glucagon, epinephrine, cortisol, and growth hormone.^{14,16,20} Counterregulatory hormone activity increases the patient's insulin resistance, thus compounding the effects of insulin deficiency. The results of this imbalance are hyperglycemia, dehydration, ketosis, and acidosis.

Precipitating events for this cascade include acute infection, inflammatory reactions, trauma, psychological stress, or medical noncompliance in patients known to have insulin-dependent diabetes mellitus (IDDM). Recurrent DKA is almost always due to insulin omission.^{6,7} Approximately 30% of cases of new-onset IDDM present as DKA;¹⁶ a high index of suspicion is required to make the diagnosis in infants and children. Mortality in DKA is primarily due to the development of cerebral edema.¹⁷

CLINICAL PRESENTATION

Children with DKA have a variable clinical picture, and the diagnosis may be difficult, particularly in patients not known to have IDDM. Acutely, the child may appear moderately dehydrated and be misdiagnosed as having viral gastroenteritis or a urinary tract infection. Presenting symptoms include nausea, vomiting, abdominal pain, hyperpnea, fruity breath odor, dehydration, and lethargy or coma. Polyuria, polydipsia, and polyphagia—three classic features of diabetes—as well as weight loss, should signal the physician to consider DKA.

DIFFERENTIAL DIAGNOSIS

Because new-onset IDDM presenting as DKA may be mistaken for gastroenteritis or a urinary tract infection, a history of polyuria and polydipsia should be sought in every case of a child who is vomiting, particularly in very young children. Occasionally, dehydrated children with gastroenteritis will have hyperglycemia and glucosuria due to stress and do not have IDDM;² they are usually nonketotic.

It is unclear whether patients with stress-induced hyperglycemia are at risk for future development of IDDM.^{19,21} If the history is obscure or unavailable in a child who presents with altered mental status, the differential diagnosis widens to include intoxication, inborn errors of metabolism, Reye syndrome, sepsis, meningoencephalitis, nonketotic hyperglycemic coma, or hypoglycemic coma.¹⁶ In children with known IDDM, the differential diagnosis includes precipitants for the development of DKA, such as bacterial infections, viral gastroenteritis, appendicitis, pancreatitis, or other acute intraabdominal disorders.

EMERGENCY DEPARTMENT EVALUATION

The initial evaluation of a child who presents as described previously consists of

1. Establishing the diagnosis of DKA
2. Assessing and correcting dehydration and electrolyte imbalance
3. Providing adequate insulin to restore normal metabolism
4. Searching for the precipitating event for DKA
5. Avoiding complications of therapy (cerebral edema, hypoglycemia, hypokalemia)

Hyperglycemia (serum glucose greater than 200 mg/dL), ketonuria, and metabolic acidosis (venous pH less than 7.3 or serum bicarbonate less than 15 mEq/L) confirm the diagnosis of DKA.^{16,18}

The physical examination should focus, as always, on the ABCs first. Next, attention is directed toward establishing the degree of dehydration, as well as identifying processes that may have precipitated DKA. Because the extracellular fluid of children with DKA is hyperosmolar, the percentage of dehydration is commonly underestimated when relying on physical signs that correlate with extracellular volume (e.g., hydration of mucous membranes, skin turgor, and temperature). In general, one should assume at least 10% dehydration in all patients with DKA.^{13,18}

Measurement of serum electrolyte levels may assist in assessment but must be interpreted in light of the physiologic derangements that accompany DKA. The measured sodium level is often low because of the dilutional effects of water flowing into the vascular compartment to compensate for hyperosmolarity generated by high plasma glucose levels. Treatment of this “pseudohyponatremia” with administration of excessive sodium is not required, as the sodium level should rise as the glucose level falls with treatment for DKA. Serum potassium is usually elevated—despite the fact that the patient's total body potassium stores are depleted—because intracellular potassium ions are exchanged for extracellular hydrogen ions in the presence of acidosis. Low-normal potassium levels in DKA indicate extreme total-body potassium depletion. Continuous electrocardiographic monitoring for evidence of cardiac dysrhythmias is necessary in DKA, particularly in patients with alterations in their serum potassium concentrations.

EMERGENCY DEPARTMENT MANAGEMENT

Fluid replacement and correction of dehydration should begin as soon as possible. Volume expansion with isotonic fluid such as normal saline, 20 mL/kg, is given during the first 1 to 2 hours. Unless the patient is in shock, initial fluid boluses beyond 20 mL/kg should be avoided because of the risk of cerebral edema. Lactated Ringer's solution is less commonly used, owing to a theoretical risk of hyperchloremic acidosis.⁶

After the first hour, fluids are adjusted to correct the remainder of the patient's water deficit (10% dehydrated = 100 mL/kg) over the next 48 hours. As a general principle, slow correction of hyperosmolarity is desirable. Maintenance fluids are calculated in the usual manner (100 mL/kg for the first 10 kg, 50 mL/kg for the second 10 kg, and 20 mL/kg for every additional kg) and added to estimates of ongoing losses and rehydration fluids to calculate an infusion rate. This calculation can be accomplished with a solution of 0.45% sodium chloride (which closely approximates the fluid lost in DKA), with the addition of 40 mEq/L of potassium as the chloride and/or phosphate salt. The use of higher sodium concentrations may prevent the development of cerebral edema during the treatment of DKA,¹⁰ although this theory has not been proved.¹⁷ Dextrose is added to fluids when the plasma glucose level approaches 300 mg/dL; the desired goal is maintenance of a glucose level between 200 and 300 mg/dL.

Hypophosphatemia and deficiency of 2,3-diphosphoglycerate are well-known features of DKA. They occur because of osmotic diuresis and phosphate competition with glucose for reabsorption at the renal tubules. Potassium phosphate has thus been proposed as an alternative to potassium replacement with the chloride salt; correction of phosphate homeostasis, however, has not been shown to clinically benefit children with DKA.^{1,12,16} Its use should be limited to those patients with extremely low serum phosphate concentrations (less than 1 mg/dL) or when potassium concentrations in the intravenous fluid greater than 40 mEq/L are needed.

Once hyperglycemia and ketosis confirm the diagnosis of DKA, a continuous infusion of intravenous insulin at a rate of 0.1 U/kg/h should be begun. While insulin administration has been effective using intramuscular or subcutaneous routes, continuous low-dose intravenous infusion allows for slower, more even correction of

hyperglycemia and fewer episodes of hypoglycemia than do other forms of insulin administration,^{3,4,16} and is preferable in children. Although some sources recommend an initial bolus of 0.1 U/kg prior to the continuous infusion, there is no evidence that it is helpful.¹⁶ When mixing the insulin for infusion, the concentration of insulin should be at least 0.5 U/mL, and the infusion line should be primed to overcome insulin binding to the intravenous infusion equipment.¹¹

The use of bicarbonate is highly controversial in the treatment of DKA, largely because its reported benefits and risks have been unproven.^{8,13,14,18} The potential advantages of bicarbonate are improved myocardial function; reduction of potential for dysrhythmias; decreased insulin resistance; and through avoidance of hypochloremia, a more rapid correction of acidosis. Major disadvantages of bicarbonate use are its potential for generation of paradoxical central nervous system acidosis, due to increased diffusion of carbon dioxide across the blood–brain barrier; increased hemoglobin affinity for oxygen (increased tissue hypoxia, due to reduced off-loading); and promotion of hypokalemia. If bicarbonate is used, it should be given as a slow infusion over several hours, not as a bolus. Rapid infusion may produce hypokalemia and exacerbate the degree of hyperosmolality.

Plasma glucose levels should be monitored hourly. Serum electrolyte concentrations and venous blood gases should be monitored every 2 to 4 hours, and calcium and phosphate concentrations should be checked every 8 hours. The rate of decrease in glucose should be no faster than 50 to 100 mg/dL/h.^{13,16}

In spite of improvements in DKA management, mortality due to cerebral edema has not changed.^{9,16} Data suggest that a large percentage of patients in DKA have subclinical cerebral edema on computed tomography scans;¹⁵ however, clinically significant cerebral edema is present in less than 1% of cases of DKA.^{5,10,17} Typically, signs of increased intracranial pressure present several hours into therapy, as the patient experiences a sudden decline in sensorium, headache, sluggish pupillary reflexes, or change in vital signs despite an apparent improvement in metabolic and other clinical parameters.

Thus, cerebral edema is thought to be the result of (overly vigorous) treatment for DKA.^{5,9,10,13,16,17} Specific mechanisms remain elusive but are thought to relate to overly rapid hydration, with a concomitant precipitous drop in effective serum osmolality, leading to intracerebral fluid shifts and intracellular swelling. Once clinically apparent, cerebral edema leads to mortality in 60% to 80% of cases, with long-term neurologic morbidity in most of the remaining patients. There are few reliable predictors of risk for significant cerebral edema, although children less than 5 years of age with new-onset IDDM and a prolonged period of untreated DKA are at increased risk.¹⁶

If evidence of cerebral edema develops, the patient should receive rapid, aggressive intervention with intravenous mannitol (1 g/kg).¹⁷ Intubation and hyperventilation should be considered. Because of the devastating outcomes in patients who develop this complication, the need for frequent neurologic reassessment and early intervention must be underscored.

DISPOSITION

Children in moderate-to-severe DKA should be admitted to a pediatric intensive or intermediate care unit because of the frequency and extent of monitoring that is required. Patients with new-onset IDDM should be admitted to a facility where age-appropriate diabetes education can be given.

Patients who can retain oral intake without vomiting and who are not significantly dehydrated or acidotic (pH greater than 7.25) may be discharged home from the emergency department if appropriate follow-up care can be arranged. Follow-up includes frequent telephone contact over the ensuing 24 hours with an individual knowledgeable in diabetes management.

COMMON PITFALLS

- Failure to administer adequate insulin, which may result from errors in insulin dilution or infusion. Concerns about therapy-related hypoglycemia are addressed by adding dextrose to the fluid replacement, not by slowing or stopping the insulin infusion.
- Failure to treat the precipitating process. Patients with refractory DKA should be thoroughly reexamined for a source of infection or intraabdominal disorder, such as pancreatitis or appendicitis.
- Inadequate volume expansion from failure to monitor the patient's fluid input and output
- Too-rapid correction of the hyperosmolality may lead to cerebral edema and brainstem herniation.
- Inadequate potassium replacement during correction of acidosis, which leads to a shift of potassium into the cells and resultant hypokalemia

CHAPTER 268

Diaper Rash

Lindsey Alan Johnson

[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgement](#)
[Chapter References](#)

Diaper rash is a nonspecific term used to describe a variety of dermatologic conditions that occur in the diaper area of the infant. Diaper rashes are the most common dermatologic problem seen in infants and children from birth to 24 months old, with a peak incidence at 7 to 9 months of age. ^{5,7,8 and 9}

The cause of diaper dermatitis can be complex. In simplest terms, it is caused by irritation, infection, or an underlying skin condition, but factors such as friction and increased permeability of skin, as well as how often the baby's diaper is changed, may contribute to the development or severity of the rash. The role of urine and feces in the pathophysiology of diaper rash has been the subject of much debate. ^{2,3,6,7,9,10}

The practice of using disposable diapers has become commonplace, and use of the traditional cloth diaper has become relatively uncommon in the United States. The disposable diaper, with its exterior plastic film, maintains humidity and heat between the skin and the diaper, predisposing to the growth of *Candida albicans* and bacteria. Injuries to the epidermis from prolonged exposure to urine and feces result in areas easily infected.

Alterations in gastrointestinal flora due to viral infections or antibiotic use contribute in particular to the development of candidal dermatitis with satellite lesions. The most frequently seen diaper rash is that which arises after the onset of diarrhea caused by a viral gastroenteritis or diarrhea associated with antibiotic therapy. The usual sequence of skin changes following the onset of diarrhea is an initial hyperemia to the skin covered by the diaper, with development of candidal colonization within 72 hours.

As the diarrhea continues, the initial candidal colonization may progress to the development of satellite *C. albicans* lesions. When the diaper area is then cleansed during diaper changes, the infant may experience pain due to the irritation of cleaning solutions or commercially prepared wipes, or the skin may become excoriated and secondarily infected with bacteria.

The infant is usually brought for medical attention because the diaper rash has been prolonged or unresponsive to over-the-counter preparations or is worsening in severity and extent.

DIFFERENTIAL DIAGNOSIS

Diaper rash due to irritation is common and may be divided into causes such as mechanical, intertrigo, miliaria, and contact irritation. Mechanical irritation is caused by constant friction of the wet, excessively hydrated skin of the diaper area against both the diaper and skin folds. It is aggravated by frequent overvigorous cleansing. The infant's diaper area appears chafed, with shiny, erythematous patches that tend to wax and wane in severity. Any diaper dermatitis induced by other factors can be aggravated by mechanical irritation.

Intertrigo occurs in areas where skin surfaces are apposed, such as the groin or intergluteal cleft. It is produced when heat, moisture, and sweat retention combine to cause maceration and irritation. Intertrigo is characterized by red denuded areas in the skin folds.

Miliaria, or prickly heat, is the result of contact of the hot, moist diaper with the infant's skin. It is characterized by small, clear superficial vesicles that are nonerythematous in the newborn, or by small erythematous papules and pustules in the older infant.

There are two types of contact irritation: allergic and primary irritant. Allergic contact diaper dermatitis is caused by the development of a sensitivity to detergents, chemicals in the diaper, or creams and medications used in the diaper area. The rash of contact dermatitis usually begins with tiny erythematous vesicles that rupture and adopt an eczematous appearance. The distribution of the rash is characteristic and involves skin surfaces in contact with the diaper, such as the convexities of the buttocks, the medial thighs, and scrotum, while the skin folds are spared.

Primary irritant contact dermatitis is thought to be caused by the effect of noxious components of urine and feces on skin that is already sensitive or irritated from other causes.¹ Primary irritant dermatitis is most often described as a parchment-like erythema, resembling a scald, that involves the convex surfaces. In boys, inflammation of the urethral meatus is common.

Infectious causes of diaper rash are yeast, bacterial, viral, and fungal. *C. albicans* is commonly found in the gastrointestinal tract of infants and is frequently implicated as a cause of diaper rash.⁶ The rash consists of small, beefy-red papules that may be coalesced centrally but appear to spread outward as small satellite lesions. Usually, the perianal area and skin folds are spared. Examination of the mouth may show the characteristic lesions of thrush, the finding of which will help support the diagnosis.

Staphylococcus aureus can cause bullous impetigo in the diaper area. The bullae are large and flaccid and tend to rupture very quickly. Very often, only the red, moist, denuded base with peeling edges will be apparent on presentation. *S. aureus* is also the cause of folliculitis.¹⁰ The distribution is usually over the buttocks, thighs, and lower abdomen. The lesions are small red follicular papules or pustules. Folliculitis is most prevalent in the summer and occurs as a complication in infants with chronic miliaria.

Although uncommon as a cause of diaper rash, several viruses may produce vesicular eruptions in the diaper area. Among these are herpes simplex, herpes zoster, coxsackievirus, and varicella. Herpes simplex infection is usually either congenitally acquired or caused by sexual abuse.¹⁰ The lesions are small singular, coalescing, or grouped vesicles that rupture to form small crusted ulcers on an erythematous base. Herpes zoster is recognized by the dermatomal distribution of the vesicular eruption. Hand-foot-and-mouth disease, caused by coxsackievirus A16, and chickenpox are distinguished by the involvement of other skin surfaces.

Dermatophytosis of the diaper area has been described by several authors and may be more common than traditionally thought.^{4,8,10} The most common fungi responsible are *Trichophyton rubrum*, *Epidermophyton floccosum*, and *Microsporum audouinii*, the same fungi responsible for tinea cruris in adults. Patients present because of a diaper rash that has been unresponsive to conventional therapy. The rash consists of slightly raised erythematous patches with scaly margins. If topical corticosteroids have been applied to the area, the rash may be atypical and difficult to recognize.

Underlying skin conditions that cause rashes in the diaper area vary. Seborrheic dermatitis is common in infancy and appears at 3 or 4 weeks of age. Most cases subside spontaneously by 3 to 4 months of age. Seborrheic dermatitis is characterized by a sharply demarcated zone of erythema that commonly starts in the skin folds and spreads out over convex skin areas. It may be accompanied by small papules that are similar in appearance to the satellite lesions of *C. albicans*. Seborrheic dermatitis can be distinguished from intertrigo by the involvement of other areas of the body, such as the axilla, face, and scalp.

Atopic dermatitis usually does not occur in warm, moist environments such as the diaper area.¹⁰ When it does present in the diaper area, the lesions are red and scaly, similar to seborrheic dermatitis. The primary differentiating points are that atopic dermatitis generally has its onset later in life, at about 2 months of age, and is intensely pruritic.⁶ Atopic dermatitis also has the tendency to become eroded, with the development of crusting, oozing, eczematous-appearing lesions. At this point, the infant runs the risk of secondary infection of the involved areas.

Other less common causes of diaper rash should be considered when clinical presentation varies or response to therapy is not adequate. These include syphilis, Letterer-Siwe disease, psoriasis, granuloma gluteale infantum, nutritional disorders, and other bullous eruptions.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis can usually be established on the basis of history and physical examination. The history for the rash should include age at onset; laundering and diapering practices; frequency of bathing; use of creams and medications, especially antibiotics that may alter gastrointestinal flora; any recent gastroenteritis with accompanying diarrhea; response to previous therapy; and family history. The physical examination should note the morphology, color, and distribution of the rash. Diagnostic errors occur because of failure to do a full physical examination to rule out underlying conditions that may present as a diaper rash.

Diaper rash is common and usually easily diagnosed and treated. Because more serious clinical entities may initially present as a diaper rash, however, several clinical caveats are in order:

- Seborrheic dermatitis in an infant younger than 6 months of age that does not respond to conventional therapy should alert the physician to the possibility of Letterer-Siwe disease.
- Many conditions may be secondarily infected with yeast or bacteria and should be treated accordingly.
- Sexually transmitted diseases are a cause of diaper rash. The possibility of congenital infection or sexual abuse must be entertained.
- Dermatophytosis is uncommon but occurs in the diaper area.
- Psoriasis presents after the resolution of another primary skin condition and may lack the typical thick, silvery scale.

EMERGENCY DEPARTMENT MANAGEMENT

The management of diaper rash begins with a discussion of the pathophysiology of the rash in terms the parents can understand. The emergency department physician must explain the effects that infrequent diaper changes, prolonged exposure of the skin to urine and stool, diarrhea, and antibiotic use have on the production of the diaper rashes.

For mild irritant dermatitis or seborrheic dermatitis, a 1% hydrocortisone cream is usually effective. For more severe dermatitis, such as atopic dermatitis, or psoriasis, a more potent fluorinated corticosteroid, such as 0.1% betamethasone valerate, is used twice daily initially. As inflammation subsides, 1% hydrocortisone is used. Infection with *C. albicans* is common and may be treated with 1% hydrocortisone cream and a topical imidazole or nystatin cream twice daily, or after each diaper change, if the area is cleaned. If thrush is a consideration, oral nystatin suspension, 1 mL three times a day for 5 to 7 days, is prescribed.

Dermatophytes are treated with topical antifungal agents, such as miconazole nitrate 2% applied twice daily for 2 to 4 weeks. Bullous impetigo or folliculitis is treated with systemic antibiotics, such as cephalexin 40 to 60 mg/kg/d, divided into three to four doses, or other antibiotics with good activity against *S. aureus*, such as mupirocin 2% ointment topically, three times a day.

Zinc oxide ointment can be used to protect the area once the primary rash has resolved, but one must remember that creams are generally preferred to ointment bases, because ointments tend to be occlusive and cause sweat retention. Potent corticosteroids are used only for short periods of time to avoid local and systemic side effects.

DISPOSITION

Consultation or admission is rarely needed for the treatment of a diaper rash. Exceptions are cases refractory to therapy, those in which an underlying systemic disorder is suspected, or those in which parental neglect or inability to properly care for the child is suspected.

COMMON PITFALLS

- Failure to do a full history and physical examination
- Neglecting attention to simple general care
- Not providing the parents with specific, written instructions
- Failure to recognize secondary infection and treat it accordingly
- Overuse of potent corticosteroids
- Failure to recognize more serious underlying disorders or infections, especially when they present as a chronic or refractory problem

ACKNOWLEDGEMENT

The author gratefully acknowledges the contribution of Jane Knapp, who wrote the previous version of this chapter.

The sudden onset of a rash, particularly with fever, is a frequent cause of emergency department (ED) visits. Definitive diagnosis may not be possible in the ED. Most patients have a nonspecific, self-limited viral illness rather than a classic disease such as measles. The physician should focus on identifying diseases that require specific therapy (e.g., scarlet fever) or have public health implications, and should exclude life-threatening illnesses with rash (see [Chapter 247](#)).

Patient history should establish the initial location, spread, duration, and changes in appearance of the rash. Any fever or other associated symptoms, such as sore throat, cough, vomiting, headache, and neck pain, should be characterized. A history of recent exposure to a highly contagious disease, such as varicella or measles, is often helpful. Recent medication use may suggest a drug reaction. If either the patient or a household contact is a neonate, pregnant, or immunocompromised, the management of an otherwise benign illness may be altered.

Physical examination should focus on assessing the general severity of illness (e.g., irritability, state of hydration) and should thoroughly characterize skin and mucous membrane lesions. Complications such as otitis media, cellulitis, pneumonia, and encephalitis should be sought.

DISEASES WITH MACULOPAPULAR ERUPTIONS

Nonspecific viral eruptions commonly have maculopapular lesions, often resembling the classic childhood diseases. Differentiating features of illnesses with characteristic maculopapular eruptions are shown in [Table 269.1](#).

Disease	Age Group	Season	Prodrome	Exanthem	Systemic Symptoms	Complications
Measles	Children, young adults	Spring	High fever, cough, coryza, conjunctivitis	Maculopapular, bluish-white specks (Koplik's spots) on buccal mucosa	High fever, cough, coryza, conjunctivitis	Common: pneumonia, encephalitis, subacute sclerosing meningitis, SSPE
Rubella	Children, young adults	Winter, spring	Low-grade fever, lymphadenopathy	Maculopapular, bluish-white specks (Koplik's spots) on buccal mucosa	Low-grade fever, lymphadenopathy	Common: arthritis, orchitis, meningitis, encephalitis, congenital rubella syndrome
Scarlet fever	Children, young adults	Spring, fall	High fever, sore throat, strawberry tongue	Maculopapular, bluish-white specks (Koplik's spots) on buccal mucosa	High fever, sore throat, strawberry tongue	Common: otitis media, cellulitis, pneumonia, meningitis, encephalitis, toxic shock syndrome
Erythema infectiosum	Children, young adults	Spring	Low-grade fever, malaise	Maculopapular, bluish-white specks (Koplik's spots) on buccal mucosa	Low-grade fever, malaise	Common: arthritis, orchitis, meningitis, encephalitis, congenital rubella syndrome
Scarlet fever	Children, young adults	Spring, fall	High fever, sore throat, strawberry tongue	Maculopapular, bluish-white specks (Koplik's spots) on buccal mucosa	High fever, sore throat, strawberry tongue	Common: otitis media, cellulitis, pneumonia, meningitis, encephalitis, toxic shock syndrome

TABLE 269.1. Differentiating Features of Selected Diseases with Maculopapular Eruptions

EPIDEMIOLOGY AND CLINICAL PRESENTATION OF SPECIFIC DISEASES

Measles

Measles (rubeola) is caused by a paramyxovirus. The incidence of measles has declined greatly since widespread vaccination began, but outbreaks still occur. Recent outbreaks that occurred between 1989 and 1991 involved primarily unvaccinated preschool-aged children in urban areas, but cases may also be seen in older children and young adults, particularly those receiving only a single dose of vaccine. Many recent measles cases in the United States have been due to importation from endemic areas.⁷ The diagnosis of measles has important public health implications, as prompt recognition of a local outbreak helps control spread. Health-care facilities, including EDs, may serve as sites of significant exposure risk to patients and staff.^{8,13}

Measles has a characteristic 3- to 4-day prodrome, characterized by fever, malaise, and the “3 C’s”—cough, coryza, and conjunctivitis. A pathognomonic enanthem known as Koplik’s spots precedes the rash and consists of small red patches capped by bluish-white specks (resembling sprinkles of salt), seen first on the buccal mucosa opposite the molars, with subsequent spread and coalescence within the mouth. Koplik’s spots resolve by the second or third day of rash and have often disappeared by the time the patient is seen. The rash appears on the third or fourth day of illness, and consists of purplish-red maculopapules that begin at the hairline and spread downward, tending to be confluent on the face and neck.

A comparison of the progression of skin findings in measles, rubella, and scarlet fever is shown in [Fig. 269.1](#). The child with full-blown measles appears miserable (“measly”), with high fever, impressive conjunctivitis, marked cough, and rhinorrhea. The severity of symptoms peaks on the second day of the rash, with subsequent rapid recovery in uncomplicated cases. Measles is highly contagious, with infectivity from about 2 days before onset of illness to 4 days after the rash appears. The incubation period is 8 to 12 days from exposure to onset of illness.

Figure 269.1. Differences in appearance and progression of rashes in measles, rubella, and scarlet fever. (From Krugman S, et al. *Infectious diseases of children*, 8th ed. St. Louis: CV Mosby, 1985, with permission.)

Otitis media, diarrhea, dehydration, pneumonia, and croup are common complications of measles. Severe laryngotracheobronchitis has been a frequent complication among recently hospitalized infants and young children; endotracheal intubation may be required to relieve airway obstruction.^{9,16} Encephalitis is a rare complication. Although measles is seldom fatal in the United States, approximately 1 million deaths per year occur worldwide.⁷ Vitamin A deficiency is associated with increased morbidity and mortality from measles; treatment with vitamin A appears to reduce measles complications in developing countries.² Significant numbers of children with measles in the United States have been found to have low levels of vitamin A; supplementation may be indicated in selected patients (see [Emergency Department Management](#)).^{1,2}

Rubella

Rubella (German measles) is a mild disease caused by *Rubivirus*. Its major significance is its ability to cause severe illness and birth defects in prenatally infected infants. Since vaccination began, the incidence of rubella and congenital rubella syndrome has greatly decreased; however, approximately 10% of young adults remain susceptible.¹

Rash is usually the first symptom of rubella, beginning with discrete pink-red maculopapules on the face that rapidly spread downward (see [Fig. 269.1](#)). A nonspecific enanthem of small reddish dots on the soft palate (Forchheimer's spots) may be seen. The rash often coalesces on the trunk and usually fades within 3 days. Generalized lymphadenopathy, particularly postauricular and suboccipital, is typical. Adolescents and adults tend to have a febrile prodrome and commonly develop arthralgias or arthritis. Serious complications, such as encephalitis or purpura, are extremely rare. First-trimester prenatal infection may cause severe anomalies and illness in the fetus, including congenital heart disease, deafness, cataracts, microcephaly or mental retardation, hepatosplenomegaly, and purpura.

Roseola

Roseola infantum (exanthem subitum) is a commonly recognized clinical syndrome in young children. Human herpesvirus 6 (HHV-6) is the primary etiologic agent, although human herpesvirus 7 (HHV-7) appears to cause a similar illness.¹⁷ HHV-6 is a very common cause of acute febrile illness in young children seen in the ED, peaking at 6 to 9 months of age.¹⁰ However, only about 15% to 20% of HHV-6 infections present as typical roseola.^{10,11} Almost all children acquire HHV-6 by 2 years of age.

Classic roseola has a characteristic history of abrupt onset of high fever for 3 to 4 days, followed by sudden defervescence that coincides with the onset of rash. The skin lesions are small, discrete, rose-pink macules or maculopapules that appear first on the trunk before spreading to the rest of the body. The rash resolves within 1 to 2 days. When seen during the febrile phase, the child may be irritable but often appears otherwise well. Diarrhea and cough are common associated symptoms. Physical findings may include a bulging fontanelle, periorbital edema, erythematous papules on the soft palate and base of the uvula (Nagayama's spots), inflamed tympanic membranes, and cervical adenopathy.^{6,11} Febrile seizures are common. Serious complications such as encephalitis are rare.

Erythema Infectiosum

Erythema infectiosum, or "fifth disease," is caused by human parvovirus B19. Parvovirus B19 is also responsible for other illnesses, including nonspecific febrile illnesses and rashes, aplastic crises in patients with chronic hemolytic anemia (e.g., sickle cell anemia), chronic anemia in immunocompromised persons, and arthritis. Maternal infection, particularly in the first half of pregnancy, may result in fetal anemia, hydrops, and fetal death.

Erythema infectiosum typically affects school-aged children in epidemics. A viremic phase occurs approximately 1 week before the onset of rash; some children have a nonspecific febrile illness during this time, but many are asymptomatic. The skin findings appear in three stages. A bright red, raised macular rash on the cheeks that spares the nasal bridge and mouth appears first, giving the child a distinctive "slapped-cheek" appearance. The second stage begins about 1 day later with a symmetric maculopapular rash on the extremities and trunk (appearing first on the arms and extensor surfaces), which becomes lacy-appearing as confluent areas clear. During the third stage, lasting weeks to months, the rash may reappear with various stimuli, such as bathing, temperature extremes, or local irritation.

Occasional complications in children include arthralgias and arthritis; symmetric polyarthritides is common in women. Patients with fifth disease are not contagious once they have a rash; however, patients with aplastic crisis are highly infectious. The risk of fetal death in proven infection in the first half of pregnancy is under 10%, and less in the second half.¹ The overall risk of an adverse fetal outcome when a pregnant woman is exposed to parvovirus B19 is only 1% to 2%; at least 50% of women have had previous unrecognized infection and are immune.^{1,12}

Scarlet Fever

Scarlet fever (scarlatina) is a rash seen in association with group A beta-hemolytic streptococcal (GABHS) infections caused by strains producing an erythrogenic toxin. A similar clinical picture may be caused by other organisms, including *Staphylococcus aureus* and *Arcanobacterium haemolyticum*. Scarlet fever is most common in school-age children in the winter and spring and is more prevalent in temperate or colder climates. The clinical symptoms are usually those of streptococcal pharyngitis, although other types of GABHS infections, such as pyoderma, may occasionally present with scarlatina. The rash appears within 1 to 2 days, beginning on the trunk and spreading rapidly. The skin is red, blanches, and has fine punctate bumps that feel like sandpaper. The face is flushed and has circumoral pallor. The rash is prominent in skin folds, and Pastia lines (areas of hyperpigmentation and petechiae) may be seen in joint creases such as the antecubital fossae (see [Fig. 269.1](#)). Desquamation after resolution of symptoms is characteristic. The complications of scarlet fever are the same as those of streptococcal pharyngitis (rheumatic fever, glomerulonephritis).

Other Agents

Many other agents cause nonspecific maculopapular eruptions. A rash that is usually maculopapular but may be urticarial, vesicular, hemorrhagic, or similar to erythema multiforme occasionally accompanies infectious mononucleosis. Rashes are seen commonly in patients with mononucleosis who have received ampicillin. *Mycoplasma pneumoniae* infections have a wide variety of associated rashes, including maculopapular and vesicular types. Enteroviruses are a common cause of nonspecific febrile exanthems as well as more distinctive vesicular eruptions.

DIFFERENTIAL DIAGNOSIS

The presumptive diagnosis of a specific disease or nonspecific "viral exanthem" is usually made clinically, because definitive diagnosis requires methods such as viral culture or titer tests that are generally not useful in the ED. Many other conditions are associated with maculopapular skin lesions, including drug reactions, rheumatic diseases, and Kawasaki disease. Scarletiform rashes are commonly seen in streptococcal and staphylococcal toxic shock syndromes. Other life-threatening

infections, such as meningococemia and Rocky Mountain spotted fever, occasionally present with a benign-appearing rash. These possibilities should be considered in the child with severe or unusual symptoms.

EMERGENCY DEPARTMENT EVALUATION

The child's overall degree of illness is the most important assessment, as laboratory tests are rarely helpful or indicated in the child who is only mildly ill. A throat culture or rapid strep test (with confirmatory culture if negative) should be obtained if the child has a sore throat or suspected scarlet fever. Antibody titers may be useful for confirming suspected cases of measles, rubella, and parvovirus B19 exposure (pregnant contacts). White blood cell counts and blood cultures are helpful in evaluating the ill-appearing child who is suspected of having complications or a more serious disease. Further workup should be aimed at confirming clinically suspected complications such as pneumonia or encephalitis.

EMERGENCY DEPARTMENT MANAGEMENT

A child with an uncomplicated, presumably viral illness should be treated symptomatically with acetaminophen or ibuprofen and oral fluids; antibiotics should be reserved for secondary bacterial infection. Scarlet fever requires treatment with penicillin or an alternative.

Children with suspected measles or rubella should be isolated within the ED and reported to the health department. Treatment with vitamin A may be indicated for selected children with measles, such as infants 6 months to 2 years of age hospitalized with complications, and children with immunodeficiency, impaired intestinal absorption, malnutrition, or recent immigration from areas with high measles mortality rates.^{1,2}

Attempts at prevention or amelioration of measles may be indicated for susceptible household contacts, particularly infants younger than 1 year, pregnant females, and immunocompromised persons. Intramuscular immune globulin, given within 6 days of exposure, is the primary mode of prevention in such cases. Measles vaccine may be used for susceptible household contacts (unless pregnant or immunocompromised) if given within 72 hours of exposure; however, this is seldom possible, because the diagnostic findings of measles are not present until the third or fourth day of illness.¹

DISPOSITION

A pediatrician or infectious disease specialist should be consulted if the child appears to have a serious complication, is a neonate, or is immunosuppressed, or if a potentially serious disease is under consideration. Indications for hospitalization include dehydration, pneumonia, measles croup, encephalitis, and clinical toxicity.

Obstetric follow-up should be arranged for pregnant patients who may have been exposed to rubella or parvovirus B19; antibody titer tests may be indicated. Children with erythema infectiosum need not be isolated or restricted from school or daycare attendance, because they have already passed their period of infectivity.

Patients discharged home should follow up with their private physician or the ED if their illness worsens or does not resolve within the expected time course. Occasionally, the physician or parent may be uncomfortable with a diagnosis of "nonspecific viral exanthem." If the child is not acutely ill, outpatient consultation is appropriate.

Transfer to a tertiary pediatric facility should be considered if the child needs a level of care or expertise (e.g., intensive care or subspecialists) that is not available at the treating facility.

COMMON PITFALLS

- Children with benign, nonspecific febrile exanthems do not need lengthy diagnostic evaluation unless they are ill-appearing.
- Early scarlet fever may be subtle and easily overlooked, especially in children with minimal pharyngitis.

DISEASES WITH VESICULAR OR PUSTULAR LESIONS

Viral vesicular rashes and enanthems are frequently distinctive, allowing a presumptive diagnosis in many cases. The basic approach to the history and physical examination is described earlier in this chapter.

EPIDEMIOLOGY AND CLINICAL PRESENTATION OF SPECIFIC DISEASES

Varicella

Varicella (chickenpox) is a common contagious childhood disease caused by the varicella-zoster virus. Most cases occur in children, but adolescents and adults tend to have a severe course, with more frequent complications. Chickenpox is most common in late winter and spring. The frequency of varicella is likely to decrease as the vaccine becomes more widely used.

Signs and symptoms of varicella in healthy children include mild systemic symptoms, fever, and rash following an incubation period of 10 to 21 days. The skin lesions appear in crops, beginning as macules that rapidly progress to papules, then vesicles that eventually rupture and crust. The classic early vesicle is small and surrounded by erythema, resembling a dewdrop on a rose petal. The first lesions often develop on the face and scalp.

As the rash spreads, lesions of all stages (papules, vesicles, crusts) are characteristically present within a single affected area. Shallow ulcers often occur in the mouth but may also be seen on other mucous membranes. The number of skin lesions generally correlates with the height of fever and severity of symptoms. Pruritus is common, and scarring may result if the lesions are traumatized by severe scratching or become infected. The patient is contagious from 1 day before onset of the rash until all of the lesions are crusted, or until 6 days from the onset of rash.

Serious complications are unusual in normal children. Secondary bacterial skin infections, manifested by impetigo, cellulitis, or local abscess, are the most common complications seen in young children. Recently, there have been increased reports of invasive group A beta-hemolytic streptococcal (GABHS) infections associated with chickenpox, including necrotizing fasciitis and streptococcal toxic shock syndrome.^{3,18} GABHS infection should be suspected in children with varicella who develop localized skin swelling, warmth, redness, or pain, and in those with fever persisting beyond the fourth day of illness or who have recurrence of fever after becoming afebrile.³ Pain out of proportion to the degree of clinical findings is common.

Other serious complications seen occasionally in children include neurologic problems such as acute cerebellar ataxia, encephalitis, and Reye syndrome. Varicella pneumonia is relatively common in adolescent and adult patients but is rare in children. Unusual complications include hepatitis, eye involvement (keratoconjunctivitis or uveitis), coagulopathy, arthritis, orchitis, nephritis, and other invasive bacterial infections (e.g., osteomyelitis).

Patients with altered cell-mediated immunity, such as leukemic children receiving chemotherapy, are susceptible to disseminated varicella with hemorrhagic lesions, pneumonitis, and encephalitis. Fetal infection during the first or early second trimester of pregnancy may result in the congenital varicella syndrome. Newborns exposed to perinatal maternal varicella are at risk for severe illness. Children recently treated with corticosteroids (particularly systemic, high doses) may be at increased risk of severe varicella, although this is controversial. A case-control study found little increased risk in otherwise normal children.¹⁵

Herpes Zoster

Herpes zoster (shingles) is caused by reactivation of latent varicella-zoster virus in sensory ganglia. Children are less commonly affected than are adults, and younger patients tend to have a less painful course and little postherpetic neuralgia. The characteristic findings include grouped, vesicular lesions in a dermatomal distribution, accompanied by pain and tenderness along the pathway of the nerves involved. Fever and local lymphadenopathy are common. The presence of lesions

on the tip of the nose signals possible eye involvement.

Herpes Simplex

Primary infection with herpes simplex viruses (usually HSV-1) in childhood is extremely common and often asymptomatic. The most common form seen in the ED is acute herpetic gingivostomatitis, primarily affecting children aged 1 to 4 years. Symptoms include high fever, irritability, and reluctance to eat or drink. The child looks uncomfortable, drools, and has marked gingival redness, swelling, and friability. Ulcerations or plaques may be seen on the tongue, buccal mucosa, palate, and pharynx. Vesicles may be present on the lips, and there is tender cervical adenopathy. Lesions can occasionally be seen on the fingers or genitalia from autoinoculation. Dehydration is not uncommon. Symptoms may last 1 to 2 weeks.

Other primary and recurrent herpes infections, including herpes labialis, herpetic whitlow, and herpes keratoconjunctivitis, may be seen in children. Children with atopic dermatitis may develop extensive herpes simplex infection on eczematized areas (eczema herpeticum, also called Kaposi's varicelliform eruption). Although herpetic vulvovaginitis can be a rare manifestation of innocently acquired primary herpes simplex infection in young children, the possibility of sexual abuse must be strongly considered.

Enteroviruses

Nonpolio enteroviruses are a frequent cause of febrile illnesses and exanthems. Pathogens include group A and B coxsackieviruses, echoviruses, and enteroviruses. Epidemics occur during the summer and fall, affecting primarily 1- to 4-year-old children. The vesicular exanthems and enanthems are often distinctive and easily recognized. Occasional complications include dehydration and aseptic meningitis.

Hand-foot-and-mouth disease is a distinctive clinical syndrome. Children have fever and lesions on the oral mucosa and tongue that progress from small red macules to vesicles on an erythematous base to discrete ulcers. The skin lesions are oval or linear vesicles (about 3 to 7 mm) surrounded by erythema. They occur on the dorsum of the hands and feet, the interdigital areas, and the palms and soles. Some patients have mild diarrhea or cervical adenopathy. Serious complications, such as meningitis, myocarditis, and pneumonia, are unusual.

Herpangina presents with fever, sore throat, and dysphagia. Examination discloses small vesicles or punched-out ulcers involving the tonsillar pillars, tonsils, pharynx, and soft palate. The illness resolves in 5 to 6 days.

DIFFERENTIAL DIAGNOSIS

Classic varicella is usually easily recognized, although early cases may require a meticulous search to find the first vesicles. Herpes zoster and herpes simplex infections can overlap in presentation, and viral vesiculopustular lesions are sometimes confused with impetigo. Herpetic gingivostomatitis may be confused with herpangina, Vincent's angina, or aphthous stomatitis. Herpetic whitlow is often misdiagnosed as a paronychia. Many other disorders may present with vesicular lesions.

A definitive diagnosis of herpes simplex or varicella-zoster virus infection may be needed in immunocompromised or severely ill patients. There are numerous testing methods available (e.g., enzyme immunoassay, latex agglutination, indirect fluorescent antibody, fluorescent antibody-to-membrane antigen); the practitioner should consult with the laboratory and pertinent specialists, if necessary (i.e., infectious diseases), to determine the best available methods. Immunofluorescent staining of vesicle scrapings, using monoclonal antibodies, can distinguish between herpes simplex virus and varicella-zoster virus.

Herpes simplex is easily cultured; polymerase chain reaction (PCR) testing for herpes simplex virus is sensitive, but false positives occur. Less accurate but helpful when more sophisticated tests are unavailable is the Tzanck preparation, which demonstrates multinucleated giant cells in both varicella-zoster and herpes simplex infections.

Virus isolation or PCR testing (e.g., from throat, stool, cerebrospinal fluid) may be helpful in the diagnosis of enterovirus infections, although isolation from stool is of uncertain clinical significance.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

ED evaluation includes assessment of the child's degree of clinical toxicity, state of hydration, and ability to take oral fluids. Laboratory evaluation is indicated for suspected complications or in high-risk patients in whom definitive diagnosis is necessary.

Symptomatic therapy for chickenpox includes acetaminophen and measures to decrease itching and discomfort. Children with chickenpox should not receive aspirin because of its association with Reye syndrome. Recently, there has been concern that ibuprofen use may be associated with an increased risk of necrotizing fasciitis in children with chickenpox.¹⁸ Although causal evidence is lacking, some authors caution against the use of ibuprofen and other nonsteroidal antiinflammatory drugs in patients with varicella. Topical measures, such as cool baths, calamine lotion, and colloidal oatmeal baths, may help alleviate pruritis. Oral antihistamines (diphenhydramine or hydroxyzine) may be helpful for severe itching; topical antihistamines are less desirable because of the risks of sensitization and excessive systemic absorption through nonintact skin.

Oral acyclovir started within 24 hours of rash onset in normal children with chickenpox has shown modest benefit in reducing the number of lesions, duration of fever, and severity of constitutional symptoms.⁴ However, most authorities do not recommend the routine use of acyclovir in healthy children who are likely to have an uncomplicated course. Acyclovir treatment (20 mg/kg four times a day for 5 days; maximum single dose, 800 mg) beginning within 24 hours of rash onset may be advisable for children with varicella who appear to be at risk of moderate-to-severe disease. Such patients include adolescents (over age 12), children older than 12 months of age with chronic skin or pulmonary disorders, children on chronic salicylate therapy, and patients recently treated with short, intermittent, or aerosolized courses of corticosteroids.¹ Although acyclovir and related drugs are commonly used to treat adults with shingles, normal children seldom have severe symptoms or develop postherpetic neuralgia, and treatment is not routinely recommended. Significantly immunocompromised patients with varicella-zoster infections should be hospitalized and treated with intravenous rather than oral acyclovir.

Acyclovir and related drugs are commonly used to treat adults with severe or recurrent herpes simplex infections, but there is little pediatric data. One study found that oral acyclovir (15 mg/kg five times a day for 7 days) started within 72 hours of the onset of herpes gingivostomatitis reduced symptoms and duration of illness.⁵ Although some authors recommend routine use of acyclovir for children with gingivostomatitis and other herpes simplex infections,¹⁴ the optimal dose has not been established, and routine use remains controversial. There seems to be more agreement that children with severe illness requiring hospitalization should be treated; immunocompromised patients (including neonates) should receive intravenous acyclovir.

Children with oral vesicles and ulcers, especially those with herpetic gingivostomatitis, may refuse to drink. Cold substances such as Popsicles, ice cream, and nonirritating fluids are often accepted. Acetaminophen or ibuprofen usually suffices for symptomatic relief in mild cases. However, children with severe mouth pain may require narcotic analgesia. Oral anesthetics (e.g., viscous lidocaine) are seldom helpful in children with widespread stomatitis and should be used sparingly to avoid toxicity. Intravenous hydration may be required. Antibiotics should be given only for secondary bacterial infections.

Patients with varicella should be isolated in the ED. Passive immunization with varicella-zoster immune globulin may be indicated within 96 hours of exposure of a susceptible, high-risk patient.¹

DISPOSITION

Children with chickenpox who have significant or rapidly progressing cellulitis should be hospitalized for intravenous antibiotics and carefully observed for the development of necrotizing fasciitis. Neonates or immunocompromised patients with suspected varicella-zoster or herpes simplex infection should be referred to a specialist (e.g., for infectious disease, oncology, neonatology, pediatrics). These patients usually require hospitalization for intravenous acyclovir. An ophthalmologist

should be consulted when herpes keratoconjunctivitis is suspected.

Children with uncomplicated viral stomatitis or rash are discharged on symptomatic therapy, with outpatient follow-up scheduled if further symptoms develop or the child does not improve within a few days.

Transfer to a tertiary pediatric facility should be considered if the child is seriously ill or needs intensive care, or when subspecialty consultation is indicated.

COMMON PITFALLS

- Children with vesicular skin infections or stomatitis are often uncomfortable, and their parents are frequently frustrated. Give reassurance and careful explanations about the expected course, communicability, and self-limited nature of the disease.
- If the term *herpes infection* is used, explain to the parents the innocent acquisition of most childhood infections, to avoid confusion and anxiety.
- Avoid potentially toxic preparations such as oral viscous lidocaine or topical diphenhydramine.
- Antibiotics should be prescribed only for the infrequent bacterial superinfection.
- Acyclovir is not indicated for healthy children presenting more than 24 hours after the onset of chickenpox lesions.

A complete pediatric eye examination includes inspection of the eyelids, conjunctivae, pupil, and iris; evaluation of the extraocular muscles; funduscopy; and testing of visual acuity. This examination is an essential part of the evaluation in any child presenting with primarily ophthalmologic conditions such as conjunctivitis, periorbital edema, visual change or loss, trauma, or neurologic complaints.

Inspection of the eyelids and conjunctivae should document the presence of erythema, ecchymosis, edema, proptosis, or masses. The cornea should be evaluated for normal contour and clarity. A bulging or hazy cornea in a neonate may indicate congenital glaucoma. The cornea should be stained, using topical anesthetic drops and fluorescein test strips, after the rest of the examination is completed so as not to interfere with visual acuity testing. Shining a Wood's light on the cornea in a darkened room will reveal stain adherent to corneal defects caused by an abrasion, herpetic infection, or ulcer. The pupil should be assessed for contour, bilateral symmetry and reactivity to light. An abnormally shaped or reactive pupil may indicate defects in the iris or disruption of the afferent or efferent nerve pathways to the eye.

Extraocular muscle testing can be accomplished by 4 months of age. By this age, a normal, full-term infant should be able to fixate on and follow a small, brightly colored toy held 6 to 12 in. from the baby's face. By 5 to 6 months, the infant should fixate and follow an object through the full range of motion. By 2 to 3 years of age, most children, with gentle encouragement, will follow a light or finger.²

Evaluation of the posterior chamber via direct ophthalmoscopy is dependent on the child's age and cognitive development, becoming easier as cooperation increases. The use of a short-acting topical parasympatholytic such as tropicamide (Mydracyl 0.5%), will facilitate the examination of the retina. To encourage the child to look beyond the examiner and away from the direct light, use a brightly colored toy or have the parent wave at the child from directly behind the examiner. The minimal examination in an infant is the documentation of a normal red reflex. The presence of an abnormal red reflex (leukocoria), which could indicate a cataract or intraocular tumor, mandates formal consultation with a pediatric ophthalmologist.

The corneal light reflex, or Hirschberg test, is useful in detecting strabismus or an ocular muscle palsy. It is conducted by shining a penlight, held 3 ft (1 m) away, centrally onto the child's face. In a normal child, the light will reflect centrally on both pupils when the child is fixated on the light or a small toy held in front of the face. If the light reflex is eccentric on one eye, a strabismus or palsy is present.²

Visual acuity testing is an extremely important aspect of the complete eye examination. The manner of testing is dependent on the age and cognitive ability of the child. Visual acuity also varies by age ([Table 270.1](#)). To assess an infant, have the baby fixate (on a bright toy or light) and cover one eye gently with your thumb. If the uncovered eye has normal vision, the child will continue to fixate on the object. If the uncovered eye has poor vision, the child may lose interest, push the covering thumb away, or protest.⁶

Age	Visual Acuity
6 mo	20/60 to 20/100
3 yr	20/25 to 20/30
5-7 yr	20/20 to 20/25
By 8 yr	20/20

TABLE 270.1. Visual Acuity by Age

By 3 years of age, depending on developmental and cognitive ability, more objective visual testing can be achieved. The Allen chart, HOTV matching test, or “Tumbling E” game can be used. By 5 years of age, most cognitively normal children can use the Snellen chart. Testing with the Snellen, Tumbling E, or HOTV chart should be performed at a distance of 20 ft (6 m). The Allen test can be performed at 10 ft (3 m).²

In all of these charts, letters or objects are presented as a group. Children with poor vision have increased difficulty identifying objects when presented as a group (the crowding phenomenon) and will perform better when objects are presented singly.²

THE RED EYE

Children frequently present to the emergency department (ED) with a complaint of one or both eyes being reddened. The most common diagnosis will be conjunctivitis due to bacterial or viral infection, chemical, or allergic exposure. The etiologies of infectious conjunctivitis after the neonatal period are nontypable *H. influenzae*, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, herpesvirus, and adenovirus.²⁶ Uncommonly, gonococcal conjunctivitis may occur after the neonatal period and in the prepubescent child, who is not sexually active. Sexual abuse must be excluded; however, cases of transmission from an infected caregiver who is not abusing the child have been reported.¹

The syndrome of conjunctivitis–otitis was first described in 1982 by Boder. Nontypable *H. influenzae* will commonly cause concomitant otitis and conjunctivitis. Additionally, as many as 60% of children presenting with conjunctivitis without clinical findings or symptoms of otitis will develop an otitis within 2 weeks.²⁴

Herpesviruses can cause ocular involvement during primary or recurrent infections. Herpes simplex virus (HSV) is ubiquitous and is transmitted from person to person during primary and recurrent infections that may or may not be symptomatic. Periocular inoculation can occur from the HSV-1 perioral infections so common in children. Herpes zoster represents a reactivation of latent varicella-zoster virus. When it occurs in the dermatomal distribution of the trigeminal nerve, it can cause a keratitis with conjunctivitis.¹

Adenoviral conjunctivitis may be associated with two distinct clinical syndromes: pharyngoconjunctival fever and epidemic keratoconjunctivitis. Pharyngoconjunctival fever is caused by adenovirus types 3 and 7. It is most commonly spread by person-to-person contact, but has also been reported to be spread through swimming; thus, the infection may be referred to as “swimming pool” conjunctivitis. Adenovirus types 8, 19, and 37 cause epidemic keratoconjunctivitis. This entity is transmitted by direct contact with infected people or contaminated instruments and is often iatrogenic. Attention to frequent hand washing prevents transmission.²⁶

Infectious neonatal conjunctivitis is caused by *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and, less commonly, HSV. The infant is infected at birth during passage through the birth canal. The incubation period for gonococcal conjunctivitis (ophthalmia neonatorum) is 2 to 7 days. Neonatal prophylaxis for ophthalmia neonatorum with a 1% silver nitrate solution, 0.5% erythromycin ophthalmic ointment, or 1% tetracycline ophthalmic ointment is recommended universally in the United States. Only silver nitrate solution is effective in prevention of infection by a penicillinase-producing gonococcus. Neonatal chlamydial conjunctivitis develops a few days to several weeks after birth. Fifty percent of infants born to infected women acquire *C. trachomatis*, and, of those, 25% to 50% develop conjunctivitis. Neonatal ophthalmic prophylaxis is not effective in the prevention of chlamydial conjunctivitis. Neonatal HSV infection occurs in one per 3,000 to one per 20,000 live births. The infant is most at risk if the mother has a primary infection at the time of delivery. The risk to an infant born to a mother with a recurrent infection is much lower. Neonatal infections are of three types: generalized infection, localized central nervous system (CNS) infection, or disease localized to the skin, eye, and mouth (SEM).¹

The most common cause of allergic conjunctivitis in children is seasonal rhinoconjunctivitis. The symptoms are caused by a localized IgE-mediated hypersensitivity reaction to airborne allergens, with resultant release of histamine and other products from mast cells. Pollens and grasses are the most common allergens. In up to 25% of children, ocular findings may be the sole manifestation. The findings are caused by the release of products from mast cells, predominantly histamine.^{4,21}

Chemical conjunctivitis is most often caused by ocular medications. Neomycin has the greatest incidence of contact sensitivity. Silver nitrate is a common cause in the neonate. Accidental environmental exposure to a toxin, such as cleaning agents, is also common.

CLINICAL PRESENTATION

The clinical presentation, while not completely specific, may help the clinician determine the etiology of conjunctivitis. Bacterial conjunctivitis is more often unilateral and occurs predominantly in infants and preschool-aged children. There is usually a mucopurulent exudate, and the palpebral and bulbar conjunctivae are erythematous but not hemorrhagic. Eyelid erythema and swelling may be present, and the child may be febrile. A neonate with ophthalmia neonatorum may appear toxic, with a copious purulent discharge. *C. trachomatis* infection causes a beefy red conjunctiva.¹

Viral conjunctivitis, on the other hand, is often bilateral and occurs in school-aged children. A mucopurulent discharge may be present, but the presence of a conjunctival inflammatory membrane is diagnostic. The discharge is often copious and clear. Marked periorbital edema can be present, leading to a false diagnosis of periorbital cellulitis.²⁰ Pharyngoconjunctival fever is manifested by pharyngitis, fever to 40°C (104°F), and conjunctivitis. Conjunctival findings may persist from 4 days to 2 weeks. Epidemic keratoconjunctivitis lacks upper respiratory symptoms and fever. Corneal involvement predominates, with an early keratitis that causes photophobia and a foreign-body sensation. Subepithelial opacities develop 7 to 10 days after onset, which may cause a temporary mild decrease in visual acuity. These opacities resolve without scarring of the cornea.²⁶

HSV infection of the eye is of the SEM type; however, skin and mouth lesions may not be present at the time of presentation. The conjunctiva is erythematous, and keratitis may be present. Characteristic dendritic keratitis may be seen with fluorescein staining for both varicella-zoster virus and herpes simplex virus. Varicella-zoster infection of the first division of the trigeminal nerve affects the eye. There may be characteristic vesicular lesions on the forehead and eyelid. The conjunctivae are usually injected. Herpes zoster is a unilateral infection, and, often, periorbital pain precedes the appearance of the vesicles.¹

Allergic conjunctivitis is bilateral, with variable conjunctival injection and watery eye discharge. Other allergic symptoms, such as boggy nasal turbinates, watery nasal discharge, and allergic shiners (dark circles around the eye), may or may not be present.

Chemical conjunctivitis presents with conjunctival injection and, often, a burning sensation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the red eye includes conjunctivitis, periorbital cellulitis, corneal abrasion, uveitis, iritis, Kawasaki syndrome, glaucoma, dry-eye syndromes, blepharitis, dacryocystitis and Parinaud oculoglandular syndrome (a syndrome of cat scratch disease involving the conjunctiva and ipsilateral preauricular

lymph node).

EMERGENCY DEPARTMENT EVALUATION

The ED evaluation of the red eye begins with a detailed history and physical, including a complete age-appropriate eye examination. A slit-lamp examination in an older child who is cooperative is helpful. Outside of the neonatal period, conjunctival cultures are rarely obtained. Fluorescein staining should be considered, especially with severe photophobia or corneal changes.

All young infants in whom the diagnosis of ophthalmia neonatorum or SEM secondary to HSV is being considered require a full evaluation for disseminated disease. In addition to blood and cerebrospinal fluid (CSF) studies (complete blood count, chemistries, blood culture, CSF culture for bacteria and viruses, glucose, protein, Gram stain), conjunctival cultures for bacteria and viruses should be obtained. In suspected gonococcal infection, a Gram stain of the eye is helpful in early confirmation of the diagnosis.²⁶ A Tzanck preparation may be helpful in herpetic infections. A conjunctival scraping is more sensitive than swab cultures.²⁶ When a chlamydial infection is suspected, cultures or specimens for rapid antigen testing of the conjunctiva and nasopharynx should be obtained.¹ A chemical conjunctivitis is suggested when a history of ocular exposure to a toxin or ophthalmic medication is elucidated in the presence of conjunctival injection.

EMERGENCY DEPARTMENT MANAGEMENT

The management of conjunctivitis is dependent on the suspected etiology and the age of the child. Treatment ranges from supportive care to hospital admission for parenteral antibiotics. Bacterial conjunctivitis is most frequently treated with topical ophthalmic antibiotics. Trimethoprim–polymyxin B, gentamicin sulfate, and sodium sulfacetamide all have high rates of cure.²⁵ Trimethoprim–polymyxin B eradicates *H. influenzae* most effectively.²⁴ The topical agent is administered every 4 hours, while the patient is awake, for 5 to 7 days.

In the instance of conjunctivitis–otitis syndrome, oral therapy with an appropriate antibiotic to treat *H. influenzae*, such as amoxicillin–clavulanate, will cure both the otitis and the conjunctivitis. Oral therapy for conjunctivitis without otitis has been shown to decrease the occurrence of otitis in the ensuing 2 weeks.²⁴ Further data are needed to substantiate the efficacy of oral treatment of conjunctivitis.

Table 270.2 lists the etiologies of neonatal conjunctivitis with the indicated treatment.

Organism	Medications	Other Therapy
<i>N. gonorrhoea</i>	Ceftriaxone 25–50 mg/kg i.v. or i.m., not to exceed 125 mg, given once or Cefotaxime 30 mg/kg i.v. or i.m.	Frequent eye irrigation with saline
<i>C. trachomatis</i>	Erythromycin 50 mg/kg/d divided q.i.d. PO for 14 d	
Herpes simplex virus	Acyclovir 30–60 mg/kg/d i.v. divided q8h Duration: 14 to 21 d and 1% to 2% trifluridine, 1% iodocyclopuridine, or 3% vidarabine, applied topically	Ophthalmologic consultation

Data from American Academy of Pediatrics.¹

TABLE 270.2. Etiology of Neonatal Conjunctivitis and Therapy

Localized herpesvirus infections involving the eye should be treated with intravenous acyclovir 30 mg/kg/d in three divided doses for children less than 1 year of age, and, for older children, 1500 mg/m²/d in three divided doses for 7 to 10 days. Higher dosing is used for disseminated or CNS disease.¹

Adenoviral conjunctivitis is treated with supportive therapy. To prevent the spread of infection to other family members, the family should be counseled to wash hands frequently and to avoid sharing wash cloths. The infected child should be kept away from immunocompromised persons and neonates, because this group is at increased risk for severe disease.

The treatment of allergic conjunctivitis is avoidance of the allergen and topical therapy with antihistamines, vasoconstrictors, or nonsteroidal antiinflammatory agents.²¹ Cool compresses may be soothing.

DISPOSITION

Bacterial conjunctivitis outside of the neonatal period is an outpatient disease. Follow-up with a primary care provider should be recommended.

If large corneal defects or defects involving the visual axis are detected, emergent ophthalmologic evaluation by a provider skilled in pediatric ophthalmology is necessary. All cases of suspected ophthalmia neonatorum, HSV, and varicella-zoster ophthalmic infection should be referred to a pediatric ophthalmologist emergently. The risk for ocular damage and permanent visual loss is high.

Neonatal and herpetic conjunctivitis requires inpatient therapy at a facility well versed in pediatric care and with pediatric ophthalmologic resources. When chlamydial infection is suspected, consultation with a pediatrician is helpful.

COMMON PITFALLS

- Failure to recognize herpetic infection of the eye. Delay in treatment can often lead to visual loss, CNS disease, or systemic disease.
- Failure to treat bacterial conjunctivitis results in delayed cure and progression of disease.
- Failure to recognize otitis in association with conjunctivitis

THE SWOLLEN EYE

Children with a swollen, red eye represent a relatively common problem in the ED. Most children with periorbital (PO) or orbital cellulitis (OC) are under the age of 5, with very few older than 10 years of age. The pathogenesis of PO/OC may occur via three different routes. The skin barrier near the eye may be broken by local trauma, an insect sting, or the lesions of varicella or herpes zoster, with local spread of infected material to the periorbital tissues. There may be contiguous spread to the orbital tissues from infected frontal, ethmoidal, or maxillary sinuses. Alternatively, there may be seeding of periorbital tissues from bacteremia.¹⁸

A bacterial pathogen is identified in only up to 30% of cases, with most of these, in the past, identified by blood culture. Prior to the introduction of the *H. influenzae* vaccine (HIB), 50% of the cultures were positive for *H. influenzae*. Widespread usage of the vaccine has resulted in a 90% decrease in the incidence of *H. influenzae*-related PO/OC.^{3,8} The most common organisms, currently, are *S. aureus*, group A *Streptococcus* species, and *S. pneumoniae*. *S. aureus* and group A *Streptococcus* are more likely to be involved when there is a history of local trauma or a wound. *S. pneumoniae* is more likely in the younger child with a history of an upper respiratory infection and sinusitis. Anaerobic bacteria and *M. catarrhalis* should be considered in the older child with documented sinusitis.⁸ *H. influenzae* should still be considered in the child who has not received, or not completed, the primary series of HIB vaccination (2, 4, 6 months).²²

Periorbital cellulitis is defined as an inflammatory or infectious process superficial to the orbital septum. If untreated, it has the potential to spread via blood vessels to the CNS or to penetrate the orbital septum and result in OC. *Orbital cellulitis* is thus defined as inflammation or infection deep to the orbital septum. OC may involve

the ocular structures, causing abscess formation and loss of vision. It may also spread to the CNS via the cavernous sinus, causing cavernous sinus thrombosis or meningitis.

CLINICAL PRESENTATION

The thin skin and loose connective tissue of the eyelid allow for easy and rapid accumulation of fluid. A child with PO/OC may often present within hours of onset with a red and swollen eyelid. Ninety-five percent of cases are unilateral, with the actual color of the lid described as violaceous or purple. Seventy-five percent of children are febrile. Two-thirds will have an upper respiratory infection; one-third, a history of minor trauma; one-fourth, an acute otitis media; and one-fifth, an associated conjunctivitis.¹⁸ In PO, palpation of the periorbital tissues will elicit tenderness, but the eye itself should move freely and painlessly. In advanced OC, the eye may be proptotic and extremely painful to voluntary movement of the extraocular muscles, and visual acuity may be reduced. There may be diplopia on upward gaze. The child may appear "toxic" or irritable, with early meningeal signs.

DIFFERENTIAL DIAGNOSIS

The most common differential diagnoses to consider are local allergic reactions, blunt trauma, swelling secondary to an underlying sinusitis, and bulbar or retrobulbar neoplasms. The history of an insect bite, the presence of loose swelling and itching, and the absence of systemic symptoms should aid in the diagnosis of a local allergic reaction. Likewise, the history of recent trauma to the area surrounding the eye, the presence of a "shiner," or the dissection of hematoma downward from a frontal contusion should be obtainable on careful questioning of the parent and child. Sinusitis is thought to cause swelling by obstruction of venous drainage from the overlying skin. The swelling is usually painless and not erythematous, but it sometimes may be difficult to distinguish from true PO. The time course for neoplasms of the lids and orbit is usually much more insidious. While retrobulbar tumors may cause proptosis and decreased vision, the lid swelling and periorbital cellulitis are usually not present.

EMERGENCY DEPARTMENT EVALUATION

The ED evaluation begins with a careful history and physical. The rapidity of onset; the history of trauma, insect bite, or skin lesions; the presence of an upper respiratory infection or sinusitis; and immunization status, particularly HIB, must be ascertained. The examination of the eye must include not only gentle palpation of the periorbital area, but also an assessment of whether the globe is proptotic, the function of the extraocular muscles, and whether there is any pain with movement of the eye. Visual acuity must be assessed, if necessary, with the use of lid retractors.

Laboratory studies are of limited value, although a white blood cell count greater than 15,000 may suggest bacteremia. Cultures of any wounds near the eye should be obtained; however, conjunctival or nasopharyngeal swabs are generally not helpful.¹⁸ Blood cultures have been reported positive in up to 30% of children; however 70% to 80% of these were *H. influenzae* in the prevaccine era.^{3,8,22} It seems likely that blood cultures will identify fewer and fewer organisms. In the pre-HIB era, lumbar puncture (LP) was considered almost mandatory in the young child because of the invasive and virulent character of *H. influenzae* bacteremia. Currently, most authors reserve LP for children under 1 year of age (increased risk of *S. pneumoniae* bacteremia),¹⁰ those who are "toxic" or irritable, or those who have not yet received or completed the HIB vaccination series.

Computerized tomography (CT) of the orbit may be useful in delineating sinusitis, orbital involvement, proptosis, abscess, or foreign body. It should be reserved for the child who presents with proptosis, pain on extraocular movement, decreased visual acuity, or inability to conduct a full eye examination.¹⁰

EMERGENCY DEPARTMENT MANAGEMENT

After appropriate cultures have been obtained, an intravenous line should be started and antimicrobial therapy initiated with a third-generation cephalosporin:

Ceftriaxone 50 to 75 mg/kg intramuscularly or intravenously q24h, or

Cefotaxime 50 mg/kg per dose intravenously q6h

plus Clindamycin 10 mg/kg per dose q8h, or nafcillin 100 to 200 mg/kg/d q6 h.¹⁸

DISPOSITION

Immediate consultation with an ophthalmologist should be undertaken if there are any physical findings suggestive of orbital involvement (proptosis, pain on eye movement, or decreased visual acuity), if there is difficulty obtaining an adequate eye examination, or if there has been failure to respond to parenteral antimicrobial therapy. Some of these children may be found to have an abscess that will require emergent surgical evacuation.

All children with OC and most children with PO should be admitted to the hospital. The inpatient unit should have the capability to care for children and have an ophthalmologist available for urgent consultation. Recently, certain selected children with PO have been managed on an outpatient basis. There are several criteria that need to be met before the child can be discharged: There must be *no* orbital involvement (proptosis, ophthalmoplegia, decreased visual acuity), the child should be well-appearing, and there should be no purulent wound near the eye. Furthermore, the support system should be such that, not only are the parents willing and able to take the child home, but also willing and able to return the child immediately should there be a worsening in the child's condition. If *all* of these criteria are met and appropriate cultures are taken, an initial dose of ceftriaxone 50 mg/kg intramuscularly or intravenously (not to exceed 1 g) is given, followed by ampicillin-clavulanate 45 mg/kg/d in two divided doses orally for 7 to 10 days.⁸ In the penicillin-allergic child, give azithromycin 12 mg/kg (max, 500 mg/d) once a day for 5 days.¹³ The choice of outpatient antibiotics should reflect *S. pneumoniae* and group A *Streptococcus* resistance within the community. The child should be brought back for daily examinations to document and follow resolution, until blood cultures are negative (usually 48 hours).^{18,22}

COMMON PITFALLS

- Failure to conduct a thorough eye examination, thus missing signs of orbital involvement
- Failure to perform an LP in a child under 12 months of age or in a child with early meningeal signs or irritability, thereby missing CNS involvement
- Failure to consult an ophthalmologist early in cases of orbital involvement, which could result in a poor outcome, possible visual impairment, or loss of the eye
- Discharging a child who does not meet all of the criteria for outpatient management, resulting in a poor outcome from OC or abscess or spread to the CNS

ABNORMAL VISION

Children with complaints related to vision rarely present to the ED. When they do, the visit is prompted by their own complaints of abnormal vision or complaints from their parents, teachers, or school nurses. Occasionally, the ED physician, during the course of an examination, discovers a particular finding that necessitates urgent ophthalmologic referral. The complaints and etiologies for visual loss can vary greatly with the age of the child.

Cataracts, glaucoma, intraocular tumors, optic nerve problems, and nystagmus may all present in infancy. The incidence of congenital cataracts is one to four of 10,000 live births in industrialized countries and five to 15 of 10,000 births in the developing world. Cataracts usually present in the newborn nursery.¹¹ However, with home births and the easy movement of populations between developing countries and the industrialized world, it is conceivable that the first presentation may be in the ED. Cataracts are strongly associated with several chromosomal abnormalities (trisomy 13, 18, 21), perinatal infections (rubella, toxoplasmosis, or varicella-zoster), and inborn errors of metabolism.¹¹ Infantile glaucoma has an incidence of less than one in 10,000 live births. The sclera of an infant is more elastic than that of an older child. Increased intraocular pressure results in a gradual expansion of the globe. While the predisposition is congenital, the term *infantile* is used to express the variability in the time of onset from birth to clinically apparent disease.¹⁶

Retinoblastoma is the most common intraocular malignancy. The average age of presentation is 18 months, with most occurring prior to 3 years of age. One-third of tumors are bilateral and present earlier than unilateral tumors. The underlying genetic defect is felt to be associated with changes to one of the genes on chromosome

Nystagmus in childhood may be congenital or acquired. The etiologies of congenital nystagmus are essentially the same as those that cause visual impairment in infancy. Nystagmus that develops in the older child is usually either drug-induced or associated with severe visual loss or intracranial neoplasm.¹⁹

By far, the most common complaint in the toddler and preschool-age child that is seen in the primary care office is strabismus, or ocular malalignment. The prevention of amblyopia (abnormal vision in an anatomically normal eye) is the major visual concern in this age group. If not detected and treated appropriately, the child may be left with a functionally blind eye.^{12,16}

Visual loss in childhood may result from compression of the optic nerve by tumor, inflammation of the optic nerve, and hereditary degenerative conditions. Ten percent of rhabdomyosarcomas occur in the eye, arising from the intraocular muscles. The peak incidence is at age 8, with 75% occurring before age 10.¹⁶ Optic neuritis in the child is felt to be a postviral autoimmune phenomenon. The most common preceding infections are measles, mumps, varicella, pertussis, mononucleosis, and postimmunization. Unlike in young adults, there is not a strong association with multiple sclerosis.¹⁹

Optic gliomas and craniopharyngiomas are the two most common tumors that compress the optic nerve. Optic gliomas are intrinsic tumors of the optic nerve. They usually occur between 4 and 8 years of age. There is a strong association with neurofibromatosis. Craniopharyngiomas are the third most common brain tumor of childhood, representing 10% of all tumors in childhood. They arise from the embryonic rests of Rathke's pouch near the sella turcica. Craniopharyngiomas affect visual acuity by compressing the optic chiasm or the optic nerve.¹⁹

CLINICAL PRESENTATION

The clinical presentation of visual loss varies with age and ability to express oneself. The infant may be brought to the ED because the parents have noted unilateral swelling of the globe or haziness of the cornea. The parents may complain that the 2- to 3-month-old infant does not seem able to fix on and follow objects. There may be no complaints at all, and the physician may discover one of these findings or note an abnormal red reflex or the presence of nystagmus.

The parents of a preverbal child may bring him or her to the ED because of perceived strabismus or a persistent head tilt. Intraocular tumors may present as decreasing visual acuity, leukocoria (absent red reflex), strabismus, or gradually increasing proptosis and corneal edema.¹² Rhabdomyosarcoma may present explosively, with rapid development of proptosis and decreased visual acuity.²³ Craniopharyngiomas may present with advanced visual defects, with or without headache, and sometimes with an unusual vertical "see-saw" nystagmus.¹⁹ By contrast, optic neuritis presents with sudden, severe visual loss, often bilateral. There may be a history of an antecedent viral infection.

On examination, there is reduced vision, nonreactive pupils, and swollen optic nerves. Hemorrhages and exudates may be seen on the optic disc.¹⁹ For a general differential diagnosis, refer to [Table 270.3](#).

Physical Finding	Age	Differential Diagnosis
Leukocoria	Infant	Retinoblastoma
	Older child	Coats disease Intraocular tumor Congenital lens dislocation
Tearing	Infant	Congenital nasolacrimal duct obstruction
Failure to fix or follow	3-3 mo	Abnormal visual development Any cause of decreased vision
Nystagmus	Infant	Strabismus
	Older child	Any cause of decreased vision
Decreased visual acuity (unilateral)	Infant	Retinoblastoma Coats disease Intraocular tumor Congenital lens dislocation
	Child	Retinoblastoma Coats disease Intraocular tumor Congenital lens dislocation
	Older child	Coats disease Intraocular tumor Congenital lens dislocation
	Adolescent	Coats disease Intraocular tumor Congenital lens dislocation
Decreased visual acuity (bilateral)	Variable ages	Retinoblastoma Coats disease Intraocular tumor Congenital lens dislocation
Proptosis	All ages	Intraocular tumor Congenital lens dislocation Intraocular hemorrhage
Strabismus	All ages	Strabismus Intraocular tumor Large refractive error

TABLE 270.3. Differential Diagnosis of Abnormal Vision^a

EMERGENCY DEPARTMENT EVALUATION

A complete history is very important to help narrow the differential diagnosis. The second most important step is a methodic and complete, age-appropriate eye examination. When a tumor is suspected, neuroimaging, beginning with a CT scan, is imperative. Particularly, any finding of proptosis, with or without decreased vision, necessitates an urgent CT scan. The evaluation of optic neuritis includes magnetic resonance imaging and an LP. The LP usually reveals a monoclonal pleocytosis and mild protein elevation.¹⁹

EMERGENCY DEPARTMENT MANAGEMENT

The emphasis in management, in the majority of these conditions, should be on recognition of the potential severity of the problem; timely neuroimaging, when applicable; and prompt, sometimes emergent, referral.

Therapy for optic neuritis is based on randomized clinical trials conducted in adults. However, because the use of high-dose steroids is felt to be associated with more rapid visual improvement, most ophthalmologists also offer this treatment to children. Treatment is begun with methylprednisolone 15 to 30 mg/kg/d for 10 to 14 days.⁵ This is followed by a slow prednisone taper over 1 to 2 months. Too rapid a taper has been associated with a recurrence of optic neuritis and compounded visual loss.¹⁹

DISPOSITION

Tumors, glaucoma, cataracts, and optic neuritis often involve urgent admission to the hospital. The facility, as well as the consultant, should be experienced in pediatric eye disorders. Because the growth of some tumors, such as rhabdomyosarcoma, can be explosive, consultation with an experienced ophthalmologist is emergent.

The presence, in an infant, of leukocoria or a swollen anterior chamber requires urgent referral to an ophthalmologist comfortable with the treatment of pediatric cataracts, tumors, or glaucoma. The treatment of these conditions is largely surgical. Because infancy represents a critical period in normal visual maturation, failure to remove the obstruction to clear vision could result in a functionally blind eye.

Because nystagmus can represent a structural lesion as well as amblyopia, referral on a semiurgent basis to an ophthalmologist should be done.

The finding of strabismus in the preverbal or preschool child mandates outpatient referral to an ophthalmologist.

COMMON PITFALLS

- Failure to perform an age-appropriate, complete eye examination
- Failure to refer a time-dependent process urgently to an appropriate ophthalmologist

CORNEAL ABRASION IN INFANTS

Corneal abrasion occurs in infants as a result of known or occult trauma. Infants under 1 year of age are more likely to present without a history of trauma and without any physical findings that point to the eye.¹⁷

CLINICAL PRESENTATION

Infants may present, as with older children, with eye pain, tearing, photophobia, blepharospasm, conjunctival injection, eye-rubbing, and lid edema. On the other hand, they may present with only excessive crying or irritability. The infant may present only with grunting respirations, without any evidence of respiratory compromise.¹⁷

DIFFERENTIAL DIAGNOSIS

In the infant who presents with injection, tearing, and blepharospasm, the differential diagnosis includes other etiologies of the “red eye.” In the infant who presents with crying, irritability, or grunting, the differential needs to include systemic causes, such as respiratory insufficiency, sepsis, and meningitis.

EMERGENCY DEPARTMENT EVALUATION

A history and full eye examination should be done in infants with physical findings pointing to the eye. A corneal abrasion is diagnosed by staining the cornea with fluorescein-impregnated strips and shining a Wood light on the surface of the eye. An abrasion will stand out as a stained defect on the surface of the cornea. Both eyelids should be everted to search for a retained foreign body.

In the infant who presents with excessive crying, irritability, or grunting, a drop of topical anesthetic may be diagnostic as well as therapeutic.¹⁷ The infant may calm down almost immediately.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment of corneal abrasions includes the use of a lubricating antibiotic ointment, such as erythromycin, bacitracin, or Polysporin. Cyclopentolate 1% drops may be used if significant pain or ciliary spasm is present. Patching the affected eye may also be comforting to the infant. Any contact lenses should be removed.

DISPOSITION

Immediate consultation with an ophthalmologist should be sought if penetration past the superficial layers of the cornea is suspected. The abrasion should be followed daily until resolution of symptoms. This can be accomplished by the ED physician or primary care physician. If the abrasion is large or central (involving the visual axis), the infant should be referred to an ophthalmologist for examination within 24 hours.

COMMON PITFALLS

- Failure to recognize a deep abrasion or corneal ulcer, which could result in corneal scarring or deep infection of the eye
- Failure to consider corneal abrasion in the infant with otherwise unexplained crying or irritability

CONGENITAL NASOLACRIMAL DUCT OBSTRUCTION AND DACRYOCYSTITIS

Congenital nasolacrimal duct obstruction (CNLDO) is a common problem of infancy, with 20% of children exhibiting some symptoms within the first year of life.¹⁶ Canalization of the nasolacrimal duct may not be complete at birth. In most of these children, a membranous obstruction is the etiologic factor; however, a nasolacrimal duct cyst may also result in obstruction.¹⁴ Ninety-six percent of infants with CNLDO show spontaneous resolution of the obstruction by the first birthday.¹⁶

Dacryocystitis, or infection of the nasolacrimal duct, may be acute or chronic. It may occur as a complication of CNLDO or of acquired nasolacrimal duct obstruction (ANLDO). In the neonatal period, dacryocystitis is rare, occurring in less than 2% of infants with CNLDO. However, if a duct cyst is the etiology of the obstruction, the risk of dacryocystitis is greater, with earlier presentation, usually by 2 weeks of age.¹⁴ The causative organisms are most often *S. aureus*, *S. epidermidis*, and alpha-hemolytic streptococci. *Corynebacterium* diphtheria and Epstein-Barr virus have also been reported.⁷ The risk of bacteremia is higher in the neonatal period than in the older infant or child. ANLDO may occur as the result of ethmoidal sinusitis or maxillary fracture through the wall of the nasolacrimal duct.⁷

CLINICAL PRESENTATION

Symptoms of CNLDO may be present at birth or may be delayed for several weeks, until normal tear production develops. Signs include excessive tear lake, tear overflow, or a mucoid discharge that is produced by the lacrimal sac. There may be crusting or stickiness of the eye; however, the conjunctivae are clear, the eye is neither red nor swollen, and fever should not be present. The tearing is often distressing to the parent.¹⁶

Dacryocystitis is characterized by erythematous and swollen skin over the lacrimal sac and purulent drainage from the punctum. Fever may be present, and periorbital or orbital cellulitis may develop as a complication of dacryocystitis.⁷

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes corneal abrasion, conjunctivitis of various etiologies, local insect bite, or local trauma with resultant infection.

EMERGENCY DEPARTMENT EVALUATION

A careful history and physical should differentiate CNLDO from dacryocystitis. In the latter case, cultures of any purulent drainage, as well as blood cultures, need to be obtained. A complete blood count may be helpful, a high white blood cell count indicating a higher risk of bacteremia. In the infant who is 1 month old or younger, a full sepsis workup, including LP, should be done.

EMERGENCY DEPARTMENT MANAGEMENT

In dacryocystitis, antibiotics to cover *Staphylococcus* and *Streptococcus* species should be started immediately after cultures are obtained. The choice of particular antibiotics should reflect *Staphylococcus* and *Streptococcus* resistance within each community.

Suggested choices include the following:

Nafcillin 150 mg/kg/d intravenously in four divided doses

Cefuroxime 150 mg/kg/d intravenously in three divided doses

In the penicillin-allergic infant or child, vancomycin can be used.

DISPOSITION

All patients with acute dacryocystitis should be admitted to the hospital, on the service of a pediatrician capable of dealing with the potential complications of sepsis and/or meningitis. Immediate consultation with an ophthalmologist is needed, because early nasolacrimal duct probing is important to the successful treatment of acute dacryocystitis. Because neonatal dacryocystitis is often associated with a nasolacrimal duct cyst, a complete intranasal examination at the time of surgery and marsupialization of any cyst are imperative to prevent recurrence.¹⁴

The treatment of chronic or "low-grade" dacryocystitis is primarily surgical, with duct probing within several weeks. Systemic antibiotics are not necessary, although some consultants recommend a topical antibiotic ointment such as polymixin B.⁷

Dacryocystitis after facial fracture or sinusitis requires referral to the appropriate specialist; ophthalmology; ear, nose, and throat; or plastics.⁷

Conservative management of CNLDO includes warm-water compresses (to remove the mucoid discharge) and nasolacrimal duct massage. The latter is performed by occluding the common canaliculus with the index finger and then stroking firmly downward. This maneuver increases the hydrostatic pressure in the nasolacrimal sac, with the ultimate goal of overcoming the membranous obstruction. The massage should be repeated five to ten times, four to six times a day. Erythromycin ophthalmic ointment applied four times a day is recommended; however, its efficacy in speeding recovery has not been proved. Referral to an ophthalmologist is recommended for those cases that do not resolve with conservative management. Probing will cure 90% of these infants.⁷

COMMON PITFALLS

- Failure to consider bacteremia, sepsis, or meningitis in the neonate or young infant
- Failure to consult an ophthalmologist early in cases of acute dacryocystitis

PARASITIC INFESTATION OF THE EYELASHES

Lice infestation of the eyelashes is caused by the genus *Phthirus*, otherwise known as the crab or pubic louse. Transmission may occur via the hand from infestation in the genital area, but it may also occur from contaminated towels and bedding. Infants may become infected as a result of close contact with an infested caretaker.

The adult lice feed on the host's blood, depositing their excrement at the base of the lashes. The females lay eggs (nits), which are firmly cemented in groups to the lashes. Exposure to the lice saliva and feces results in a dermal hypersensitivity reaction, causing severe pruritus. The intense desire to scratch often results in excoriations of the eyelids and, often, secondary bacterial infections.

CLINICAL PRESENTATION

Patients present with a history of itching and irritation of the eyes and eyelids, often of several weeks' duration. The lids may appear reddened, with a brownish crust at the base of the lashes. Close observation may reveal adult lice as well as clusters of nits on the upper and lower lashes. The nits appear as small, pearly, oval structures cemented to the base of the lashes. The palpebral conjunctiva may be red and inflamed. The cornea is rarely involved. There may be preauricular node swelling, reflecting secondary bacterial involvement.⁹

DIFFERENTIAL DIAGNOSIS

Bacterial, viral, or allergic conjunctivitis represents the main differential diagnoses. Identification of adult lice and nits should effectively rule these out.

EMERGENCY DEPARTMENT EVALUATION

Slit-lamp examination should reveal, in addition to adult lice and nits, a brownish granular crust at the bases of the lashes (lice feces). Blue spots (maculae ceruleae) on the lid margins are characteristic of lice infestation and represent bite marks. A full eye examination, including fluorescein staining of the cornea to rule out concomitant corneal abrasion, should be done.

EMERGENCY DEPARTMENT MANAGEMENT

Eliminating lice infestation involves several management issues: killing adult lice, removing existing nits, and preventing reinfestation. In the cooperative patient, mechanical removal can be accomplished by using a slit-lamp, cotton swabs, and fine-toothed forceps. This needs to be followed by medical treatment aimed at killing the lice when they hatch. Several ophthalmic preparations have been endorsed over the years. The only clearly nontoxic preparation is petroleum jelly, applied to the eyelashes several times a day for 8 days, in order to suffocate the organisms.⁹ Yellow mercuric oxide ointment is pediculicidal, but a case of mercury poisoning has been reported in a 4-month-old infant. Physostigmine ointment likewise kills the lice, but it may cause such unwanted side effects as miosis and ciliary spasm. The argon laser has been used to kill lice and nits, but its use requires a cooperative patient as well as a skilled operator.

DISPOSITION

The patient needs to be evaluated for infestation of other body sites, and appropriate therapy instituted. If genital infestation is found, the possibility of sexually transmitted diseases needs to be addressed and treated. In order to prevent reinfestation, the caretaker needs to be educated on the sterilization of bedding, towels, and clothing, as well as the discarding of any cosmetic products used about the eye. Evaluation of potential infestation in the parent, especially in the case of an infant, should also be done.⁹

COMMON PITFALLS

- Failure to entertain the diagnosis of louse infestation in the eyelashes
- Failure to educate the caretaker on the necessary measures needed to prevent reinfestation

SUPERGLUE IN THE EYE

Superglue (cyanoacrylate glue) in the eye usually occurs as the result of an accidental "squirt" while using the glue to repair an object, or by mistaking the bottle for an ophthalmic preparation and directly instilling glue in the eye. Cyanoacrylates form strong bonds between opposing surfaces within seconds. In the eye, they may form a layer covering the conjunctival and corneal surfaces, or they may tightly seal the lids and lashes together. They may also cause corneal abrasions, eyelid skin excoriation, and loss of eyelashes.¹⁵

CLINICAL PRESENTATION

The clinical presentation is usually that of eyelids firmly glued together. If the cyanoacrylate has seeped into the eye, there may be pain, photophobia, tearing, and decreased vision. A film of glue may be adherent to the corneal surface of the eye, or there may be fragments under the lids.

DIFFERENTIAL DIAGNOSIS

Corneal abrasions present with similar symptoms, and may result from glue in the eye.

EMERGENCY DEPARTMENT EVALUATION

When the eyelids are firmly sealed together, the condition of the underlying eye needs to be inferred indirectly from complaints of pain, foreign-body sensation, tearing, and ability to move the globe without pain. As complete an examination as possible should be carried out.

EMERGENCY DEPARTMENT MANAGEMENT

Eyelids that are firmly bonded together are generally allowed to separate on their own, which will occur in 1 to 4 days. Trimming the involved eyelashes may facilitate separation of the lids. If the lashes are not pulled out, they should grow back normally. In the case of glue that is adherent to the cornea, the treatment is the same as for a corneal abrasion, with antibiotic preparations, mydriatic agents, and possible eye patching. Pain medication should be administered as needed.

DISPOSITION

Reexamination in 24 hours is recommended to evaluate for any signs of infection. The appearance of purulent drainage necessitates ophthalmologic consultation and surgical separation of the lids in order to evaluate fully the cornea and the globe. In the case of glue that is adherent to the cornea, follow-up evaluation often reveals spontaneous separation of the glue from the cornea, with a resultant epithelial defect. This corneal abrasion is usually superficial and requires continued therapy with antibiotic drops and mydriatics.¹⁵

COMMON PITFALLS

- Unnecessary, early surgical separation of the lids, with pulling and subsequent loss of eyelashes
- Application of “home remedies” or chemicals that are potentially harmful to the eye, in an effort to “unbond” the lids

CHAPTER 271

Foreign-Body Ingestion

Linda L. Settle

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Infants enjoy using their mouths to help them assess new objects. They continue this into the toddler years, when they are mobile and therefore have greater opportunities to find small objects. It is not surprising, then, that the peak years for foreign-body ingestions are the toddler ones.⁶ Of the more than 94,023 foreign-body ingestions reported to 66 poison control centers in 1997, 72% occurred in children younger than 6 years of age.¹⁷

CLINICAL PRESENTATION

When children present with a history of foreign-body ingestion, a choking or gagging episode has usually been witnessed by an adult or has been reported to the parent by an older child. Many of these children are asymptomatic on presentation. The greater diagnostic challenge is the symptomatic child who presents without a positive history. Diagnosis in this case requires awareness of the range of presenting symptoms. In one review of 125 children with foreign-body ingestions, the most frequent complaints were gagging or vomiting, choking, neck and throat pain, foreign-body sensation, and dyspnea.⁶ In a review of esophageal foreign bodies, the most common presenting symptoms of the 343 children studied were refusal to eat, salivation, pain and discomfort on swallowing, and vomiting.¹⁹

In addition to the more common presentations, children with esophageal foreign bodies may present with symptoms referable to the respiratory tract (i.e., stridor, persistent cough, wheezing, and chronic pneumonia).

DIFFERENTIAL DIAGNOSIS

When there is a positive history for ingestion, localizing the foreign body within the gastrointestinal tract is important, even if the child is asymptomatic.² One study showed that 17% of asymptomatic children with a history of coin ingestion were found to have coins in the esophagus.¹⁴ Delay in removal of esophageal foreign bodies may result in obstruction, because an inflammatory reaction and edema develop, with the resultant possibility of aspiration; perforation or erosion through the esophagus; or formation of a tracheoesophageal fistula or tracheo-aortic fistula.

Esophageal foreign bodies may present very much like airway foreign bodies. Again, it is important to remember that stridor, cough, or wheezing may represent an esophageal foreign body.^{3,22}

EMERGENCY DEPARTMENT EVALUATION

When there is a clinical suspicion of ingested foreign body, radiographic evaluation should include a lateral soft-tissue view of the neck in addition to an anteroposterior view, as well as films of the chest and abdomen. Foreign bodies are often missed when only an anteroposterior view is ordered. Lateral views are also necessary to demonstrate multiple coins in rouleau. Nonradiopaque items can usually be demonstrated with contrast.

There is some controversy about obtaining x-rays on asymptomatic children with a history of coin ingestion, even though there are reports of esophageal placement in asymptomatic children, as previously noted. With a clear history for coin or similar object ingestion, an alternative way to locate the coin is with a metal detector.¹⁰ If it can be located clearly below the diaphragm, an x-ray could be deferred. If it can be located low in the chest, where it is most likely at the lower esophageal sphincter, an observation period and repeat metal detector scan would be indicated, as objects at this location are likely to pass into the stomach. If the metal detector places the coin or other round object high in the chest, an x-ray is indicated.^{1,24}

EMERGENCY DEPARTMENT MANAGEMENT

Most foreign bodies pass through the digestive tract without problems. Although most objects lodged in the esophagus require immediate removal because of the reasons listed earlier, a brief observation period (12 to 24 hours) has been recommended by some clinicians for asymptomatic patients with coins in the esophagus, particularly at the lower esophageal sphincter.^{9,20} Once objects have been demonstrated to have passed beyond the esophagus, however, they rarely represent a hazard to the patient: 95% pass without incident.¹² Objects can enter a Meckel's diverticulum or appendix and cause obstruction; therefore, a repeat x-ray should be done in a week if the object has not passed. Instructions are given to the parents to return the child for repeat x-ray if any abdominal symptoms are noted. Sharp objects pose an increased risk for perforation, and elongated objects sometimes cannot traverse the C loop of the duodenum. For such objects, closer follow-up is needed to monitor development of signs of potential obstruction or peritonitis. A repeat x-ray is mandatory if the object has not passed in a few days.

Endoscopic removal is indicated for objects retained in the stomach or rectum. Operative removal is indicated if the object remains at the same site in the duodenum or small intestine longer than 7 days or if symptoms develop. Enemas are usually successful at dislodging retained colonic foreign bodies.¹²

The amount of time it takes for a foreign body to pass through the entire gastrointestinal tract varies widely. In one study, 85% had passed within 72 hours and 99.9% within 7 days.¹⁷

Removal of esophageal foreign bodies traditionally has been done by using a rigid endoscope. Recently, use of the flexible scope has been reported and may be an alternative for select patients when done by those skilled in its use with children.⁴ In the 1960s, reports described removal of blunt objects by using a Foley catheter under fluoroscopy.^{5,23} This method avoids the use of general anesthesia, which is necessary for rigid endoscopy. The largest report of experience with this method in children describes successful removal of foreign bodies in 322 of 337 patients, without complications.¹³ This procedure should be done only by someone skilled in management of the pediatric airway and with the necessary equipment available. Some recommend that an individual be present who can use the rigid endoscope, if that becomes necessary.¹⁵ This method should be used only with recent ingestions of blunt, nonorganic radiopaque objects and in patients with a normal esophagus. At some centers, esophageal bougienage is used for coin ingestions, with low complication rates, when strict selection criteria are used.^{8,11} With both Foley catheter removal and esophageal bougienage advancement into stomach, there is no direct visualization of the esophagus. Therefore, there are the risks of missing a second radiolucent object and intrinsic disease.

Disk batteries lodged in the esophagus pose a high risk for serious injury to the patient. However, a review of 2,382 battery ingestions, including 2,320 button cells and 62 cylindrical cells, showed that most cases follow a benign course.¹⁶ There were no deaths, and only two cases demonstrated a major effect (both of these represented lodgement in the esophagus). All patients with a history of battery ingestion should have a radiograph done to determine the battery's location. If it is lodged in the esophagus, immediate removal is indicated. Burns have occurred at 4 hours and perforation at 6 hours after ingestion of a battery.^{7,21,25} If the battery is not in the esophagus and is less than 15 mm in diameter, stools should be checked, and radiography considered at 1 week if the battery does not pass. Earlier evaluation would be indicated by abdominal pain with tenderness or hematochezia.

If the battery is greater than 15 mm in diameter (3% of cases), radiography in 48 hours is recommended because of delayed transit through the stomach for this size battery in children younger than 6 years old. Endoscopic removal is recommended if the battery is still present in the stomach at 48 hours.

Mercuric oxide batteries (usually 15.6 mm) have a greater likelihood of splitting. Mercury (blood or urine) levels should be obtained only if splitting or radiopaque

droplets are noted. Elevated mercury levels and mercury poisoning are rare.

Ipecac is contraindicated with battery ingestions. One study suggests that cimetidine and metoclopramide may have a protective effect against tissue injury when there is gastric retention of batteries.¹⁵

For objects with possible lead content, such as bullets, shot, fishing sinkers, and curtain weights, a baseline lead level and close follow-up are indicated. A rising level indicates the need for medical and surgical treatment.¹⁸

DISPOSITION

Children with retained esophageal foreign bodies should be referred to a physician that is skilled in the removal of foreign bodies in children. Foreign bodies beyond the gastroesophageal junction may be observed on an outpatient basis, with follow-up to include x-ray if the object is elongated, sharp, or a disk battery. Forty-eight-hour follow-up radiographs are recommended for disk batteries lodged in the stomach that are greater than 15 mm in diameter.¹³

COMMON PITFALLS

- Failure to recognize the child with an esophageal foreign body who presents with *respiratory* symptoms
- Failure to obtain lateral radiographic views, which may result in failure to visualize opaque foreign bodies

ACUTE GLOMERULONEPHRITIS

Glomerulonephritis is a term that is generally reserved for a variety of renal diseases in which proliferation and inflammation of the glomerulus occurs. Poststreptococcal acute glomerulonephritis (PSAGN) is the most common form of glomerulonephritis seen in children in the United States.⁸ It is rare in children younger than 3 years of age; the mean age at onset is 6 to 7 years. The true incidence is unknown, because many cases are subclinical.

PSAGN is known to follow infections of the skin or upper respiratory tract with certain nephrogenic strains of group A β-hemolytic streptococci. PSAGN is associated with pharyngitis more often during the winter months and with pyoderma more often during the summer. Pyoderma-related AGN is typically seen more in the southern regions of the United States and may account for as many as 60% to 70% of the cases.¹⁵ Characteristically, there is a latent period between the onset of the streptococcal infection and the onset of nephritis (8 to 14 days for pharyngitis and 14 to 21 days for skin infection).³ PSAGN can occur as sporadic cases or in well-recognized epidemics.

Most AGN is immunologically mediated. In PSAGN, evidence suggests that immune complexes formed with streptococcal antigens localize on the glomerular capillary wall, activate the complement system, then initiate a proliferative and inflammatory response.¹⁸

CLINICAL PRESENTATION

The intensity of the disease varies, as does the clinical presentation, but many patients are not markedly ill. Hematuria and edema are the most common complaints. Gross hematuria (tea-colored urine) has been reported in 70% of hospitalized patients, and microscopic hematuria is present in virtually all children with the disease.¹⁶ Characteristically, the edema in PSAGN is dependent, and therefore shifting in nature. The initiating streptococcal infection usually has resolved by the time of the illness presentation, although impetigo may still be present. [Table 272.1](#) lists the clinical manifestations in patients with PSAGN in order of frequency.^{10c} A variety of laboratory and radiographic abnormalities are observed in these patients. [Table 272.2](#) summarizes some of these abnormalities.

MOST FREQUENT PRESENTING MANIFESTATIONS
Edema (periorbital-anasarca)
Hematuria (microscopic-gross)
Hypertension (mild-moderate)
Oliguria
Non-specific systemic symptoms
Anorexia, nausea, fever, malaise, abdominal pain
Pallor
LESS FREQUENT ASSOCIATED FINDINGS
Urinary tract syndrome
Flank-loin pain, dysuria, frequency
Circulatory congestion
Mild symptoms of congestive heart failure
Frank pulmonary edema
Hypertensive encephalopathy
Headaches, vomiting, confusion, somnolence, visual disturbances, aphasia, emulsions

Disease	Distinguishing Features
Acute exacerbation of chronic glomerulonephritis	Absence of latent period
Idiopathic hematuria (isolated nephritis, benign hematuria, IgG/IgA nephropathy)	Significant azotemia and anemia History of known renal disease Usually hematuria without edema, hypertension, or azotemia Coincides with infection or exercise
Nephritis of Henoch-Schönlein purpura	History of preceding upper respiratory tract infection Abdominal pain, purpura, rash, arthralgia C3 usually normal
Lupus nephritis	Rash, arthralgia, lupus serology (antinuclear, antihistone, anti-DNA) Prolonged hypocomplementemia, hemolytic anemia common
Mononeuropathic glomerulonephritis (MPGN)	Most likely if C3 still decreased after 4-6 wk and glomerular filtration rate still decreased after 3 wk Rising antistreptolysin O titer favors poststreptococcal glomerulonephritis, but 25% of patients with MPGN have preceding streptococcal infection
Nephritis secondary to toxins (e.g., lead, mercury, hydrocarbons)	Suggested by history and other clinical findings of suspected toxin

TABLE 272.3. Differential Diagnosis of Acute Poststreptococcal Glomerulonephritis

EMERGENCY DEPARTMENT EVALUATION

Many patients have no symptoms, and their disease is discovered only by examination of the urine. At the other extreme is the child with severe disease manifested by edema, hypertension, oliguria, and azotemia. The history should include questions about previous illnesses and medications. It is important to obtain a full set of vital signs. The unstable patient should be placed on a cardiac monitor. The glomerular filtration rate is usually reduced, and physical examination may reveal signs of circulatory overload. Periorbital edema is a common finding. Laboratory abnormalities vary with the severity of the disease.

Hematuria is the most consistent urinary abnormality, but the urinalysis can be normal.¹⁵ The sediment reveals red blood cell casts. Pyuria and hyaline granular casts are common. Proteinuria may be present but is usually less than 2 g/m²/24 h.

In a small number of patients, there is profound azotemia with elevations of blood urea nitrogen (BUN), serum creatinine, and even serum inorganic phosphate, the latter signifying a reduction of approximately 80% in glomerular filtration. Hyponatremia, hyperkalemia, and metabolic acidosis also can occur. The complete blood cell count may show a dilutional anemia. Rising antistreptolysin-O titers suggest previous streptococcal infection; however, anti-DNase B is more apt to be increased following streptococcal pyoderma. Early antibiotic use may interfere with rising antibody titers. The C3 component of complement is decreased in most patients.¹⁶ Cultures from the throat and skin should be sent for analysis in an effort to isolate a nephrogenic strain of *Streptococcus*.

Consistent findings on chest radiography include cardiomegaly, pulmonary edema, pleural effusion, and edema of the soft tissues.⁴

EMERGENCY DEPARTMENT MANAGEMENT

In most cases of acute poststreptococcal glomerulonephritis, there is no specific therapy that influences healing of the glomerular lesions. Antibiotics do not alter the course of the disease but may decrease the spread of nephrogenic strains of *Streptococcus* in patients with positive cultures.¹³

Appropriate therapy, as listed in [Table 272.4](#), should be instituted promptly for the child who presents with acute renal failure, hypertension, or hyperkalemia. Symptoms suggestive of hypertensive encephalopathy consist of headache, nausea, vomiting, seizures, and transient cortical blindness. Although there is an armament of medication to treat hypertensive emergencies in children,^{6,11} experience with PSAGN hypertension is limited to the medications listed in [Table 272.4](#).

A. Acute Renal Insufficiency
1. Fluid restriction
2. Intractable water loss (300 mL/m ² /24 hr) + urine output < planned weight loss
3. Electrolytes
a. Low sodium (132 g NaCl/200 mL)
b. Low potassium (3.0 mg/dL or 0.6 mmol/L)
c. Correction of metabolic acidosis (sodium bicarbonate <120)
d. Ca ²⁺ < 1.0 mmol/L (observed - observed/100) gives Ca ²⁺ over 1.0 mmol/L
B. Hypertension
1. Nifedipine
a. 1 mg/kg
b. Dose range 3-5 mg/kg (maximum dose of 150 mg)
c. Furosemide 1 mg/kg per dose (a)
2. Atenolol
a. Atenolol 5-10 mg/kg per dose PO (a) may repeat in 4-6 hr
b. Hydrochlorothiazide 1-2 mg/kg (a)
C. Hyperkalemia
1. Calcium 10-15 mg/kg with ECG changes
2. Calcium 10-15 mg/kg of elemental calcium (a) over 10-30 min with continuous ECG monitoring
3. Bicarbonate 3-5 mEq/kg (about 100 mL 8.4%)
4. Citrate and sodium 3 mEq/kg (a) with 0.1 M bicarb per gram of glucose given
5. Respiration 1 g/kg with device and water removal or with ventilated lung
6. Exchange if above measures are unsuccessful
D. Hypocalcemia
1. Fluid restriction
E. Congestive Cardiac Failure
1. Oxygen
2. Fluid restriction
3. Current hypernatremia
4. Electrolytes (a), furosemide
5. Diuretic

TABLE 272.4. Emergency Department Management of Complications of Acute Glomerulonephritis

DISPOSITION

When a child with AGN presents to the emergency department, a pediatrician or nephrologist should be consulted for admission or follow-up care. Because of the possible complications, such as hypertension, hyperkalemia, and acute renal failure, most consultants choose either to admit all children with AGN or to ensure close follow-up. The decision to discharge a patient with possible AGN should never be made without consulting the primary care physician.

COMMON PITFALLS

- Hematuria is the most common urinary abnormality, but the presence of polymorphonuclear leukocytes and renal epithelial cells may be the only abnormalities early in the disease. Thus, the patient may be mistakenly diagnosed as having a urinary tract infection.
- It is extremely important to differentiate between AGN and the nephrotic syndrome, because the management may be entirely different. Patients with nephritis may have signs of fluid overload and should be fluid restricted. Diuretics should be used in the management of circulatory congestion. Those with the nephrotic syndrome may also present with edema despite being intravascularly volume depleted. The use of diuretics, here, however should be done with great care, because it may lead to severe hypovolemia.
- It is important to remember that too rapid a correction of the elevated blood pressure can be dangerous, and it is therefore essential that the patient be monitored closely during treatment.⁶

NEPHROTIC SYNDROME

The nephrotic syndrome is a clinical entity characterized by proteinuria, hypoalbuminemia, hypercholesterolemia, and edema.¹⁶ Hypertension, hematuria, and reduced glomerular filtration rate are not usually observed in idiopathic nephrotic syndrome of childhood, although a small number of patients may have these features. The primary abnormality is increased permeability of the glomerular capillary wall to plasma proteins, resulting in excessive urinary loss of protein, principally albumin.¹²

The nephrotic syndrome is categorized into primary and secondary forms, as listed in [Table 272.5](#). Minimal-change nephrotic syndrome, or “nil” disease, is the most common primary form seen in children, accounting for 80% to 85% of cases.⁹ In these patients, renal biopsy reveals minimal glomerular abnormalities. Ninety-two percent of such patients will respond to a course of corticosteroid therapy with complete cessation of proteinuria, unlike other forms of nephrotic syndrome, which carry a worse prognosis.¹⁹ Nephrotic syndrome can occur at any age, but 70% of children with minimal-change nephrotic syndrome have the onset of their disease between ages 2 and 7 years, with a male-to-female ratio of 2:1. The incidence and prevalence of this condition in children younger than 16 years of age are about 1.6

and 13 per 100,000, respectively.²

PRIMARY OR MINIMAL CHANGE
Congenital
Acute postinfectious
Secondary
SECONDARY
Associated with Systemic Diseases
Systemic lupus erythematosus
Henoch-Schönlein purpura
Wiskott-Aldrich syndrome
Diabetes mellitus
Lymphoma
Severe chronic glomerulonephritis
Phenylketonuria
Cystinosis
Adipositas
Drugs
Sulfonamides
Streptomycin
Cytomegalovirus
HIV
Amphotericin
Associated with Medications
Nonsteroidal antiinflammatory drugs
Penicillin
Gold salts
Tetracycline
Hexamethylenamine
Associated with Venues or Allergens
Sea water
Foreign fish
Worms
Food allergy

TABLE 272.5. Etiology of Nephrotic Syndrome

CLINICAL PRESENTATION

Regardless of the histopathologic abnormalities, edema is the most prominent clinical manifestation of the nephrotic syndrome in most children. The classic explanation for edema formation in the nephrotic syndrome is that hypoalbuminemia leads to decreased intravascular oncotic pressure, allowing water to extravasate into the interstitial space. The resulting contraction of intravascular volume stimulates renin release and provides an osmotic stimulus for the release of antidiuretic hormone, with activation of the renin–angiotensin–aldosterone sequence. The result is small volumes of concentrated urine containing little sodium. When plasma volume is measured in patients with the nephrotic syndrome, however, it is not uniformly decreased. This latter observation suggests that sodium retention in the nephrotic syndrome is due to intrarenal factors.

Other symptoms, such as anorexia, abdominal pain, diarrhea, and vomiting, also can be present and may be related to the severity of the edema. With anasarca and abdominal distention, respiratory distress, umbilical and inguinal hernias, and rectal prolapse may be seen. Family members may notice that the child has puffy eyes (periorbital edema) or has gained weight recently. Some children have proteinuria for 1 to 2 months before the edema becomes apparent.

The initial episode and subsequent relapses may follow a viral upper respiratory tract infection. Microscopic hematuria occurs in approximately 20% of children with minimal-change nephrotic syndrome and in 50% of those with membranoproliferative glomerulonephritis. Thus, hematuria is not a common presenting symptom in most cases of prednisone-responsive childhood nephrotic syndrome.

Blood pressure is usually normal in minimal-change nephrotic syndrome, but in 6% to 13% of patients, hypertension (above the 98th percentile for age) has been reported. Persistent hypertension is uncommon and should suggest a histologic lesion other than minimal-change nephrotic syndrome.

Laboratory findings diagnostic of the nephrotic syndrome include the following:

1. Proteinuria
 - a. Greater than 3 g/1.73 m² of body surface area/24 h, or 50 mg/kg/24 h or 40 mg/h/m² of body surface area.⁹ (This is usually compatible with a 4+ reading on the urinary dipstick.)
 - b. Spot urine protein-to-creatinine ratio greater than 2
2. Hypoproteinemia: serum albumin value less than 2.5 g/dL
3. Hyperlipidemia: Elevation of serum levels of triglycerides, cholesterol, and total lipids is a constant feature of minimal-change nephrotic syndrome.
4. Serum creatinine is usually normal.
5. Serum BUN is normal or sometimes slightly increased secondary to hypovolemia.
6. Increased hemoglobin is frequently observed secondary to hemoconcentration.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes the various causes of the nephrotic syndrome (see [Table 272.5](#)). Although nephrosis may be the presenting manifestation in the secondary forms, there is usually other clinical evidence of the underlying disorder.

Minimal-change disease carries a better prognosis, with a relatively good response to corticosteroid therapy. Disorders in which gross hematuria occurs in association with the nephrotic syndrome are listed in [Table 272.6](#).

Urinary tract infection
Acute postinfectious glomerulonephritis
Sickle cell hemoglobinopathies
Renal vein thrombosis
Membranoproliferative glomerulonephritis
Systemic disease (e.g., systemic lupus erythematosus, syphilis, vasculitides)
Congenital or inherited renal diseases (e.g., Alport syndrome, Finnish type)
IgA nephropathy

TABLE 272.6. Disorders in Which Gross Hematuria Can Occur with the Nephrotic Syndrome

EMERGENCY DEPARTMENT EVALUATION

Many children with nephrotic syndrome are apparently healthy and have edema as their only obvious presenting abnormality. The emergency physician should perform a thorough physical examination, however, paying particular attention to the cardiovascular and respiratory systems, because respiratory difficulties secondary to ascites and pleural effusions can occur. The presence of edema can be deceptive, giving the impression of fluid overload, when, in fact, many patients are intravascularly volume-depleted secondary to their hypoproteinemia. The child with tachycardia and hypotension may require prompt fluid resuscitation.

Children with the nephrotic syndrome are prone to serious infections, and fever in such a child warrants careful evaluation. Coagulation abnormalities and thrombotic tendencies are infrequently observed. Common sites for thrombosis include cerebral veins, renal veins, pulmonary arteries, femoral arteries, and cerebral arteries.

Initial laboratory investigations fall into two categories: those necessary to establish the diagnosis and those that may elucidate its cause. Initial diagnostic tests should include a complete blood cell count, serum electrolytes, calcium, phosphorus, BUN, creatinine, total protein, albumin, globulin, cholesterol, triglycerides, complement (C₃ and C₄), urinalysis, and a spot urine protein-to-creatinine ratio. It is also important to consider testing for the human immunodeficiency virus.

Depending on the clinical findings, other laboratory studies may be performed, such as antinuclear antibodies, antistreptolysin-O titer, syphilis serology, and hepatitis B surface antigen.

The chest radiograph may be helpful in differentiating the nephrotic syndrome from glomerulonephritis. In the nephrotic syndrome, the heart may be normal to small in size; the lungs are relatively clear, and there is usually a much greater accumulation of pleural fluid than is seen in glomerulonephritis. ⁴

EMERGENCY DEPARTMENT MANAGEMENT

Specific treatment of the nephrotic syndrome is not an emergency. Most consultants will admit all newly diagnosed patients to the hospital; admission provides an opportunity to make a specific diagnosis and initiate treatment. During this time, the family can be educated about the disease, its natural course, and its long-term management, such as diet modification. They also can be given instructions regarding the serious complications of this disease, how to recognize complications, and when to seek emergency care. It is in the management of these complications that the emergency physician plays an important role.

General measures to treat nephrotic syndrome include salt restriction (no-added-salt diet) and bed rest. ⁹ The initial treatment of minimal-change nephrotic syndrome of childhood consists of oral prednisone, 2 mg/kg/d (not to exceed 80 mg daily) divided into three doses ¹⁰ or given as one dose. Ninety-two percent of patients with this form of the disease will respond by becoming proteinuria-free. ¹⁹ This dose is continued for 1 week beyond this point. The dose is then doubled and given every other day; it is then gradually tapered until the patient is weaned off of prednisone at about 8 to 10 weeks after initiation of therapy. Parents can be taught to use the urinary dipstick and should be advised to return should relapse occur.

Relapses are common, and these patients may present to the emergency department. Patients who are otherwise stable do not necessarily need admission to the hospital. The treatment of relapses is not usually emergent, and the emergency physician can contact the patient's primary care pediatrician or nephrologist to ensure follow-up within the next few days.

Many complications of the nephrotic syndrome can be life-threatening and require prompt treatment. ^{1,2c} A number of these complications are related to the edema. The patient may present in respiratory distress, with pleural effusions or massive ascites that further impairs respiration. Such patients will require diuretic therapy, but extreme care must be taken when using diuretics. The intravascular volume may be low in these patients, and giving potent diuretics may lead to hypotension and shock. The patients should be placed on a cardiac monitor, and the physician should pay close attention to the heart rate and blood pressure. Serum electrolyte levels should also be monitored.

Furosemide (Lasix) is the diuretic of choice for nephrotic patients with severe discomfort due to fluid retention. It is given orally or intravenously in a dose of 1 to 2 mg/kg and is usually given in combination with an infusion of salt-poor albumin. A useful regimen is to give furosemide intravenously, then 1 g/kg of 25% salt-poor albumin solution intravenously over 2 hours, followed by a second dose of furosemide at the end of the infusion. Again, the patient should be observed closely for hypotension or hypertension.

Some patients will require thoracentesis for relief of their respiratory distress. Paracentesis should only be performed for ascites that impairs respiration, because there is a risk of causing peritonitis with this procedure.

It is not uncommon for the nephrotic patient to present to the emergency department in hypovolemic shock. Clinically, this can be a difficult diagnosis, because the patient is edematous. Treatment here consists of prompt fluid resuscitation and hospital admission. Albumin, when available, is the preferred fluid for intravascular resuscitation.

Infections and related complications account for up to 70% of deaths in patients with childhood nephrotic syndrome. This is because of their altered immune systems. There is a high incidence of invasive infections, such as septicemia, pneumonia, cellulitis, and peritonitis caused by *Streptococcus pneumoniae*. These patients are also susceptible to gram-negative organisms such as *Escherichia coli*, *Pseudomonas*, and *Haemophilus influenzae*. Because the pneumococcal vaccine incorporates antigen from a limited number of strains of *S. pneumoniae*, immunization with this vaccine does not guarantee protection against these organisms. Any child with nephrotic syndrome and fever should be evaluated thoroughly and admitted to the hospital with broad-spectrum antibiotic coverage, taking into account the emergence of penicillin-resistant *S. pneumoniae* in some regions. ⁷ Because their immune systems are compromised, children with the nephrotic syndrome are particularly at risk for severe varicella infections. Treatment with acyclovir and or varicella-zoster immune globulin may be indicated in these patients. Consultation with a pediatric infectious disease specialist should be obtained in this circumstance. ¹⁴

Total serum calcium is decreased in patients with the nephrotic syndrome. Hypoalbuminemia leads to a decrease in protein-bound calcium, but ionized calcium levels can also be decreased because of excessive loss of vitamin D-binding protein in the urine, leading to decreased absorption of calcium. Symptomatic hypocalcemia is rare, although bone demineralization and osteomalacia may occur.

Occasionally, a patient will present to the emergency department with tetany or muscle cramps. Such a patient should be placed on a cardiac monitor and given an initial dose of 0.5 to 1.0 mL/kg of a 10% solution of calcium gluconate intravenously over 3 to 5 minutes. Calcium gluconate is preferable to calcium chloride because it is less sclerosing to the patient's veins. When symptoms are relieved, calcium gluconate may be added to the intravenous solution at a dose of 100 mg elemental calcium/kg/24 h, or calcium may be administered orally (10% calcium gluconate contains 9 mg elemental calcium/100 mg of the salt).

Another serious complication of the nephrotic syndrome is the increased risk of vascular thromboses. ⁵ Thromboses have been demonstrated in all the major arteries and veins and may occur more commonly in children than is recognized by clinical symptoms and signs. Renal vein thrombosis should be suspected in a patient with acute flank pain, renal enlargement, hematuria, unexplained deterioration in renal function, oliguria, and renal failure. Many reasons for this susceptibility to thromboses have been proposed. Nephrotic patients have increased levels of plasma fibrinogen and coagulation factors V and VIII. A decrease in the circulating level of antithrombin III has been observed, and the platelets of some patients show an increase in spontaneous aggregation. Hyperviscosity of the plasma resulting from hyperfibrinogenemia and volume depletion may increase the likelihood of vascular thromboses; thus, diuretics should be used with caution. The value of routine anticoagulant and antiplatelet therapy has not been adequately assessed. An existing thrombotic lesion should be managed as for a nonnephrotic patient.

DISPOSITION

Children who are newly diagnosed as having the nephrotic syndrome should probably be admitted to the hospital for evaluation, initiation of therapy, and education of family members about the disease. Patients who were in remission and present to the emergency department with a relapse do not necessarily need to be hospitalized. The primary care pediatrician or nephrologist should be contacted, and, if follow-up can be arranged within a few days, treatment may be postponed until then. If timely follow-up is impossible, the emergency physician, usually in consultation with the primary care pediatrician, may restart prednisone therapy. Patients with life-threatening complications, such as respiratory distress, infection, hypovolemia, and thromboses, should be admitted to the hospital.

COMMON PITFALLS

- Children with the nephrotic syndrome have an increased risk of life-threatening infections; those on corticosteroid medications are even more immunocompromised. It may be safer to isolate these children in the emergency department, where they are in danger of contracting a serious infection from other patients.
- Patients presenting with periorbital edema as the only obvious manifestation of their disease may be mistakenly diagnosed as having an allergy. It is advisable to perform a urinary dipstick test on these patients to check for the presence of proteinuria.
- Emergency physicians should resist the temptation to treat the edema of the nephrotic patient in the absence of respiratory compromise or significant discomfort because of the risk of profound hypotension.

CHAPTER 273

Human Immunodeficiency Virus (HIV)

Ronald M. Ferdman and Jeffrey F. Linzer

- [Clinical Presentation](#)
- [Differential Diagnosis](#)
- [Emergency Department Evaluation](#)
- [Emergency Department Management](#)
- [Chemoprophylaxis after Suspected Exposure to HIV](#)
- [Disposition](#)
- [Common Pitfalls](#)
- [Bibliography](#)

In the early 1980s, a novel immunodeficiency was first seen in children. Its clinical presentation was similar to that of severe combined immunodeficiency (SCID), but included distinct clinical and pathologic findings. In 1982, these first cases of pediatric acquired immunodeficiency syndrome (PAIDS) were reported. By 1983, the causative agent of AIDS was identified as human immunodeficiency virus (HIV), and, in 1985, a commercial assay to detect HIV became available.

HIV is an RNA retrovirus that attacks primarily CD4+ T-lymphocytes (T-helper), though other cells, including monocytes and macrophages, are at risk as well. The chemokine receptors CXCR4 and CCR5 have been recently identified as necessary coreceptors. Viral RNA is transcribed by reverse transcriptase to DNA. A provirus is formed that can remain “latent” for a prolonged period (up to several years). New virus copies are produced after activation of the host cell. This activation can lead to direct cellular cytotoxicity and the spread of virus to cause eventual depletion, and through a variety of mechanisms, dysregulation of the immune system. T-helper cells become depleted and the ratio of T-helper to T-suppressor cells becomes reversed.

The most serious clinical consequence of HIV infection—AIDS—is defined in children according to certain immunologic ([Table 273.1](#)) and clinical parameters ([Table 273.2](#) and [Table 273.3](#)), as defined by the Centers for Disease Control and Prevention (CDC). Between 1982 and 1998, over 8,000 cases of PAIDS were reported to the CDC. Many more children are HIV infected, but do not meet the criteria for AIDS.

Immunologic Category	Age of Child		
	<12 mo	1-5 yr	6-12 yr
	cells/cc (%)	cells/cc (%)	cells/cc (%)
1: No suppression	>1,500 (>25)	>1,000 (>25)	>500 (>25)
2: Moderate suppression	750-1,500 (15-24)	500-999 (15-24)	200-499 (15-24)
3: Severe suppression	<750 (<15)	<500 (<15)	<200 (<15)

Modified from Centers for Disease Control and Prevention, 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. *MMWR* 1994;43(RR-12):1-10.

Category C: Severely Symptomatic HIV Infection

TABLE 273.3. Conditions Included in Clinical Category C for Children Infected with Human Immunodeficiency Virus

Of the reported cases with PAIDS, 78% occurred in children under 5 years and 90% in children born to HIV-infected mothers. Currently, vertical transmission accounts for all but a few isolated cases of new pediatric HIV infections. Children born to untreated HIV-infected mothers have approximately a 20% to 30% chance of being infected. With recent recommendations for universal HIV screening of pregnant women and effective prenatal and postnatal prophylaxis, transmission can be reduced to below 5%, and it is expected that the number of new cases of PAIDS will dramatically decline.

CLINICAL PRESENTATION

The presentation of an HIV-infected child may vary, depending on whether the diagnosis of HIV infection had been previously known. The child with HIV may be outwardly growing well and have no more than the usual number of routine childhood infections. Therefore, it is not uncommon for previously undiagnosed HIV-infected children to present through the emergency department (ED) with the first clinical manifestations of HIV disease, and an index of suspicion must be kept for HIV, even in relatively healthy older children. Suspicion for HIV should be raised in children with unexplained poor growth and developmental delay, with recurrent or chronic infections. Recurrent infections do not need to be severe or debilitating. The most common infections seen are frequent otitis media, sinusitis, pneumonia,

adenitis, and diarrhea. Certainly, any opportunistic infection (OI) should immediately suggest an underlying immunodeficiency. Probably the most common physical finding is diffuse lymphadenopathy (LAD), especially with axillary or subclavicular involvement and hepatic or splenic enlargement. Parotid enlargement is a common finding. The presence of persistent or chronic oral candidiasis, especially in a child over 1 year of age should suggest immune dysfunction. Common hematologic findings include anemia, leukopenia, and especially thrombocytopenia. Nonspecific liver enzyme elevation is often seen, as is hypoalbuminemia and hyperproteinemia, with a resultant increased globulin fraction. Sedimentation rate, though nonspecific, is often markedly elevated.

Sudden presentation with an OI is not an uncommon manner in which a child with undiagnosed HIV may present to the ED. *Pneumocystis carini* pneumonia (PCP) remains the most common presenting OI in undiagnosed children. Although it can occur at any age, it typically presents at under a year of age. Symptoms include dyspnea, tachypnea, cough, and fever, with relatively clear lung sounds and disproportionate hypoxemia. Severity of symptoms may range from mild upper respiratory symptoms to severe respiratory distress. A chest radiograph shows a diffuse interstitial pattern. Lymphoid interstitial pneumonitis (LIP) and pulmonary lymphoid hyperplasia (PLH) are common causes of respiratory symptoms and may mimic respiratory infections. Children with LIP/PLH often have radiographic findings out of proportion to their respiratory symptoms; they usually have LAD and hepatosplenomegaly (HSM) and can have digital clubbing. The most common organisms causing respiratory infections in HIV-infected children remain the typical pediatric respiratory pathogens, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*.

Mycobacterium avium-intracellulare (MAI), seen in children with advanced disease, can present with prolonged fevers and nightsweats, chronic diarrhea, abdominal pain, and weight loss. Oral thrush is common, and esophageal candidiasis should be suspected in a child with oral thrush accompanied by fever, refusal to eat, irritability, and weight loss. Diarrhea is common and is most often due to *Salmonella* sp., *Shigella* sp., and *Campylobacter* sp. Infections with *Clostridium difficile*, *Escherichia coli*, *Yersinia* sp., and *Vibrio cholerae* are also seen with increased prevalence. Parasitic infection, specifically with *Giardia* and *Cryptosporidium*, is also prevalent. Cytomegalovirus (CMV) and herpes simplex virus (HSV) can cause especially severe enteritis.

Other OIs, such as toxoplasmosis, histoplasmosis, and cryptococcosis, can be seen in children but are rare; these occur primarily in adults. Herpesvirus infections (HSV, varicella-zoster virus [VZV], CMV) can be particularly severe and can present as disseminated disease. CMV retinitis, a common cause of acute blindness in adults, is very uncommon in children, but it can occur with advanced disease. Malignancies, especially lymphomas, occur at an increased rate, and may be primary central nervous system (CNS) or disseminated. Kaposi's sarcoma, common in immunocompromised adults, is rare in children. Acute cardiac and renal manifestations are uncommon, but myocarditis with congestive heart failure and acute renal failure have been described. Although chronic HIV-associated encephalopathy and developmental delay are common, acute CNS manifestations are not, and etiologies such as infection, space-occupying lesions, and thromboembolic events should be investigated. Infected children are at increased risk for sepsis and meningitis with the usual pediatric pathogens.

Less acute symptoms commonly seen in the ED include skin rashes, such as molluscum, warts, and drug eruptions. The child with PAIDS is at greater risk for cutaneous herpesvirus infections, and can have recurrent or chronic chickenpox, zoster, or mucocutaneous HSV. Oral aphthous ulcers are common and present with shallow oropharyngeal ulcers, which can be quite painful and result in decreased oral intake and dehydration. Aphthous ulcers need to be differentiated from oral HSV infections, as corticosteroids are often needed to resolve the aphthous ulcer.

Children previously diagnosed with HIV may present differently. In patients on appropriate drug regimens who are compliant with recommended therapy, most OIs, especially PCP and MAI, are much more rare. If the child is on effective antiretroviral therapy, in general, infections should be less common and less severe, though he or she remains at risk for all of the previously listed conditions.

Common presentations for HIV-infected children under treatment often involve adverse effects from their medications. Acute pancreatitis can be seen with several of the antiretroviral agents and can be quite severe and life-threatening. Drug eruptions, ranging from mild nonspecific erythroderma and urticaria to overwhelming Stevens-Johnson syndrome, can be seen with many of the agents used to treat HIV. Nausea, vomiting, diarrhea, and hepatitis are common adverse effects. Drug-induced hematologic abnormalities that may be seen in the ED include bleeding from thrombocytopenia, congestive heart failure from anemia, and secondary infections from granulocytopenia.

DIFFERENTIAL DIAGNOSIS

Because HIV can cause such a wide and varied pattern of symptoms, its differential diagnosis is extensive, and there are a number of conditions that can cause a child to present to the ED with manifestations similar to those of HIV infection. The symptoms of primary immunodeficiencies can be virtually identical to those of HIV.

PAIDS most resembles the T-cell deficiencies, the most common being severe SCIDS and DiGeorge syndrome. There are many variants of SCIDS, and they can be either autosomal recessive or X-linked. Children with SCIDS usually present with overwhelming infections within the first few months of life and rarely live more than 1 or 2 years without treatment. Patients with DiGeorge syndrome can have similar infections, but often also have severe hypocalcemia, cardiac, and other anatomic and morphologic abnormalities. Other T-cell disorders have similar presentation but are much rarer. Of the B-cell disorders, the most common are X-linked agammaglobulinemia and common variable immune deficiency. Both result in immunoglobulin deficiency and typically present with recurrent encapsulated bacterial infections, mostly of the respiratory tract. *Giardia* and enteroviral disease are also commonly seen.

In the newborn and young infant, other congenital infections, such as CMV, rubella, syphilis, toxoplasmosis, HSV, and Epstein-Barr virus (EBV), can present with developmental delay, failure to thrive, HSM, and LAD. Lymphoma, leukemia, and other malignancies can present with weight loss, HSM, LAD, fevers, cytopenias, and OI. Recurrent pneumonias and sinus disease, along with chronic diarrhea and poor weight gain, are common presenting symptoms for cystic fibrosis. Certain autoimmune diseases, such as lupus or systemic juvenile rheumatoid arthritis, as well as metabolic and mitochondrial diseases may have similar initial presentations. Many chronic conditions can cause secondary immunodeficiencies with presenting symptoms similar to those of HIV. Examples of secondary immunodeficiencies include protein calorie malnutrition or specific nutrient (i.e., zinc) deficiencies, nephrotic syndrome, inflammatory bowel diseases, and protein-losing enteropathies, among many others.

EMERGENCY DEPARTMENT EVALUATION

The ED evaluation depends on whether the child has known HIV infection or is presenting for the first time with a suspected but undiagnosed immunodeficiency. A careful physical examination and history should be taken, especially for parental HIV risk factors. However, absence of risk factors should not override clinical suspicion of HIV. In a well-appearing child with suspicious history, physical, or laboratory findings, a referral for in-depth testing and evaluation may be more appropriate than testing in the ED. A child with significantly abnormal physical findings, laboratory values, or illness should be admitted for a full immunologic evaluation.

For the child with known HIV infection, ED evaluation should be based on the presenting problem (e.g., fever, diarrhea, respiratory distress), taken in conjunction with immunologic status. The risk of significant bacterial infections and OI is related to the degree of the child's immunocompetency as well as to the medication regimen.

In general, children who are in the CDC clinical category N (no signs/symptoms) or A (mild signs/symptoms) or in immunologic category 1 (no evidence of immune suppression) can receive the same evaluation as would a noninfected child with similar clinical symptoms. Children in more advanced categories are at higher risk for serious illness and require proportionately more intensive evaluations.

Because the range of possible presenting symptoms is wide, it is impossible to list all evaluations that should be done in every case. Oftentimes, an HIV-infected child will have so many chronic problems that evaluation in any system will yield abnormal results. Therefore, evaluations should be acute symptom-specific.

A source of fever should always be sought. Febrile children should have a complete blood count (CBC) and routine blood culture. Children with severe immunosuppression should have blood cultures sent for acid-fast bacilli, viral (especially CMV), and fungus as well. Chest radiographs and pulse oximetry (blood gases, if severe) are indicated in patients with cough, wheeze, or respiratory distress. Elevated lactate dehydrogenase (LDH) is suggestive of PCP, although it can be elevated with other pneumonias. Sputum culture should be obtained in older children.

With any acute diarrheal illness, stool cultures for routine bacteria, ova and parasite, and rotavirus, as well as fecal leukocytes, are indicated. Specific evaluation for *Giardia* and *C. difficile* should be considered, and in children with advanced disease, cultures for *Cryptosporidium*, acid-fast bacilli, and other viruses (CMV, adenovirus) can be included. In patients with chronic or severe acute diarrhea, electrolyte abnormalities are common, and levels of electrolytes, including calcium and magnesium, should be monitored.

For acute abdominal pain, serum amylase and lipase, especially if the patient is on antiretrovirals, and tests of liver function should be ordered. Abdominal imaging may be indicated for severe or chronic pain. For acute skin rashes, a history of recent changes in medication within the past few weeks should be obtained. When possible, cultures should be taken of any infectious-appearing skin lesion of unknown etiology. Children with acute CNS symptoms should have appropriate CNS imaging studies, as well as consideration for lumbar puncture, if deemed safe.

The diagnosis of HIV in adults and children over 2 years old is relatively straightforward, and is made by demonstrating the presence of HIV antibodies in the blood. In young children, the diagnosis is more difficult. All children born to HIV-infected mothers will have transplacentally acquired HIV antibodies, which may persist until 18 to 24 months. Therefore, although HIV antibody testing identifies a child at risk, definitive diagnosis in children under 2 years requires demonstration of the presence of the virus itself, not only antibody to the virus. The preferred method of testing is via polymerase chain reaction (PCR) against proviral DNA. Serial testing is often necessary to prove infection, but PCR is highly reliable, with over 90% accuracy with one test alone. Because results of testing are rarely available during the ED stay, the decision to test patients in the ED should be done only when appropriate counseling and follow-up are available. As the HIV-infected child is often the index case, the implications of testing a child or the parents and other siblings must be taken into account.

EMERGENCY DEPARTMENT MANAGEMENT

The presenting illness in the HIV-infected child in CDC immune category 1 or clinical categories N or A can generally be managed similarly to that of any noninfected child. For other categories, the stage of the underlying disease needs to be taken into consideration to determine appropriate ED management. Consultation with the child's primary care physician or infectious disease specialist is indicated to help determine appropriate management. Often, ED-determined abnormalities are well known to the primary service and may, in fact, be chronic changes. Other times, the primary service is aware of factors unique to the patient that need to be incorporated into the management plan.

It is important to remember that HIV is not spread by casual contact; as with all patients, however, take universal precautions when dealing with body fluids.

The principles of empiric antibiotic treatment in a child with HIV are similar to those in ill-appearing, non-HIV infected children. Obviously, children with advanced HIV disease require more aggressive treatment, both in terms of threshold to begin treatment as well as in antibiotic choice. Empiric antibiotic therapy is based on source of infection and likely organisms. For the febrile child in whom bacteremia is suspected but who does not appear septic, ceftriaxone (50 to 75 mg/kg) parenterally could be considered in a child to be sent home from the ED. Ceftriaxone, followed by a course of an oral antibiotic effective against beta-lactamase-positive agents, is also a good choice for community-acquired pneumonia or a chronic otitis media or sinusitis. Children with relatively good immune function or with mild infections can often be treated with oral antibiotics alone.

Broader spectrum antibiotics are indicated if the child has failed previous antibiotics or is on chronic antibiotic prophylaxis. Occasionally, quinolone antibiotics are the only oral antibiotics available, but they should be started only after consultation with the child's primary service and should be restricted to patients with documented *Pseudomonas* infections or failure of conventional antibiotics. If the patient's clinical condition warrants hospital admission, then broad-spectrum intravenous antibiotic coverage should be started. The presence of a central venous catheter should suggest the use of an agent effective against gram-negative and coagulase-negative *Staphylococcus* organisms, especially if the child appears septic.

A high index of suspicion should be kept for unusual organisms and OI. The presentation of PCP is varied, and any child at risk ([Table 273.4](#)) who presents with respiratory symptoms and hypoxemia, especially with characteristic radiographic and laboratory findings, should be suspected of having PCP. Children with early or mild PCP often have only minimal changes on chest radiograph, and their only symptoms may be tachypnea, and dyspnea and hypoxemia on exertion. Even children with mild PCP, although often treatable with oral antibiotics alone, should be admitted for definitive diagnosis with bronchioalveolar lavage (BAL) and to ensure nonprogression of respiratory symptoms. Empiric treatment with trimethoprim-sulfamethoxazole (TMP/SMX) should be started immediately, as BAL will detect *P. carinii*, even several days after initiation of treatment. Administration of corticosteroids is definitely indicated in any child with moderate-to-severe PCP, and is typically given even in mild cases.

Age	Risk for PCP
<4 wk	Low
4 wk-12 mo	Any infected infant
1-5 yr	CD4 <500 cells/cc or <15%
6-12 yr	CD4 <200 cells/cc or <15%
Any age	If history of previous PCP If CD4 (count or %) rapidly decreasing or class C disease present

Modified from Centers for Disease Control and Prevention. 1995 Revised guidelines for prophylaxis against *Pneumocystis carinii* pneumonia for children infected with or perinatally exposed to human immunodeficiency virus. MMWR 1995;44:RR-4:1-11.

TABLE 273.4. Risk for PCP in HIV-Infected Children

The differentiation of community-acquired pneumonia from other respiratory conditions can be a challenge for the ED clinician. While the radiographic findings in LIP/PLH may mimic respiratory infections, they rarely cause acute respiratory symptoms. Acute exacerbations are usually due to a superimposed viral infection and may manifest with fever, cough, wheezing, and dyspnea. If it is possible to obtain previous radiographs, they can be useful to differentiate old from new findings. For acute exacerbations, symptomatic treatment with bronchodilators and oral corticosteroids is often effective. Antibiotics should be reserved for patients with suspected secondary infections or with new radiographic changes. Short courses of oral glucocorticoids, such that might be used for LIP/PLH, acute asthma attacks, or a severe allergic reaction, are rarely absolutely contraindicated in HIV-infected children. The rare exceptions include patients with an active viral infection, such as herpesviruses, and those with severe underlying immune dysfunction. Nevertheless, it is always appropriate to contact the patient's primary service before beginning home systemic glucocorticoids.

Diarrhea is treated as in non-HIV-infected children, and dietary changes are often all that is necessary to control symptoms. Dehydration can be treated with oral or intravenous rehydration, depending on the severity.

Specific therapy should be withheld pending culture results, but, in certain cases, empiric antibiotics can be started. Children with fever and more than 5 white blood cells per high-power field may benefit from empiric TMP/SMX treatment. Infectious diarrheas often become chronic (such as with *Giardia*, *C. difficile*, and *Cryptosporidium*), and empiric therapy is based on past response to medications.

It is generally not appropriate to institute or make major changes in antiretroviral therapy, prophylactic therapy, or other chronic medications in the ED. Changes should be made only after discussion with the child's primary service, and they are best left to the outpatient clinic setting.

Chemoprophylaxis after Suspected Exposure to HIV

Children may present to the ED after exposures that put them at risk for HIV infection. Such exposures include accidental puncture wounds they might incur by playing with discarded needles found outside or inside the house, or from sexual abuse.

Determination must first be made as to the risk of HIV transmission. If the source is known to be HIV-infected, then recommendations for chemoprophylaxis are based on type of exposure (percutaneous, mucous membrane, or skin) and source material (blood, other infectious body fluids, such as semen and vaginal secretions). Larger volume or area of exposure, higher HIV titer, and prolonged contact all increase the risk of transmission. Most often, the HIV status of the previous needle user or sexual contact is not known. In such an instance, recommendations for chemoprophylaxis should be made, case by case, on the basis of the exposure risk and likelihood of HIV infection of the source. Chemoprophylaxis should be recommended for children with high-risk exposure. Prophylaxis should be offered to children

with low but nonnegligible exposures, balancing the lower risk versus the use of drugs of uncertain efficacy and toxicity. For exposures with negligible risk (i.e., exposure to urine, normal household contacts, etc.), chemoprophylaxis should not be offered.

There is no drug regimen that has proven superiority, and certainly there are many cases of chemoprophylaxis failure. Drug regimens should be based on the profile of antiretroviral drug resistance of the source case, local availability of drugs, the patient's preexisting medical condition and drug therapy, and drug toxicity.

In general, triple-drug combination therapy is recommended. In most cases, the combination should include zidovudine combined with another reverse transcriptase inhibitor and a protease inhibitor. Recent CDC guidelines suggest zidovudine, lamivudine, and indinavir as empiric therapy. When possible, these drugs should be started after consultation with specialists having expertise in antiretroviral therapy. Postexposure prophylaxis should be initiated as soon as possible after exposure, preferably within 1 to 2 hours.

Although animal studies suggest that prophylaxis is not effective when started more than 36 hours after exposure, the interval after which there is no benefit in humans is not known. Some sources recommend initiating therapy as long as 1 to 2 weeks after a very high risk exposure, so that even if infection is not prevented, early treatment of HIV infection may be of benefit. The optimal duration of postexposure prophylaxis is unknown, but the regimen should be administered for at least 4 weeks if tolerated, or until the source is proven HIV-negative. The child should be tested for HIV at initiation of chemoprophylaxis to confirm the absence of preexisting HIV infection. Chemoprophylaxis should be offered in conjunction with appropriate counseling as to the risks and benefits of antiretroviral therapy and the risk of the exposure. Arrangements should be made for ongoing counseling and follow-up testing.

DISPOSITION

As with any chronic disease, children who are suspected of having HIV infection need to be followed by a primary service experienced in their management. Children who are suspected of having undiagnosed HIV and who do not have significant clinical findings should be referred to an appropriate consultant in infectious disease or immunology. Discussion with the consultant prior to discharge from the ED can help to determine whether the child may be safely evaluated as an outpatient, and to arrange for a definitive appointment. Known HIV-infected children with mild disease can be managed at home and should have follow-up arranged with their primary service.

Children requiring hospitalization should be carefully evaluated to determine whether admission to an intensive care or step-down unit is required. For most infectious processes, consultation with an infectious disease specialist is indicated. If BAL is required, a pediatric pulmonologist should be contacted. If the hospital is not equipped to manage seriously ill, HIV-infected children, or if the necessary specialist consultations are not available, the patient should be transported to an appropriate center by qualified transport personnel.

COMMON PITFALLS

- Not all parents will volunteer that their child is HIV-infected, and may deny their own risk factors. Every attempt should be made to elicit appropriate historic information, but decisions on whether to suspect a child is HIV-infected may need to be based on strong clinical suspicion.
- In any suspected immunodeficient patient under a year of age, the presence of tachypnea and hypoxemia should suggest PCP, and empiric therapy should not be withheld while waiting for definitive diagnosis. Although breakthroughs are rare, even children on prescribed PCP prophylactic medications may develop PCP.
- Any child over a year old with persistent or recurrent oral thrush should be considered immunodeficient until proven otherwise.
- Because of the risk of more serious disease, significantly immunosuppressed children should receive more intensive evaluation and treatment than might be done in an otherwise normal child. When in doubt, it is better to err on the side of caution when deciding to treat or admit.
- If a child's HIV status is unknown, but there is risk for HIV, either by history or suggestive clinical findings, he or she should be assumed to be infected and treated accordingly.
- As much as possible, a source for any fever should be sought, and all appropriate cultures should be obtained.
- As with any immunodeficient patient, all live virus vaccines should be avoided in the ED, and all blood products should be irradiated and CMV-free.
- Reasonable efforts should be made to contact the HIV-infected child's primary service before final evaluation and disposition. Effective follow-up is key to successful management and minimization of future ED visits.

[Chapter References](#)

Although the vast majority of routine immunizations are administered by private physicians and health departments, an emergency department (ED) visit by an underimmunized child can be viewed as an opportunity for vaccination, and some authors promote the administration of missed vaccines in the ED. ¹¹

[Table 274.1](#) summarizes recent recommendations from the American Academy of Pediatrics (AAP), the Centers for Disease Control and Prevention (CDC), and the American Academy of Family Physicians (AAFP) for routine childhood immunizations. Immunization practices are rapidly changing; many new vaccines and changes in the vaccine schedule are expected. Updated information on vaccines, adverse events, and schedules can be found on AAP websites (<http://www.aap.org>), AAFP (<http://www.aafp.org>), the National Immunization Program of the CDC (<http://www.pcdc.gov/nip>), or in the American Academy of Pediatrics *Red Book*.¹

PCV		2	4	6	12	18	24	36	48	60			

TABLE 274.1. Routine Childhood Immunization Schedule United States, June 2000

Serious complications from currently used vaccines are rare; minor febrile and local reactions are common. In addition to specific vaccine reactions, the general complications associated with intramuscular injections (e.g., sterile and infected abscesses, nerve or vascular injuries) are sometimes seen.

Recent controversy over rare vaccine complications, particularly encephalopathy and other possible neurologic sequelae, has heightened parental anxiety toward immunization reactions.⁶ The Institute of Medicine has extensively analyzed suspected vaccine complications and categorized adverse effects into five categories that favor or reject a causal relationship for the vaccine involved. For many suspected vaccine complications, there is insufficient evidence to accept or reject a causal relationship, and further study is needed.^{7,9,10,12}

CLINICAL PRESENTATION: VACCINE COMPLICATIONS

Diphtheria, Tetanus, and Pertussis

Diphtheria, tetanus, and pertussis combination vaccines contain diphtheria and tetanus toxoids and either whole-cell pertussis (DTP/DTwP) or acellular pertussis antigens (DTaP). Acellular pertussis vaccines are now recommended for the initial series, as they are highly effective and cause fewer local and systemic reactions, such as fever, seizures, and constitutional symptoms, than whole-cell vaccine.^{1,2}

Common adverse reactions to DTwP vaccine are seen in more than half of recipients and usually occur within 48 hours. They include local redness, swelling, pain, fussiness, and moderate fever (less than 40.5°C). Giving acetaminophen at the time of administration and 4 to 8 hours later reduces the incidence of febrile and local reactions.¹ The occurrence of immediate anaphylaxis or encephalopathy within 7 days of administration contraindicates further doses of any pertussis vaccine. The following findings (less common after DTaP than dTwP) are considered “precautions,” which should be considered before further doses of either pertussis vaccine are administered^{1,7}:

1. Seizures within 3 days
2. Persistent, inconsolable screaming or crying for more than 3 hours within 48 hours
3. Collapse or shocklike state (hypotonic–hyporesponsive episode) within 48 hours
4. Unexplained fever over 40.5°C within 48 hours

Recent estimates of the risk of acute encephalopathy after whole-cell pertussis vaccine are from zero to 10.5 episodes per million immunizations.⁷ The American Academy of Pediatrics has concluded that pertussis vaccine has not been proven to be a cause of brain damage.^{1,3} It should be stressed that neurologic complications occur with much higher frequency in natural pertussis disease.

Haemophilus influenzae Type B

There are four *Haemophilus influenzae* type b conjugate vaccines (HbCV) licensed for use in the United States: PRP-OMP (PedvaxHIB), HbOC (HibTITER), PRP-T (ActHIB/OmniHIB), and PRP-D (ProHIBit). The vaccines differ in their carrier proteins, polysaccharide molecular size, and method of conjugation; as a result, they differ in immunogenicity.

The primary series begins at 2 months of age (two doses for PRP-OMP, three doses for HbOC or PRP-T), with a later booster dose of any of the vaccines. A dramatic decrease in the incidence of invasive *H. influenzae* disease has occurred since the introduction of these vaccines, with a 99% decline in invasive disease in children less than 5 years of age.⁸ All of the vaccines are well tolerated, with about 25% of children having mild local reactions. HbCV vaccines are also available in combination with other vaccines (see later section, [Combination Vaccines](#)).

Hepatitis B

Universal immunization with hepatitis B vaccine, beginning at birth, is now recommended. Currently used recombinant vaccines may occasionally cause local soreness or fever but are otherwise well tolerated.

Measles, Mumps, Rubella

The live measles, mumps, and rubella (MMR) vaccine is generally well tolerated; occasionally, children develop fever or rash 7 to 12 days after immunization. Thrombocytopenia may occur within 2 months of administration; it is usually transient and benign. The risk of thrombocytopenia appears to be increased in children with a history of prior thrombocytopenia or thrombocytopenic purpura. Acute arthralgia or arthritis may be seen, particularly in postpubertal girls. Allergy to egg is no longer considered a contraindication to MMR administration; rare anaphylactic reactions to MMR are thought to be due to traces of gelatin, neomycin, or other substances in the vaccine.¹

Polio

Oral polio vaccination programs have resulted in the eradication of wild polio in the Americas, and progress continues to be made toward worldwide eradication. There is an extremely small risk of vaccine-associated paralytic polio in live oral polio vaccine (OPV) recipients and their contacts; this low risk is now felt to be unacceptable in the United States. Therefore, inactivated polio vaccines (IPVs), which do not carry a risk of paralysis, are now recommended for the entire series of vaccinations in the United States. Allergic reactions are rare after polio vaccines, which contain trace amounts of neomycin and other antibiotics.

Pneumococcus

Heptavalent pneumococcal conjugate vaccine (PCV7, PREVNAR[®]) has recently been recommended for universal use in children less than or equal to 23 months of age and for selected older children.⁵ The vaccine contains seven pneumococcal antigens conjugated to a nontoxic diphtheria protein. The most common adverse effects seen after pneumococcal vaccine (usually given simultaneously with other routine immunizations) include local reactions, fever, irritability, drowsiness, and decreased appetite.

Varicella

Live-attenuated varicella vaccine is generally well tolerated; adverse effects include local pain and redness, occasional fever, and rash at the injection site or elsewhere (up to a month after vaccination). Vaccine-induced immunity appears to be long lasting, with no increased incidence of zoster.¹ Varicella may occur in vaccinated children but is usually mild.

Combination Vaccines

Many new combination vaccines are being marketed or are under investigation. They aim to limit the number of injections and health-care visits, thereby limiting discomfort and increasing compliance with the extensive schedule of recommended immunizations. Current combination vaccines include DTP plus *H. influenzae* (Tetramune), and hepatitis B plus *H. influenzae* (Comvax). When *H. influenzae* vaccine is administered simultaneously with DTP, there is no change in the expected rate of systemic or local reactions from that expected with DTP alone.

DIFFERENTIAL DIAGNOSIS

The cause of neurologic problems that appear temporally related to vaccination is often difficult to determine, because infants are in an age group in which neurologic disorders and seizures commonly first occur. Most seizures seen shortly after immunization are simple febrile seizures. The child with fever after vaccination may have an infection (e.g., otitis media) as the cause.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Mild febrile or local reactions require only reassurance and symptomatic treatment. Children with suspected serious neurologic complications often require further evaluation, such as lumbar puncture or neuroradiologic imaging.

Passage of the National Childhood Vaccine Injury Act of 1986 instituted strict legal requirements for administering immunizations. There is now a National Vaccine Injury Compensation Program, which is a no-fault system for compensating persons experiencing severe or fatal vaccine complications. Detailed written information about risks and benefits, using official Vaccine Information Statements (VISs), must be provided before giving vaccines with pertussis, measles, mumps, rubella, polio, or tetanus–diphtheria toxoids, and the provision of such materials and informed consent should be documented. VISs will likely be required for other routine vaccinations in the future.

When a vaccine is administered, the following information must be recorded: (1) date; (2) vaccine type; (3) manufacturer; (4) lot number and expiration date; (5) site and route of administration; and (6) name, address, and title of the person administering the vaccine. Serious events suspected to be related to vaccine administration, including anaphylaxis, encephalopathy, brachial neuritis (tetanus toxoid), paralytic polio, chronic arthritis (rubella), thrombocytopenic purpura (measles), and early onset Hib disease (within 7 days of vaccination), must be reported to the United States Department of Health and Human Services Vaccine Adverse Event Reporting System (VAERS), telephone 1-800-822-7967 or website (<http://www.cdc.gov/nip/vaers.htm>).

DISPOSITION

Consultation with a pediatrician, infectious disease specialist, or neurologist should be obtained when a severe immunization reaction is suspected. Children with significant neurologic symptoms, anaphylaxis, or other serious vaccine complications should be hospitalized. Serious vaccine complications must be reported (see VAERS information in preceding section). The child's physician should provide follow-up care for discharged patients and be notified of the suspicion of an immunization reaction. Transfer to a tertiary pediatric facility should be considered if further subspecialty consultation or intensive care is needed.

COMMON PITFALLS

- Do not automatically attribute fever occurring after immunization to vaccination; thoroughly examine the child for a treatable focus of infection.
- Typical local and febrile reactions are not a contraindication to further doses of the vaccine.
- Routine immunizations are not contraindicated in children with minor febrile illnesses.

CHAPTER 275

Impetigo

Jeffrey G. Michael and Jane F. Knapp

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Impetigo is the most common infection of the skin in children.^{7,8,12} It is more prevalent during warm, humid summer months in temperate climates, but year round in more tropical climates. Impetigo affects the entire pediatric population, with a mean patient age of 5 years.⁸

Impetigo is caused by either *Staphylococcus aureus* or group A beta-hemolytic streptococci (usually *S. pyogenes*), or both. Within the past decade, penicillin-resistant *S. aureus* has emerged as the predominant pathogen causing impetigo.^{4,5,7,9,10}

Generally, bacterial invasion occurs through a break in the skin traumatized by a scratch, abrasion, or insect bite. Two distinct clinical forms have been described. Classic or nonbullous impetigo may be either staphylococcal or streptococcal or a mixed infection. Bullous impetigo is generally agreed to be due to *S. aureus* alone. In nonbullous impetigo, the lesion begins as a papule or vesicle that erodes and forms a thick, honey-colored crust. The lesions are initially discrete but may coalesce with progression of infection. When the crust is removed, a cloudy serous fluid exudes from a moist erythematous base. The lesions of bullous impetigo are flaccid bullae filled with a cloudy fluid. The bullae are often ruptured before presentation, leaving a shiny, lacquered, erythematous base with peeling edges.

The lesions of both forms of impetigo are usually not painful. Impetigo is most commonly encountered on the extremities, face, or buttocks. Fever and systemic involvement are rare, although nonbullous impetigo frequently is accompanied by lymphadenopathy. When treated, impetigo heals completely without scarring.

CLINICAL PRESENTATION

The patient with nonbullous impetigo generally seeks treatment because the infection is spreading or has been unresponsive to topical antibiotics. The child with bullous impetigo is usually brought for medical attention soon after infection because of parental alarm at the appearance of the bullae. The neonate with bullous impetigo is at risk for systemic involvement. The source of infection is often the nursery where the baby was born. When the possibility of bullous impetigo secondary to *S. aureus* occurs in a neonate in the period 2 weeks post discharge from the nursery, the emergency department should alert the newborn nursery of the possibility of an *S. aureus* epidemic.

The major complication of impetigo, acute poststreptococcal glomerulonephritis, has an incidence of 1% to 5%, with higher occurrences during epidemic infections.^{7,12} Treatment with antibiotics does not prevent the development of acute glomerulonephritis. The nephritis most commonly affects patients between 3 and 7 years of age and has a latent period averaging 18 to 21 days. Anti-DNAase B titers are elevated when the source of infection is the skin, with antistreptolysin-O titers rising minimally to none at all. Rheumatic fever has not been established as a sequel of impetigo.^{7,8}

Other rare but possible complications of impetigo include cellulitis, regional adenitis, osteomyelitis, and sepsis.

DIFFERENTIAL DIAGNOSIS

The diagnosis of impetigo is commonly made on the basis of the typical appearance of the lesions. The differential diagnosis includes other vesicular or crusted dermatologic conditions or thermal burns. On occasion, impetigo may be mistaken for burns, especially cigarette burns, but cigarette burns are usually deeper, more punched-out-appearing lesions and do not have the distribution characteristic of bullous impetigo. Bullous impetigo on the buttocks has been difficult to differentiate from suspected child abuse due to submersion scald burns.¹¹ Chickenpox is distinguished by the appearance of a macular, papular erythematous rash, which then turns into vesicles. The rash and vesicles start centrally and progress peripherally, appear in crops, may be present on mucous membranes, and are often accompanied by systemic symptoms of illness.

Herpes zoster is distinguished by its characteristic dermatomal distribution. Herpes simplex should be suspected when the vesicles have a grouped or tightly coalesced appearance. The child may complain of itching, burning, or pain, and there may be a history of previous occurrences at the same site. Hand-foot-and-mouth disease is usually caused by a coxsackievirus infection. The vesicles are individual, firm, and oval and are most often located on the palms and soles and in the mouth. Scabies is frequently vesicular or pustular in children. Helpful points in differentiation of scabies are its characteristic distribution on the wrists and in the web spaces of the fingers and toes, complaints of intense pruritus, and presence of similar lesions in other family members.

Contact dermatitis such as poison ivy can be vesicular or crusted. There is usually a history of exposure, and the lesions are pruritic and grouped in streaks. Occasionally, tinea corporis may be mistaken for impetigo when the lesions are crusted.

EMERGENCY DEPARTMENT EVALUATION

Impetigo can usually be identified by the characteristic appearance of its lesions, and cultures are not typically needed. Many skin conditions in children become impetiginized. Common examples are chickenpox, scabies, and atopic dermatitis. Patients with atopic dermatitis have been noted to have an increasing incidence of streptococcal impetigo in addition to increased colonization of *S. aureus*.¹ All patients with impetiginized skin conditions need to be treated with antibiotics.

EMERGENCY DEPARTMENT MANAGEMENT

Impetigo is treated with systemic antibiotics, although mupirocin 2% (Bactroban) has been studied extensively and has been found to be as effective as systemic antibiotics when used alone for limited infections, which are generally described as a few lesions to one area of the body.^{2,3} Penicillin is no longer recommended as a therapy option due to resistance issues.⁸ The oral antibiotics chosen should have good *S. aureus* coverage. Infants with bullous impetigo may need admission and intravenous therapy if they have systemic signs of illness. Appropriate oral therapy includes the macrolides, clindamycin, cloxacillin, and cephalexin. The dosage of cloxacillin is 50 to 100 mg/kg/d, divided in four equal doses. Erythromycin estolate can be given as 40 mg/kg/d, divided in two or four equal doses. The dosage for erythromycin ethylsuccinate is 40 to 50 mg/kg/d, divided in three or four equal doses. The maximum dosage for each is 1 g/kg/d, not to exceed 250 mg four times per day.

In 1994, clarithromycin was approved for uncomplicated skin infections in children at a dosage of 15 mg/kg/d, divided two times per day. This medication has been shown to have fewer gastrointestinal side effects, and the dosing schedule suggests improved compliance, perhaps offsetting the increased cost.⁷ Cephalexin can be given as 40 to 50 mg/kg/d, divided three to four times per day. The dosage of clindamycin is 15 mg/kg/d, divided three or four times per day. Concern for increased association of the development of *Clostridium difficile* toxin-associated diarrhea has been reported with clindamycin. Thus, tempered with the fact that any antibiotic can change the normal intestinal flora, leading to overgrowth of *C. difficile* and the risk of toxin-mediated diarrhea, clindamycin is a less desirable choice. All oral therapy is recommended for 7 to 10 days.

Currently, the rate of erythromycin resistance to *S. aureus* in children reported from studies in the United States is 10% to 20%. Israel and Australia have reported rates in the range of 30% to 50%. Treatment failure rates with erythromycin are higher in areas of known erythromycin-resistant strains than in areas with erythromycin-sensitive strains. The treating physician's knowledge of regional sensitivity of erythromycin against *S. aureus* is helpful when making a decision to use

this medication.^{6,7,9}

DISPOSITION

Consultation with a dermatologist or infectious disease specialist is generally not required. Rarely does a child need to be admitted to the hospital, except in cases of extensive disease, immunocompromised states, or infants with bullous impetigo with systemic involvement. Unfortunately, some cases of impetigo may be unresponsive to therapy due to parental inability to effectively provide the medication, and thus these children may warrant admission for compliance issues. In most cases, follow-up is not indicated unless a satisfactory clinical response is not achieved in 7 days, at which point, a culture of the site is recommended to evaluate for resistance.⁷

COMMON PITFALLS

- Treatment failures due to error in diagnosis, poor compliance with medication, or medication resistance
- Difficulty differentiating impetigo from burns due to child abuse
- Recognition that bullous impetigo in neonates may be related to nursery epidemics

SCABIES

Scabies (from the Latin *scabere*, meaning “to scratch”) is a highly contagious, pruritic skin rash caused by the mite *Sarcoptes scabiei*. The female mite, 0.3 mm in length, burrows beneath the skin while laying two to three eggs per day. Eggs hatch after 3 to 4 days, and the larvae migrate toward the surface of the skin, where they mature from the nymph stage into adults in 2 weeks. After mating, the adult female migrates more deeply into the skin, continuing the mite’s life cycle (which totals 30 days).

Transmission usually occurs via close personal contact. Other varieties of scabies (dog, cat, bird, horse) may transiently infest humans, but this is a self-limited infestation, as these mites cannot reproduce in humans. Scabies is most commonly seen during the winter. Live mites have been recovered from floors, furniture, and clothing, but transmission from fomites is thought to be unusual. The incubation period is 10 to 30 days. However, the rash is a delayed type IV hypersensitivity, so a recurrent infestation may produce symptoms within 24 hours.

Prevalence has increased in the United States over the past several years. The highest incidence is in the pediatric age group.

CLINICAL PRESENTATION

Patients usually present with persistent generalized pruritus. Itching is typically worse at night, and it may precede the actual rash. The rash may consist of papules (often crusted), vesicles, pustules, or nodules. The classic lesion (not seen in the majority of patients) is a 2- to 10-mm-long, threadlike, raised serpiginous burrow with a terminal papule or vesicle. The mite may be visible as a black dot at the leading end. More commonly, lesions consist of multiple, small, erythematous papules, often excoriated. Lesions have a predilection for the hands and feet (particularly the web spaces), axilla, flexor aspects of the wrists or forearms, buttocks crease, genitalia, female breasts and nipples, and umbilicus or belt line. The face and scalp are generally spared, except in young children.

Chronic lesions tend to be more nodular and reddish brown. They are most likely to be seen on the genitalia or in the axillae. Mites may not be found in these lesions.

Neonatal scabies is uncommon but tends to be more generalized, with pustules and eczematoid changes. Such an infant may manifest irritability due to pruritus.

Norwegian scabies presents with gross scaling, especially of the hands, feet, scalp, and pressure-bearing areas. Pruritus is variable and may be minimal. This form is more likely to be seen in the immunocompromised or debilitated patient. Norwegian scabies is extremely contagious: An affected individual may harbor millions of mites (versus the usual dozen or so that are present in a typical infestation).

Secondary bacterial infection of lesions is not uncommon, and scabies may also complicate other dermatoses. Treatment with topical steroids may alter the inflammatory component of the rash and decrease pruritus.

DIFFERENTIAL DIAGNOSIS

Atopic dermatitis is commonly confused with scabies, but it tends not to involve the web spaces, axilla, or wrists. Hand-foot-mouth disease is usually seen with fever and mucosal lesions. Dyshidrotic eczema may manifest as vesicles on the sides of the fingers. Papular urticaria may cause confusion with scabies, but these lesions are self-limited and do not spread over time. Acropustulosis of infancy consists of recurring crops of pruritic papules, vesicles, and pustules. Other considerations in the differential diagnosis include contact dermatitis, dermatitis herpetiformis, syphilis, folliculitis, pityriasis rosea, impetigo, seborrhea, nodular lymphoma, psoriasis, lichen planus, fiberglass exposure, histiocytosis X, and keratosis follicularis.

EMERGENCY DEPARTMENT EVALUATION

Microscopic examination of a skin scraping for mites, eggs, or feces is 90% to 95% sensitive when done properly (many emergency departments are not equipped to do this test). To perform this test, choose a nonexcoriated burrow or papule. Place a drop of mineral oil on the lesion, then scrape it with a no. 15 blade deeply enough to produce no more than a speck of blood. Transfer the scraping to a glass slide and examine it under 40x magnification.

Detection of burrows may be facilitated by applying topical tetracycline, wiping it away, then using a Wood lamp (burrows retain the tetracycline and fluoresce). Alternatively, rub a suspected site with a washable felt-tip marker and wipe it away with alcohol (the burrow retains the ink).

EMERGENCY DEPARTMENT MANAGEMENT

Permethrin 5% (Elimite) has replaced lindane (Kwell) as the treatment of choice for scabies. In randomized studies, permethrin has proved more efficacious than lindane and is also less absorbed through the skin (less than 2% vs. 10%), with lower potential for toxicity. Permethrin is neurotoxic to mites, causing paralysis.

Permethrin should be applied from the neck or hairline to the toes and washed off in 10 to 12 hours. Many authorities advise a second application in 1 week. The only

contraindication to its use is known hypersensitivity to permethrin (or formaldehyde, one of its ingredients). It has been classified as category B for pregnant patients (usually safe, but benefits must outweigh risks). The patient may experience mild stinging or burning. Children, adolescents, and adults should apply cream over the entire body below the head. Permethrin may be safely used in children past 2 months of age. With infants and toddlers, the cream should be applied over the head, neck, and body (avoiding the eyes), with special attention to postauricular areas, hands, and feet, and should be washed off after 10 to 12 hours.

Alternative therapies, which should be needed rarely, include lindane (Kwell , Scabine), crotamiton (Eurax) cream or lotion, sulfur in petrolatum, and Ivermectin (0.2 mg/kg orally for one dose). Lindane is contraindicated in infants less than 6 months of age and in pregnant women, and it is applied as the permethrin cream. Lindane should not be applied after a warm bath, because absorption may be enhanced. It should be removed in 8 to 12 hours, with a repeat application in 1 week. Crotamiton is applied to the whole body once a day for 2 days followed by a bath 48 hours after the last application. Retreatment with crotamiton in 2 weeks is suggested. Sulfur ointment 6% to 8% is an old treatment that is less effective, smelly, and causes stains.

Response to treatment is not dependent on the number of lesions present. The patient should be advised that symptoms may not resolve for 2 to 4 weeks; the nodular form may persist for many weeks after treatment. Therefore, it is prudent to prescribe antipruritic therapy: diphenhydramine, hydroxyzine, or a judicious use of topical steroids. Usually, patients are no longer infectious 24 hours after treatment.

All clothing, bedding, and towels contacted within the 2 days prior to treatment should be either washed in hot water, dry cleaned, or stored for 1 week. It is best to treat every person in the household simultaneously (even asymptomatic individuals), as the prolonged incubation period makes it difficult to know with certainty who is infested. Secondarily infected lesions should be treated with appropriate antimicrobial medication.

DISPOSITION

Follow-up in 2 weeks with the patient's primary care physician should suffice in most cases. Dermatology consultation may be prudent in severe cases or in immunocompromised patients.

COMMON PITFALLS

- Consider scabies in any patient with pruritus, even if skin findings are minimal. Be alert to the varying manifestations.
- Treat all family and household contacts simultaneously, whether symptomatic or not.
- Consider other sexually transmitted diseases in those who have contracted scabies through sexual contact.
- Do not prescribe repeated courses of Lindane, due to its cumulative neurotoxicity.
- Do not fail to treat secondary bacterial infection with appropriate antimicrobials.
- Provide families with adequate anticipatory guidance regarding the use of medications. Inform patients that even successful treatment may result in little improvement for several weeks afterward.
- Inadequate anticipatory guidance related to environmental measures: At the time of treatment, all clothing and linens should be dry-cleaned or washed with hot water and put in a hot dryer for 20 minutes. Items unable to be washed or dry-cleaned should be placed in a sealed plastic container for at least 7 days (until eggs hatch).
- Inadequate anticipatory guidance related to personal care: Avoid overbathing, as it may cause further irritation of the skin.

LICE

Lice are blood-sucking, wingless ectoparasites. Three species commonly infest humans: *Pediculus humanus capitis* (head louse), *Pediculus humanus corporis* (body louse), and *Phthirus pubis* (pubic louse or crab). *Pediculus* species can interbreed. The pubic louse is morphologically distinct from the other two and primarily infests the pubic and anogenital areas, but it may infest the eyelashes, brows, beard, axilla, and, rarely, the scalp.

P. capitis has worldwide distribution. In the United States, it is the louse that most commonly produces infestation. Most infestations involve between 10 and 20 lice. Hair length and cleanliness are not significant factors in infestation. The louse is spread by close physical contact and by shared fomites, such as combs, brushes, hats, or bedding. School-age children have the highest prevalence—an estimated 10% to 40% in U.S. schools. Incidence is greatest in late summer and autumn. African Americans in the United States have a lower rate of infestation than do other racial or ethnic groups. Head lice are not known vectors for other diseases.

P. corporis has a life cycle similar to that of the head louse, except that it lives in clothing and inhabits the host's skin only to feed. It is generally found on those with poor hygiene and living in overcrowded conditions. Unlike the head louse, the body louse is a known vector of rickettsial diseases.

P. pubis is commonly transmitted via sexual contact. Infested individuals have a 30% to 40% risk of another sexually transmitted disease, and should therefore be investigated for such infections. If found on children, sexual abuse should be suspected. *P. pubis* can inhabit any hair-bearing area, but it is usually found in the pubic and perineal regions. It is the only louse known to infest eyelashes and eyebrows.

CLINICAL PRESENTATION

Pruritus is the most common symptom. Careful inspection may reveal nits cemented in place at the base of the hair shaft. Detection is aided by the use of a Wood lamp to reveal the fluorescent nits. Nits greater than 10 mm from the scalp are either hatched or nonviable. Body lice lay nits in the seams of the clothing, not on the host directly. Head lice most commonly inhabit the hair line near the ears and the nape of the neck.

DIFFERENTIAL DIAGNOSIS

Any condition with itching and scalp or skin irritation should be considered:

Tinea capitis
Contact dermatitis
Seborrheic dermatitis
Atopic dermatitis
Superficial skin infections
Scabies
Eczema

EMERGENCY DEPARTMENT EVALUATION

A history of exposure and/or intense pruritus should prompt a careful search for nits or adult lice, using a Wood lamp to help find the nits. Excoriations, secondary infections, and local lymphadenopathy may be present.

EMERGENCY DEPARTMENT MANAGEMENT

Pediculicides

Body lice do not require medications if infested clothing can be removed and destroyed (or disinfected).

For head lice, 1% permethrin (available over the counter under the brand name Nix) is effective in over 90% of cases. It is a topical cream rinse, applied after the hair is washed with an over-the-counter shampoo. In addition to killing adult lice, it also has ovicidal activity. Hair should not be rewashed for 24 hours after application.

Pyrethrins, which contain piperonyl butoxide (A-200, Rid) is another class of agents for treatment. These medications are contraindicated in patients with ragweed

allergy. Pyrethrin is not ovicidal, so retreatment is necessary in 7 to 10 days to kill newly hatched nymphs.

Lindane (1%) shampoo (Kwell) is also available but has been associated with seizures. Therefore, lindane is usually recommended for patients who fail to respond to permethrin or pyrethrin. Lindane is contraindicated in infants and pregnancy. The lindane shampoo is applied as a cream rinse after washing the hair with a nonmedicated shampoo. Allow the medication to remain in place for no more than 4 minutes and then rinse thoroughly. For body lice, apply it as a cream or lotion, leave it on for 8 to 12 hours, and then rinse. For pubic lice, apply it as a shampoo for 10 minutes, then rinse, and apply it again in 2 weeks.

Malathion lotion (0.5% and 1.0%) is an alternative therapy that binds to the hair shaft for 4 weeks. However, it is flammable and must be used with caution. Its potential for toxicity is still being investigated. This medication is no longer available in the United States. In other countries, the recommended use is for the 1% shampoo. It is to be utilized in two 10-minute applications approximately 7 days apart.

New on the market is the oral anthelmintic, ivermectin. A single dose of 0.2 mg/kg is highly effective, with virtually no side effects. Retreatment is often recommended in 7 days to kill any residual surviving adults and nits.

An infestation of the eyelashes can be treated with petroleum ointment (Vaseline) applied to coat the lashes two to three times a day for 8 to 14 days. Using a small beard or mustache comb to mechanically remove nits on eyelashes is a necessary adjunct to petroleum ointment.

Nit Removal

An important adjunct to the use of pediculicides is the use of a fine-tooth comb to remove nits in treated individuals. Most U.S. schools have a “no-nit” policy to prevent the classroom spread of lice infestations. Therefore, it is important to instruct patients and families on the differentiation between nits and benign hair casts. This will prevent reinfection as well as unnecessary retreatment, which can be a toxic hazard.

A proper comb and correct technique in combing the hair are essential for adequate nit removal. Most pediculicides include a nit-removal comb. A minimum of 20 minutes should be spent combing damp hair—divided into 1-in. sections—working from the crown of the head downward. Special attention should be given to the postauricular and nape areas, because head lice preferentially seek these regions of the scalp.

The cement used to attach the nit to the hair shaft can be loosened using a 50:50 rinse solution of vinegar and water. The solution should be applied to the hair, covered with a warm, moist towel for 30 minutes, and then the hair combed as described previously. A commercial product (Step 2) containing 8% formic acid may also aid in nit removal. When infestation is heavy, a haircut may be preferable to tedious nit removal.

Environmental Measures

Environmental measures are necessary for adequate treatment and prevention of reinfection. Machine washing in hot water and hot-cycle drying of all clothing, headgear, bedding, and linen kills adult lice and nits. Combs, brushes, and hair accessories should be soaked in hot water (128.3°F), with or without a pediculicide shampoo, for 15 minutes, followed by a hot-water rinse. Items unable to be washed (stuffed animals, etc.) should be either dry cleaned or placed in a well-sealed plastic bag for 10 days to kill both adults and nits.

Family members, friends, school or daycare contacts, and other contacts should be examined for asymptomatic infestation.

DISPOSITION

Simultaneous treatment of all family members is recommended to prevent intrafamily reinfection. In addition, children found to be infested with *P. pubis* should be evaluated for other sexually transmitted diseases and possible sexual abuse.

COMMON PITFALLS

- Failure to reassure patients and families that lice infestation is not a social disease
- Inadequate evaluation and treatment of close contacts
- Failure to adequately educate patients and families regarding procedures to fully remove nits and nit differentiation
- Failure to educate patients and families on the necessity to retreat in 7 days
- Failure of the health-care provider to suspect sexually transmitted diseases and sexual abuse in children infested with *P. pubis*
- Failure to treat secondary infection with appropriate antimicrobial agents
- Inadequate anticipatory guidance to patients and/or parents regarding adequate procedures to remove nits and adult lice from fomites and the environment
- Failure to remember that pyrethrins are contraindicated in patients with ragweed allergy

ENTEROBIASIS (PINWORMS)

Enterobius vermicularis, a small nematode, is a common cause of helminthic infestation in the United States. All socioeconomic levels are affected, and infestation often occurs in family clusters. Infestation does not equate with poor home sanitary measures. Prevalence is greatest in 5- to 9 year-old children, but all ages can be affected. One widely quoted source (Pomeranz and Fairley, 1998) estimates a prevalence of 5% to 15% in the general population, with this rate declining in recent years.

E. vermicularis is an obligate parasite, with humans as the only natural host. Both males and females are affected. Fecal-oral contamination via fomites (toys, clothes) is a common method of infestation. After ingestion, eggs usually hatch in the duodenum within 6 hours. Worms mature in as little as 2 weeks. Adult worms normally inhabit the terminal ileum, cecum, vermiform appendix, and proximal ascending colon. The worms live free in the intestinal lumen, and little evidence exists to support invasion of healthy tissue under normal conditions. The female worm migrates to the rectum after copulation. If not expelled during defecation, she migrates to the perineum (often at night), where she releases an average of 11,000 eggs and then dies. Eggs can survive in the environment for up to 3 weeks under optimum conditions.

CLINICAL PRESENTATION

Pruritus ani and pruritus vulvae are common presenting complaints. One study (Hogan et al., 1991), however, failed to find an increase of these symptoms in infested children, compared with matched controls. Occasionally, the gravid female may migrate aberrantly into the human female genitalia and produce vaginitis. Association with small and large intestine ulcerations, appendicitis, perianal abscesses, intestinal pain, transient synovitis, or enuresis is not causal.

DIFFERENTIAL DIAGNOSIS

Other diagnoses to consider include appendicitis (more severe abdominal discomfort), cervicitis (localized tenderness and inflammation of the cervix), dermatitis, contact dermatitis, giardiasis, inflammatory bowel disease (mucoid or bloody stools), roundworm or tapeworm infestation (eosinophilia), and vulvovaginitis.

EMERGENCY DEPARTMENT EVALUATION

Patients often have excoriation or erythema of the perineum and/or vulvae, but infestation can occur without these signs. Visual sighting of a worm by a reliable source (i.e., a parent) is usually accepted as evidence of infestation and grounds for treatment. Worms are commonly found among stools or on the patient's perineum at night. Without a visual report, diagnosis can be confirmed by using the knowledge that eggs are normally deposited in great quantities on the perineum of a host at night. Wide (2-in.) transparent tape pressed against the perineum in the morning before the patient washes will capture eggs. Diagnosis is made by identifying eggs under the low-power lens of the microscope, using a slide to which dilute sodium hydroxide or toluene is added.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment of pinworms is via family education and medications administered as an outpatient. Fear and guilt are common parental reactions to parasitic worm infestation. Many families come to the emergency department with misconceptions about pinworms. It is helpful to inform them that infestation occurs in spite of proper child and household hygiene. Families also should be counseled to avoid overreaction through aggressive sanitary measures.

DISPOSITION

Pyrantel pamoate (11 mg/kg; maximum, 1,000 mg) with a repeat treatment in 2 weeks is effective. An alternative is mebendazole (100 mg, regardless of weight), also repeated in 2 weeks. Because asymptomatic infestation of other members in a household is frequent, it may be reasonable to treat all household members simultaneously. Families should be informed that repeat infestations are common. If reinfestation occurs, it is treated in the same fashion as an initial infestation.

Symptomatic relief of pruritus can be obtained by applying topical antipruritic ointments or creams (1% hydrocortisone) to the perianal region.

COMMON PITFALLS

- Failure to assure patients and families that pinworm infestation is not a social disease, and is a self-limited disease with frequent reinfections
- Failure to consider that families may need to be treated as a group
- Failure to instruct patients and families that no special hygienic measures are necessary. However, reassurance can be provided that using simple, prudent measures, such as clipping fingernails (a favorite repository for eggs), washing hands frequently, showering daily in the morning, and normal laundering of linen weekly, are activities that can help prevent recurrence.

CHAPTER 277

Intussusception

Jonathan I. Singer

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Intussusception, an invagination of a proximal portion of the intestine into a distal adjacent part, is a common cause of intestinal obstruction. Classically, it occurs in well-nourished children, most often boys. Approximately two-thirds of cases are seen prior to age 2, with most of those occurring between the fifth and ninth month.¹⁴ Intussusceptions that occur beyond age 2 tend to cluster around the third year, but intussusceptions have been reported throughout the age spectrum, including adulthood.¹¹

In all age groups, ileocolic intussusceptions predominate (75% to 95%), and greater than 90% are idiopathic.¹ Abnormal lead points include Meckel's diverticulum, polyps, duplication cysts, hemangioma, and tumors.³ Irrespective of cause, early diagnosis is essential; the duration of intussusception before treatment bears a close relationship to its morbidity and mortality.^{5,14}

CLINICAL PRESENTATION

The cardinal symptoms of intussusception are abdominal pain, vomiting, and rectal bleeding. In a typical case, there is a sudden onset of severe abdominal pain that may last several minutes. After an asymptomatic interval, repeated paroxysms will cause the child to cry out again. The child may be impossible to console or may seem comfortable only in a knee–chest position in the arms of an attendant. Vomiting may occur either with the initial painful episode or soon after. Concurrent with vomiting, the child usually has one or more bowel movements, which vary from thin liquid to formed stools. Within 12 to 24 hours, mucus, blood, or both may be passed per rectum.²⁰

This classic triad of paroxysmal pain, vomiting, and rectal bleeding is found in less than one-third of all patients.^{1,5} Only 85% manifest colicky abdominal pain. Approximately 75% of patients experience vomiting. Nonbilious vomiting may become bilious as bowel obstruction progresses. Rectal bleeding is a less constant historic feature and may be found in as little as 40% of patients.¹¹ Frank blood, or blood-streaked stools, may be present within a few hours of the first painful episode. “Currant jelly” stools, which are bloody, maroon, and mucus-laden, account for a minority of bloody stools and are typically seen after prolonged symptomatology.^{2,20}

Recognition of the stereotypic history facilitates the diagnosis. When there is historic aberrancy, a less than classic presentation contributes to diagnostic uncertainty.¹⁶ Among the factors that contribute to misdiagnosis, several predominate. Altered mental status contributes most to delayed diagnosis. Apathy or listlessness may occasionally be the dominant concern of the parent. This altered sensorium with intussusception may be seen in the context of prolonged symptomatology or as the initial complaint.^{12,15} Intussusception may not be considered when it occurs later in childhood.¹¹ A painless event may occur in 15% of cases and reduces diagnostic accuracy.² Sometimes, blood never passes per rectum. Stool from the rectal examination early in the course may be normal-appearing, and guaiac may be negative.

The physical appearance of an affected child may be variable.⁵ Most children will be alert and hydrated. Those with advanced disease complicated by either fluid or electrolyte imbalance or blood loss may appear less responsive.⁷ Not uncommonly, a child with a very brief history of enteric manifestations may be obtunded at presentation.⁶ Other findings are limited to the abdominal examination.

On inspection, the abdomen may appear scaphoid. The right lower quadrant may seem empty (Dances sign).⁹ A sausage-shaped, sometimes ill-defined, and variably tender mass is present in 25% to 89% of patients. The mass will be subhepatic early in the course of ileocolic intussusception. Abdominal guarding and distention are infrequent. A mass may be palpable on rectal examination. On rare occasions, even with a short history, the advancing mass prolapses through the anus.

DIFFERENTIAL DIAGNOSIS

Intussusception is readily diagnosed in the 10% to 17% of young children who present with the constellation of abdominal pain, vomiting, rectal bleeding, and abdominal mass.^{5,16} When the picture is less complete, other diagnoses that may be entertained include intestinal obstruction from other causes, such as malrotation with midgut volvulus or incarcerated hernia. Other considerations include pseudomembranous or infectious enterocolitis, acute gastroenteritis, Hirschsprung disease, appendicitis, appendiceal abscess, and peritonitis.^{1,2} Metabolic derangement, endocrinopathy, intoxication, occult cranial trauma, sepsis, and meningitis may be considered in those patients with intussusception who present with altered mental status.^{6,8}

EMERGENCY DEPARTMENT EVALUATION

Several laboratory investigations may guide the medical decision making in patients with a provisional diagnosis of intussusception.^{7,14} A stool examination for occult blood has a high benefit-to-cost ratio. A negative guaiac should not be used to exclude the diagnosis, yet a positive stool guaiac should reduce the threshold for further evaluative and management decisions. When symptoms are brief and the child appears nontoxic and well hydrated, blood chemistries and a hemogram are not warranted. However, a complete blood count, serum electrolytes, blood urea nitrogen, creatinine, and urinalysis may facilitate decision making concerning a child who appears to be volume depleted. A blood sugar is required for the child with altered mental status. Further, the child who appears septic should have cultures of blood, urine, stool, and cerebrospinal fluid.¹⁵

A variety of imaging procedures can be utilized for a provisional diagnosis of intussusception.^{17,18} When there is a high index of suspicion, supine and upright or supine and left lateral decubitus radiographs of the abdomen should be obtained.^{9,9} Depending on the time course at presentation, age of the patient, and presence of a lead point, films may be normal or reveal nonspecific findings such as localized air–fluid levels or reduced intestinal air. The presence of a mass or obliteration of usual gas shadows of the colon is suggestive of intussusception. The presumed diagnosis can be confirmed only by plain film findings if the head of the intussusception is clearly visible in the bowel lumen. Those with nonspecific or suggestive findings should have either a barium or an air contrast enema.¹⁹ Those patients with radiographic evidence of complete bowel obstruction, intraperitoneal air, ascites, or pneumatosis intestinalis should not be subjected to contrast enema.

When there is a lower index of suspicion for intussusception, ultrasonography may be useful.⁸ Suggestive findings are created by the edematous head of the intussusception.² Findings include a “target” or “donut” sign on transverse section and a “pseudokidney” sign viewed on longitudinal section.⁹

EMERGENCY DEPARTMENT MANAGEMENT

Unless there is ischemic bowel with peritonitis, sepsis, massive volume loss, coagulopathy, or respiratory distress from massive pneumoperitoneum, the patient with intussusception should not require airway intervention, respiratory support, or volume resuscitation. Monitoring should be initiated that is appropriate for the degree of patient instability. Those who evidence mild-to-moderate dehydration should be given a normal saline bolus, followed by polyionic intravenous fluids pending serum electrolytes. Although not universally performed, pending imaging procedures, a nasogastric tube is recommended. All patients should be placed NPO.

If imaging is to be carried out beyond the emergency department, provide information to the radiologist and surgeon. A decision must be made concerning whether there are contraindications to nonoperative attempts at reduction of the intussusception. For patients without contraindication, the surgeon and radiologist can

determine whether air inflation or barium should be employed. Attempts at reduction should never be done without the consent of the surgeon, who must accept the responsibility of operating if the reduction is unsuccessful or if the patient sustains a perforation. If either hydrostatic pressure or pneumatic reduction techniques fail to reduce the intussusception, sedation of the patient, with repeated efforts at nonoperative reduction or operative interventions, is an option. ^{3,9}

DISPOSITION

Whether under ultrasonographic or fluoroscopic guidance, both air and barium reductions have success rates ranging from 65% to 90%. ^{3,13} Recurrence of a successfully reduced intussusception within 1 to 3 days following reduction may occur in approximately 10% of patients. ^{3,13} It is not possible to establish which patients are likely to have recurrent intussusception based on presenting signs and symptoms, age, or sex. Therefore, admission for a 24-hour period may be customary at many institutions but considered unnecessary at others. If the child is discharged home, the emergency physician must ascertain that parents know the indications that warrant a return for further medical attention.

COMMON PITFALLS

- Obstacles to accurate diagnosis include failure to recognize the typical history, failure to perform a rectal examination, reluctance to accept the diagnosis in a well-appearing child with a prolonged history, and failure to consider the disease in older children.
- Marked variation from the classic picture may lead to misdiagnosis. The absence of pain, lack of a mass, the presence of bright red rectal bleeding, or neurologic aberrations should not dissuade one from the diagnosis. ^{4,11,12}
- A normal plain abdominal radiograph should not deter performance of the reduction techniques. ¹⁴
- An inopportune hour of the patient encounter should not prevent recruitment of the radiologist or the surgeon.

CHAPTER 278

Kawasaki Disease

James A. Wilde

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Kawasaki disease (KD), also known as mucocutaneous lymph node syndrome, was first described in Japan in 1967⁴ and reported in the United States literature in 1974.⁵ Although initially thought to be a new disease, KD was soon recognized to be clinically indistinguishable from infantile periarteritis nodosa.⁶ The disease is primarily a vasculitis that affects the coronary arteries most significantly, but it can also produce pathology in the central nervous system, liver, gallbladder, lungs, and digits.

There are 2,000 estimated cases of KD in the United States annually, most commonly in children less than 5 years of age (80%), although it has also been reported in young adults.^{11,12} Peak incidence is the second year of life. Intense efforts to identify the causative agent have failed to yield an etiology, although certain clinical and epidemiologic features favor an infectious cause.

There is no diagnostic assay that can definitively identify a case of KD, so cases must be presumptively diagnosed based on characteristic clinical features and laboratory findings. Adding to the difficulty in identifying cases of the disease is that some children have been described with an incomplete form of KD that does not fit the classic case definition.^{1,3,7} These children are also at risk for development of significant cardiac sequelae. Twenty-five percent to 30% of KD patients will develop coronary artery aneurysms without therapy, while only 5% to 8% do so with the current recommended regimen of intravenous immune globulin (IVIG) and aspirin.⁹ The overall mortality rate is 1% to 3% in untreated KD,⁸ but, with recommended therapy, may be as low as 0.08%.¹⁵

CLINICAL PRESENTATION

Classic KD is diagnosed by clinical criteria as originally described by Dr. Kawasaki, with only slight modifications. These criteria include fever of at least 5 days' duration, at least four of five physical findings, and no other explanation for the illness ([Table 278.1](#)). A diagnosis of KD can be made in a patient with less than 5 days' fever if all the remaining clinical criteria are met.¹⁰ The fever is generally over 39°C, spiking, remittent, and prolonged in untreated patients, with some children remaining febrile for 2 to 4 weeks.

Fever of at least 5 days' duration
Presence of four out of five physical findings:
Bilateral, nonpurulent conjunctival injection
Inflammatory changes of the lips and oral mucosa
Erythema or swelling of the hands or feet
Nonvesicular rash, primarily truncal
Cervical lymphadenopathy, usually unilateral
Illness not explained by other known disease

TABLE 278.1. Diagnostic Criteria for Kawasaki Disease

The conjunctivitis is primarily bulbar, spares the area around the limbus, and is not associated with an exudate. Changes in the lips may include erythema, bleeding, dryness, and fissuring. The oral mucosa may show erythema with a strawberry tongue, but exudates and oral ulcerations are not found. Hands and feet may show edema, erythema, or both, primarily on the palms and soles, with characteristic desquamation 1 to 2 weeks after the onset of the illness. The rash can be quite variable, but it is most commonly diffuse, maculopapular, and erythematous.

Cervical lymphadenopathy is usually unilateral, is nonfluctuant, and is defined by a node diameter of at least 1.5 cm. Each of the clinical criteria is found in approximately 90% of cases, with the exception of the cervical lymphadenopathy, which occurs in only 50% to 75% of cases. An additional, commonly reported finding is extreme irritability in excess of that seen in other childhood febrile illnesses.¹⁰

Multiple organ system involvement has been reported, including pericarditis, myocarditis, arthritis, cerebrospinal fluid pleocytosis,² peripheral extremity gangrene,¹³ pulmonary infiltrates, and hydrops of the gallbladder.¹⁰ A desquamated, erythematous, perineal rash in the first 3 to 4 days is an early finding that is helpful in making a diagnosis.¹⁴

Approximately 1 to 2 weeks after the onset of the acute symptoms, resolution of the fever, rash, and lymphadenopathy can be expected, although the conjunctival injection often persists. It is during this subacute stage that desquamation of the digits occurs. This is also the stage at which coronary artery aneurysms develop and the risk of sudden death is at its highest.

Incomplete KD, or atypical Kawasaki disease (AKD), was first described in a number of case reports and case series in the early 1980s.¹ Most of these patients were under 6 months of age, but cases in older children have also been reported.⁷ AKD is a febrile illness that does not meet the case definition for KD but that can result in similar cardiac sequelae. In most cases reported to date, one to three of the physical findings typical of KD have been present, but several cases of AKD have been manifested solely by fever. Indeed, one investigator has suggested that AKD be considered in any child with prolonged fever of unknown etiology.⁷

DIFFERENTIAL DIAGNOSIS

There are several diseases that can mimic KD, but careful attention to the clinical criteria, as outlined, can help to avoid misdiagnosis. Among these diseases are scarlet fever, measles, toxic shock syndrome, Stevens-Johnson syndrome, leptospirosis, and Rocky Mountain spotted fever. Tonsillar exudates help to differentiate KD from an illness caused by group A streptococci, such as scarlet fever, as does the characteristic scarlet fever rash. Prominent respiratory symptoms, particularly cough, should suggest measles. Many of the symptoms of toxic shock are similar to those of KD, but hypotension is an uncommon finding in KD unless heart failure secondary to severe carditis is present.

Recent exposure to inciting drugs, the presence of oral lesions, an exudative conjunctivitis, and the typical "target lesion" rash can serve as a clues to the diagnosis of Stevens-Johnson syndrome. The centripetal spread of a petechial rash that begins on the hands or feet, severe myalgias, and seasonal and epidemiologic clues might point to Rocky Mountain spotted fever. Chills, myalgia, and abdominal pain may lead to the diagnosis of leptospirosis. Serologic tests are of limited value in the acute stage of any of these illnesses, but they can be helpful during the recovery phase for retrospective diagnoses.

In the emergency department, the diagnosis of KD is usually one of exclusion and is often not considered until a child has presented to a clinic or emergency setting

multiple times.

EMERGENCY DEPARTMENT EVALUATION

Immediate workup of a suspected case of KD should include a complete blood count and differential, platelet count, blood cultures, erythrocyte sedimentation rate (ESR), and a chemistry panel including serum transaminases, total protein, and albumin. White blood cell counts are usually elevated, with polymorphonuclear cell predominance; leukopenia is uncommon. Platelet counts are usually normal in the acute stage, but after a week increase markedly, often rising to above 1 million per microliter. The ESR is virtually always elevated during the acute stage. ¹⁰

Serum transaminases are often two to three times the normal value. Marked rises in serum immunoglobulin levels in the acute stage may result in an elevation in the serum protein level. Lumbar puncture may reveal aseptic meningitis, ² and urinalysis may reveal a sterile pyuria.

Further workup should include a baseline electrocardiogram to search for evidence of myocarditis or pericarditis. A baseline echocardiogram should also be obtained but should not delay therapeutic interventions.

EMERGENCY DEPARTMENT MANAGEMENT

Uncomplicated presentations require no more than supportive management in the emergency department: an antipyretic for fever and intravenous fluids for rehydration and maintenance. Cardiovascular decompensation must be treated as appropriate, and may require inotropic support.

DISPOSITION

Children with a presumptive diagnosis of Kawasaki disease should ideally be admitted to a tertiary care pediatric center with pediatric cardiologists and infectious disease consultants available. Therapy to be instituted in the hospital includes high-dose IVIG at 2 g/kg over a 10-hour period. IVIG has been shown to substantially reduce the incidence of serious cardiac sequelae, particularly coronary artery aneurysms, if administered early in the course of the disease. ^{9,11} High-dose aspirin therapy at 100 mg/kg is also begun on admission and is continued until the acute phase has resolved. Transfer to a pediatric intensive care unit should be considered for patients with signs of cardiac decompensation.

COMMON PITFALLS

- Failure to consider KD in the differential diagnosis of prolonged fever in young children
- Failure to consider AKD in prolonged fever in children
- Failure to monitor for or identify cardiac decompensation
- Failure to use certain laboratory screening tests, such as ESR, to help differentiate KD from common childhood viral exanthems
- Failure to obtain early input from an experienced pediatric cardiologist
- Failure to recognize the importance of early admission and institution of therapeutic interventions such as IVIG and aspirin

[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Lymph nodes are commonly palpated in children's necks. Cervical nodes greater than 10 mm are considered abnormal and are often referred to as lymphadenopathy.⁵ Lymphadenitis is one type of lymphadenopathy. Although some define *lymphadenitis* as broadly as an “inflammation of a lymph node,” others restrict the definition to include only bacterial infections of the lymph gland.^{5,18}

After invading regional tissues, microorganisms enter the lymphatic system, where they are trapped and destroyed by phagocytes. This, in conjunction with the lymphocytic proliferation and transformation that occurs, results in swelling of the node. Abscess formation ensues when neutrophils accumulate.^{5,7}

Group A b-hemolytic streptococci and *Staphylococcus aureus* are the most frequent pathogens of bacterial lymphadenitis. Children with staphylococcal infections generally have a longer history of symptoms and an increased incidence of fluctuance, compared with those with streptococcal infections.^{5,7,15}

CLINICAL PRESENTATION

Cervical lymphadenitis presents most commonly in children between 1 and 4 years of age, and there is no significant difference in incidence between genders. It is helpful to determine whether the cervical lymphadenitis developed in an acute, subacute, or chronic manner. The acute bacterial nodal enlargement usually develops acutely and unilaterally. These nodes are typically very tender and sometimes feel fluctuant. Erythema of the overlying skin is occasionally noted. Affected children often experience malaise and irritability and may be febrile. Frequently, a concurrent pharyngitis, otitis media, upper respiratory tract infection, dental abscess, or adjacent skin infection can be detected, or a recent history of infection can be elicited. Subacute or chronic lymphadenitis develops over 2 to 3 weeks and tends to be relatively painless. It may be caused by cat-scratch disease, atypical mycobacteria, or tuberculosis.

There are rarely significant sequelae when adenitis is managed appropriately. Of particular concern is the possibility of misdiagnosing and consequently mismanaging another more serious problem.²

DIFFERENTIAL DIAGNOSIS

Obtaining a careful history and performing a complete examination can often differentiate the disorders most commonly confused with adenitis.²

Viral Lymphadenopathy

Viral illnesses, especially those that produce viremia, are common causes of lymphadenopathy that subsides within a few days to 2 weeks. Often bilateral, causative agents include respiratory viruses such as adenovirus, Epstein-Barr virus (EBV), cytomegalovirus (CMV), human herpesvirus 6, coxsackievirus, rubella, rubeola, and varicella.^{5,7}

Bacterial Lymphadenitis

The presence of erythema, warmth, and tenderness overlying a node typically indicates the acute inflammatory response of pyogenic bacterial lymphadenitis. Most acutely infected nodes in children are rubbery or firm in consistency and are freely mobile. Left untreated, these nodes, often unilateral, tend to suppurate and may rupture onto the skin or, less commonly, dissect into the underlying soft tissues.^{5,7,15}

Infectious Mononucleosis

EBV causes infectious mononucleosis. It often presents as acute or subacute cervical lymphadenopathy. These nodes tend to be posterior cervical, bilateral, and moderately painful.⁷ Associated findings include malaise, fever, tonsillopharyngitis, hepatosplenomegaly, and generalized lymph node enlargement. A positive heterophil test (Monospot) confirms the diagnosis, except in children less than 4 years of age, for whom specific EBV titers should be done. Treatment is supportive. The patient should be instructed to avoid contact sports for several months after the illness.

Cat-Scratch Disease

Most cases of cat-scratch disease are caused by *Bartonella henselae*. In approximately 50% of cases, there is a primary lesion at the site of a 7- to 14-day-old scratch or bite by a cat. This lesion begins as an indurated erythematous papule and later may become vesicular or pustular. It resolves within 10 to 20 days. Cat-scratch disease usually presents subacutely. Several days to weeks later, the lymph nodes draining this area become progressively enlarged. These nodes are typically only moderately tender, but, occasionally, they will suppurate. Sometimes, patients are febrile and may experience headache, myalgia, or malaise. Other complications, such as encephalitis, hepatosplenic abscesses, and osteolytic lesions, are uncommon. Although the diagnosis is usually made on clinical grounds, it should be confirmed serologically. Antibiotics are of no proven value, and the adenopathy generally resolves in 6 to 8 weeks, with supportive treatment only. Fluctuant nodes often need surgical intervention.^{5,8,9,16}

Atypical Mycobacterial Lymphadenitis

Atypical mycobacterial cervical lymphadenitis usually presents as subacute or chronic unilaterally enlarged lymph nodes that do not respond to antibiotics.^{5,10} Nontuberculous mycobacterial lymphadenitis generally occurs in early childhood. Infected nodes tend to be relatively painless but are sometimes tender and may even suppurate and drain. Systemic symptomatology is uncommon. Tuberculin skin testing is unreliable. Antituberculous drugs are not recommended, and the treatment of choice is excisional biopsy.¹¹

Kawasaki Disease

Also known as mucocutaneous lymph node syndrome, Kawasaki disease is diagnosed in the presence of fever, plus four of the five diagnostic criteria (cervical lymphadenopathy, rash, oral exanthem, conjunctival injection, and swelling and redness of palms and soles) and exclusion of other illnesses. Cervical lymphadenopathy is found in only 50% of cases. Nodes are usually unilateral and confined to the anterior triangle, moderately tender, nonfluctuant, and firm, with or without overlying erythema. The early diagnosis of Kawasaki disease is critical, because treatment with salicylates and intravenous immunoglobulin can prevent the most serious complication, namely, coronary aneurysm.¹⁶

Tuberculous Lymphadenitis

Tuberculous lymphadenitis is rarely seen.^{6,16,17} Diseased nodes are similar to those of nontuberculous mycobacterial adenitis. To exclude the diagnosis, the family should be questioned about exposure to tuberculosis, a tuberculin skin test should be done, and a chest radiograph should be ordered. Tuberculous lymph nodes should never be aspirated, because this could lead to sinus development. Antituberculous drugs are effective in treating this condition. Infection should be reported to public health authorities.

Group B Streptococcal Cellulitis–Adenitis Syndrome

The group B streptococcal cellulitis–adenitis syndrome occurs in neonates.¹⁴ The neonate presents with the abrupt onset of fever and facial or submandibular erythema and swelling. An affected infant is irritable, feeds poorly, and appears toxic. About 80% have an ipsilateral otitis media. Meningitis may accompany lymphadenitis. The organism can be isolated from blood and from aspirates of the lymph node or the cellulitis. A complete sepsis workup should be performed, and the infant must be admitted to the hospital for intravenous antibiotic therapy.^{1,14,16}

Toxoplasmosis

Acquired toxoplasmosis sometimes presents as a single, enlarged, posterior cervical node that may or may not be tender.^{5,12,19} These nodes tend to vary in size but do not suppurate. The diagnosis can be made by performing serial toxoplasma titers. Pharmacologic therapy should be withheld unless fever or a complication such as pneumonitis, myocarditis, meningitis, or encephalitis ensues.

Neoplasms

Neoplasms are rare in children, occurring in 1.4% of patients younger than 17 years of age with a superficial lump on any part of the body. Cancerous nodes may be single or multiple. They are classically painless and are often immobile and indiscrete. Careful follow-up of all lymphadenopathy is mandatory, especially if it is associated with fever or weight loss or if it fails to resolve.^{4,5,9}

Other causes of cervical lymphadenopathy are even more uncommon and include *Pasteurella multocida*, *Yersinia pestis*, histoplasmosis, and CMV.

A few other entities may be confused with adenopathy or adenitis. These include dermoid cysts, thyroglossal duct cysts, benign neoplasms, branchial cleft defects, cystic hygromas, and hematomas.⁴

EMERGENCY DEPARTMENT EVALUATION

Many of the aforementioned diagnoses can be made simply by taking a complete history and performing a thorough examination. The following points should be addressed when questioning the family: duration of adenopathy, history of an adjacent skin lesion, earache, upper respiratory tract infection, sore throat, or dental problem; presence of fever or weight loss; exposure to tuberculosis; contact with cats; and travel.^{5,7} The size, consistency, mobility, and tenderness of each affected node must be noted.^{5,15} Marking the dimensions with ink and recording them in the emergency department record can be helpful to the next physician who evaluates the patient. The head, ears, eyes, nose, oropharynx, and neck are examined, and the child is evaluated for hepatomegaly, splenomegaly, and other adenopathy.⁵

Useful studies include a complete blood cell count, erythrocyte sedimentation rate, a Monospot or EBV serology, a throat culture for group A *Streptococcus*, and a tuberculin skin test. It is, however, unnecessary to order all of these tests on every patient. They prove most helpful when the cause of the adenopathy is unknown. A blood culture should be obtained if the patient appears particularly ill. Older children with cervical adenitis are rarely bacteremic, but neonates often are and must be evaluated for possible sepsis.¹ Additional studies may be needed in the older child, depending on the history and physical examination (e.g., serology for cat-scratch disease or EBV might be drawn). Sometimes, a definitive diagnosis is not made until a biopsy is performed and results evaluated.

Needle aspiration is useful both diagnostically and therapeutically, and any fluctuant node should be aspirated if tuberculous lymphadenitis can be excluded. An ultrasound can help determine whether a node is cystic or solid, if necessary.¹³ The largest, most fluctuant node is selected, the overlying skin is cleansed, a 20-gauge needle attached to a 20-mL syringe is inserted into the fluctuant region, and aspiration is done. If pus is not obtained, 1 to 2 mL of sterile, nonbacteriostatic saline is injected into the node, which is reaspirated. The aspirate is sent for Gram stain and cultures for aerobic and anaerobic bacteria, mycobacteria, and fungi.^{5,7,15}

EMERGENCY DEPARTMENT MANAGEMENT

In addition to percutaneous needle aspiration of fluctuant nodes, if bacterial cervical lymphadenitis is suspected, it should be treated with antibiotics effective against the principal bacterial pathogens, group A *Streptococcus* and *S. aureus*. Analgesics and warm compresses may also be helpful.⁵

Outpatient therapy is as follows:^{3,5,12}

Cephalexin: 50 mg/kg/d, divided q6h PO
Clindamycin : 20 mg/kg/d, divided q6h PO
Dicloxacillin: 25 mg/kg/d, divided q6h PO

Failure to respond to oral antibiotics does not necessarily mean that the cause of adenitis is not bacterial; parenteral antibiotics may be required. For inpatients, the following agents can be used:^{3,5,12}

Cefazolin: 100 mg/kg/d, divided q8h i.v.
Cephalothin: 125 mg/kg/d, divided q4h–6h i.v.
Oxacillin: 125 mg/kg/d, divided q6h i.v.

If the lymphadenitis is associated with dental disease, anaerobic infection needs to be considered, and the following agents are recommended:^{3,5}

Clindamycin: 20 mg/kg/d, divided q6h PO; 40 mg/kg/d, divided q6h–8h i.v.
Amoxicillin–clavulanate (Augmentin): 45 mg/kg/d, divided q12h PO

Treatment should last at least 10 days.^{5,12} After a good response to parenteral antibiotics is observed, oral agents can be substituted.⁵

DISPOSITION

Most children can be managed successfully as outpatients. They should be reevaluated, to monitor their progress, within 2 to 3 days of the emergency department visit. Follow-up is very important and is done best by the patient's primary care physician, who should reexamine the child serially until the node regresses.

Admission for intravenous antibiotics is warranted if the child appears to be toxic, if the adenitis is severe (e.g., node diameter greater than 3 to 4 cm, or high fever), if the adenitis fails to respond to oral medications, or if the patient is a neonate or cannot tolerate oral antibiotics.¹² Admission for further evaluation is recommended if there is mediastinal adenopathy on the chest radiograph or if the child has lost weight or been febrile for more than 1 week, or if Kawasaki disease is suspected.⁹

Biopsy is indicated if the node increases in size or does not decrease in 4 to 6 weeks or return to normal in 8 to 12 weeks.⁹ Particularly worrisome findings are weight loss, persistent fever, or fixation to adjacent tissues or overlying skin.^{4,5,7}

COMMON PITFALLS

- Treating patients with severe adenitis orally and delaying an inevitable admission for intravenous antibiotics
- Failure to consider atypical mycobacterial lymphadenitis, Kawasaki disease, and cat-scratch disease in the differential diagnosis

Central nervous system (CNS) infections are a source of significant morbidity and mortality, and are often included in the differential diagnosis of a febrile child. Bacterial meningitis and viral disease presenting as meningitis, encephalitis, or meningoencephalitis are the most common forms of CNS infection in children. They present a formidable challenge to the emergency physician, both diagnostically and therapeutically, because of their relative rarity, often subtle presenting signs and symptoms, and, sometimes, fulminant course.

The organism that causes bacterial meningitis bears a relationship to the age of the patient. Among neonates, group B *Streptococcus* (GBS) is, by far, the most commonly isolated bacterium. Other less common but significant organisms include *Listeria monocytogenes* and gram-negative enteric bacilli such as *Escherichia coli*, *Klebsiella* and *Enterobacter* spp., *Citrobacter diversus*, and *Salmonella* spp. GBS and *L. monocytogenes* typically present as “late-onset” meningitis at 1 to 12 weeks of life, while meningitis due to the gram-negative enteric bacteria often presents during the first 2 weeks. Beyond the age of 3 months, *Streptococcus pneumoniae* and *Neisseria meningitidis* are the major pathogens, with *S. pneumoniae* predominating from 1 to 23 months and *N. meningitidis* predominating from 2 to 18 years.³⁸ Meningitis due to *Haemophilus influenzae* type B (HIB) is now rare because vaccines have improved.

The leading pathogens caused an estimated 2,800 cases of bacterial meningitis in U.S. children under 18 years in 1995.³⁹ This represents a dramatic decline, resulting from the near disappearance of HIB meningitis over the preceding decade. While two-thirds of patients with bacterial meningitis in 1986 were between 1 month and 5 years of age, by 1995 meningitis in this age group had dropped by 87%, and the median age of bacterial meningitis cases rose from 15 months to 25 years.

Bacterial meningitis is almost always preceded by a hematogenous spread of bacteria. The mechanism whereby bacteria gain access to the intravascular space is unclear, although some data indicate that a breach of the normal mucosal barriers may be caused by viral upper respiratory infections.³¹ It is also unclear how bacteria gain access to the CNS from the bloodstream.

One point that is clear is that most instances of bacteremia do not progress to invasion of the CNS.¹¹ Once in the CNS, bacteria can initially multiply relatively unimpeded because of poor immunologic defenses in normal cerebrospinal fluid (CSF).²⁷ It is only after local release of bacteria-associated chemotactic factors that a significant defense is mounted in the CNS. The resulting inflammation, edema, and CNS dysfunction are manifested as severe headache, nuchal rigidity, photophobia, or seizures (i.e., classic symptoms of meningitis). A patient with fever can be anywhere on this continuum, but in the absence of CSF for evaluation, it is impossible to state definitively that the child has reached the meningitic stage. Bacterial meningitis can also result from direct invasion of the CNS after trauma or erosion through an infected sinus, but this is a much less common mechanism.

Several infectious or noninfectious agents can cause aseptic meningitis, that is, meningitis without evidence of a bacterial pathogen detectable in CSF. Among the most common infectious etiologies are the enteroviruses (ECHO and coxsackievirus) and mumps virus.

Encephalitis is an inflammation of the brain that can occur as the primary pathologic event, as in arbovirus encephalitis, or as a simultaneous event with a primary meningitis. The latter is more correctly termed *meningoencephalitis*, and is common in bacterial meningitis. Among the many infectious causes of encephalitis are the enteroviruses, arboviruses (La Crosse strain of the California encephalitis virus [CEV], St. Louis encephalitis), herpes simplex virus (HSV), varicella virus, and mumps virus.⁴² The enteroviruses and the arboviruses occur during the warmer months, with the latter paralleling mosquito activity. Infection by CEV is typically seen in young boys exposed to hardwood forests or small pools of stagnant water, where mosquitoes breed.¹⁴ HSV encephalitis can occur at any age, including a neonatal form that presents during the second to third week of life.

CLINICAL PRESENTATION

Due to the protean clinical manifestations of bacterial meningitis in infants and young children, physicians must maintain a high index of suspicion for meningitis. Inflammation of the meninges can be manifested by headache, nausea and vomiting, fever, photophobia, mental confusion and lethargy, or excessive irritability in children. Clinical findings indicative of CNS dysfunction, such as seizures, focal neurologic signs (hemiparesis, quadriparesis, cranial nerve palsies, visual field defects), and ataxia suggest meningitis, but no single sign is pathognomonic. The symptoms and signs of meningitis vary and depend, in part, on the patient's age, the duration of illness, and the host's response to the infection,¹⁹ especially in neonates and young infants, in whom the clinical findings may be subtle and may include only such nonspecific manifestations as disinterest in feeding, lethargy, respiratory distress, or jaundice. Fever is commonly not present in neonates with bacterial meningitis.⁶

A change in the child's affect or state of alertness is one of the most important signs of bacterial meningitis. In one study, 36% to 60% of children with this diagnosis were described as toxic or moribund, and 73% to 100% lethargic or comatose, depending on the age of the patient.⁴⁵ These findings were generally not present in infants younger than 3 months in this study. *Lethargy* refers to a decreased level of consciousness and interaction with the environment, bordering on unconsciousness. True lethargy is an ominous finding and warrants further investigation. A febrile child who is playful, smiling, or interactive is unlikely to have bacterial meningitis in the absence of other signs or symptoms suggestive of the disease.

Seizures are found at presentation in 20% to 30% of children with bacterial meningitis.³⁷ However, seizures are rarely the sole manifestation of meningitis in febrile children; most children with seizures secondary to bacterial meningitis will have a significant, prolonged alteration in their level of consciousness or focal findings on physical examination.²¹ This is in marked contrast to children with simple febrile seizures, who, after a short postictal period, usually return quickly to their baseline mental status and have no neurologic deficits on examination.

Bacterial meningitis in infants and children can present either insidiously over several days or acutely in a fulminant fashion. The prognosis may be worse for the second group,²³ a group that is generally not difficult to recognize at presentation. Delays are common in diagnosing those with an insidious presentation, despite the best efforts of physicians. It is unclear whether these delays contribute to the subsequent morbidity or mortality.^{9,18,22,36} Enteroviral infection is typically insidious in

onset and may have a biphasic presentation. The patient does not usually appear seriously ill unless the infection occurs during the neonatal period. ¹³

Differentiating HSV infection of the CNS from bacterial meningitis may be difficult because the nonspecific symptoms just described are found in both. Helpful clues include the absence of bacteria on CSF Gram stain, negative cultures of blood and CSF, the presence of focal seizures, and difficult-to-control seizures. Cutaneous vesicles are found at presentation in only 30% to 50% of infants with neonatal HSV, and are uncommon at any stage of HSV encephalitis in older children. St. Louis encephalitis and La Crosse encephalitis can present either in a mild form, consisting of a 2- to 3-day prodrome of low-grade fever, headache, malaise, and vomiting with subsequent development of higher fever, lethargy, and meningeal signs, or a severe form, characterized by the abrupt onset of fever and headache, followed rapidly by generalized or focal seizures, focal neurologic signs, and coma. ⁴² HSV encephalitis in the older child may be similar to this severe form of arboviral encephalitis.

An altered state of consciousness is apparent in most children with encephalitis due to the brain parenchymal involvement. This may be manifested by only lethargy or delirium, but in severe cases, the lethargy may progress to a stuporous state or frank coma.

DIFFERENTIAL DIAGNOSIS

Although not always apparent at presentation, nuchal rigidity is probably the one clinical sign that physicians most consistently associate with meningitis. However, nuchal rigidity may be associated with a variety of illnesses: ⁴³

- Infections: meningitis, encephalitis, brain abscess, epidural abscess, Guillain-Barré syndrome, transverse myelitis, acute cerebellar ataxia, poliomyelitis, tetanus, cervical adenitis, retropharyngeal abscess, vertebral body osteomyelitis, discitis, epiglottitis, trichinosis, tonsillitis, otitis media, pyelonephritis, mumps, hepatitis, shigellosis, malaria, typhoid fever
- Vascular abnormalities: subarachnoid hemorrhage, intracranial venous thrombosis
- Neoplasms: meningeal leukemia, intracranial and brainstem tumors, tumors of the cervical vertebrae (osteoid osteoma, eosinophilic granuloma)
- Metabolic disorders: infantile Gaucher disease, maple syrup urine disease, kernicterus
- Toxins: phenothiazines, strychnine, lead
- Bony or muscular disorders: vertebral anomalies; sublaxations, dislocations, and fractures of the cervical spine; myositis; fibromyositis; congenital torticollis
- Miscellaneous causes: juvenile rheumatoid arthritis, black widow spider bite, effects of lumbar puncture (LP), Arnold-Chiari malformation.

Viral infections such as influenza, dehydration, and lethargy due to gastroenteritis, and other febrile illnesses often mimic meningitis. Children often look toxic one minute and then become alert and playful an hour later, when their fever decreases.

EMERGENCY DEPARTMENT EVALUATION

History

A careful history can help to differentiate a child with a serious systemic bacterial infection such as sepsis or meningitis from one with a self-limited viral infection. It is important to remember that the overwhelming majority of children with fever do not have bacterial meningitis; if each child under 2 years of age had only one febrile illness per year of life, the expected rate of bacterial meningitis in this age group in the United States would be approximately one case per 4,000 febrile episodes. Most children in this age group have more than one febrile illness per year, so the actual rate is much less than one case per 4,000 febrile episodes. Information gathered from the history and physical examination can help to determine who requires LP for further evaluation ([Table 280.1](#)).

Recommended	Strongly Consider
Unexplained fever and lethargy	Unexplained fever and seizure in child under 18 mo or over 5 yr of age
Coma	Severe headache
Shock	No obvious source for fever, child under 3 mo of age
Extreme irritability in infant	Poor feeding in infant
Age <1 mo	Increased sleep in infant
New neurologic deficit	Petechial or purpuric rash
Nuchal rigidity	Any afebrile, toxic-appearing child with symptoms from either column
Photophobia	
Uncontrolled seizure	
Seizure in child under 6 mo of age	
New-onset focal seizure	

TABLE 280.1. Indications for Lumbar Puncture and/or Immediate Empiric Treatment for Meningitis

Bacterial meningitis leads to inflammation of the brain and meninges, which causes symptoms such as extreme irritability, photophobia, vomiting, headache, lethargy, and seizures. In infants, excessive sleep or poor feeding may result. The emergency department physician should initially focus on these historic items when assessing a febrile child. Their absence does not rule out meningitis but does make it less likely. Conversely, their presence should heighten suspicions of meningitis.

In addition, questions should be directed toward establishing a source for the fever. Are there any ill contacts with fever? Are there signs or symptoms that are temporally related to the fever and that together constitute a self-limited viral illness? Prior or current antibiotic administration is another important historic item to ascertain.

In evaluating a neonate with fever, ask the mother about infections during pregnancy or at delivery. The physician should ask about pruritic or burning vaginal lesions, antibiotic use during pregnancy, ingestion of raw dairy products during pregnancy (listeriosis), parental history of or exposure to HSV, perinatal complications in the mother or child, prolonged care in the nursery after delivery, the mother's GBS status at the time of delivery, and any antibiotic use in the child since birth.

In all febrile children, a history of exposure to someone with tuberculosis, HIB or *N. meningitidis* should be sought. Travel history and animal contact are important factors to consider when dealing with the less common causes of CNS infections. Mosquito bites may suggest an arbovirus infection.

A history of lethargy should be cause for concern. However, parents tend to use the word *lethargic* to describe their children when, in fact, true lethargy is not present. A less playful or a sleepier child is not necessarily a lethargic child. These symptoms are almost universally present in young children with febrile illnesses. Questions should be directed toward establishing the presence or absence of true lethargy.

Physical Examination

A complete physical examination is critical in the evaluation of a febrile child to detect a CNS infection or to establish a reasonable alternative explanation for the fever. An abnormal blood pressure or prolonged capillary refill time in the absence of dehydration suggests a potentially life-threatening bacterial infection. Does the child have symptoms of an acute upper respiratory infection? Does the child have an obvious pharyngitis, or oral lesions consistent with herpangina or herpetic gingivostomatitis? Is there a rash consistent with a clear etiology, such as varicella or the sandpaper rash of scarlet fever? Does the child have conjunctivitis or otitis?

Examine the chest, abdomen, and extremities to rule out other foci of involvement, including pneumonia, myopericarditis, hepatitis, arthritis, and osteomyelitis. Look for the presence of a bulging anterior fontanelle in infants in the seated position, an indication of increased intracranial pressure (ICP). Although the fundoscopic examination is usually normal in acute CNS infections, the presence of papilledema should raise concern for a brain abscess, subdural empyema, or venous sinus thrombosis. A complete neurologic examination is required to determine the presence and severity of a CNS insult and to document a baseline against which the response to therapy can be gauged.

In all patients with suspected CNS infection, signs of meningeal irritation are sought by examining for nuchal rigidity and Kernig and Brudzinski signs. Especially in a very young child who is frightened by the emergency department setting, forceful flexion of the neck can be misleading, because the child's natural tendency is to resist the examiner. A toy or flashlight placed at the sitting child's umbilicus usually causes the child to flex the neck spontaneously, and may be more helpful in excluding nuchal rigidity. Kernig's sign is positive when pain is elicited with the knee extended from its initial flexed position, with the patient supine and the leg flexed at the hip. The Brudzinski sign consists of spontaneous flexion of the lower extremities after passive flexion of the neck. Meningeal signs are almost invariably present at the time of diagnosis in children older than 13 months with bacterial meningitis, but are only rarely present in children younger than 6 months. ⁴⁵

Careful attention to the child's affect or state of alertness is critical, to distinguish those who should undergo LP for further evaluation from the vast majority who need no further invasive tests. The emergency physician should carefully document the general appearance of the child.

Laboratory Evaluation

The definitive diagnosis of meningitis requires CSF analysis, generally after performance of an LP. This procedure should include an opening pressure, if available, cellular analysis, glucose (including simultaneous serum glucose) and protein determinations, Gram-stained smear, and appropriate cultures. Viral, mycobacterial, and fungal cultures should be reserved for special circumstances, and are not considered routine in otherwise healthy children.

LP should be delayed in the presence of cardiopulmonary instability, signs of significantly increased ICP, evidence of bacterial infection in or around the LP site, coma, focal seizures, and new focal neurologic deficits, or if there are signs or a history of a bleeding disorder. These situations may warrant immediate therapeutic interventions aimed at saving the child's life, or radiologic procedures to assess for increased ICP.

If the LP is to be delayed, blood cultures are obtained and empiric antibiotics administered immediately; lifesaving therapy takes priority over diagnostic procedures. The laboratory diagnosis of bacterial meningitis rests on demonstration of bacteria or inflammation in the CSF. While early antibiotics may prevent the isolation of bacteria in subsequent CSF culture, obvious laboratory markers of inflammation persist for days to weeks in most cases. ⁷ In addition, bacteria can be isolated from blood culture in up to 80% of patients with bacterial meningitis. ⁸ The various rapid antigen diagnostic tests, including countercurrent immunoelectrophoresis, latex particle agglutination, and enzyme-linked immunosorbent assay, also may be helpful in establishing the etiologic agent if antibiotics have already sterilized the CSF.

A head computed tomography (CT) scan is not necessary before performance of LP ^{26,28} if the clinical scenario is consistent with uncomplicated meningitis or encephalitis. However, if the patient has focal neurologic findings, has signs of a severe increase in ICP, or is comatose (making neurologic examination unreliable), a brain imaging study such as a contrast-enhanced CT would be prudent to determine the advisability of performing an LP.

Results of CSF analysis can give important clues to the etiology of the CNS infection ([Table 280.2](#)). However, in approximately 1% of cases of bacterial meningitis, CSF cell counts, glucose, and protein are normal, and there are no organisms on Gram stain. ⁴¹ A "normal" CSF profile does not rule out the possibility of bacterial meningitis, but it does render this diagnosis very unlikely. Viral infections of the CNS are typically associated with a lymphocyte pleocytosis of less than 500/ μ L, with relatively normal glucose and protein concentrations initially. However, the first CSF examination in a child with enterovirus meningitis may have a predominance of polymorphonuclear leukocytes, and the cell count may rarely exceed 1,000/ μ L.

Component	Normal Children	Normal Newborn	Bacterial Meningitis	Viral Meningitis	Herpes Meningitis
Leukocytes/ μ L	0-5	0-30	>1000	100-500	10-1000
Neutrophils (%)	0	3-33	>50	<40	<50
Glucose (mg/dL)	40-80	32-121	<30	>30	>30
Protein (mg/dL)	20-30	15-149	>100	50-100	>75
Erythrocytes/ μ L	0-2	0-2	1-10	0-2	10-500

^a The values shown should be used only as a guide to diagnosis, because there is considerable overlap in CSF values for the different etiologic categories.
 Modified from Waddell, McCracken GH. Management of bacterial meningitis. *Pediatr Rev* 1986; 7:73-84.

TABLE 280.2. Typical Cerebrospinal Fluid in Infants and Children ^a

Interpreting a traumatic tap is difficult, and previous recommendations for estimating the number of white cells based on the ratio of white to red cells in peripheral blood may be inaccurate. ¹⁰

In addition to blood culture and CSF analysis, the minimum laboratory evaluation should also include a complete blood count with differential and platelet count, coagulation studies if thrombocytopenia is present, serum electrolytes, urine sodium concentration, urinalysis, and, in some cases, a chest radiograph.

In suspected cases of encephalitis, helpful studies include viral cultures of CSF and mucosal surfaces, specific viral detection in CSF by polymerase chain reaction, electroencephalogram, and brain imaging studies. ^{29,38}

EMERGENCY DEPARTMENT MANAGEMENT

Supportive care and stabilization are of the utmost importance with CNS infections. Among the initial complications encountered are septic shock with its associated metabolic derangements, coagulopathy, intracranial hypertension, seizures, and hyponatremia resulting from the syndrome of inappropriate antidiuretic hormone (SIADH) secretion. The emergency department physician must be prepared to support the patient with acute meningitis and manage complications until transfer to an intensive care unit (ICU) setting can be arranged for definitive care.

Septic Shock

Simultaneous shock and cerebral edema present a theoretic therapeutic dilemma, because the treatment of one may adversely affect the other. However, correcting systemic hypotension must take priority, and fluid resuscitation is an integral part of the management of septic shock. Massive amounts of crystalloid or colloid may be required, but if there is no response after 40 mL/kg, pharmacologic support should be instituted with pressor agents such as dopamine. Patients who require this level of intervention should ideally be managed in an ICU setting, with a central venous pressure line, Foley catheter, and cardiorespiratory monitors.

Previous recommendations for the fluid management of children with meningitis have stressed fluid restriction to avoid cerebral edema resulting from SIADH. ¹² New data, however, have led to the hypothesis that an elevated ADH and the concomitant increase in extracellular water may be part of a compensatory mechanism to overcome elevated ICP and maintain adequate cerebral blood flow. ^{34,40} A study in children with acute bacterial meningitis demonstrated poorer survival among those who received restricted fluids. ⁴⁰ Further studies are required to determine optimal fluid management in these patients, ¹⁷ but restriction of fluids should no longer be considered standard. ⁴⁶ If the patient is not dehydrated and the cardiovascular system is stable, maintenance fluids can be initiated, using a solution containing one-fourth to one-half normal saline in 5% dextrose.

Increased Intracranial Pressure

The upper limit of normal for ICP is about 50 mm H₂O in neonates and 85 mm H₂O in older infants and children, but it can be much higher in CNS infections. ^{18,19} and ²⁰ In patients with suspected intracranial hypertension, the head of the bed is elevated 15 to 30 degrees. ⁴⁷ Although the practice is somewhat controversial, some physicians use mannitol (0.25 to 1.0 g/kg infused over 10 minutes), with or without diuretics, to treat intracranial hypertension. Hyperventilation is another effective

means of decreasing ICP in the severely affected patient. If hyperventilation is utilized, the PaCO₂ should be kept at 25 to 30 mm Hg.¹⁶ ICP should be monitored continuously in patients requiring hyperventilation and mannitol infusions.

Several clinical trials have advocated the use of adjunctive dexamethasone therapy for bacterial meningitis, particularly in disease due to HIB.^{25,33} However, a recent large multicenter study failed to demonstrate any improvement in neurologic or developmental outcome in children who received steroids for bacterial meningitis.⁴⁴ Other authors have pointed out that, in light of the low incidence of side effects and the potential benefits, administration of steroids is appropriate,³⁰ particularly if CSF Gram stain or epidemiologic clues point to a likely case of HIB meningitis. The AAP Committee on Infectious Diseases has suggested the use of dexamethasone in suspected bacterial meningitis but has stopped short of recommending it as routine therapy, unless disease is due to HIB.² If dexamethasone is used, it should be given only to children over age 6 weeks with suspected bacterial meningitis, at a dose of 0.15 mg/kg intravenously just before the first parenteral dose of antibiotic.

Seizures

Early seizure activity occurs in 20% to 30% of patients with bacterial meningitis. Effective anticonvulsants include diazepam or lorazepam acutely, and phenobarbital or phenytoin as maintenance. Seizures associated with hyponatremia require infusion of hypertonic sodium solutions. Generally 4 cc/kg of 3% NaCl is infused over 10 minutes; repeat doses may be necessary.³⁵

Disseminated Intravascular Coagulation

Treating the underlying disease process and correcting the shock and metabolic derangements constitute the best approach to reversing disseminated intravascular coagulation (DIC). If the patient is actively bleeding from peripheral sites or from the gastrointestinal or urinary tract, treatment options include platelet transfusions to raise the count above 50,000/μL, vitamin K to correct a prolonged prothrombin time, and infusions of fresh-frozen plasma to correct a prolonged activated partial thromboplastin time. In the setting of DIC and thrombotic manifestations, heparin therapy may be considered, although its use in this setting is controversial.

Antimicrobial Therapy

Table 280.3 lists the antibiotics and dosages suggested for the initial therapy of suspected bacterial meningitis.^{19,35} Because penicillin- and cephalosporin-resistant pneumococci have been reported throughout the United States, vancomycin should be added to the regimen any time infection due to *S. pneumoniae* is suspected.²⁴ Previous concerns about reduced penetration of vancomycin into the CNS after administration of dexamethasone appear to be unwarranted.¹ If HSV encephalitis is strongly suspected, acyclovir therapy is instituted at 10 mg/kg every 8 hours.

Age	Drug	Dosage (mg/kg)
Newborn-30 d	Ampicillin and Gentamicin	50-75
	or Cefotaxime	25
30 d-3 mo	Ampicillin and 3rd-generation cephalosporin	50
	• Ceftriaxone	50-75
>3 mo	• Cefotaxime	80-100
	Ceftriaxone or cefotaxime and Vancomycin	50-75
		15

TABLE 280.3. Initial Antimicrobial Therapy for Suspected Bacterial Meningitis

DISPOSITION

Role of the Consultant

Pediatric infectious disease consultation is suggested for the management of CNS infections in children. Neurosurgical consultation for placement of an ICP monitoring device may also be required.

Indications for Admission

All patients with potential bacterial meningitis or HSV encephalitis require immediate hospitalization with intensive monitoring. CNS infections of probable enteroviral or arboviral origin may require hospitalization for diagnostic purposes or for supportive care. Sometimes, the results of the initial CSF examination do not distinguish between a bacterial and a viral process. If patients have been pretreated with antibiotics, are younger than 6 months, or are clinically unstable, they should initially be managed as if bacterial meningitis were present.

If clinical signs and symptoms and laboratory analysis of CSF suggests viral meningitis, outpatient management may be appropriate. Some authors suggest observation for 4 to 8 hours and repeat LP for suspected viral meningitis cases.⁴⁶ Lymphocyte predominance, no significant worsening of pleocytosis, normal glucose and protein, and continued absence of bacteria on CSF Gram stain would be expected on the second LP in the setting of viral meningitis.

Transfer Considerations

According to the report of the Task Force on Diagnosis and Management of Meningitis, "It is advisable to manage infants and children with meningitis in a hospital that has specialized equipment and staff with expertise in caring for infants and children who are critically ill. The staff should include physicians who are capable of managing the complications of meningitis."¹⁵ Therefore, transport to a pediatric referral center should be strongly considered for any child with meningitis. If LP has been performed, an aliquot of the CSF should be sent with the patient, along with documentation of clinical management up to the point of transfer.

PREVENTION

If meningitis is due to *N. meningitidis* or HIB, rifampin chemoprophylaxis should be considered for the child's household contacts.^{3,4} The dosage regimen is 10 mg/kg (maximum dose, 600 mg) every 12 hours for four doses, and 20 mg/kg (maximum dose, 600 mg) once daily for 4 days, respectively. With HIB, chemoprophylaxis is given only if there is at least one unvaccinated household contact younger than 48 months. Rifampin should not be given to a pregnant patient. Medical personnel exposed to a case of meningococcal infection need chemoprophylaxis only if that exposure was intimate (e.g., mouth-to-mouth resuscitation). The use of appropriate isolation precautions (mask and gown, hand-washing) for suspected cases of bacterial meningitis eliminates any need for prophylaxis in most situations.

RISK MANAGEMENT

Failure to diagnose meningitis is one of the leading causes of malpractice litigation among physicians who care for children.¹⁵ While failing to diagnose and treat meningitis in a child with a fulminant presentation probably does constitute a breach of the standard of care, failing to recognize meningitis in a child with an insidious presentation may not. Consider a 10-month-old child who presents to Doctor "A" on day 2 of a febrile illness. If the child is not toxic-appearing, has no nuchal rigidity or photophobia, is alert, has good state variation (cries when examined but is easily consolable when left with the mother), and has symptoms consistent with a viral illness, few (if any) physicians would perform an LP.

If the child is then diagnosed with bacterial meningitis 2 days later, a reasonable explanation is that the child had not yet seeded the meninges when seen by the first

physician. However, that physician may still find him- or herself the defendant in a lawsuit. The physician can do substantial harm to the case by failing to fully document the aforementioned findings, particularly the general appearance of the patient. After good medical care, good documentation is the best defense against malpractice litigation. Finally, careful follow-up instructions, including specific symptoms or circumstances that should prompt the parent to seek immediate care, are a part of good medical practice and also serve to protect the physician who may be a target in malpractice litigation.

COMMON PITFALLS

- Consider bacterial meningitis and perform an LP in lethargic, irritable infants, even in the absence of classic signs of meningitis.
- Consider meningitis in infants with fever without a source.
- Consider CNS infection in febrile or afebrile, vomiting children, with or without diarrhea.
- Do not discount the diagnosis of bacterial meningitis in the presence of strong clinical clues simply because the CSF white cell count is normal or the Gram-stained smear is negative for bacteria.
- Always obtain a Gram-stained smear of the CSF if bacterial meningitis is in the differential.
- Consider repeat LP if the clinical setting suggests meningitis, even if a CSF culture obtained hours or days earlier was negative.
- Always reassess a child with a positive blood culture. LP should be considered if the febrile illness persists or if any suggestions of meningitis are present.
- Consider the possibility of a CNS infection in a child who has had a simple febrile seizure. Although LP is not mandatory, it should be considered in a child less than 18 months of age, especially if the child has not returned to the baseline mental status.
- Always obtain a blood culture before instituting antibiotic therapy for suspected bacterial meningitis.
- Document the physical examination thoroughly, particularly the general appearance of the child.
- Always provide adequate discharge instructions, especially reasons for immediate return to the emergency department.

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of William J. Barson, who wrote the previous version of this chapter.

Neonates present to the emergency department (ED) with a wide range of minor to life-threatening problems. Their assessment is more difficult than that of older children or adults because the history is often incomplete and unclear, or it is based on a care provider's opinion of the problem. In addition, signs are usually subtle and, even when recognized, may not be helpful in pinpointing the exact diagnosis. For example, respiratory distress may be due to respiratory or cardiac disease, sepsis, intraabdominal pathology, or metabolic derangements, or it may be factitious. Evaluation of the neonate is time consuming, requiring knowledge of the infant's postconceptual age as well as requiring special skills in approaching both the infant and the parents. Many visits to the ED are triggered by parental concerns regarding breathing, feeding, weight gain, and the consistency, color, or frequency of stools. Physicians caring for neonates in the ED, therefore, should be aware of the patterns of normal vegetative functions of the neonate.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Significant physiologic changes occur in the newborn to allow the transition from intrauterine to extrauterine life. Some of these changes occur in the first few days of life, but others occur in the weeks following birth. The fetus depends on uteroplacental blood flow while in the uterus and pulmonary blood flow and alveolar gas exchange following delivery. *In utero*, the pulmonary vascular resistance is high, which leads to significant shunting across the foramen ovale and ductus arteriosus. At birth, systemic vascular resistance is increased, with a subsequent decrease in pulmonary vascular resistance, leading to a substantial reduction in the right-to-left shunt across the foramen ovale and ductus arteriosus. In addition, pulmonary blood flow increases, improving oxygenation, allowing increases in left atrial pressure, which eventually reduces the shunt across the foramen ovale. This adult circulatory pattern can revert to the neonatal pattern within the first 2 weeks of life (longer in premature infants). This occurs when the neonate is exposed to stress (e.g., hypoxemia, acidosis, shock, hypothermia, hypercarbia and hypovolemia).

In the neonate, maturation of the cardiovascular system is incomplete. Contractile elements, such as mitochondria and myofibrils in myocardial muscle mass, are not well organized in the neonate. There is a reduction in the muscle mass in neonates, with 30% of muscle mass composed of contractile mass compared with 60% in adults. This is partly responsible for the neonate's cardiac output being heart rate dependent.

The neonate has a respiratory system that is efficient for growth but inefficient for gas exchange. In the upper airway of the neonate, the large head, small face, short neck, small external nares, small mandible, relatively large tongue for mouth size, high larynx, long and floppy epiglottis, and small cricoid ring in the subglottic area make the maintenance of a patent airway in the unconscious neonate difficult. This configuration makes it easier for the neonate to protect the airway during swallowing, but it increases the chance of aspiration in cases in which conscious level is decreased. The development of lung tissue is not complete until 7 years of age, with immaturity of the alveoli leading to high closing volumes. There is a deficiency in elasticity of the lungs, which leads to an increased tendency to atelectasis. This decrease in total lung volume in the neonate makes the neonate less tolerant to hypoxia.

Neonates are at risk for hypothermia because of a large surface area in relation to their mass; lack of subcutaneous tissue for insulation; a large scalp, which has a large blood flow; and lastly, their inability to alter surroundings to prevent heat losses. A sick or unconscious neonate will be unable to increase heat generation and, because of limited mass, will cool rapidly. Hypothermia in the neonate is a significant stress, as the neonate will try to maintain body temperature by increasing oxygen consumption and cardiac output. These can be the final decompensating events in the sick neonate.

The neonate is at much greater risk from dehydration, in view of the increased fluid losses related to body surface area, and during illnesses, when water losses are high (e.g., fever or diarrhea) or when water intake is restricted (e.g., coma, vomiting, etc). For growth and development, the neonate requires a high caloric expenditure, and hence high oxygen consumption. In addition, neonates have high glucose needs and low glycogen stores. As a result, during periods of stress and high-energy requirements, the infant may become hypoglycemic.

NORMAL VEGETATIVE FUNCTIONS OF THE NEONATE

Respiratory Patterns

Respiratory patterns vary widely in the first month of life. During sleep, the normal full-term infant may have episodes of "central apnea." Central apnea is an absence of drive from the central nervous system (CNS) respiratory control center. When central apnea occurs in a regular repeating pattern (three or more episodes of apnea of less than 20 seconds each), with short bursts of breathing in between, it is referred to as periodic breathing. Normal infants may exhibit apnea of 25 to 30 seconds without apparent adverse effects. Recent studies suggest that some apnea associated with hypoxemia is normal in young infants.

Feeding

Most normal newborns dictate their own feeding pattern by the first month of life. Breast-fed infants may require feeding every 2 to 4 hours, whereas bottle-fed infants usually require six to nine feedings every 24 hours. Most term infants rapidly increase their intake from 30 mL to 90 mL every 3 to 4 hours at 4 to 5 days of life. Infants have wide variation in their intake and parents require frequent reassurance that their infant is obtaining adequate nutrition. Adequate nutritional intake should be judged by factors other than frequency of feeding, such as weight gain.

Weight Gain

In the bottle-fed infant, caloric intake can be determined accurately, but this is rarely necessary. In the breast-fed neonate, estimation of intake is difficult. Consistent and appropriate weight gain in an infant who is content between feedings indicates adequate intake. Intake is deemed satisfactory if the neonate is back to its birth weight by 5 to 7 days and gains 10 to 30 g/d by 12 to 14 days of age.

Stool Characteristics

The normal bowel patterns in neonates vary widely. The number, color, and consistency of bowel movements vary greatly in the same infant and between infants, regardless of diet or environment. Breast-fed infants tend to have more frequent stools, but frequency ranges from one every few days to six to ten per day. Infrequent

bowel movements do not necessarily mean constipation; both bottle- and breast-fed infants may go 5 to 7 days without a bowel movement. The presence of blood in the stool is the most significant color change and should prompt an examination for benign lesions, such as fissures, or for significant pathologic conditions, such as bleeding diathesis or enterocolitis.

CLINICAL PRESENTATION

[Table 281.1](#) lists the presenting signs and symptoms of the neonate in the ED. These complaints should be more accurately described as “symptom complexes” because they are nonspecific and indicative of the diverse diseases seen in the neonate.

Crying/irritability/lethargy
 See Table 281.2 for differential diagnosis
 Cardiorespiratory symptoms and signs
 Tachypnea (see Table 281.3)
 Cough and nasal congestion
 Noisy breathing and stridor
 Apnea and periodic breathing
 Blue spells and cyanosis
 Other organ systems
 Neurologic
 Seizures
 Intracranial bleed
 Encephalitis, meningitis
 Gastrointestinal tract symptoms and signs
 Feeding problems
 Regurgitation
 Vomiting
 Diarrhea
 Constipation
 Abdominal distention
 Jaundice
 Eye discharge/redness
 Diaper rash and oral thrush
 Periantheloma
 Sudden infant death syndrome

TABLE 281.1. The Neonate in the Emergency Department: Presenting Signs and Symptoms

DIFFERENTIAL DIAGNOSIS, EVALUATION, AND MANAGEMENT

An astute emergency physician is alert to the possibility of either an acquired or congenital disorder to account for the symptom complexes listed in [Table 281.1](#).

The neonate who is crying, irritable, or lethargic is difficult to treat, even when there is an identifiable cause. Most neonates cry at times during a 24-hour period. The infant who exhibits acute inconsolable crying, however, should be assessed for an underlying cause ([Table 281.2](#)).

Improper feeding practices
 Intestinal colic
 Infections
 Otitis media
 Meningitis
 Generalized sepsis
 Urinary tract infection
 Gastroenteritis
 Septic arthritis
 Surgical
 Incarcerated hernia
 Testicular torsion
 Pyloric stenosis
 Anal fissure
 Metabolic Disorders
 Hypoglycemia
 Hypocalcemia
 Trauma
 Child abuse (eg, burns, fractures)
 Accidental injuries, skull or extremity fractures
 Strangulation of fingers or penis
 Abrasion of cornea, foreign body in eye

TABLE 281.2. Differential Diagnosis of Neonate with Uncontrollable Crying/Irritability/Lethargy

Improper Feeding Practices

An inexperienced parent may engage in improper feeding practices, such as overfeeding, with inadequate burping during feeds. The infant swallows large amounts of air, with progressive bowel distention and, occasionally, respiratory distress. Improper feeding with bowel distention may result in an irritable infant with periods of inconsolable crying. A thorough history and physical examination usually provide clues to the diagnosis. Instructing the parent in proper feeding techniques alleviates the problem.

Intestinal Colic

One of the most common causes of repeated crying episodes in neonates is intestinal colic. The incidence of colic is higher in premature infants. Colic usually occurs in healthy, thriving babies in the second or third week of life and persists until 3 months of age. Episodes commonly occur in the late afternoon or evening. The infants scream, draw up their knees as if in pain, and often pass flatus. Although intestinal colic does not have any grave clinical significance or long-term effects, it may be complicated by gastroesophageal reflux. Treatment of colic should begin with a careful history, physical examination, and appropriate laboratory investigations. This approach is important in the ED to exclude the more serious conditions listed in [Table 281.2](#). If the physician is in doubt as to the diagnosis, the infant should be admitted for observation. In many cases, parents have already seen several physicians and are angry, frustrated, exhausted, or dissatisfied with the advice or care given.

Colic cannot be cured in the ED, but the physician can assist by recommending some calming techniques, such as swaddling the infant; using slow, smooth motions; holding the infant in a flexed position; and rocking and holding the infant. Other suggestions include changing the environment (e.g., changing background noise, taking a car ride, or trying a feeding change). Changes in diet are helpful if the infant has other manifestations, such as visible peristalsis, persistent regurgitation, or symptoms following ingestion of cow's milk protein. Removal of cow's milk from the diet of a mother who is breast feeding may also be attempted. However, the discontinuation of breast feeding or the routine switching of formula is not recommended. The use of medications, such as sedatives or antispasmodics, especially in premature babies, should be discouraged. A sympathetic and supportive ED physician who emphasizes the normalcy of the infant and parents may be the best therapy.

Metabolic Disorders

One of the common causes of lethargy and subsequent collapse in the neonate is hypoglycemia. Hypoglycemia may be secondary to multiple causes, but in the first few days of life, it is often seen in infants of diabetic mothers. The physician should be aware of other causes, such as sepsis or inborn errors of metabolism. Hypoglycemia accompanied by lethargy, jitteriness, and seizures requires urgent treatment. Hypoglycemia can be rapidly diagnosed by a bedside test using a drop of blood and a reagent strip. Intravenous glucose at a dose of 1 to 2 mL/kg of 10% dextrose is required, followed by an infusion of D₁₀W at a rate of 100 mL/kg/d or 4 mL/kg/h. Rebound hypoglycemia frequently occurs, and it is therefore important that a continuous glucose infusion follows the bolus.

The neonate is particularly susceptible to hypocalcemia due to hypoparathyroidism, abnormal vitamin D metabolism, a low calcium intake, or a high phosphate intake. Infants of diabetic mothers as well as critically ill neonates are also often hypocalcemic. In symptomatic neonates, irritability, muscular twitching, jitteriness, and tremors are common clinical manifestations. However, apnea and seizures may occur. A serum calcium concentration below 7 mg/dL establishes the diagnosis. Serum phosphate as well as an electrocardiogram should be performed. In the symptomatic neonate, treatment consists of intravenous injection of 2 mL/kg of a 10% solution of calcium gluconate.

Infections

Infections in the neonate may be of varied etiology and nonspecific symptomatology. The infected neonate presents with a variety of symptoms and signs, such as feeding difficulties, fever, jaundice, or respiratory distress. The classic signs, such as stiff neck and the Kernig or Brudzinski sign, are usually absent in the presence of meningitis. The septic neonate may present with a normal temperature, fever, or hypothermia. The documented temperature at home should be considered in decision making. Infants who are bundled and have borderline fever should be unbundled, and their temperatures should be documented again in 10 to 20 minutes. Urinary tract infections in neonates may manifest as irritability, diarrhea, or poor feeding. The diagnosis is established by urine culture, preferably obtained by suprapubic puncture.

Opinions differ regarding the management of the febrile infant younger than 28 days of age. There is general consensus, however, that all neonates with possible sepsis should be hospitalized and given broad-spectrum antibiotics after initiation of a full sepsis workup (complete blood count, blood and urine cultures, urinalysis, chest radiograph, and cerebrospinal fluid examination).

In the neonate, herpes simplex virus (HSV) infection can manifest as (1) generalized, systemic infection involving the liver and other organs, including the CNS; (2) localized CNS disease; or (3) disease localized to the skin, eyes, and mouth. HSV infection in the neonate should be considered when there is any history of a sexually transmitted disease in the mother. If HSV infection is considered in the differential diagnosis, the antiviral agent acyclovir should be added to the broad-spectrum antibiotics.

Surgical Lesions

Surgical lesions such as incarcerated hernia (umbilical or inguinal), pyloric stenosis, and testicular torsion may present with nonspecific signs in the infant. The more common symptoms and signs include irritability, crying, poor feeding, vomiting, constipation, and abdominal distention. Projectile vomiting in a baby 2 to 3 weeks of age, especially if the infant is a first-born male, should suggest a diagnosis of pyloric stenosis. In the infant with a testicular torsion or an incarcerated hernia, physical examination may reveal a red, edematous, tender lump at the site of a hernia or testicular torsion. Examination of the infant with possible pyloric stenosis should be done with the infant relaxed and the stomach empty. Prominent gastric waves may be seen going from left to right, and a firm olive-sized mass may be felt by palpating under the liver edge. Malnutrition and dehydration may be evident if symptoms are prolonged. Hospitalization is required for rehydration and surgical consultation. Anal fissures may also present at this age. If the anal fissure is not obvious during the physical examination, it may be diagnosed by inserting a small test tube into the anal verge and inspecting the area through the bottom glass surface.

Trauma

Trauma is not common in the neonate. However, the infant is at risk for both accidental and nonaccidental (child abuse) trauma. A careful history, looking for inconsistent or implausible explanations, should be obtained in every case of neonatal trauma. The diagnosis of child abuse can often be based on the history alone, although physical examination may provide further support by revealing unexplained injuries. Injuries may include multiple bruises or bruises of varying ages, burns, extremity fractures, and skull fractures. Neonates who are shaken are at risk for “whiplash” or “shaken-baby syndrome,” which may present with subtle, nonspecific signs; seizures; coma; or respiratory insufficiency. A thorough funduscopic examination is important in these patients, because the presence of retinal hemorrhage, especially in the absence of external signs of trauma, is a common finding.

The examination of the eye is also useful to rule out an eyelash in the eye or a corneal abrasion as a reason for an infant's irritability and crying. Although rare, congenital glaucoma may also present with irritability and crying. Other uncommon reasons for distress in the neonate include piercing of the skin with an open diaper pin and strangulation of integuments with hair.

Cardiorespiratory Symptoms and Signs

The anatomic and physiologic characteristics of the neonatal respiratory system predisposes the child to frequent respiratory problems. Unfavorable anatomic factors include small nares, a relatively large tongue relative to the size of the mandible, smaller upper and lower airway diameters, flattened diaphragm, limited movement of diaphragm by abdominal compression, and barrel-shaped chest. In addition, the higher closing volumes and high compliance of the chest wall, low compliance of the lung, and less fatigue-resistant fibers in the diaphragm and intercostal muscles contribute to diminished respiratory reserve.

The cardiorespiratory symptoms listed in [Table 281.1](#) are nonspecific and may be due to primary organ failure (cardiovascular or respiratory) or secondary to a variety of systemic diseases, such as sepsis, metabolic acidosis, abdominal pathology, and severe meningitis. Regardless of the cause, the first priority is assessment and stabilization of airway, breathing, and circulation. Establishment of the diagnosis is a secondary concern.

Tachypnea

Tachypnea can be due to a life-threatening illness (e.g., sepsis) or to a minor problem (e.g., abdominal distention due to swallowed air) ([Table 281.3](#)). A neonate who is grunting or breathing rapidly should be considered to have a serious pathologic illness. Hospital admission for investigations, monitoring, and therapy should be considered in all cases. If a cause for tachypnea cannot be identified on initial presentation, a full sepsis workup is warranted, and broad-spectrum antibiotic therapy should be instituted.

Pneumonia
Bacterial
Viral
Chlamydial
Aspiration
Bronchiolitis
Bronchopulmonary dysplasia
Nongastrointestinal symptoms
Septicemia
Gastrointestinal tract—abdominal distention, gastroenteritis
Metabolic acidosis
Cardiac—supraventricular tachycardia
Congenital disorders
Respiratory
Tracheal stenosis, with
Tracheoesophageal fistula
Tracheomalacia
Delayed presentation of diaphragmatic hernia
Lobar emphysema
Cardiac
Cardiac failure (e.g., critical aortic coarctation of aorta, aortic stenosis, hypoplastic left heart, patent ductus arteriosus)
Cyanotic disease (e.g., transposition of great arteries)
Vascular ring
Neuromuscular disease (e.g., myopathy)

TABLE 281.3. Causes of Tachypnea in the Neonate

Pneumonia. Pneumonia, whether bacterial or viral, may present with irritability, nasal congestion, and poor appetite, followed by either low- or high-grade fever, nasal flaring, grunting, retractions, tachypnea, and tachycardia (see [Table 281.3](#)). Bacterial pneumonias are usually caused by *Streptococcus pneumoniae* (pneumococcus), *Haemophilus influenzae*, *Staphylococcus aureus*, or other *Streptococcus* species. Viral pneumonias caused by respiratory syncytial virus (RSV) and parainfluenza, however, are more common. *Chlamydia* pneumonia usually occurs after 3 weeks of age and is accompanied by conjunctivitis in more than 50% of cases. The infants are usually afebrile and have tachypnea and a prominent cough. Chest examination reveals rales but few wheezes. A chest radiograph shows hyperinflation with diffuse patchy infiltrates. Aspiration pneumonia is more likely to occur in debilitated infants and in those with tracheoesophageal fistula or swallowing dysfunction. Aspiration of gastric contents may result in cough, tachypnea, and wheezing. Neonates with pneumonia should be admitted to the hospital for monitoring and institution of antibacterial therapy. Immunocompromised infants, such as the children infected with the human immunodeficiency virus (HIV), should be suspected of having an infection with *Pneumocystis carinii*.

Bronchiolitis. Acute bronchiolitis usually presents in infancy as a serous nasal discharge accompanied by sneezing. These symptoms are followed by fever (38.5°C to 39°C), diminished appetite, cough, dyspnea, irritability, and, commonly, periods of apnea. Apnea is more common in infants less than 3 months of age and usually presents in the first 3 days of the illness. On examination, the infant usually has tachypnea (respiratory rate greater than 60 breaths per minute), is cyanotic, has

intercostal and subcostal retractions, and has a palpable liver and spleen due to hyperinflation of the lungs. Expiration is prolonged, and wheezes and fine rales are present. Chest radiographs usually reveal hyperinflation with atelectasis. A trial of a β_2 -agonist, such as albuterol, is warranted in all cases, because it is difficult to differentiate infants with pure reactive airway disease. All infants with a history of apnea should be admitted to the hospital for monitoring; infants who are moderately ill should be considered for admission as well. All high-risk infants should be admitted, and antiviral therapy should be considered. Infants with a history of severe prematurity, chronic lung disease, congenital heart disease, and immune deficiency are at high risk for respiratory failure, and should all be admitted.

Bronchopulmonary Dysplasia. Bronchopulmonary dysplasia (BPD) is the chronic pulmonary disease of infancy that usually follows ventilator and oxygen therapy for neonatal respiratory distress syndrome. Although new therapies, such as exogenous surfactant administration, high-frequency ventilation, and administration of steroids (prenatal and postnatal), and other changes in patient care may have altered the severity of BPD, chronic lung disease remains a major clinical problem. With continued improvement in survival of extremely preterm newborns, BPD is one of the most significant sequelae of neonatal intensive care; therefore, these surviving infants will be increasingly seen in EDs. Chronic abnormalities in lung function and gas exchange, as well as cardiovascular problems, such as pulmonary and systemic hypertension and cardiac hypertrophy, are among the long-term complications. Other clinical problems include growth, nutrition, metabolic, neurologic, and developmental issues.

The underlying pulmonary disease results in limited reserve and in visits to the ED with respiratory tract infections. RSV is the most frequent cause of respiratory distress in these patients during winter and early spring months. Other viral infections, such as influenza and parainfluenza, are also implicated. Bacterial organisms may also be likely pathogens. Infections in the infant with BPD can rapidly progress to severe respiratory failure, especially if treatment is delayed. Respiratory distress is generally due to severe airflow obstruction, which may be alleviated by bronchodilator therapy. Early hospitalization of the patient with BPD should be considered in an infant with even mild-to-moderate distress.

Congenital Disorders

Respiratory Disease. Although rare, H-type tracheoesophageal fistula may present in the first month of life or later, with recurrent pneumonia, respiratory distress after feeds, or difficulty handling mucus and secretions. Congenital stenosis of the trachea may initially present with noisy breathing, high-pitched cry, or respiratory distress, especially when associated with mild upper respiratory infection. Tracheomalacia, weakness of the cartilaginous rings of the trachea, may present in the neonate with cough, stridor, dyspnea, and cyanosis. This is often a diagnosis of exclusion, and management is usually conservative therapy.

Cardiac Disease. Neonates with congenital heart disease may present with rapid breathing, but this is usually not associated with significant retractions or use of accessory muscles. Congenital heart disease should be considered in the neonate with unexplained tachypnea and cyanosis. Neonates may present in congestive heart failure due to transposition of the great arteries, with a ventricular septal defect, critical coarctation of the aorta, or supraventricular tachycardia. Signs of heart failure may be subtle but are life-threatening and require emergent referral. Clinical examination may reveal dyspnea, cyanosis, weak peripheral pulses, cardiomegaly, and hepatomegaly.

Neuromuscular Disease. Muscle weakness from any cause, including myopathies, may be associated with shallow breathing and an increase in respiratory rate as a compensatory mechanism.

Cough/Nasal Congestion

Coughing may be a primary symptom of many respiratory illnesses as well as cardiac disease. It may also be the initial presentation of a variety of congenital anomalies, including cleft palate, laryngotracheomalacia, laryngotracheal cleft, tracheal webs, tracheoesophageal fistula, tracheal hemangiomas, and vascular rings. Cough and nasal congestion in the neonate may be a result of congenital malformations, but, in most instances, cough is due to a viral upper respiratory infection. Treatment of the underlying condition is the treatment of choice in the coughing neonate. Cough suppressants should be avoided in neonates because there is a possibility of respiratory depression. Nasal congestion is best treated with instillation of saline drops and suctioning with a bulb syringe.

Noisy Breathing/Stridor

In the neonate, noisy breathing is a common presenting complaint and is usually benign. Stridor is usually due to congenital anomalies (webs, cysts, atresia, stenosis, clefts, hemangiomas) extending anywhere from the nose to the tracheobronchial area. Infants requiring prolonged intubation in the neonatal period are prone to develop subglottic stenosis. Infection (croup, epiglottitis, retropharyngeal abscess) as a cause of stridor is rare in the neonate. Stridor, which worsens with crying, is suggestive of laryngomalacia or subglottic hemangioma; stridor and feeding difficulties are suggestive of vascular ring, laryngeal cleft, or tracheoesophageal fistula; stridor with hoarseness is suggestive of vocal cord paralysis. Laryngomalacia is the most common cause of stridor in the neonate and is characterized by noisy, crowing inspiratory sounds. The first upper respiratory infection usually accentuates these noisy sounds. This condition usually improves in the first year of life.

Periodic Breathing and Central Apnea

Normal neonates may have episodes of *periodic breathing*, defined as absence of breathing for less than 20 seconds, which is not usually accompanied by bradycardia or color changes. This pattern of breathing is different from apnea, which is usually associated with adverse effects such as bradycardia or cyanosis. Periodic breathing may precede apnea, however, and both may occur in the same patient. Apnea in a neonate usually signifies critical illness and warrants prompt investigation and hospital admission. Central apnea may be precipitated by any of the causes of rapid breathing listed in [Table 281.3](#). Because there is a deficiency in fatigue-resistant respiratory muscle fibers in the neonate, apnea may indicate respiratory muscle fatigue and impending respiratory arrest. After the apneic infant is stabilized, that is, after airway support and ventilation are provided, a thorough search for the inciting condition should be undertaken. If an obvious cause is not found, the neonate should be presumed to be septic, and the appropriate cultures obtained. Broad-spectrum antibiotics should then be started. Antibiotic therapy should not be delayed, however, if there is difficulty in obtaining all cultures.

Blue Spells and Cyanosis

Blue spells or cyanosis in infants may be caused by a variety of disorders. If breathing is rapid but not labored, the most likely cause is cyanotic congenital heart disease with right-to-left shunting. Although rare, methemoglobinemia may present with similar findings. Sepsis, meningitis, cerebral edema, or intracranial hemorrhage may be associated with irregular or shallow breathing and cyanosis. Labored breathing (grunting, in-drawing) is most likely due to pulmonary disease (pneumonia, bronchiolitis). Infants with cyanosis should be admitted to the hospital for monitoring and further investigation.

Other Organ Systems

Illness involving other organ systems, such as generalized sepsis, meningitis, gastroenteritis, or metabolic acidosis, may cause tachypnea in the newborn. Disease outside of the lung should always be suspected in the infant with respiratory distress as the predominant symptom.

Neurological Symptoms and Signs

Neonatal seizures are fairly common. Arriving at the diagnosis of seizure in the neonate may be difficult, as seizures manifest in a variety of nonspecific symptoms due to immaturity of the nervous system. Seizures may be either generalized, tonic-clonic, absence, focal or associated with subtle motor activities such as ocular changes, oral-buccal-lingual movements, cycling-swimming limb movements, or apnea. There are several possible etiologies for seizure-like activity in the neonate. These include metabolic causes (e.g., hypoglycemia), infections, intracranial hemorrhage, and cerebral malformations. The first step in management of these infants is to ensure stability of vital functions, such as airway, breathing, and circulation. Evaluation should include a blood count, bedside glucose determination, serum glucose, a serum calcium, lumbar puncture, and, possibly, a brain imaging study such as computed tomography or magnetic resonance imaging. The usual first choice of anticonvulsant in a neonate is phenobarbital, although some physicians favor a benzodiazepine such as lorazepam or diazepam. For adequate blood levels (20 to 40 mg/mL), a full 18- to 20-mg/kg phenobarbital load must be given. Thereafter, additional 5- to 10-mg/kg boluses may be given until a serum level of 40 mg/mL is reached. When considering the differential diagnosis of CNS infections in the neonate, in addition to broad-spectrum antibiotics to cover gram-positive and gram-negative organisms, strong consideration should be given to the initiation of intravenous acyclovir for the possibility of HSV encephalitis.

Gastrointestinal Tract Symptoms and Signs

Neonates presenting with gastrointestinal symptoms may either have no significant problems or be seriously ill.

Feeding Difficulties. Feeding difficulties could arise from parental misconceptions or improper feeding, anatomic abnormalities (e.g., cleft palate), obstruction to the esophagus, or localized or systemic infection.

Regurgitation. Regurgitation of small amounts is common in the neonate, due to reduced lower esophageal sphincter pressure and relatively increased intragastric pressure. Rare causes, such as compression of the esophagus or, occasionally, compression of the trachea, however, may also cause regurgitation. Dysphagia, irritability, anemia due to chronic blood loss, and malnutrition are sequelae of chronic regurgitation with esophagitis, but this condition is rare. If the neonate has a history of significant regurgitation, as evidenced by weight loss, pulmonary infiltrates, and irritability, consultation with a pediatrician or a pediatric gastroenterologist should be arranged as an in- or outpatient depending on patient stability. In most instances, reassurance and referral are all that is necessary from the ED physician. Specific investigations and therapy in the ED are rarely required.

Vomiting. Vomiting during the first few weeks of life is uncommon and often is confused with regurgitation. The neonate who vomits from birth is likely to have an anatomic abnormality, such as tracheoesophageal fistula, upper gastrointestinal obstruction, or midgut rotation. Acute-onset vomiting, however, is more commonly part of the symptom complex of some other disease, such as infection, raised intracranial pressure, or hepatobiliary disease. Projectile vomiting usually indicates pyloric stenosis, especially in male neonates. Inborn errors of metabolism should also be considered as a cause of vomiting in this age group. The physical examination of the neonate with vomiting should include assessment of hydration status, level of consciousness, and nonspecific signs such as jaundice. Laboratory evaluation should include electrolytes, glucose, and acid–base status. Infants less than 2 months of age who are vomiting should be admitted to the hospital for evaluation and therapy.

Diarrhea. The complaint of diarrhea often reflects ignorance of the normal variation in neonatal stool frequency and consistency. Diarrhea may be associated with systemic diseases, however, such as generalized sepsis or localized infections of the ear or bladder. Nonspecific diarrhea that neither contains blood or mucus nor is associated with other illnesses is termed *parenteral diarrhea*.

Diarrhea may be secondary to infectious causes and is usually associated with fever. The most common cause is a viral infection, with rotavirus and enteroviruses being the most common. Bacterial causes include *E. coli*, *Salmonella*, and *Shigella*. Parasitic causes include *Entamoeba histolytica* and are rare in immunocompetent neonates. Diarrhea may be one of the presenting features of HIV infection in infants. Causes of bloody diarrhea in the neonate include necrotizing enterocolitis, bacterial enteritis, antibiotic-associated diarrhea, milk allergy, and, rarely, intussusception. The neonate with diarrhea should be assessed for signs of dehydration. Close attention should be paid to the nutritional status as well as to fluid and electrolyte balance. Infants who are moderately or severely dehydrated should be admitted to the hospital for treatment, whereas infants with mild dehydration can be followed closely as outpatients if periodic reassessment can be arranged.

Necrotizing enterocolitis occurs more commonly in the premature neonate than in the older infant. It may occur in the full-term neonate, however, and usually presents with other signs of sepsis (jaundice, lethargy, poor feeding, poor perfusion). Abdominal radiography may demonstrate pneumatosis intestinalis. True milk allergy presents with abdominal distention, explosive bloody diarrhea, and, in severe cases, shock. Intussusception usually occurs in the older infant and toddler but can also occur in the neonate. It may present with abdominal distention, feeding difficulties, and a mass in the right upper quadrant.

Constipation. True constipation in the neonate may suggest meconium ileus or plug, Hirschsprung disease, hypothyroidism, intestinal stenosis, or atresia. Hirschsprung disease should be suspected in the constipated neonate when there is absence of feces on rectal examination and an abrupt change in bowel luminal size on barium enema. The diagnosis is confirmed by the absence of ganglion cells on a rectal biopsy. In a neonate with constipation, feeding problems, a weak and hoarse cry, hypothermia, hypotonia, and peripheral edema, a diagnosis of hypothyroidism should be entertained.

Abdominal Distention. Abdominal distention in the neonate is common and is usually due to lax abdominal musculature, relatively large intraabdominal organs, and frequent swallowing of air. If the neonate is feeding well and has a soft abdomen, there should be no concern. Generalized sepsis, gastroenteritis, or constipation, however, may also result in an ileus and abdominal distention. Organomegaly from congenital or acquired hepatomegaly, splenomegaly, or renal enlargement may also present as abdominal distention.

Jaundice. Jaundice is a yellowish green or yellowish orange pigmentation of the skin and sclera due to excess bilirubin ([Table 281.4](#)). It may appear at various times during the neonatal period but usually appears on the second or third day of life and resolves in 7 to 10 days in the term infant. If jaundice persists for more than 10 days, however, a complete diagnostic evaluation is warranted. Jaundice during the first 24 hours rarely presents to the ED. The most common cause of jaundice seen in the ED is physiologic, which is usually benign, and treatment is rarely necessary. Other common causes seen in the ED include jaundice secondary to sepsis, breast milk jaundice, and, occasionally, hemolysis due to other immune congenital causes.

FIRST DAY OF LIFE
Erythroblastosis fetalis
Sepsis
Congenital infections (rubella, toxoplasmosis, cytomegalovirus)
Hematoma
2 TO 3 DAYS
Physiologic
Sepsis
Intrauterine infections
3 DAYS TO 1 WEEK
Breast milk jaundice
Sepsis, atresia of bile ducts
Viral hepatitis
Congenital hemolytic anemias (spherocytosis, sickle cell anemia)
Hemolytic anemia due to drugs (e.g., in glucose-6-phosphate dehydrogenase deficiency)
Hypothyroidism
Rubella
Galactosemia

TABLE 281.4. Common Causes of Jaundice in Neonates

Physiologic jaundice is due to the breakdown of fetal red blood cells, with bilirubin rising at a rate of less than 5 mg/dL/24 h, with a peak of 5 to 6 mg/dL during the second to fourth day of life, returning to less than 2 mg/dL by 5 to 7 days. The infant with sepsis and hyperbilirubinemia has other features of sepsis, such as vomiting, abdominal distention, respiratory distress, and poor feeding. Like physiologic jaundice, breast milk jaundice is associated with prolonged unconjugated hyperbilirubinemia, which may start as early as the third to fourth day of life and reach a peak of 10 to 27 mg/dL by week 3. Discontinuation of breast feeding causes a rapid decline of the bilirubin in 2 to 3 days. This is thought to be due to the presence of substances that inhibit glucuronyl transferase in breast milk.

A complete history and physical examination often provide a clue to the cause of jaundice in the newborn. The well-looking infant who is gaining weight and feeding well is unlikely to be septic. Laboratory evaluation should include a full blood count for anemia, a smear for hemolysis, direct and total bilirubin evaluation, a reticulocyte count, and a Coombs' test. For the neonate who looks unwell and has any of the symptoms or signs listed in [Table 281.4](#), appropriate cultures should be drawn, broad-spectrum antibiotics should be instituted, and the patient should be admitted to the hospital. In all cases, arrangements should be made to monitor bilirubin and hemoglobin levels. Most well infants can be monitored out of the hospital, but infants who are anemic or have bilirubin levels approaching exchange transfusion levels (approximately 20 mg/dL) should be admitted for phototherapy and close observation.

Eye Discharge and Redness

The most common cause of red eye in the neonate is conjunctivitis, and although the most common cause of neonatal conjunctivitis is chemical, due to silver nitrate administration, this rarely presents to the ED. The most common causes of conjunctivitis during the first 2 weeks of life are infection with *Chlamydia*, *Neisseria gonorrhoeae*, and gram-negative bacilli (*E. coli* and *Pseudomonas*). Neonates older than 2 weeks of age may also have conjunctivitis secondary to infections with

such organisms as herpesvirus and *Staphylococcus* and *Streptococcus* species.

Gonococcal conjunctivitis begins after an incubation period of 2 to 5 days with a mild inflammation accompanied by a serosanguineous discharge that becomes purulent within 24 hours. *Chlamydia trachomatis* has an incubation period of 5 to 14 days and is associated with a thick, purulent discharge in an afebrile and alert infant. It may also accompany pneumonia in the neonate older than 3 weeks of age. After obtaining appropriate cultures, infectious causes should be treated. A neonate with a red eye and irritability may also be suffering from a corneal irritation or abrasion that is usually due to an eyelash or fingernail scratch. Acute glaucoma is rare and presents as a red, teary eye. In these instances, the cornea may be stained or cloudy, the anterior chamber shallow, and intraocular pressure increased. Prompt ophthalmologic consultation should be obtained in all cases of suspected glaucoma.

Diaper Rash and Oral Thrush

Diaper dermatitis is fairly common in the neonate. *Candida albicans* is the most common cause of diaper dermatitis and presents as an erythematous plaque with a scalloped border and a sharply demarcated edge studded by satellite lesions. It usually occurs in the moist, occluded diaper area and intertriginous zones and results from the action of organisms harbored in the gastrointestinal tract. Treatment consists of applying an anticandidal agent with each diaper change, or four times daily. Protection of the area with zinc oxide paste overlying the cream prevents friction. In severe cases, an oral course of treatment is warranted to prevent colonization of the gut.

Oral lesions are white, flaky plaques covering the tongue, lips, and gingival and mucous membranes. These lesions are common in debilitated infants, especially those with immunodeficiency disorders and those neonates on antibiotic therapy. A neonate with oral lesions may have decreased intake because of the pain and discomfort associated with these lesions. Treatment consists of administration of a topical antifungal agent and an anesthetic gel before feeding. Cool liquids may prevent discomfort and pain. Infants with significantly decreased intake or who exhibit evidence of dehydration should be admitted for further management.

Fever and Sepsis

Fever in the neonate is most commonly due to infectious causes. Infections occurring in the first 5 days of life are usually acquired by vertical transmission from the mother. Bacterial infections are usually caused by streptococci (30%), *E. coli* (30% to 40%), other gram-negative enteric organisms (15% to 20%), and gram-positive cocci (10%). Viral infections are common, however, and are most likely due to enteroviruses (coxsackievirus and echovirus) acquired at the time of delivery or to RSV acquired postnatally. All toxic-appearing infants and all febrile infants younger than 28 days of age should be hospitalized for parenteral antibiotic therapy after a full sepsis workup (Table 281.5 and Table 281.6).

Temperature instability
Fever, hypothermia
Central nervous system dysfunction
Lethargy, irritability, seizures
Respiratory distress
Apnea, tachypnea, grunting
Feeding intolerance
Vomiting, poor feeding, gastric distention, diarrhea
Jaundice
Itching, rash

TABLE 281.5. Signs and Symptoms of Neonatal Sepsis

Indications	Drops
Bacterial pneumonia	Ampicillin (100 mg/kg/d q6h) and gentamicin (7.5 mg/kg/d q8h) or cefotaxime (300 mg/kg/d q8h)
Generalized sepsis	
Necrotizing enterocolitis	
Bacterial meningitis	
Conjunctival infections	Length of therapy depends on infection being treated.
Urinary tract infections	
Bronchitis (respiratory syncytial virus)	Ribavirin (mebuharol), 20 mg/mL, water for 12–18 hr for 3–5 days
Conjunctivitis (bacterial)	Sodium sulfamid 10% or topical erythromycin 2 drops to each eye, q4h for 5–7 days or erythromycin 40 mg/kg/d q8h for 14 days
Pneumonia (chlamydial)	Erythromycin 40 mg/kg/d q8h for 14 days
Oral thrush	Oral nystatin suspension 100,000 U q4–6h after feeds for 7–14 days
Candida dermatitis	Nystatin or amphotericin cream to affected area q4–6h for 7–14 days
Herpesvirus infection	Acyclovir 30 mg/kg/d q8h

TABLE 281.6. Antibiotic Therapy for Infections^a

Listeria monocytogenes is an uncommon but potentially lethal cause of sepsis and meningitis in neonates. Like group B *Streptococcus*, it tends to occur in an early and a late form, and the signs and symptoms are similar to those seen with group B *Streptococcus* infection. The differential diagnosis should also include the possibility of HSV infection. In addition to broad-spectrum antibiotics, the antiviral agent acyclovir should be added if there is a clinical suspicion of an HSV infection.

Apparent Life-Threatening Events

Apparent life-threatening events (ALTEs) should be considered a chief complaint rather than a specific diagnosis. ALTE is defined as “an episode that is frightening to the observer and is characterized by some combination of apnea, color change, marked change in muscle tone, choking or gagging. In some cases the observer fears that the infant has died.” There has been previously used terminology such as *aborted crib death* or *near-miss SIDS*. These terms should be abandoned because they imply a possibly misleading, close association between this type of event and SIDS (sudden infant death syndrome). Although SIDS should be considered in these cases, catastrophic deterioration is more likely to be due to infectious causes (septicemia, meningitis), trauma (intracranial bleed, child abuse), inborn errors of metabolism (medium-chain acyl dehydrogenase deficiency), gastroesophageal reflux, seizures, cardiac dysrhythmia, or Munchausen syndrome by proxy. In most cases of SIDS, cardiopulmonary resuscitation is unsuccessful because the myocardium has suffered severe hypoxic ischemic damage. If the infant appears hemodynamically stable at the time of presentation, a very careful history and physical examination should be performed. Most infants, who present acutely after an ALTE, require hospitalization. If the infant presents with a history of apnea, following stabilization of airway support and ventilation, a thorough search for the inciting condition should be undertaken. If an obvious cause is not found, the neonate should be presumed to be septic, and the appropriate cultures (blood, urine, and cerebrospinal fluid) should be obtained. Broad-spectrum antibiotics, and possibly antiviral therapy with acyclovir, should then be started. However, antibiotic therapy should not be delayed if there is difficulty in obtaining all cultures. In true cases of SIDS, the cause of death is unknown; therefore, appropriate samples (blood, urine, skin biopsy) and a complete autopsy should be obtained.

DISPOSITION

Role of the Consultant

The emergency physician should be aware of the conditions that require urgent medical or surgical subspecialty evaluation. These include the cyanotic infant with possible congenital heart disease, requiring a pediatric cardiology consultation, or the neonate with an acute abdomen, requiring pediatric surgical evaluation.

Transportation

Transporting the neonate either in the prehospital setting or during interhospital transport requires attention to the airway, breathing, and circulation. Because of their increased heat loss, neonates also need maintenance of temperature. Continuous monitoring to ensure adequate oxygenation, temperature, and other vital signs is necessary. Transport personnel should be able to provide advanced pediatric life support in case the neonate becomes unstable during transport. Appropriate-sized resuscitation equipment and medications should be readily available during transport. Consideration should always be given to the risk–benefit of any transport action.

COMMON PITFALLS

- Unfamiliarity with the patterns of normal vegetative functions in the neonate
- Failure to recognize the extent of volume loss in the critically ill neonate
- Missing the signs of child abuse
- Excluding congenital causes in the differential diagnosis
- Not obtaining appropriate samples to exclude a metabolic disorder in a child dying of SIDS
- Failure to recognize signs and symptoms of impending respiratory failure
- Failure to provide parental reassurance and support

CHAPTER 282

Nursemaid's Elbow

Julide Ayse Ozan

[Clinical Presentation and Emergency Department Evaluation](#)
[Differential Diagnosis](#)
[Emergency Department Management and Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

Subluxation of the radial head (nursemaid's elbow or pulled elbow) is a common injury in the preschool-aged child.⁴ The synonymous terms *supermarket elbow* and *temper tantrum elbow* lend further causal description to this injury. It often occurs in grocery stores, on stairways, or in other situations, when the parent or guardian is in a hurry or the child is misbehaving. The injury is caused by sudden traction of the hand, with the elbow extended and the forearm pronated. There may be a history of pulling a child as he or she stumbles to prevent a fall, lifting a child by the hand, or pulling the hand through the sleeve of a garment. Occasionally, it may be attributed to a fall on the arm.

The peak incidence occurs in children aged 1 to 4 years. It is rare after age 5 and has been reported in 6- to 12-month-old infants.² It occurs more often in boys, and the left elbow is involved more often than the right.

The pathophysiology is partly explained by the anatomic features of the region. The annular ligament is thinly attached to the periosteum of the radial neck in children younger than 5 years of age, whereas this attachment is stronger in the older child. Traction exerted on the upper extremity when it is in a pronated, extended position causes a transverse tear in the distal attachment of the annular ligament to the periosteum of the radial head. The head of the radius then moves distally. When traction is released, the ligament is carried up and becomes impacted between the radius and the capitellum (Fig. 282.1). Because the shape of the radial head is not completely regular, the ligament can be replaced by slight flexion and supination—thus, the method of treatment.

Figure 282.1. Pathology of pulled elbow. (A) Normal annular ligament that attaches the radius to the ulna. (B) Traction on the radius, causing a tear in the attachment of the annular ligament. (C) When traction is released, fibers of the ligament are caught between the radial head and the capitellum.

CLINICAL PRESENTATION AND EMERGENCY DEPARTMENT EVALUATION

The diagnosis of subluxation of the radial head is made by the typical clinical findings. Immediately after injury, the child cries in pain and refuses to use the affected arm. The child holds the elbow slightly flexed and the forearm pronated. Local tenderness may be palpated over the anterolateral aspect of the radial head. There is no restriction to flexion and extension of the elbow, but supination of the forearm is markedly limited and voluntarily resisted. The diagnosis may be missed if supination of the forearm is not tested. A clear history should be obtained before examining the toddler in the parent's arms. Gentle manipulation of the contralateral arm first may make examination of the injured arm easier.

Radiographic findings are minimal and generally not helpful. It is a soft-tissue injury, and although subluxation of the radial head does occur, it is minimal and usually not demonstrable radiographically.^{1,5} A radiograph to rule out fracture may be made, however. This may prove therapeutic rather than diagnostic, because reduction is often accomplished when the arm is positioned by the technician.

DIFFERENTIAL DIAGNOSIS

Other causes of pain and limited motion should be kept in mind. Shoulder dislocations, brachial plexus injuries, fractures, and wrist sprains can present in a similar manner, as can infectious processes (i.e., osteomyelitis and septic arthritis).

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Reduction of the subluxation is usually effected readily in the emergency department. A parent or assistant restrains the child in the sitting position. The palm of the child's hand is grasped as if to shake it. The elbow is encircled with the other hand, with the thumb over the annular ligament of the radius. Then the palm of the hand is gently supinated, and, with a continuous motion, the elbow is flexed to the shoulder. During the flexion maneuver, the physician may feel a "click" with the thumb that lies over the radial head. This maneuver results in instantaneous relief of pain and reuse of the arm within 30 minutes in 90% of patients.^{2,4}

Recent studies have shown that hyperpronation of the wrist of the affected arm may provide an alternative method of reducing the subluxation if the supination maneuver is initially unsuccessful.² Also, the supination maneuver may be repeated several times during the initial visit. The child should be seen again in 24 hours for repeated manipulation if he or she is still not using the arm normally. At the second visit, if the child does not use the arm within 30 minutes, he or she should be completely reevaluated. Septic arthritis, osteomyelitis, and fractures above and below the elbow, including the clavicle and humerus, should be considered.

Immobilization is unnecessary if it is the first time subluxation has occurred. A sling may be applied if the child does not use the arm, to prevent anyone pulling on the elbow. If treatment is delayed for more than 12 hours, some clinicians immobilize the upper arm in a long-arm posterior splint with the elbow in 90-degree flexion and the forearm in full supination for 10 days.

Recurrence of subluxation as a result of a subsequent pull on the hand occurs in about 25% of cases.⁶ After manipulative reduction of a recurrent case, it is best to immobilize the upper limb in a long-arm cast for at least 2 or 3 weeks.

In a small number of children, the subluxated radial head is irreducible by closed manipulation and requires open reduction by an orthopedic surgeon.

COMMON PITFALLS

- With nursemaid's elbow, there is usually no swelling, bruising, or other evidence of injury. If these are present, another diagnosis should be considered.
- Before discharge, the mechanism of injury should be explained to the parents. This might help prevent a recurrence.

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of Ann K. Leahy, who wrote the previous version of this chapter.

CHAPTER 283

Osgood-Schlatter Disease

Todd Wylie

[Clinical Presentation](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

In 1903, Osgood and Schlatter each described, in separate papers, a disturbance of the tibial tuberosity in adolescents, which came to be known as Osgood-Schlatter disease.^{6,9} The condition is thought to be a traction apophysitis of the tibial tubercle resulting from repeated normal stresses or overuse.⁷ Generally, the pathology is considered to be a result of partial avulsion of developing ossification centers and overlying cartilage from the anterior surface of the tibial apophysis.⁵ Radiologic studies have demonstrated changes in the patellar tendon at the insertion on the tibial tuberosity, suggesting that patellar tendinitis may be a significant source of the clinical symptoms seen in patients with Osgood-Schlatter disease.⁸

Patients are usually between 10 to 15 years of age at onset of Osgood-Schlatter disease.⁵ Boys are affected more often than girls. The condition is usually unilateral, but it may be bilateral in 35% to 56% of boys and approximately 18% of girls.^{3,4} It is usually a self-limiting condition but should be distinguished from a fracture, tumor, or infection.

CLINICAL PRESENTATION

Osgood-Schlatter disease rarely presents as an acute complaint. The pain may have been present intermittently for a period of time before the patient seeks medical attention. Common complaints include knee pain that is exacerbated by running, kneeling, squatting, and climbing or descending stairs.⁷ Children almost always point specifically to the tibial tubercle as the site of discomfort. There may also be a history of relief of pain with rest or cessation of strenuous activities.

Physical findings include localized swelling and tenderness over the tibial tuberosity at the site of patellar tendon insertion. Effusion and other abnormalities of the joint should be absent. The pain is reproducible by extending the knee against resistance.

EMERGENCY DEPARTMENT EVALUATION

A reasonably certain diagnosis can be made from the history and physical examination. If Osgood-Schlatter disease is suspected from the history, the diagnosis usually can be confirmed by having the patient sit on the edge of the examination table, hang his or her legs off the table, and point to the site of greatest tenderness. If the patient points to the tibial tubercle, the diagnosis is reasonably certain.

Radiographs are not necessary in all cases of Osgood-Schlatter disease. Radiographs may help confirm the diagnosis but are more helpful in ruling out other disorders, such as fractures and occult bone tumors. Anteroposterior knee radiographs usually appear normal. A lateral knee radiograph is best for demonstrating abnormalities, which may include areas of calcification in the tibial tubercle region, separate ossicles from the anterior border of the tubercle, and prominence of the tubercle.⁷

EMERGENCY DEPARTMENT MANAGEMENT

Treatment of Osgood-Schlatter disease is usually symptomatic. Restriction of vigorous activities for 2 to 4 months is recommended, based on the severity of symptoms. Total restriction from all athletic activities is generally not necessary. Stretching exercises for the quadriceps and hamstrings are advisable. Icing after sporting activities and use of nonsteroidal antiinflammatory agents may be helpful. Corticosteroid injections are not recommended and may actually cause complications.^{10,11} In severe or persistent cases, a knee immobilizer is recommended for 3 to 6 weeks. In rare cases, immobilization in a cylinder cast may be necessary.

DISPOSITION

Patients with Osgood-Schlatter disease should be referred to their primary care physicians for follow-up care. Orthopedic referral may be indicated in persistent or severe cases. Symptoms usually resolve with conservative treatment. In almost all cases, resolution of symptoms is final at skeletal maturity, when the apophysis of the tibial tubercle fuses to the metaphysis of the tibia. Occasional patients develop chronic pain, associated with a discrete ossicle in the patellar tendon. Surgical excision provides predictable relief in these rare cases.¹

COMMON PITFALLS

- Radiographs may be incorrectly interpreted as an acute fracture.
- Do not forget to stress the importance of activity restriction to the patient, parents, and school.

CHAPTER 284

Otitis Externa

Katalin I. Koranyi

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

External otitis is an inflammatory condition of the auricle, the ear canal, or the outer surface of the tympanic membrane. It is caused by infection, inflammatory dermatitis, or local trauma to the skin. Acute diffuse external otitis (swimmer's ear) is the most common infection of the external ear in children. Perspiration and hearing aids contribute to the retention of moisture in the ear canal.⁴ It must be differentiated from acute *localized* external otitis (impetigo, folliculitis, herpes simplex) and from chronic external otitis (infection secondary to a coexisting drainage from the middle ear) or as secondary to seborrhea.

CLINICAL PRESENTATION

This bacterial (occasionally fungal) infection usually affects persons after prolonged and frequent swimming, particularly when the weather is hot and humid. As water is retained in the external ear canal, the normal resident flora of the area are altered, with an increase in the proportion of gram-negative organisms. The normally acid pH of the ear canal becomes more alkaline, and this wet and alkaline debris is a good culture medium. The infection causes edema and pain, which may be severe. The presenting symptoms are itching and ear pain. The pain is worse on touching the ear and on swallowing. Most cases are caused by *Pseudomonas*, gram-negative organisms, and *Staphylococcus aureus*.³ Anaerobic bacteria or a polymicrobial etiology is also possible.² Fungal external otitis (*Aspergillus*, *Candida*) is rare in the United States.

DIFFERENTIAL DIAGNOSIS

Ear pain may be due to infection *outside* the ear (mastoiditis, parotitis, periauricular adenitis, tonsillitis, temporomandibular joint dysfunction). If the pain originates *in the ear*, foreign body, impacted cerumen, and otitis media must be differentiated from external otitis. Differentiation from otitis media may be, at times, difficult or impossible, because both conditions may coexist, and also, the tympanic membrane may not be visualized due to edema of the ear canal. Acute otitis media is more common in the spring and winter, fever may be present, and, on examination, the tympanic membrane appears red, bulging, or retracted and has decreased mobility. External otitis, in contrast, is more common in the summer, and the tympanic membrane appears normal on examination, or it may be covered by whitish debris. In cases of uncertainty, physicians may have to treat for both otitis media and external otitis.

Another differential diagnosis of swimmer's ear is necrotizing "malignant" external otitis. Although it occurs mainly in the elderly, the diabetic, and the immunocompromised adult, it may occasionally occur in children.¹ The patient is febrile and appears ill. The infection (usually *Pseudomonas*) often spreads to deeper tissues. Patients with malignant external otitis require hospital admission and parenteral antimicrobial therapy.

EMERGENCY DEPARTMENT MANAGEMENT

The most important step in the management of external otitis is the careful cleaning of all debris and the drying of the ear canal. In the very mild case of external otitis, dry-mopping with a small tuft of cotton attached to a wire applicator is sufficient. In the more severe cases, in which the ear canal is occluded by secretions, gentle suction can be used in the external ear canal. This is followed by irrigation with a warm solution (at body temperature). The irrigant solutions include 3% saline, acetic acid 2% in Burow solution (Otic Domeboro solution), or a solution of rubbing alcohol and acetic acid in equal parts. After irrigation, drying can be accomplished by suctioning, compressed air, or use of a hair dryer. When the tympanic membrane is perforated or a perforation is suspected, solutions containing acid or rubbing alcohol should be avoided (because they produce a stinging sensation); 3% saline solution is used in these situations. Home rinsing with Otic Domeboro or a solution of rubbing alcohol and vinegar is often useful and prescribed.

The infection usually can be treated with 2% acetic acid ear drops (Otic Domeboro or propylene glycol V₂O Sol, V₂O Sol HC otic drops). Otic preparations containing antibiotics are more expensive but are not more effective in treating the infection. However, in the presence of a perforated tympanic membrane, the antibiotic preparations are better tolerated. Polymyxin–neomycin–hydrocortisone (Cortisporin otic suspension) four times a day can be prescribed. Cortisporin otic solution is more irritating. Ciprofloxacin (Cipro HC Otic) solution or ofloxacin (Floxin Otic) solution is appropriate for *Pseudomonas* infection. For fungal external otitis (otomycosis), the therapy is the same as for bacterial infections. If this treatment fails, 25% M-cresyl acetate (Cresylate), given three times a day, or tolnaftate (Tinactin) may be prescribed.⁵ For external otitis secondary to seborrhea, control of seborrhea with regular use of dandruff shampoo is a helpful additional measure to the use of antibiotic ear drops.

In the treatment of external otitis, instructions need to be given regarding the proper application of ear drops. The child should lie on his or her side, with the affected ear up. The ear drops are instilled, with the child remaining in this position for 1 to 2 minutes. A piece of cotton can be applied to occlude the ear canal. If there is significant edema of the ear canal, a wick can be placed and left in for 24 hours, with periodic soaking with the ear drops. The treatment is continued with administration of ear drops directly into the ear canal four times a day thereafter, usually for 7 to 10 days. For the treatment of pain, oral analgesics such as acetaminophen alone or in combination with codeine are prescribed. Swimming is not allowed during the course of treatment. If there is therapeutic failure in 48 hours, the patient should be reexamined and a deeper infection, such as an abscess or cellulitis, should be sought. For prophylaxis of the patient with frequent episodes of swimmer's ear, ear drops containing 2% acetic acid (Otic Domeboro solution, V₂O Sol) or a solution of rubbing alcohol and acetic acid in equal parts soon after swimming can be prescribed.

DISPOSITION

Patients with cellulitis extending beyond the external ear canal require admission to the hospital and parenteral antibiotic therapy. When necrotizing malignant external otitis is suspected, consultation with an otolaryngologist needs to be sought and the patient admitted for intensive parenteral antimicrobial therapy.

COMMON PITFALLS

- Diagnosis of swimmer's ear when the problem is really pus in the ear canal draining from a perforated tympanic membrane or through ventilation tubes. In this case, local therapy should be complemented with administration of systemic antibiotics. Improper application of the ear drops into an edematous ear canal may be the cause of "therapeutic failure" (the ear drops do not penetrate completely, or they do not penetrate at all). A cotton wick needs to be left in the ear canal for 24 hours and soaked periodically with the medication.
- Diagnosis of swimmer's ear in the child who has a different dermatosis (seborrheic dermatitis, folliculitis, or herpetic eruption)

OTITIS MEDIA

Acute otitis media is one of the most common infectious conditions for which children visit a physician.⁷ It is the most common indication for the prescription of an antimicrobial agent in childhood. By 3 years of age, 80% of children have had at least one episode of otitis media.⁶ The peak occurs between 6 and 24 months of age and during the periods of high incidence of viral upper respiratory tract infections in winter and spring.

The most important factor in the pathogenesis of otitis media appears to be eustachian tube dysfunction.² The increased incidence of otitis media in young children is due to the fact that their eustachian tubes are shorter and lie more horizontally than in the older child and adult. Dysfunction of the eustachian tube prevents middle ear secretions from draining into the nasopharynx, and the negative pressure created in the middle ear allows the aspiration of nasopharyngeal secretions into the middle ear. Other important factors include infection, immunologic status, allergy, passive smoking, breast feeding, and socioeconomic status.

CLINICAL PRESENTATION

The usual presentation is that of a child who, having had several days of symptoms of an upper respiratory tract infection, suddenly develops ear pain, fever, decreased hearing, or ear drainage. In infancy, irritability, crying, and difficulty sleeping can be the presenting features. Some children have minimal symptoms or none at all, and otitis media is diagnosed during a routine physical examination. Tugging at the ears may be a sign of otitis media, but often a misleading one, because children may tug or pull at their ears for other reasons.

Thus, the diagnosis of otitis media is based on the appearance and the mobility of the tympanic membrane rather than on symptomatology. The tympanic membrane is red or yellow, dull, and bulging; it has decreased or absent mobility when examined with a pneumatic otoscope. Bulging is best interpreted by the absence of the normal bony landmarks, which, in an early case, may be limited to the pars flaccida.

Some of the difficulties in diagnosing otitis media include the presence of wax in the ear canal, which obscures the visualization of the tympanic membrane, and a crying or febrile child in whom a hyperemic tympanic membrane could be falsely interpreted as early otitis media. Bullous myringitis is a form of acute otitis media in which bullae form between the outer and middle layers of the tympanic membrane. Children with bullous myringitis usually present very acutely with severe otalgia. Purulent otorrhea constitutes a reliable sign for an otitis media with perforation. Hearing loss may be a presenting sign of otitis media, but it will not be the complaint in the young child and it can also easily be missed by parents.

The diagnosis of otitis media in the newborn and very young infant is even more difficult, because their tympanic membranes may be naturally gray and dull. In these infants, the diminished or absent mobility may be the only physical findings for otitis media. If tympanocentesis is performed, a purulent middle ear aspirate is usually obtained. Although not an emergency department procedure, tympanometry usually reveals an effusion pattern.

The microbiology of otitis media from middle ear aspirates demonstrates that the three most common pathogens are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. *Streptococcus pyogenes* group A, *Staphylococcus aureus*, *Mycoplasma pneumoniae*, and viruses have also been isolated from the middle ear. The microbiology of acute otitis media in the newborn (i.e., a child in the first 4 weeks of life) is different from that in later life. *S. aureus* and gram-negative enteric organisms should be considered in addition to the other organisms that cause otitis media in the older child.² *Chlamydia trachomatis* also may cause acute otitis media in the first few months of life.²

DIFFERENTIAL DIAGNOSIS

Earache could be caused by pain referred from sore throat, toothache, external otitis, parotitis, a foreign body in the ear canal, or impacted ear cerumen. Injected blood vessels at the periphery of the tympanic membrane and along the malleus can be seen with fever or crying.

COMPLICATIONS

Acute otitis media may resolve without treatment, but spontaneous rupture of the tympanic membrane and otorrhea may occur. Complications such as ossicle necrosis, retraction pockets, cholesteatoma, mastoiditis, meningitis, cerebral thrombophlebitis, hearing loss, and speech delay are rare but may occur. The introduction of antimicrobial therapy has produced a decline in the frequency of these complications.

EMERGENCY DEPARTMENT MANAGEMENT

Most children who present with symptomatology of otitis media or fever can be easily diagnosed by examining the tympanic membranes and pneumatoscopy. If obscured by cerumen, the ear canals should be cleaned, remembering that irrigation of the ear canal could cause a temporary injection of the blood vessels in the tympanic membrane. Newborns with fever or irritability and otitis media are often hospitalized for a sepsis evaluation and parenteral antibiotic treatment pending culture results.

Systemic Antibiotics

Many episodes of acute otitis media resolve spontaneously. Antimicrobial therapy is directed against the major pathogens: *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Drug resistance is now common in otitis media. Surveillance data from 1998 demonstrate that up to 34% of all clinical isolates of pneumococci are no longer susceptible to penicillin, and many of these strains are also resistant to other classes of antimicrobials.⁹ In the United States, the incidence of β -lactamase-producing *H. influenzae* varies but can be as high as 20% to 25% (for *M. catarrhalis*, up to 70%). *M. catarrhalis* and *H. influenzae* tend to clear

spontaneously and have few suppurative complications.

For most physicians, amoxicillin is the drug of choice. Amoxicillin is inexpensive and has only a few side effects (diarrhea, rash). Physicians now favor the higher dosing range of amoxicillin to treat the intermediates and some of the highly resistant *S. pneumoniae*.⁷ In the very ill appearing and febrile child (particularly the young infant or the child already on amoxicillin), or for therapeutic failures, an alternative drug should be used.

Second-line therapy includes amoxicillin–clavulanate or cefuroxime axetil.⁷ The reformulated amoxicillin–clavulanate (7:1) has fewer gastrointestinal side effects than the old formulation (4:1). Safety and tolerability of a new formulation (90 mg/kg/d, divided every 12 hours) of amoxicillin–clavulanate (14:1) was recently reported.³ Many of the 13 other Food and Drug Administration–approved otitis media drugs are not very effective against drug-resistant pneumococcus.⁴ (For dosages, see [Table 285.1](#).)

Drug	Dosage
Amoxicillin	80–90 mg/kg/d PO q8h or q12h
Amoxicillin-clavulanate	45 mg/kg/d PO q12h
Azithromycin	10 mg/kg/d loading dose, then 5 mg/kg/d PO q24h
Cefixime	8 mg/kg/d PO q12–24h
Cefpodoxime proxetil	10 mg/kg/d PO q12h
Cefibuten	9 mg/kg/d PO q24h
Ceftriaxone	50 mg/kg/d im. or i.v. q24h
Cefuroxime axetil	30 mg/kg/d PO q12h
Clarithromycin	15 mg/kg/d PO q12h
Trimethoprim-sulfamethoxazole	8–12 mg/kg/d of trimethoprim component PO q12h

TABLE 285.1. Antimicrobial Therapy for Otitis Media

If the physician shortens the previously recommended course of therapy from 10 days to 7 days in the child over 24 months, and to 5 days in the child under 24 months of age, the patient is less likely to develop antibiotic resistance and more likely to comply with the regimen. Ceftriaxone as a single daily dose for 1 to 3 days is reserved for the child who is vomiting or unlikely to take oral antibiotics.⁵

Amoxicillin and trimethoprim-sulfamethoxazole are the least expensive drugs. Trimethoprim-sulfamethoxazole does not reliably treat *S. pyogenes* group A. Cefixime has increased activity against *H. influenzae* but decreased activity against *S. pneumoniae*.

Symptomatic relief should occur within 48 to 72 hours after the initiation of therapy. The patient and the parents should be advised to seek medical attention if symptomatology continues beyond that time. If, at this point, the child still has very red and bulging tympanic membranes, a change to a broader spectrum antimicrobial (a b-lactamase-resistant one) should be considered.

In the child who clinically responds well to therapy, a reexamination must be performed by the child's physician in 2 to 3 weeks, in a search for resolutions of acute signs of otitis media. At this checkup, about half of the children still have evidence of serous effusion of the middle ear.

Antibiotic Ear Drops

In the child with considerable purulent drainage from the ear, ear drops can occasionally be prescribed. Gentle cleansing with normal saline solution or diluted sterile vinegar may be followed for a few days by use of an antibiotic–corticosteroid ear drop suspension. Chronic otorrhea may be caused by *Pseudomonas* species, *S. aureus*, or fungal pathogens.

Also, careful evaluation as to possible complications of the acute otitis media or to a coexisting condition (meningitis, brain abscess, or mastoiditis) should be done. In addition, the emergency physician needs to advise the parents to seek prompt medical attention if, during the course of treatment, symptoms of lethargy, irritability, vomiting, or relapse of the fever develop.

Analgesics and Antipyretics

The child with severe earache may need acetaminophen or even codeine during the first 2 or 3 days of treatment. The use of an oral decongestant is ineffective in the treatment of otitis media; it should be prescribed only for relief of symptoms of concomitant upper respiratory tract infection.

DISPOSITION

The vast majority of children with acute otitis media can be discharged with subsequent follow-up by their physicians in about 2 weeks. In older children, follow-up may be arranged in 6 weeks. Most infants in the first 6 weeks of life, those older children who appear toxic and severely ill, or those with immunodeficiency must be evaluated for a coexisting, more serious infection, such as sepsis or meningitis. Some of these children will require hospital admission. Children who have mastoiditis complicating otitis media need otolaryngologic consultation and possible hospital admission.

COMMON PITFALLS

- Overdiagnosis of otitis media in a febrile or crying child who has only hyperemic (injected) tympanic membranes on otoscopic examination
- Failure to consider other diagnoses and neglecting to consider a more serious and even life-threatening disease, such as meningitis, sepsis, or pneumonia, coexisting with acute otitis media

MASTOIDITIS

Mastoiditis is an infection of the mastoid air cells of the temporal bone. Due to the anatomic contiguity of the middle ear, cleft, and the mastoid air cells, mastoiditis is actually part of the otitis media.¹ It becomes clinically relevant when the inflammation of the mastoid air cells progresses, causing invasion of the bony structures of the mastoid. At this stage, the signs and symptoms of mastoiditis are distinguishable from those of acute otitis media.

The incidence of mastoiditis has greatly decreased since the advent of antimicrobial agents, but it still occurs, causing significant morbidity and, rarely, life-threatening conditions. The clinical significance of the mastoid air cells is their proximity to contiguous structures such as the posterior cranial fossa, the semicircular canals, the facial nerve, and the petrous tip of the temporal bone.

According to the pathologic stage, acute mastoiditis is subdivided into acute mastoiditis, acute mastoiditis with periostitis, and acute mastoid osteitis with or without subperiosteal abscess.¹

Acute mastoiditis is caused by the same organisms responsible for acute otitis media, namely *S. pneumoniae*, group A *Streptococcus*, *S. aureus*, and *H. influenzae* (rare). Chronic mastoiditis is caused by gram-negative enteric bacteria such as *Escherichia coli*, *Proteus*, *Pseudomonas*, and *S. aureus*.

CLINICAL PRESENTATION

Due to the communication of the middle ear (antrum) with the mastoid air cells through the aditus ad antrum, inflammation of the mastoid air cells is a natural extension of acute otitis media. At this stage, the signs and symptoms are those of acute otitis media, and they are not specific for mastoiditis. These signs and symptoms include otalgia, decreased hearing, and fever. On examination, the signs are those of acute otitis media. Radiographically, the mastoids are hazy or cloudy, and the bony structures are intact. Therapy for *acute mastoiditis* is the same as for acute otitis media. Most cases resolve spontaneously or respond to antimicrobial therapy. Surgery is not indicated. If resolution does not occur, acute mastoiditis may progress, causing a more severe involvement of the mastoid air cells.

In *acute mastoiditis with periostitis*, the infection spreads, involving the periosteum covering the mastoid process and causing periostitis. This condition may or may not be accompanied by subperiosteal abscess. There is no radiologic evidence for osteitis, and, clinically, it is difficult to differentiate from acute mastoiditis.

Acute mastoid osteitis (also known as acute coalescent mastoiditis or acute surgical mastoiditis) may be accompanied by subperiosteal abscess. At this stage, the infection within the mastoid air cells has progressed, causing destruction (i.e., "coalescence") of the bony trabeculae that separate the mastoid cells. Physical examination reveals mastoid empyema. The clinical findings include swelling, tenderness to touch, and erythema of the mastoid bone. The pinna is displaced outward and downward. A fluctuant subperiosteal abscess of the mastoid area may be evident, occasionally accompanied by a draining fistula.

On examination of the external ear canal, swelling of the posterior and superior ear canal wall can be found. A purulent drainage through the perforated tympanic membrane is present. In most acute cases, the patient appears febrile and toxic. Pus from acute mastoid osteitis may spread to the middle ear through aditus ad antrum with resolution of this process. It also may spread to the soft tissue below the pinna or behind the sternocleidomastoid muscle of the neck (Bezold abscess). When it spreads to the petrous air cells, it causes petrositis. If the extension is to the calvarium, it may cause osteomyelitis. At times, the acute middle ear effusion drains through the eustachian tube with resolution of the otitis media, but the obstruction due to swelling of aditus ad antrum causes infection of the mastoid air cells with development of osteitis.

In the case of a normal-appearing tympanic membrane, and especially when there are no external signs such as subperiosteal abscess, computed tomography of the mastoid is necessary to demonstrate mastoiditis. Radiographs show haziness and destruction of the septa between the mastoid air cells (i.e., coalescent mastoiditis).

Chronic mastoiditis is always associated with chronic suppurative otitis media. It can be treated medically, but it is most often managed surgically (mastoidectomy) by the otolaryngologic specialist.

DIFFERENTIAL DIAGNOSIS

A displaced pinna with swelling around it due to mastoiditis can be confused with parotitis (mumps or bacterial parotitis). In the case of parotid involvement, the swelling is behind, below, and anterior to the pinna, causing the displacement of the ear lobe out and upward. In addition, the tympanic membrane and the external ear canal are normal on examination. Lymphadenitis of occipital and suboccipital nodes could mimic mastoid swelling, but the ear examination is normal. Severe external otitis with spread of the cellulitis to the surrounding tissue could be confused with mastoiditis, but radiographs of the mastoid air cells are normal in this case.

EMERGENCY DEPARTMENT MANAGEMENT

A diagnosis of acute mastoiditis calls for consultation with an otolaryngologist. In the case of subperiosteal abscess, the child should be admitted. Treatment should include analgesia, administration of parenteral antimicrobial agents, and evacuation of the pus by tympanocentesis or myringotomy. The material obtained should be sent for Gram stain and culture.

The initial antimicrobial therapy is a penicillinase-resistant penicillin such as nafcillin at 150 mg/kg/d, or a cephalosporin such as cefuroxime, 100 to 150 mg/kg/d for 10 days.⁶ Once the culture and susceptibility tests return, the antimicrobial agent may need to be changed accordingly. Parenteral therapy can be switched to oral therapy once adequate drainage has been accomplished and the child has been afebrile for 36 to 48 hours. Surgery should be done only after the culture has been obtained, antibiotic therapy has been initiated, and the child is stable. The type of surgery will depend on the stage of infection. For chronic *Pseudomonas* mastoiditis, in preparation for surgery, intravenous mezlocillin or ticarcillin, 200 to 300 mg/kg/d, given intravenously and divided every 4 to 6 hours for 7 days, is recommended.⁶ Daily cleansing of the ear canal is also important.

DISPOSITION

The child should be admitted to the hospital, and consultation with an otolaryngologist obtained. If it is necessary to transfer the child to another medical center, do so after initial stabilization and initiation of antibiotic therapy.

COMMON PITFALLS

- Failure to be aware of the clinical presentation of mastoiditis because of its infrequent occurrence, which may lead to nonaggressive management of this serious condition
- Failure to consider other coexisting or complicating conditions, such as meningitis or brain abscess

CHAPTER 286

Pertussis

Samir Midani and Hanif Kamal

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Pertussis is a common respiratory illness that occurs worldwide in all age groups, but it is recognized primarily in young, unprotected infants and children. The source of infection is usually an infected older sibling or adult who has mild or asymptomatic infection.^{3,8} The risk of the disease is highest in children less than 5 years of age. Mortality and hospitalization rates are highest in unimmunized infants younger than 6 months of age.⁴ Neonatal pertussis is particularly severe with maternal peripartum pertussis as the usual source. Premature infants are more likely to have severe presentations.

The etiologic agent is *Bordetella pertussis*, a gram-negative, pleomorphic bacillus. Less frequently, the disease can be caused by *Bordetella parapertussis*. The descriptive name of the disease, “whooping cough,” is derived from the characteristic sound of the inspiratory effort that follows the paroxysmal coughing. Transmission is by respiratory droplets, with extremely high attack rates (70% to 100%) for susceptible hosts. The incubation period is 6 to 20 days, with a mean of 7 to 10 days.²

The incidence of pertussis has decreased markedly since the institution of the pertussis vaccine. Although immunization reduces the incidence and mortality of pertussis, it is neither complete nor permanent. There is no evidence of a causal relationship between pertussis vaccine and brain damage.¹ Natural immunity to pertussis could be lifelong, whereas 12 years after vaccination, 95% of the vaccinees are susceptible to pertussis.⁶ Susceptible hospital staff can acquire the infection easily, and although most of these infections are mild, on occasion, the infection can be incapacitating.

CLINICAL PRESENTATION

The clinical manifestation of pertussis depends on age and previous immunization or infection. The classic illness, which lasts for 6 to 10 weeks, occurs as a primary infection in unimmunized children and is generally divided into three stages: the catarrhal stage, the paroxysmal stage, and the convalescent stage. The course of the disease may not always be typical in adults or in infants.⁷

The catarrhal stage is characterized by rhinorrhea, lacrimation and mild cough, and low-grade or no fever. This stage lasts 1 to 2 weeks, and the diagnosis is usually not suspected, yet patients are more contagious in this stage than during any other.

In the paroxysmal stage, episodes of coughing increase in severity and number. A characteristic repetitive series of six to 12 forceful coughs during a single expiration is followed by a sudden, massive inspiratory effort that produces the classic whoop as air is inhaled forcefully against a narrow glottis. Cyanosis, bulging eyes, protrusion of the tongue, salivation, lacrimation, and distention of the neck veins may occur during these episodes of coughing. The paroxysms are frequently precipitated by a variety of events, such as feeding, crying, or even hearing another person cough.

Physical examination during this stage may reveal conjunctival hemorrhages and petechiae over the neck and head. Some patients can have diffuse rhonchi and rales on auscultation. In very young infants, the paroxysm and whoop are often absent. Infants usually present with choking spells, apnea, bradycardia, cyanosis, and unresponsiveness. Seventy percent of fatal cases occur in infancy, and it is estimated that 18% of infants who were victims of sudden infant death syndrome had positive tests for *B. pertussis*.

In the convalescent stage, which usually lasts 1 to 2 weeks, symptoms gradually abate, but the cough may persist for several months.

Complications of pertussis include otitis, seizures, pneumonia, encephalopathy (risk, 1:12,000), and death. Pneumonia can be due to *B. pertussis* or to secondary bacterial infection. Other complications include interstitial or subcutaneous emphysema, atelectasis, ulcer of the tongue frenulum, epistaxis, melena, subdural hematoma, rectal prolapse, syndrome of inappropriate antidiuretic hormone secretion, and nutritional disturbances. The case fatality rate is 1.3% in children younger than 1 month and 0.3% in infants 2 to 11 months of age. Premature infants are especially at increased risk for severe disease, with the major cause of death being secondary bacterial infection.

DIFFERENTIAL DIAGNOSIS

In classic disease, the clinical diagnosis of pertussis should be made without difficulty. Other infectious agents that cause similar illness include *Mycoplasma pneumoniae*, *Chlamydia trachomatis*, *Chlamydia pneumoniae*, adenoviruses, and other respiratory viruses. *B. parapertussis* and *B. bronchiseptica* occasionally produce a pertussis-like syndrome.

Spasmodic attacks of coughing may be observed in infants and children with bronchiolitis, bacterial pneumonia, cystic fibrosis, tuberculosis, an airway foreign body, and other diseases that cause lymphadenopathy and extrinsic compression of the trachea and bronchi. These attacks also can occasionally be seen with sinusitis.

Difficulty in recognizing pertussis occurs in the catarrhal stage, in mild illness, and in adults or very young infants. Pertussis should be included in the differential diagnosis of all infants presenting with choking or apneic episodes and in children who present with a history of severe, spasmodic coughing or posttussive emesis.

EMERGENCY DEPARTMENT EVALUATION

A child or infant suspected to have pertussis should be observed for signs and symptoms of respiratory distress. Paroxysmal coughing episodes should be documented. These attacks may be triggered by eating, drinking, yawning, sneezing, or other physical activities. Between attacks, patients may appear normal and are usually in no distress. It is important to remember that young infants require hospitalization and close observation, in spite of looking well in between paroxysms.

Evaluation of the white blood cell count may be helpful. Leukocytosis of 20,000 to 60,000 cells/mL with an absolute lymphocytosis is characteristic in severe disease. Nasopharyngeal secretion culture remains the gold standard for diagnosis. Dacron or calcium alginate swabs are used to collect the specimen. A selective medium such as Bordet-Gengou should be rapidly inoculated (within 1 to 2 hours) for optimal isolation of the organism. Recovery of *B. pertussis* from nasopharyngeal secretions is highest during the catarrhal stage. Direct immunofluorescent assay of nasopharyngeal secretions has a low sensitivity and a variable specificity, and is not reliable for laboratory confirmation.^{2,5} Chest radiograph findings are nonspecific and may include perihilar infiltrate, atelectasis, or emphysema.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment is mostly supportive and can be managed at home for older children and for mild forms of the disease. Young infants or children with severe disease require hospitalization, and perhaps admission to an intensive care unit, for close observation.

In the emergency department, if the patients are unable to handle the mucoid secretions, they should be placed in a head-down position (45 to 60 degrees) to take advantage of gravity. Suction of the oropharynx with a catheter large enough to permit flow of tenacious secretions is required during paroxysms. In a severely ill child, oxygen may be needed. Hydration must be monitored and maintained, as well as caloric intake. Apneic infants may require active airway and ventilation management. Children less than 6 months of age are more likely to be hospitalized, tend to have longer hospitalization, and are more likely to require intensive care

monitoring.

The paroxysmal coughing episodes may prove to be exhausting, and avoidance of factors that provoke such attacks may be helpful. Patients with severe paroxysms should be monitored to ensure early recognition of hypoxia or bradycardia. Corticosteroids and albuterol may reduce the frequency and severity of symptoms, but before they can be recommended, further evaluation is required to establish their safety and efficacy. Maintenance of hydration and nutritional status is of utmost importance for optimal recovery, especially in infants with severe disease and in children with posttussive vomiting.

Antimicrobial agents, if given early during the course of illness, may ameliorate the symptoms. However, once paroxysmal coughing is established, antibiotics have no discernible effect on the course of illness, but they are recommended to limit the spread of the organism to other susceptible individuals.

The first choice for treatment is oral erythromycin. The dosage for children is 40 to 50 mg/kg/d, given every 6 hours (maximum, 2 g/d) for 14 days. Other macrolides, such as clarithromycin 15 mg/kg/d in two divided doses (maximum, 1 g/d), are likely to be effective and are thus alternatives for patients who cannot tolerate erythromycin. Trimethoprim-sulfamethoxazole (8 to 40 mg/kg/d orally in two divided doses) is another alternative, but its efficacy is unproved.

In addition to standard precautions, droplet precautions are recommended for 5 days after initiation of effective antimicrobial therapy. Chemoprophylaxis with erythromycin, 40 to 50 mg/kg/d, given every 6 hours (maximum, 2 g/d) for 14 days, is recommended for all household contacts, irrespective of age and immunization status.⁴

DISPOSITION

Patients with severe disease and those younger than 6 months of age with clinical evidence of pertussis should be hospitalized because of the high rate of complications in this age group. Older children and those with milder forms of illness may be discharged home after appropriate evaluation and initiation of antimicrobials.

COMMON PITFALLS

- Failure to recognize and diagnose pertussis, especially when presenting in an atypical fashion
- To assume that infants younger than 6 months of age will have a benign illness
- Failure to administer chemoprophylaxis to contacts
- Incorrect specimen collection and delay in plating secretions on appropriate media
- Failure to diagnosis pertussis in adolescents who present with an aura of suffocation followed by coughing episodes
- Failure to know that there is no effective transplacental immunity

CHAPTER 287

Acute Pharyngitis

Karen Camasso-Richardson and Martha S. Wright

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation and Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Sore throats often bring pediatric patients to the emergency department. Most of these children have acute pharyngitis. Many infectious agents cause acute inflammation of the tonsils and pharynx, including Epstein-Barr virus (EBV), adenovirus, parainfluenza virus, group A and other b-hemolytic streptococci, and *Mycoplasma pneumoniae*.^{1,8} Nonbacterial agents are the cause of pharyngitis in 70% to 80% of patients, especially in adolescents and in children less than 2 years of age. The most important agent for diagnostic, treatment, and public health considerations remains group A b-hemolytic *Streptococcus* (GABHS).^{1,2}

If inadequately treated, infection with this organism can lead to suppurative complications, including peritonsillar and retropharyngeal abscess, mastoiditis, and cervical adenitis, as well as the nonsuppurative complication of acute rheumatic fever (ARF).

CLINICAL PRESENTATION

Most children with pharyngitis present with one or more subjective complaints of sore throat, rhinitis, cough, headache, abdominal pain, or vomiting.⁵ The parent may report that younger children will not drink. On physical examination, these children have fever, pharyngeal inflammation with or without tonsillar exudate, and tender cervical adenopathy. Children with GABHS infection may have characteristic features, such as a fine, diffusely papular erythroderma ("sandpaper" or scarlatiniform rash) or palatal petechiae.¹⁴ Numerous studies have demonstrated that clinicians can differentiate GABHS from non-GABHS pharyngitis with only 50% to 75% accuracy.^{6,17} Although patients infected with GABHS often have more pharyngeal inflammation and tender lymphadenopathy, these findings are not reliably predictive.^{7,15} Greater than 70% of GABHS cultures will be positive in school-age children (5 to 15 years) with fever and pharyngitis and an absence of upper respiratory symptoms (conjunctivitis, rhinorrhea, or cough).¹⁷

DIFFERENTIAL DIAGNOSIS

Acute pharyngitis may be accompanied by more serious infectious entities, such as peritonsillar and retropharyngeal abscesses and peritonsillar cellulitis. All three require more aggressive treatment and possible hospitalization. Marked pharyngeal erythema, leukocytosis, and fever characterize peritonsillar cellulitis. This may progress to abscess formation in either the parapharyngeal or the tonsillar space. Clinically, patients with tonsillar and peritonsillar abscesses present with fever, trismus, a muffled ("hot potato") voice, and swelling of the affected tonsil with deviation of the uvula. Sore throat may not be a primary complaint. Younger children with acute pharyngitis may develop lymphadenitis of retropharyngeal lymph nodes, which may become retropharyngeal abscesses. This should be considered in a toxic-appearing child with dysphagia, drooling, airway obstruction, and neck stiffness.

Many organisms are known to cause pharyngitis. The majority of the time, a self-resolving virus is the causative organism. *Mycoplasma* often presents with a history of prolonged cough. EBV may present with a prolonged cough, extreme fatigue, a highly exudative pharynx, or an enlarged spleen. Gonococcal pharyngitis should be considered in both the sexually active adolescent and in the younger child in whom sexual abuse is suspected.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

When evaluating the pediatric patient with pharyngitis, it is necessary to assess for airway patency and hydration status. Edematous tonsils can cause upper airway obstruction, resulting in stridor and accessory muscle use. A nasopharyngeal airway may be necessary to ensure airway patency. Often, children refuse to drink and can become significantly dehydrated. Intravenous fluid resuscitation and pain treatment may be necessary. The patient should be evaluated for suppurative complications, such as peritonsillar abscess, by palpating edematous regions to check for fluctuance. A soft-tissue x-ray or computed tomography scan of the neck may be necessary if abscess is suspected.

The primary goal for evaluation of uncomplicated pharyngitis is to determine whether GABHS is the causative agent. Rapid antigen detection tests (RADTs) provide highly specific (95% to 99%) identification of the GABHS antigen, but lack sensitivity (75% to 85%).^{1,7,15} It is recommended that two throat swabs be done for both a rapid antigen test and culture in those patients with a higher risk of GABHS. If the rapid antigen test is negative, a confirmatory throat culture should be sent. For those patients less likely to have GABHS, a throat culture alone is recommended, to decrease the cost of evaluation.¹² The swabs should be obtained from the posterior pharynx and tonsillar pillars.¹ RADTs have been shown to increase appropriate care of GABHS in the emergency department.¹⁰

If GABHS is the responsible organism, antibiotic therapy is indicated. Penicillin, an inexpensive drug with a narrow spectrum of activity and proven efficacy and safety, remains the drug of choice for GABHS initial therapy.^{1,9} Oral penicillin V is recommended at 400,000 U (250 mg) two to four times daily for 10 days, or, in those that may not complete a 10-day course, benzathine penicillin G, 600,000 U intramuscularly in children less than 27 kg (60 lb) and 1.2 million U in larger children.⁹ In penicillin-allergic patients, erythromycin ethylsuccinate (40 mg/kg/d) or erythromycin estolate (20 to 40 mg/kg/d) in two to four divided doses for 10 days is recommended.⁴ A more recent treatment alternative is daily azithromycin for 5 days. Although there is evidence that cephalosporins may have a potentially lower failure rate of GABHS eradication and may allow a shorter course of therapy, comprehensive studies are not yet available.^{11,13} Empiric therapy is not recommended. Therapy can be postponed up to 9 days from initial symptoms and still safely prevent both suppurative and nonsuppurative sequelae, such as ARF.^{2,3} Symptomatic relief for patients with pharyngitis can be provided with topical and systemic analgesics. The adjunctive use of steroids for pain relief is not recommended, as their role has not been adequately studied in children.

Follow-up throat cultures and RADTs are not indicated in patients who are asymptomatic and have completed a full course of antibiotics. A positive culture or RADT in most properly treated individuals would indicate the carrier state. Follow-up testing is indicated in these exceptions: outbreaks of ARF and poststreptococcal glomerular nephritis, outbreaks in closed or semiclosed communities, and when a "ping-pong" spread is occurring in a family.¹ Treatment of the carrier state should be reserved for the exceptions just noted and in individuals living with someone with ARF or in health-care workers.¹⁶

DISPOSITION

Most children with pharyngitis can be evaluated and managed as outpatients. An otolaryngologist should evaluate suspected cellulitis or abscess for possible surgical intervention. Often, admission is needed for surgical treatment and intravenous antibiotics. Admission should be considered in the dehydrated patient or in the child with evidence of airway obstruction. Any airway compromise should be evaluated by an otolaryngologist, and the patient should be admitted to a monitored bed for close observation.

COMMON PITFALLS

- Avoid treatment of nonbacterial pharyngitis with antibiotics.
- The missed diagnosis of GABHS may be secondary to improper culture technique or a negative RADT not confirmed with throat culture.
- Always look closely for peritonsillar, tonsillar, or retropharyngeal abscesses.
- Do not forget to evaluate and document the airway examination.

CHAPTER 288

Pneumonia

David A. Schaeffer

[Pathogenesis and Etiology](#)
[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management and Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Pneumonia—inflammation of the lungs—typically refers to an inflammatory process of the parenchymal component of the lung that results from infection, although there are also noninfectious etiologies. Acute respiratory tract infections are a major cause of morbidity at any age, and young children characteristically develop six to eight upper respiratory infections per year, even more for children in daycare settings. The attack rates for lower respiratory tract infections (e.g., croup, tracheobronchitis, bronchiolitis, pneumonia) are highest in children ages 6 to 12 months and decline thereafter.⁹ Attack rates for pneumonia showed an average of 40 episodes for every 1000 children ages 6 months to 5 years, 22 of 1000 for children ages 5 to 9 years, 11 of 1000 for children ages 9 to 12 years, and 7 of 1000 for children ages 12 to 15 years.

Poor socioeconomic status, number of siblings, parental smoking, and prematurity may all be associated with an increased risk of pneumonia in children. There is seasonal variation in the prevalence of certain pathogens. For example, respiratory viruses cause winter epidemics of bronchiolitis and pneumonia, and every few years there are epidemics of pneumonia due to *Mycoplasma pneumoniae*.

PATHOGENESIS AND ETIOLOGY

Respiratory viruses are transmitted primarily by direct contact with infected secretions from objects or hands of one person to the hands of another. The conjunctival or nasal mucosa is then inoculated with contaminated secretions. The inoculated virus attacks the airway, and viral replication occurs. This causes sloughing of the ciliated epithelial layer of the respiratory tract mucosa, leading to loss of ciliary activity and increased colonization of the airway with bacteria. Suppression of alveolar macrophage function is thought to be the primary mechanism allowing bacterial infection of the lungs.

The causes of acute infectious pneumonia in children may be divided into bacterial and nonbacterial agents (i.e., viruses, fungi, or parasites). *Mycoplasma* infections are usually considered separately from other bacterial infections, because the clinical course and treatment differ from that of other bacterial infections. Pneumonia is also described as typical or atypical in its presentation. Typical pneumonia is characterized by sudden onset of fever, chills, pleuritic chest pain, and productive cough. Typical pneumonia is usually caused by bacteria, most commonly *Pneumococcus*. Atypical pneumonia has a gradual onset over days to weeks and is associated with low-grade fever, malaise, nonproductive cough, and, often, headache and sore throat. Atypical pneumonia may be due to viruses, *Mycoplasma*, or *Chlamydia*. In infants, an afebrile pneumonia syndrome may be caused by *Chlamydia trachomatis*, viruses, *Ureaplasma urealyticum*, or *Pneumocystis carinii*. *Bordetella pertussis* may also cause atypical pneumonia in infants and young children. *Mycobacterium tuberculosis* may cause pneumonia in healthy or immunocompromised children, and the clinical onset resembles bacterial pneumonia. Pneumonia in the immunocompromised child with immunodeficiency or immunosuppression secondary to cancer chemotherapy or human immunodeficiency virus (HIV) infection may be caused by the usual viral and bacterial pathogens as well as *Legionella* species, herpesviruses, mycobacteria, fungi, and protozoa.

Noninfectious causes of pneumonia include foreign-body aspiration (often with secondary infection), chronic aspiration of oral secretions, gastroesophageal reflux with aspiration, congenital heart disease with bronchial compression from enlarged pulmonary arteries or chamber enlargement, smoke inhalation, hypersensitivity pneumonitis, pulmonary edema, pulmonary hemosiderosis, leukemia or lymphoma, metastatic tumor, and idiopathic interstitial pneumonitis. Pneumonia may be mistakenly diagnosed when there is atelectasis secondary to mucous plugging or migratory recurrent atelectasis in children with asthma.

Bacteria are the major cause of pneumonia in newborns. Beyond 1 month of age, viruses, *Mycoplasma*, and *Chlamydia* cause most pneumonias. The diagnosis of bacterial pneumonia can be made by a positive blood culture, although blood cultures are positive in less than 10% of cases of pneumonia.²¹ Direct lung puncture and needle aspiration may be positive for a bacterial pathogen in up to 62% of children with pneumonia, but this technique is seldom used.⁵ Recent studies using bacterial antigen and antibody testing showed that bacterial causes of pneumonia are more common than previously reported. Serologic evidence of pneumococcal infection was found in 5% to 11% of children between 3 months and 14 years as a single infection and in 15% to 25% of children who had mixed infections with more than one etiologic agent. The highest incidence of pneumococcal infections was found in children of ages 3 months to 4 years.¹³ As shown in [Table 288.1](#), an etiologic diagnosis for pneumonia can be established in about half the cases, and a bacterial cause can be identified in about one-fourth of children.^{13,15,20,21,27}

TABLE 288.1. Common Causes of Pneumonia in Children (in Percentages)¹³ (n = 201)

The causes of pneumonia in children vary with age, and knowing the likely causative agents for a given age range allows the physician to select the appropriate diagnostic methods and most effective antibiotic therapy. In the first month of life, pneumonia is commonly due to group B streptococci and gram-negative bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, *Listeria monocytogenes*) acquired during or before delivery. Between 1 and 3 months of age, infants may develop an afebrile pneumonia syndrome with a staccato cough caused by infection with *C. trachomatis*, viruses, *U. urealyticum*, or *P. carinii*.²⁵ Viral infections are the most common causes of pneumonia in children ages 1 month to 5 years ([Table 288.2](#)). Respiratory syncytial virus (RSV) causes up to 70% of all viral pneumonias in children. Other viruses causing pneumonia and characteristics of the pneumonia syndromes are listed in [Table 288.3](#). Bacterial pneumonia in children of ages 1 month to 5 years is most commonly due to *Streptococcus pneumoniae*. *Haemophilus influenzae* is unlikely in children who have received the HIB vaccination. Staphylococcal pneumonia is now uncommon.

	<3 mo	4 mo-5 yr	≥6 yr
Bacterial	+	++	+
Mycoplasmal	-	++	+++
Chlamydia pneumonia	-	++	++
Viral	+++	+++	++
Alebrile pneumonia syndrome	++	-	-

+++ , most frequent; ++ , frequent; + , occasional; - , rare.

TABLE 288.2. Relative Causes of Pneumonia in Children by Age

Virus	Age	Season	Syndrome
Respiratory syncytial virus	Infants and preschool	Winter	Bronchiolitis Pneumonia
Parainfluenza viruses	Infants and preschool	Fall and spring	Bronchiolitis Croup Pneumonia
Influenza viruses	Preschool and school-aged	Winter	Pneumonia
Adenoviruses	All ages	Year-round	Bronchiolitis Pneumonia

TABLE 288.3. Viral Causes of Pneumonia in Children

Historically, in children 6 years and older, *Mycoplasma pneumoniae* is the most common etiologic agent, accounting for up to 21% of cases of pneumonia.³ *S. pneumoniae* has been the next most common bacterial pathogen in older children. Viral pneumonia from influenza, parainfluenza, or adenovirus is also frequently seen in this age group.

Pneumonia in the immunocompromised host is often caused by the usual viral and bacterial pathogens, and also by opportunistic agents that do not usually cause infections, except in patients with altered immune status. Children with agamma- or hypogammaglobulinemia are susceptible to repeated bacterial pneumonias and may develop bronchiectasis. They may also develop pneumonia from *Aspergillus* or *P. carinii*. *Legionella* species may cause a severe bacterial pneumonia in any immunocompromised child. Children with cancer and chemotherapy-induced neutropenia or anergy and decreased T-cell lymphocyte function are susceptible to viral pneumonias such as cytomegalovirus (CMV), herpesvirus, and varicella-zoster virus.²⁴ Fungal infections with *Candida* may also occur. Children with lymphomas may develop infection with *Toxoplasma gondii* and *Cryptococcus neoformans*. *P. carinii* pneumonia is uncommon in patients receiving trimethoprim-sulfamethoxazole prophylaxis. In children with the acquired immunodeficiency syndrome (AIDS), major causes of pneumonia include bacterial pneumonias, *P. carinii*, CMV, and mycobacteria.¹⁸

CLINICAL PRESENTATION

Symptoms and signs of pneumonia in children vary with age and may be nonspecific in the youngest patients. Infants under 2 months of age may present with fever and tachypnea and no signs of pulmonary consolidation. Most children have 1 or 2 days of prodromal symptoms, including rhinitis, low-grade fever, decreased appetite, and decreased activity. Common symptoms and signs are listed in [Table 288.4](#).

INFANTS < 6 MONTHS OF AGE
Fever
Cough
Poor feeding
Irritability
Tachypnea (RR >60/min)
Retractions
Apnea
Toxic appearance
Abdominal distension
CHILDREN
Fever
Cough
Chills
Chest or abdominal pain
Respiratory distress
Nasal flaring, grunting
Retractions
Decreased breath sounds
Rhonchi, crackles, wheezing
Tachypnea (RR >50/min, 6-12 mo; >40/min, 1-3 yr; >25/min, >3 yr)

RR, respiratory rate.

TABLE 288.4. Symptoms and Signs of Pneumonia in Children

Pneumonia is characterized by evidence of lung consolidation on the physical examination or chest x-ray. Typical physical findings include decreased breath sounds, dullness to percussion, or crackles on lung auscultation. On the chest x-ray, different patterns of pulmonary infection may be seen: (1) diffuse peribronchial thickening, often with hyperinflation of the lungs from air-trapping (indicated by flattening of the diaphragm); (2) a diffuse, patchy interstitial pattern; and (3) focal lobar consolidation. Diffuse, patchy infiltrates, often with shaggy peribronchial infiltrates in the perihilar regions, are commonly seen with viral infections, although bacterial infections may also show a similar pattern. Lobar consolidation may be difficult to distinguish from atelectasis secondary to mucous plugging, although signs of volume loss with a shift of the trachea and unaffected lung to the atelectatic side are usually evident. Focal lobar consolidation may sometimes present as a “round” pneumonia and be mistaken for a chest mass. Expiratory chest x-rays may be misinterpreted as pneumonia, because normal vascular and airway markings will be accentuated if the lungs are underinflated when the film is taken at the end of expiration.

Pneumonia may be complicated by pleural effusion, which may occur as a parapneumonic exudative effusion, empyema, pneumatocele, or abscess formation. A small pleural effusion is occasionally seen with viral pneumonia. About 20% of patients with mycoplasmal pneumonia develop a pleural effusion. Complicated pneumonias are now most commonly caused by *S. pneumoniae*.¹² Pleural effusions were reported in 29% of a recent series of 257 episodes of pneumococcal pneumonia, with 14% of patients having pleural fluid characteristics of an empyema.²⁵ Pneumonia due to *Staphylococcus aureus* is uncommon but unusually severe and is characterized by 80% of cases occurring in children less than 1 year of age. Staphylococcal pulmonary pneumatoceles present early in the course, pleural effusions are common in up to 70% of cases, and pneumothorax occurs in up to 41% of cases. The combination of pneumothorax and empyema or pyopneumothorax is very suggestive of staphylococcal pneumonia.

Primary tuberculosis (TB) pneumonia is more common in urban or lower socioeconomic areas, in recent immigrants to the United States, and in children exposed to contacts with TB or HIV. Usual findings of pneumonia are common, with lobar consolidation, frequently hilar adenopathy and, less frequently, cavitory lesions or pleural effusion.

DIFFERENTIAL DIAGNOSIS

The physician must try to determine which children have bacterial infections so that appropriate antibiotic therapy can be started. Although the clinical features of viral versus bacterial versus mycoplasmal pneumonia do not guarantee a correct diagnosis, it is helpful to seek the typical features of the different etiologies. Unfortunately, there are no clear radiographic patterns or laboratory studies (white blood cell [WBC] and neutrophil counts, C-reactive protein, or erythrocyte sedimentation rate) to differentiate the various causes of pneumonia (Table 288.5).

Variable	Bacterial	Viral	Mycoplasma
Age	Any	Any	Over 5 yr
Fever	>39°C	<39°C	<39°C
Chest	Crackles	Crackles	Crackles
Others at home or school	No	Yes, at same time	Yes, weeks apart
Other symptoms	Otitis media	Myalgia, rash, conjunctivitis, pharyngitis, diarrhea, otitis media	Headache, sore throat, myalgia, rash, conjunctivitis, otitis media
Cough	Productive	Nonproductive	Nonproductive
Pleurotic chest pain	Yes	No	No
Course	Marked	Mild	Mild
Auscultation	Low-distant crackles, dullness	Diffuse crackles, wheezing	Unilateral crackles, wheezing
Chest x-ray	Segmental or lobar infiltrate	Hyperinflation, peribronchovascular interstitial pattern	Peribronchovascular interstitial pattern or wedge-shaped lower lobe
Pleural fluid	Large, exudate or empyema	Small	Small
WBC count	>15,000/mm ³ increased PMNs	<15,000/mm ³ increased lymphocytes	Normal to <15,000/mm ³

TABLE 288.5. Typical Features of Acute Pneumonia in Children by Etiologic Agent

The possibility of coexistent bacterial and viral infections should also be considered. In a report of 136 infants and children ages 1 month to 6 years admitted for bronchiolitis and pneumonia, half were given antibiotics and half were not.¹⁰ A viral infection was diagnosed in about half of the patients, predominately RSV. There were no significant differences in the course of acute disease, frequency of fever relapse, or pulmonary complications between the children not given antibiotics and those treated with antibiotics. In another report of the risk of secondary bacterial infection in infants hospitalized with RSV, the frequency of a secondary bacterial pneumonia was increased to 2.7% in infants treated with parenteral antibiotics, compared with 0.6% in those who received no antibiotics. Children with serious, mixed respiratory viral and bacterial infections usually demonstrate an atypical course of bronchiolitis or pneumonia characterized by persistent fever and respiratory distress.²⁶ Atypical bacterial infections, such as *Mycoplasma* or *Chlamydia*, may also coexist with viral infections or with typical bacteria, such as *Pneumococcus*.¹¹¹³ Although other studies report the incidence of mixed respiratory viral and bacterial infections to be as high as 39%, the clinical significance of these mixed infections is unclear.^{14,17}

Other diseases that may be mistaken for pneumonia should also be considered. Asthma occurs in about 10% of children, and acute episodes are commonly triggered by viral respiratory infections associated with pulmonary infiltrates caused by atelectasis from mucous plugging. Children with asthma may experience recurrent febrile episodes with migratory atelectasis, which may be misdiagnosed as recurrent or persistent pneumonia. Often, the typical history of asthma with chronic cough and wheezing associated with common triggers of airway hyperreactivity goes unrecognized.²² Many children with clinically diagnosed pneumonia, who have wheezing and are treated with antibiotics and bronchodilators, actually have underdiagnosed asthma.

Foreign-body aspiration may also cause pneumonia due to bronchial obstruction and may be missed if the initial aspiration episode is not recognized. Thus, questions should be asked about an acute choking episode in all children presenting with suspected pneumonia. Foreign-body aspiration is most common between ages 6 months and 3 years, and food is responsible for 80% of the objects aspirated (specifically peanuts in half of the cases). Many episodes of foreign-body aspiration present more than 1 week after the aspiration episode.

Children with congenital heart disease have a greater incidence of respiratory infections, especially those with large left-to-right shunts, as in patent ductus arteriosus or atrial or ventricular septal defect. Enlarged pulmonary arteries or cardiac chamber enlargement may cause bronchial compression, resulting in atelectasis or pneumonia. Pulmonary edema may also be mistaken for pneumonia. Cystic fibrosis should be considered in the child with recurrent pneumonia associated with chronic diarrhea and failure to thrive, although 20% of children with cystic fibrosis initially present only with respiratory problems.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of pneumonia is most often suspected after clinical presentation with fever, cough, tachypnea, crackles on lung auscultation, and chest x-ray evidence of consolidation. The precise etiology may not be readily apparent without further investigation. There is general agreement that routine chest x-rays are not needed for children with acute episodes of fever in the absence of specific respiratory findings (see Table 288.4). However, a recent report shows that “occult” pneumonias were found in 26% of children with leukocytosis (WBC count greater than 20,000/mm³) and triage temperature in the emergency department of greater than or equal to 39.0°C and no clinical evidence of pneumonia as judged by absence of specific respiratory findings.¹

A complete blood count and differential do not reliably differentiate the etiology of pneumonia. In general, higher white cell counts, with a greater number of polymorphonuclear forms, are seen with bacterial infection. Eosinophilia may be seen in the afebrile pneumonia syndrome in infants. Blood cultures should be considered in all febrile patients suspected of having bacterial pneumonia, but they are positive in only less than 10% of patients with bacterial infection. Mantoux PPD tuberculin skin tests should be considered for high-risk children. Thoracentesis should be performed for analysis and culture of pleural fluid in children who are moderately ill and present with a significant pleural effusion. Analysis of pleural fluid characteristics can differentiate uncomplicated parapneumonic effusion from pleural empyema and help guide initial therapy and decision to place a chest tube for drainage.

Bacterial antigen detection by latex agglutination from samples of serum, urine, and pleural fluid is available for group B streptococci, *S. pneumoniae*, and *H. influenzae*. Bacterial antigens may still be detected in patients already treated with antibiotics. Problems with bacterial antigen detection tests include poor sensitivity, as evidenced by reports of inability to detect pneumococcal antigen in serum or urine from children with blood cultures positive for *S. pneumoniae*.¹⁵ The specificity has also been questioned by reports of *S. pneumoniae* and *H. influenzae* antigenuria in 4% of healthy children and 16% of children with otitis media without pneumonia, and also false-positive tests for *H. influenzae* in children with pneumonia as well as in controls.^{15,21}

Rapid diagnostic tests are available to detect viral and chlamydial antigen by fluorescent antibody tests performed by ELISA. Samples are obtained from nasal washings and scrapings, and test results are available quickly. Rapid diagnosis of RSV, influenza, parainfluenza, and adenovirus is readily available. The sensitivity of rapid antigen detection for viruses is as high as 90% but is less than 50% for the detection of chlamydia. Viral cultures are specific but take several days to be completed. Rapid diagnostic tests are currently being developed (but not widely available) using polymerase chain reaction (PCR) assay for antigen detection for *Mycoplasma* and *Chlamydia pneumoniae*. *Legionella* pneumonia antigen detection by immunofluorescence staining in urine is currently available for rapid diagnosis.

Antibody assays may diagnose bacterial or viral infections by demonstrating a fourfold increase in specific antibody titers over a 2- to 4-week period, but they usually are clinically impractical due to the lack of immediate results. Specific IgM antibody by complement fixation against *Mycoplasma* or an IgG titer greater than 1:128 is consistent with *Mycoplasma* infection. A positive serum cold agglutinin reaction as a bedside test is helpful to diagnose *Mycoplasma* infection, although serum cold agglutinins may also be present with viral infections. Approximately 30% to 75% of patients with *Mycoplasma* pneumonia will be positive for cold agglutinins in a titer greater than 1:32. A “bedside” cold agglutinin test can be performed by adding 0.4 mL of blood to a standard blue- or purple-top tube, then placing the tube on wet ice for several minutes. A positive test shows agglutination or clumping, which disappears when the tube is warmed.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Optimal treatment of pneumonia requires the following:

1. Knowing the most likely causative agents for a given age range

- Judicious use of available diagnostic methods
- Selecting the most appropriate antibiotic therapy when necessary
- Supportive therapy, such as hospitalization, oxygen, or intravenous fluids

Optimal treatment focuses on determining whether the child needs to be hospitalized and considering the most likely cause of pneumonia for the child's age to determine whether antibiotic therapy is required. About 20% to 30% of children require hospitalization for treatment of pneumonia. Most infants under the age of 3 months should be hospitalized, as should older children who appear toxic, have significant respiratory distress, are hypoxemic, or have a complicated pneumonia. Other indications for hospitalization include apnea or poor feeding in infants, a family that cannot care for the child at home, persistent fever for greater than 2 to 3 days, poor response to outpatient treatment, dehydration, vomiting, and underlying conditions that would increase the risk for complications. Underlying conditions include young age, prematurity, congenital heart disease, bronchopulmonary dysplasia, immunodeficiency, cancer, AIDS, multiple congenital anomalies, and neurologic or metabolic disease.

If a diagnosis of viral pneumonia is made, supportive treatment is indicated and antibiotics are unnecessary, unless an atypical course is observed with toxicity and persistent fever. A high index of suspicion for secondary bacterial pneumonia is needed in children with measles, varicella, or pneumonia due to influenza. Specific antiviral therapy with ribavirin is available but ineffective for RSV in ventilated infants and of uncertain clinical efficacy in nonventilated infants.⁴ The antiviral agents amantadine and rimantadine may be considered for treatment of influenza A infection to reduce the severity and duration of illness, although efficacy studies in children are limited.

If hospitalization is necessary, supportive treatment includes oxygen to prevent hypoxemia, intravenous fluids to maintain adequate hydration, and intravenous antibiotics for suspected bacterial infection. Close observation and monitoring for increased respiratory distress and oxygen saturation monitoring using pulse oximetry are indicated for children with severe pneumonia. Arterial or capillary blood gas measurements should be obtained for children with worsening respiratory distress or impending respiratory failure.

Suggested initial therapy for suspected bacterial pneumonia is listed in [Table 288.6](#).^{5,6,15,16,18,19,23} Most febrile infants under the age of 3 months should be admitted and treated with intravenous antibiotics for suspected sepsis. Infants aged 1 to 3 months with suspected afebrile pneumonia syndrome may be treated as outpatients if they are not significantly ill, but initial treatment in the hospital with oral erythromycin, clarithromycin, or azithromycin may be preferable. For children over age 3 months and treated as outpatients, antibiotics should be selected to cover *S. pneumoniae*, *M. pneumoniae*, and *C. pneumoniae*. Erythromycin, clarithromycin, or azithromycin are again suggested.² When a lobar pneumonia is present and atypical pneumonia is not a consideration, amoxicillin, a second- or third-generation cephalosporin, amoxicillin-clavulanate, and trimethoprim-sulfamethoxazole are alternatives to cover adequately for *S. pneumoniae*.

<3 mo	1-2 mo (Afebrile Pneumonia Syndrome)	>3 mo
OUTPATIENT		
<p>If febrile, admit</p> <p>PO erythromycin, clarithromycin, or azithromycin</p>		<p>Atypical: PO erythromycin, clarithromycin, or azithromycin</p> <p>Either as above or amoxicillin or PO second- or third-generation cephalosporin^a or amoxicillin-clavulanate or trimethoprim-sulfamethoxazole</p> <p>For selected cases of lobar pneumonia, PO cefuroxime every day × 1-2 days, followed by above^b</p>
INPATIENT		
<p>1. cefuroxime or cefotaxime or ceftriaxone or ampicillin/sulbactam</p> <p>PO erythromycin or PO clarithromycin or azithromycin</p>		<p>1. cefuroxime or cefotaxime or ceftriaxone, plus clindamycin</p> <p>PO erythromycin or PO clarithromycin or azithromycin</p>

PO, oral; sulbactam, ampicillin/sulbactam; trimethoprim-sulfamethoxazole, cotrimoxazole.

^a Second- or third-generation cephalosporins: cefuroxime, cefotaxime, ceftriaxone.

^b Consider as alternative to hospitalization only in children < 18 months old who are severely ill, are able to take oral fluids, do not require oxygen, and who receive complete supportive care for a minimum of 24 hours. Might also consider for failure of previous oral antibiotic therapy. Follow parenteral treatment with oral antibiotics to complete 10 days of therapy.

TABLE 288.6. Treatment of Bacterial Pneumonia in Children

For children over age 3 months and treated as inpatients for suspected bacterial pneumonia, intravenous cefuroxime, cefotaxime, or ceftriaxone is indicated to treat probable *S. pneumoniae*. Nafcillin or clindamycin should be added when staphylococcal disease is suspected. Clindamycin is also indicated for suspected aspiration pneumonia or a lung abscess. An oral or intravenous macrolide antibiotic may be added if an atypical pneumonia is suspected. In a recent series of children with *S. pneumoniae*, there were no differences in clinical course or outcome between patients with penicillin-resistant versus -sensitive isolates, and only three of 16 with penicillin-resistant isolates were treated with vancomycin.²⁵ Vancomycin should be considered in patients who have a high level of resistance to penicillin or are critically ill. Identification of a specific bacteria may guide further treatment by the antibiotic sensitivity pattern.

Most children with uncomplicated bacterial pneumonia can be treated with oral antibiotics. Some physicians routinely treat children initially with an intramuscular antibiotic, often ceftriaxone, followed by oral antibiotics. Dagan et al.⁶ concluded that 1 or 2 days of intramuscular ceftriaxone 50 mg/kg/d, followed by a second-generation oral cephalosporin, was safe and effective. No difference has been found between intramuscular penicillin versus oral amoxicillin in treating outpatient pediatric pneumonia. There are no strict criteria or definitive controlled studies to recommend inpatient versus outpatient treatment or oral versus parenteral treatment.

Intravenous antibiotics for children hospitalized with pneumonia should be continued until the fever defervesces and the child improves clinically. Treatment failure or the development of a complicated pneumonia should be suspected if fever persists for more than 72 hours. Oral antibiotic therapy can then be continued to complete 10 days of treatment. Children with complicated pneumonias should be treated with intravenous antibiotics for 1 to 2 weeks and then with oral antibiotics to complete a 2- to 3-week course.

Children with pneumonia should be reevaluated after 2 to 3 weeks, and a follow-up chest x-ray should be obtained at that time for a severe or complicated pneumonia. For the child with an uncomplicated course, a follow-up chest x-ray may be done at 6 to 8 weeks to look for unsuspected atelectasis or persistent infiltrate, which may indicate a retained foreign body, congenital malformation of the lung, or undiagnosed chronic lung disease such as cystic fibrosis.²⁸ If a foreign body is suspected, bronchoscopy is indicated. Rigid bronchoscopy is preferred for foreign-body removal.

COMMON PITFALLS

- Do not forget to consider congestive heart failure in the young infant or newborn with a x-ray diagnosis of pneumonia.
- Consider underlying disease, either pulmonary disease or general immunodeficiency syndrome (e.g., cystic fibrosis, AIDS), in patients with recurrent pneumonia.
- Consider foreign-body aspiration in the patient with recurrent or persistent pneumonia.
- Provide close follow-up for the patient with suspected bacterial pneumonia.
- Suspect asthma in a child diagnosed with recurrent or persistent migratory infiltrates and wheezing.

CHAPTER 289

Pyloric Stenosis

Maureen Campbell and Lisa Horton

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Hypertrophic pyloric stenosis is the most common cause of obstruction in the pediatric age group; consequently, the emergency physician should be able to recognize the clinical manifestations and treat the patient appropriately.

The incidence of pyloric stenosis is estimated at three per 1,000, affecting five times as many boys as girls. Heredity plays some role, as the incidence of pyloric stenosis in the children of affected parents rises to 6.9%.^{2,9}

The etiology of pyloric stenosis remains unclear. Infants with pyloric stenosis have significantly higher levels of prostaglandin E2, a potent smooth muscle contractor, and prostaglandin F2 than their normal counterparts, leading investigators to speculate a causative role of prostaglandins in pyloric stenosis.⁸ The pathology is characterized by diffuse hypertrophy and hyperplasia of antral smooth muscle cells. This results in elongation and thickening of the pylorus and antrum. The stomach then becomes dilated and uniformly hypertrophied.

CLINICAL PRESENTATION

Hypertrophic pyloric stenosis typically presents in the third week of life, although symptoms have been reported as early as the first week and as late as the fourth month of life.⁵ The initial symptom is occasional vomiting, which then becomes more forceful and frequent over time, until it is projectile in nature, occurring shortly after every feeding. The emesis is nonbilious and is occasionally blood tinged; in severe cases, “coffee ground” emesis is seen. The stools are small and infrequent, and the infants characteristically fail to gain weight appropriately, in the absence of anorexia. In advanced cases, infants may present with severe dehydration and electrolyte abnormalities. Electrolyte loss due to repetitive vomiting can result in a characteristic hypokalemic, hypochloremic, metabolic alkalosis. Jaundice occurs in 2% to 9% of affected infants. Currently, patients with hypertrophic pyloric stenosis present less frequently with the clinical hallmarks of the disease. The use of imaging studies to establish the diagnosis has become common practice. The result has been the diagnosis of hypertrophic pyloric stenosis before alkalosis has developed, a shorter clinical course, less morbidity, and a shorter postoperative hospital stay.^{11,12}

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for projectile nonbilious vomiting in an infant includes overfeeding, gastroenteritis, gastroesophageal reflux, pyelonephritis, sepsis, drug withdrawal, gastric or duodenal web, adrenal insufficiency, formula intolerance, pylorospasm, poor maternal infant interaction, and intracranial hypertension. Most of these entities are easily differentiated from pyloric stenosis by history, physical examination, laboratory values, and simple observation of the child when feeding. However, it is sometimes difficult to rule out gastroesophageal reflux and gastrointestinal malformations without radiologic studies.

EMERGENCY DEPARTMENT EVALUATION

The history of present illness should be obtained to determine duration of symptoms, urine output, and the infant's level of activity, so as to assess the severity of dehydration. A history of the presence of fever, diarrhea, prior surgery, or trauma is important to exclude other diagnostic entities. The physical examination reveals varying degrees of dehydration, depending on the duration of symptoms. Examination may reveal slightly dry mucous membranes in infants with mild dehydration or, in severe cases, listlessness, prolonged capillary refill, and a sunken anterior fontanelle. Skin turgor is decreased in most infants as a result of decreased caloric and fluid intake. Inspection of the abdomen often reveals peristaltic waves of the hypertrophied stomach moving from the left upper quadrant to the right upper quadrant just after a feeding. The waves are most readily visualized beneath a strong light directed tangentially to the abdomen. The peristaltic wave can sometimes be elicited by gently tapping the epigastric area. The wave begins as a ball-like prominence in the left upper quadrant, preceded by an area of depression that moves across the abdomen. Palpation of the hypertrophied pylorus, or “olive,” is pathognomonic for hypertrophic pyloric stenosis. It is said to be palpable in 70% to 90% of affected infants. Palpation of the olive is best accomplished by using the left hand and standing on the right side of the infant, while using the right hand to gently lift the feet and relax the abdominal wall. Palpation of the infant's epigastrium then should reveal a firm olive-sized mass ballottable just above and to the right of the umbilicus.⁵ The mass is the consistency of the tip of the nose and is very mobile. Decompression of the stomach, by placement of a 12F to 14F orogastric tube, further facilitates examination. Aspiration of more than 3 oz of formula from the stomach of a vomiting infant is strong evidence of the presence of pyloric stenosis, because these infants characteristically have large residual volumes. Once the olive is felt, the diagnosis is made, and further diagnostic work-up is unnecessary. If, after several minutes, an olive cannot be palpated, further evaluation is warranted. Electrolytes, glucose, blood urea nitrogen, pH, pCO₂, and urinalysis should be obtained, as well as a complete blood count. Once other diagnostic possibilities, such as pyelonephritis and sepsis, have been ruled out, one may proceed to radiologic studies.

EMERGENCY DEPARTMENT MANAGEMENT

After completing the history and physical examination, intravenous access should be obtained. If the infant is markedly dehydrated, a bolus of 20 mL/kg of an isotonic fluid should be initiated immediately. If the infant's hydration status is adequate, maintenance intravenous fluids should be started at a rate of 100 to 150 mL/kg/d. As soon as the infant voids, potassium should be added to the infusion. The blood chemistry values typically reveal a hypochloremic metabolic alkalosis due to the large loss of hydrochloric acid through vomiting. The serum CO₂ can be as high as 35 to 40 mEq/L. The alkalosis leads to an intracellular exchange of potassium for hydrogen ion. Also, the decrease in intravascular volume stimulates aldosterone secretion, which promotes sodium and water reuptake in the kidney at the expense of potassium loss. As the serum potassium level drops, the kidney preferentially exchanges hydrogen ion for sodium instead of potassium, resulting in characteristic acid urine in the presence of a serum alkalosis and a total body deficit of potassium.¹³ The complete blood count may reveal a high hematocrit due to hemoconcentration, as well as a marked leukocytosis due to stress.

In centers where sonographers are experienced in imaging the pylorus, ultrasound is the study of choice. Ultrasound avoids the radiation exposure of fluoroscopy and the risk of a reaction to contrast. In experienced hands, the differing echogenicities of the various layers of the pylorus afford clear delineation of the area. It is generally agreed that a pyloric muscularis layer of greater than 4 mm, a pyloric diameter of greater than 15 mm, and a pyloric length of greater than 18 mm are indicative of pyloric stenosis.^{1,6} A transverse section of the hypertrophic area can be seen as a “doughnut” or “bull's eye.”⁹ Ultrasound currently can diagnose pyloric stenosis in over 70% of affected infants.¹⁰ If the ultrasound is negative or not available, an abdominal flat plate and upper gastrointestinal (GI) contrast series may be obtained. It is strongly recommended that the upper GI be used only when careful physical examination and/or ultrasonography is inconclusive.⁵ On flat plate, the dilated stomach can be seen, with the gastric air bubble found as low as L2 to L3. An upper GI series characteristically demonstrates the “string sign,” a narrow stream of barium passing through the thickened pyloric canal. Once a barium study is obtained, the barium should be quickly removed from the stomach. This eliminates the possibility of the infant vomiting and subsequently aspirating the barium, as well as avoids possible leakage of barium into the peritoneum should the pyloric mucosa be entered accidentally during surgery.

DISPOSITION

Once the diagnosis is made, either by physical examination or radiologic studies, pediatric surgery consultation and admission is the appropriate disposition, even if this requires transfer of the patient to a tertiary care center. In experienced hands, the mortality rate of pyloromyotomy is 0.3%, and the average hospital stay is 2 days or less. Pending admission or transfer to the operating room, the emergency department physician should continue to provide gastric decompression and rehydration,

and follow vital signs and urine output.

COMMON PITFALLS

- Early in the course of pyloric stenosis, the diagnosis is difficult to differentiate from gastroesophageal reflux, and a high degree of suspicion is required in these cases. Examination of the infant's abdomen after feeding may be helpful. If a mass is palpated, further workup is unnecessary. If a pediatric surgeon is readily accessible, it may be more appropriate not to proceed with radiologic studies prior to surgical consultation, because physical examination by an experienced surgeon can obviate the need for further studies in the many affected infants.
- Failure of the physician to adequately rehydrate the dehydrated infant
- Failure to decompress the infant's stomach prior to sending the child to surgery

CHAPTER 290

Rheumatic Fever

Robert D. Schremmer and Jane F. Knapp

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Although Guillaume de Baillou first differentiated arthritis from gout in the sixteenth century, it was not until 1889 that acute rheumatic fever (ARF), as it is known today, was described by Walter Cheadle.³ With the early 1930s came the discovery of an association between rheumatic fever and group A *Streptococcus*, which was not proven until years later.¹⁴ T. Duckett Jones' landmark article in 1944⁷ standardized the diagnosis of ARF. By specifying major and minor criteria, Dr. Jones hoped to improve accuracy of diagnosis. A poorly understood, sudden decrease in the incidence of ARF occurred in the postwar years,^{3,14} lasting into the 1980s.^{10,15,16} During the past decade, regional outbreaks of strongly rheumatogenic strains of group A *Streptococcus* were noted.^{15,16} Even with these resurgences, the incidence of ARF has remained well below that of pre–World War II.

Rheumatic fever is an inflammatory disorder involving multiple organ systems. Peak incidence is between 5 and 18 years, with equal affinity for both sexes throughout the world.¹⁴ Sydenham's chorea, a manifestation of ARF, mainly affects postpubertal girls.¹¹ Disease prevalence is highest in developing countries,¹⁰ probably secondary to malnutrition,¹⁶ crowding, and inadequate access to medical care.

It seems that several factors are involved in the host–pathogen relationship for ARF to occur. First, the strain of *streptococcus* must be rheumatogenic. These highly contagious strains preferentially cause pharyngitis and do not infect the skin.¹⁵ The M protein, a component of the cell wall, appears to be one primary factor determining a strain's rheumatogenicity.² Second, the host must be susceptible. There are common antigens between certain human tissues (i.e., heart valves and synovium) and the streptococcal cell wall. Discovery of this “molecular mimicry” has led to a better understanding of the pathophysiology of ARF. The shared epitopes confuse the immune system's ability to differentiate self and nonself, inducing an autoimmune reaction.¹⁴ Despite this knowledge, many aspects of the pathogenesis of ARF are not understood.

CLINICAL PRESENTATION

Signs and symptoms of ARF are variable in intensity. A symptom-free period follows an episode of pharyngitis. It is notable, however, that the majority of patients from the local outbreaks in the 1980s did not recall sore throat.³ The silent period is followed by an acute onset of symptoms, such as fever, malaise, and pallor not representative of the degree of anemia.¹⁴

To establish the diagnosis of ARF, the Jones criteria must be fulfilled ([Table 290.1](#)). Although these criteria have undergone revision four times since their original publication, the general structure remains intact. The major manifestations are considered such because of their specificity and frequency of occurrence.¹⁴ On the other hand, the minor criteria are much less specific, but are frequently seen with the disease. Only three exceptions to the Jones criteria are noted in the 1992 revision. A patient who presents late in the disease course may manifest only chorea or indolent carditis. Furthermore, a patient with the presumed diagnosis of recurrent rheumatic fever may be difficult to diagnose if there is a history of rheumatic heart disease. Evidence of streptococcal infection is still required, but the diagnosis in such a patient otherwise only requires the presence of one major or several minor criteria.

MAJOR
Carditis
Arthritis
Chorea
Subcutaneous nodules
Erythema marginatum
MINOR
Clinical Findings
Arthralgia
Fever
Laboratory Findings
Elevated acute-phase reactants
Erythrocyte sedimentation rate
C-reactive protein
Prolonged PR interval
Supporting evidence of antecedent group A streptococcal infections
Positive throat culture or rapid streptococcal antibody titer
Elevated or rising streptococcal antibody titer

Adapted from Jones TD. The diagnosis of rheumatic fever. *JAMA*. 1992;266:11. modified in *JAMA*. 1992;266:2069.

TABLE 290.1. Rheumatic Fever Manifestations

Arthritis is the most common of the major manifestations, occurring in 70% to 80% of patients.^{6,14} This arthritis is typically migratory and involves larger joints, such as knees, ankles, and wrists. Erythema, warmth, swelling, and severe pain are often present, as is decreased range of motion. Untreated, the arthritis typically lasts about 4 weeks and resolves without deformity.¹ Characteristic of rheumatic arthritis is its exquisite responsiveness to salicylate therapy. If no response has been seen after the first 2 days of therapy, other diagnoses should be considered.

Carditis is the second most commonly seen manifestation, with up to 50% to 60% of patients affected.⁶ Pancarditis is classic, but patients also commonly present with symptoms of valvular disease. Mitral regurgitation is the most frequently encountered lesion, followed by aortic regurgitation.¹⁷ A new or changing murmur is the usual finding, although tachycardia, friction rubs, cardiomegaly, and, rarely, heart failure may be seen. Morphologically, valvulitis is manifested as a later finding by focal nodular thickening of the leaflets.¹⁷ The role of echocardiography in diagnosis is controversial, but it may be used to confirm the presence of valvular disease in a patient with a new or changing murmur.

The other major manifestations include Sydenham's chorea, subcutaneous nodules, and the erythema marginatum rash. Chorea, named for Thomas Sydenham, who first described it in 1686, is present in only 10% to 20% of rheumatic fever patients.¹¹ A disorder of the central nervous system, it is characterized by sudden, involuntary, and purposeless movements, usually of the upper extremities and face. Often, psychological or psychiatric symptoms may be present as well. Chorea is diagnosed by clinical signs alone, but can be easily missed if emotional lability is the only sign.⁸ Often, chorea is a late manifestation. Subcutaneous nodules, often seen in patients with carditis, are firm, small, and nontender, and they are often found on extensor surfaces, tendons, bony prominences, and the occipital region. Rarely seen, these nodules are present only a few days. Erythema marginatum is also rarely seen. A rash with a serpiginous reddish pink border, it is nonpruritic and blanches with pressure. It is usually present on areas of the body hidden by clothing and also disappears in a few days.

The minor criteria are divided into clinical and laboratory findings. Fever, a common sign in many disorders, must be at least 39°C to be considered for the diagnosis. Arthralgia, joint pain with no evidence of inflammation, should not be regarded as a minor manifestation if arthritis is also present. Laboratory findings include elevated acute-phase reactants and prolonged PR interval on electrocardiography. Erythrocyte sedimentation rate and C-reactive protein are the commonly used acute-phase reactants.

Signs and symptoms associated with, but not specific for, ARF include epistaxis, serositis, and lung, kidney, and eye involvement. Tachypnea, cough that may be nonproductive or productive of blood-streaked sputum, and chest pain are characteristic of pulmonary disease.⁴ Scleritis, uveitis, and glaucoma have been reported in

a patient with ARF.¹² Hematuria may occur in 5% of patients,¹⁴ but renal failure is rare.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of ARF is extensive. Each of the three types of juvenile rheumatoid arthritis (JRA) may resemble ARF. Systemic JRA is characterized by high fevers with chills, hepatosplenomegaly, generalized lymphadenopathy, and rash. Rheumatoid rash shares a common typical distribution with erythema marginatum, but may occur anywhere on the body and is composed of small red-pink macules that may coalesce. Many patients may also develop pleuritis or pericarditis and pleural or pericardial effusion. The arthritis may be initially overlooked, given the patient's ill appearance. Polyarticular JRA will involve five or more joints, often in the hand. A small fraction of patients may be rheumatoid factor positive, but most are negative. Girls are more commonly affected than boys. Systemic symptoms may include low-grade fever, anorexia, malaise, slight hepatosplenomegaly and lymphadenopathy, and mild anemia. Patients with pauciarticular JRA will manifest arthritis in four or fewer joints. The involved joints are often large and symmetric. Affected girls will more often have a positive antinuclear antibody, and boys will more likely show a positive HLA B27. Rheumatoid factor is generally negative in both genders. Girls show an increased risk for iridocyclitis, and boys are at an increased risk for developing ankylosing spondylitis. Systemic symptoms are similar to that of polyarticular JRA. In all forms of JRA, the joint pain tends to be less severe than that of ARF, but it lasts much longer.

Several infections can manifest joint symptoms. Septic arthritis is usually accompanied with fever and will involve a single joint. Aspiration of synovial fluid for examination and culture will confirm the diagnosis. Systemic infections that may have an associated arthritis include infectious mononucleosis, hepatitis, influenza, Lyme disease, fifth disease (erythema infectiosum), varicella, tuberculosis, gonorrhea, and brucellosis. These infections are often easily ruled out by their associated signs and symptoms.

Leukemia and sickle cell anemia patients may also demonstrate severe joint pain; both disorders may be diagnosed by a complete blood count and peripheral smear. Inflammatory bowel disease also initially presents with arthritis, but will soon be associated with gastrointestinal symptoms. Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, and toxic synovitis should be considered in any child complaining of hip pain. Although systemic lupus erythematosus can fulfill many of the Jones criteria, other aspects of the illness will differentiate it from ARF. Similarly, other collagen vascular diseases can be distinguished by other manifestations. Kawasaki disease has diagnostic criteria that may partially overlap the Jones criteria, but the clinical appearances are dissimilar. Henoch-Schönlein purpura is recognized by the characteristic rash on the lower extremities. Subacute bacterial endocarditis should be considered in any child with a new or changing murmur and fever. Finally, poststreptococcal reactive arthritis has alternatively been considered a separate disorder and an atypical presentation of ARF.

EMERGENCY DEPARTMENT EVALUATION

To establish an accurate diagnosis, the revised Jones criteria are used. The presence of two major manifestations or of one major and two minor manifestations coupled with evidence of a preceding streptococcal infection indicates a high probability of ARF.¹ The 1992 revision recognizes that the criteria are only useful during the initial attack and not during recurrences.

Only laboratory evidence of recent streptococcal pharyngitis is acceptable and may include positive throat culture or rapid antigen assay, antistreptolysin-O titer, anti-DNase B, and antihyaluronidase. A complete blood count and blood culture may be useful to rule out other diseases. Chest x-ray may be indicated if cardiomegaly, pericardial, or pleural effusion is suspected. Echocardiography can be used to confirm valvulitis, but is not indicated without auscultatory findings, unless Sydenham's chorea is present. Finally, an electrocardiogram can be obtained to determine PR interval prolongation.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment is focused on prevention of ARF through early identification and treatment of streptococcal pharyngitis. This strategy terminates the ongoing exposure of streptococcal antigen to the host immune system.¹⁴ Nonsteroidal antiinflammatory drugs (NSAIDs) are extremely useful in treating rheumatic arthritis and may also be used for mild carditis. Moderate-to-severe rheumatic carditis, however, requires oral corticosteroids. Prednisone 1 to 2 mg/kg/d for 10 to 15 days, followed by a slow taper over at least a month, will ensure adequate treatment. NSAIDs are unnecessary if corticosteroids are used.¹⁴ Treatment of Sydenham's chorea may require haloperidol, valproic acid, or carbamazepine.¹¹

DISPOSITION

Traditionally, patients with ARF have required hospitalization. Recently, however, over 50% of cases have been managed on an outpatient basis, with the severity of carditis or the presence of arthritis determining inpatient necessity.⁹ Follow-up should be with the child's primary care physician. Pediatric cardiology or neurology consultations should be considered if symptomatology warrants.

COMMON PITFALLS

- Do not fail to perform a thorough joint examination.
- Do not focus exclusively on the joint examination in a patient with obvious joint disease.
- The diagnosis of ARF is easily overlooked in the patient with vague complaints of joint pain. A new or changing murmur may be the only apparent indication of carditis.
- Chorea must be considered in the differential diagnosis of emotional lability.

CHAPTER 291

Sickling Syndromes

Paul A. Pitel and James L. Harper

[Dactylitis \(Hand–Foot Syndrome\)](#)
[Infection](#)
[Vasoocclusive Episodes](#)
[Cerebrovascular Accident](#)
[Acute Splenic Sequestration](#)
[Aplastic Crisis](#)
[Acute Chest Syndrome](#)
[Priapism](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Sickle cell anemia is an autosomal recessive hemoglobinopathy characterized by hemolytic anemia, recurrent vasoocclusion, and end-organ dysfunction. The heterozygous state (AS), sickle cell trait, is found in 8% to 10% of American Blacks. The homozygous state (SS), sickle cell anemia, occurs in one in 400 to 600 Black newborns. The disease is seen less commonly in the Hispanic, southern European, and Middle Eastern populations.

The molecular basis of the disease is the substitution of glutamine for valine at the sixth position of the globin beta chain. This permits the crystallization of the hemoglobin molecules in conditions of relative hypoxemia. The cell becomes irreversibly sickled, leading to premature cell destruction (hemolysis) and blood vessel obstruction.

Hemoglobin electrophoresis permits the accurate diagnosis of sickle cell anemia, sickle cell trait, hemoglobin sickle cell disease, and other sickle variants as early as the newborn period. The sickle cell prep (Sickledex) is inaccurate before age 4 to 6 months. In the older infant or child with sickle cell anemia, the hemoglobin averages 8 g/dl, the hematocrit 24%, and the reticulocyte count 10%, with an elevated platelet count and a white count of 13,000 to 17,000.

Unexplained anemia in a Black child should raise the issue of a hemoglobinopathy. The presence of any sickle forms on a peripheral blood smear is presumptive evidence of sickle cell anemia. Children with sickle cell trait have normal hematologic values.

The emergency department evaluation depends on the presentation or type of crisis of the current illness. Clinical symptoms may begin as early as 3 to 4 months of age, when significant amounts of hemoglobin S become present. Referral for ongoing treatment and parent education, preferably through a sickle cell center, is vital.

DACTYLITIS (HAND–FOOT SYNDROME)

The hand–foot syndrome is the most common presentation of the child with sickle cell anemia from age 6 to 24 months. Painful swelling of the hands or feet, or both, results from symmetric infarction of the metacarpals and metatarsals. Low-grade fever (less than 101.5°F) is common, and no significant changes in hematologic values are noted. Radiographs initially show only soft-tissue swelling, but osteolytic and periosteal changes are seen 2 to 3 weeks after the onset of symptoms. The presentation is often classic but must be differentiated from osteomyelitis (either unifocal or multifocal) and trauma. Therapy consists of hydration at 150% to 200% maintenance (oral or intravenous fluids) and analgesia. Pain and swelling commonly require 2 to 5 days to resolve. Recurrence is not rare, but the syndrome generally ends by age 2 as the vascular supply to these bones collateralizes.

INFECTION

Bacterial infection is the most common cause of serious morbidity and mortality in children with sickle cell anemia.⁶ The primary pathogens are the encapsulated organisms *Streptococcus pneumoniae* and *Haemophilus influenzae*, but *Salmonella* osteomyelitis and severe *Mycoplasma pneumoniae* infections are also seen. The primary cause is functional asplenia secondary to autoinfarction, which may occur as early as 5 months of age but is routine by age 5 years. Defects in complement and opsonization are also noted in sickle cell patients.

Bacterial meningitis and septicemia are more than 600 times more common in sicklers than in normal children.¹⁷ Bacterial pneumonia is 100 times more common in sicklers. Pneumococcal sepsis in sicklers carries a 14% mortality, often within hours of presentation, even when recognized and treated. Pneumococcal disease is most common before age 6 and is particularly common in the first 2 to 3 years of life.¹⁴

Prophylactic daily penicillin should be started at age 3 to 4 months and continued at least until age 5 years at a dose of 125 mg orally twice daily.⁴ A dose of 250 mg orally twice daily is given from ages 3 to 5 years. Also, *H. influenzae* type B (HIB) and pneumococcal (Pneumovax) vaccines are given routinely. Educating the family is critical.

Despite optimal treatment, children with sickle cell anemia may present with fever and potential bacterial infections. Initial evaluation should include

- A careful history of the present illness. Bacteremia is more likely to be of only several hours' duration and associated with a fever above 103°F.
- A careful review of the medical history, including penicillin prophylaxis and possible missed doses
- A careful physical examination. Focal sites of infection can coexist with bacteremia.
- For fever above 101.5°F, a complete blood count with differential, a reticulocyte count, and a blood culture are probably minimal requirements. Marked leukocytosis (above the baseline 13,000 to 17,000) or a left shift is usually seen. Lumbar puncture and chest radiographs may be indicated. The erythrocyte sedimentation rate and C-reactive protein assessment are unreliable.

Children less than age 1 year with fever are routinely admitted for appropriate intravenous antibiotics. In selected cases, older children with a fever below 103°F and no focal source of infection may be discharged home after obtaining appropriate cultures and giving ceftriaxone 75 mg/kg intramuscularly.¹⁵ Reliable follow-up must be assured. A repeat dose of ceftriaxone should be administered 24 hours later. With a focal source, blood cultures and ceftriaxone should be followed up with appropriate oral antibiotics. Children with fevers above 103°F should routinely be admitted and observed on appropriate antibiotic coverage. Antibiotic choice should depend on local patterns of bacterial sensitivity; however, coverage of both *H. influenzae* and *S. pneumoniae* is necessary in the young child. The emergence of resistant or partially resistant *S. pneumoniae* must be considered. Children older than 8 or 9 years can often be managed with penicillin alone.

VASOOCCLUSIVE EPISODES

The hallmark of sickle cell anemia is the painful “crisis” caused by arterial occlusion by irreversibly sickled cells. Vasoocclusion may be precipitated by dehydration, hypoxia, acidosis, or infection, but it often occurs without ready explanation. Symptoms vary according to the location of vascular obstruction, but pain secondary to tissue hypoxemia is common. Pain episodes commonly involve the extremities or abdomen, but head pain (calvarial) or chest wall pain (rib, sternal) is common in older children. Low-grade fever is often noted.

Therapy consists of aggressive hydration (twice maintenance) and analgesics. For mild pain, ibuprofen or acetaminophen may be adequate. For moderate pain, intravenous or intramuscular morphine sulfate or meperidine may be appropriate, followed by hydration and transfer to oral agents such as acetaminophen with codeine.^{1,18} Severe pain requires intravenous morphine sulfate, fluids, and hospitalization.¹² The use of multiple doses of meperidine should be avoided because of the drug's short duration of action and because its metabolic by-product normeperidine lowers the seizure threshold.¹¹

CEREBROVASCULAR ACCIDENT

About 7% of sickle cell patients suffer a central nervous system event, often a stroke. In the younger child, the event is usually thrombotic; in the adolescent or adult, it may be hemorrhagic.¹⁰ These events are unpredictable. They routinely involve major cerebral arteries and can be devastating. In the emergency department, any untoward neurologic event in a sickle cell patient is considered a cerebrovascular accident until proven otherwise.

Initial evaluation should include a careful history for precipitating events, a formal neurologic examination, insertion of an intravenous line, and measurement of baseline laboratory values. Computed tomography scanning without contrast is needed routinely. Neurology and hematology consultations are obtained. Arteriography is usually not needed and can precipitate further sickling in the untransfused patient.

Acute therapy usually includes intravenous hydration and exchange transfusion to decrease the percentage of hemoglobin S to below 30%. Prompt recognition and treatment in an intensive care setting usually results in a gratifying outcome.⁷ Long-term treatment necessitates hypertransfusion for several years to reduce the 66% chance of a recurrent cerebrovascular accident.^{9,13,16}

ACUTE SPLENIC SEQUESTRATION

Splenic sequestration is a life-threatening condition seen in young children before the onset of autoinfarction of the spleen. Over a period of hours, a significant portion of the circulating blood volume is sequestered in the spleen because of vasoocclusion in the splenic vein. Thus, the patient develops hypovolemia, pallor, massive splenomegaly, and, occasionally, shock and death. Families should be educated in splenic palpation. Evaluation demonstrates splenomegaly (often massive), anemia, and reticulocytosis.

Treatment is aimed at sustaining blood volume until the condition spontaneously reverses, releasing the sequestered blood. Careful monitoring and, often, a transfusion of 10 mL/kg of packed red blood cells may be required.⁸ Overtransfusion should be avoided, as the condition will reverse.

APLASTIC CRISIS

The term *aplastic crisis* refers to acute anemia that may be superimposed on sickle cell patients by episodes of marrow hypoplasia. The severely decreased red cell survival in these patients necessitates a marked reticulocytosis (greater than 10%) to maintain baseline hemoglobin levels. Episodes of erythroid hypoplasia, manifested by progressive anemia with reticulocytopenia (less than 1%), occur both sporadically and epidemically in association with the human parvovirus B19.⁵ Packed red blood cell transfusion may be necessary until erythroid production returns, usually within a few weeks. Patients with aplastic crisis require close monitoring because their hemoglobin may fall to 4 g% or lower within a few days.

ACUTE CHEST SYNDROME

Episodes of cough, chest pain, fever, and pulmonary infiltrates are common. In younger children, the cause is usually infection, and in older children and adolescents, infarction. A syndrome of progressive infection and infarction may develop, with diffuse lung involvement. *M. pneumoniae* can produce severe and unusual patterns of infection in these patients. Treatment focuses on appropriate antibiotic coverage. Oxygen supplementation, transfusion, or both, may be indicated.

PRIAPISM

Priapism is painful, involuntary penile erection. Sickling within the penile cavernous sinuses is most common in adolescents and young adults. Any episode lasting more than 3 hours is unlikely to resolve spontaneously and requires intravenous hydration and narcotic analgesia. Hematologic consultation regarding transfusion or exchange transfusion should be considered. Episodes persisting more than 24 hours require surgical intervention. Physiologic sexual impotence commonly occurs from chronic scarring of the erectile tissue.²

DISPOSITION

Most children with sickle cell disease are followed by a pediatric hematologist and a primary care physician.³ It is essential that these physicians be advised of the patient's emergency visit and consulted regarding the discharge plan.

COMMON PITFALLS

- Failing to recognize that any sickled cell on peripheral smear is presumptive evidence of sickle cell anemia
- Failing to appreciate the immune status of the sickle cell patient. The febrile sickle cell child requires careful evaluation and often hospitalization and intravenous antibiotics.
- Failing to recognize that sickle cell anemia can be diagnosed in the newborn; symptoms may begin by age 3 to 4 months. Many states have mandatory newborn screening programs.
- Failing to recognize that the sickle prep is inaccurate before 4 to 6 months of age
- Failing to consider a cerebrovascular accident when evaluating any untoward neurologic event in a sickle cell patient
- Failing to consider aplastic crisis and acute splenic sequestration in the acutely anemic sickle cell patient

CHAPTER 292

Sinusitis

Elizabeth A. Wedemeyer and Vinay M. Nadkarni

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Sinusitis is an infection or inflammation of the paranasal sinuses: the maxillary, ethmoid, frontal, and sphenoid sinuses. The sinuses develop during gestation as outpouchings of the nasal mucosae. The maxillary and ethmoid sinuses are pneumatized at birth and can potentially harbor infection in infancy. In contrast, the frontal and sphenoid sinuses are only rudimentary at birth. The frontal sinuses expand from the middle meatus of the frontal bone and do not assume their characteristic supraorbital location until about 6 years of age.⁴ The sphenoid sinuses do not pneumatize until 2 to 3 years of age, and they do not become clinically important until the second decade of life.

Acute sinusitis is usually preceded by an upper respiratory infection. The mucosal lining of the sinuses is contiguous with that of the nasopharynx. With an upper respiratory infection, this lining becomes hyperemic and edematous, causing obstruction of the sinus ostia. This obstruction, which may also result from anatomic or allergic causes, results in the development of negative pressure within the sinus. When the obstruction is relieved, this negative pressure predisposes the normally sterile sinus to bacterial invasion and infection.⁸

In most cases of childhood sinusitis, the maxillary sinus is the primary site of involvement. The location of its ostium (high on the medial wall of the sinus) hinders gravity drainage of the sinus.¹² In addition to maxillary involvement, the ethmoid sinus is readily obstructed by mucosal swelling. After the age of 10 years, the frontal sinuses are an increasingly common site of sinus infection. In children with chronic sinusitis, predisposing conditions need to be considered; these include sinus ostia obstruction from allergic rhinitis, chronic indwelling nasoenteral feedings tubes, or impaired mucociliary clearance in children with cystic fibrosis or ciliary dyskinesia syndromes.

CLINICAL PRESENTATION
