Another important factor in predicting resuscitation is the time that elapses before CPR is initiated. By providing some blood flow to the heart and other vital organs, one can extend the time in which defibrillation is effective. For example, data from Seattle show that if ACLS is started within 8 minutes of cardiac arrest, there is a successful outcome in 27% of patients. For those patients who have CPR started within 4 minutes in addition to having ACLS within 8 minutes, successful resuscitation is increased to 43%.⁶

Finally, the cause of the cardiac arrest is another factor important for prognosis.⁵ In cardiac arrest due to extracardiac causes such as pulmonary embolism and hypovolemia, the prognosis is very poor. In addition, specific pathophysiologic entities, such as complete thrombosis of the left main coronary artery, have poor prognoses, because providing adequate coronary blood flow is impossible no matter how quickly CPR and ACLS are provided.

COMMON PITFALLS

- It is important to remember that resuscitation efforts require a well-disciplined team in which each member plays a role. Often, cardiac arrests are managed in a chaotic, undisciplined environment that is not conducive to optimal patient care. Well-disciplined teams develop through frequent drills and critique. Each resuscitation should be carefully reviewed. Hospitals and prehospital care systems should constantly monitor the success of their resuscitation efforts and compare them with studies in the literature.
- After the placement of an endotracheal tube, bilateral equal breath sounds should be heard in the axilla. Correct placement of the tube can be confirmed by quantitative capnometry. Breath sounds heard anteriorly may be transmitted from the stomach. Breath sounds and capnometry readings should be checked repeatedly during the resuscitation. Asymmetry of breath sounds or a sudden absence of CO₂ excretion mandates prompt evaluation—the endotracheal tube may have slipped out or down into the right bronchus or the patient may have developed a pneumothorax secondary to the trauma of chest compressions. Either of these serious conditions can be easily treated if recognized early.
- Intracardiac medications should be avoided. If an intravenous line cannot be started, many standard advanced life-support medications, including epinephrine, atropine, and lidocaine (*but not bicarbonate*), can be administered through the endotracheal tube.
- Hyperkalemia should be suspected as the cause of cardiac arrest in any patient with renal failure. The ECG may show a characteristic sine wave pattern, which should not be mistaken for ventricular fibrillation. Patients with hyperkalemia will not respond until the potassium level is lowered. Vigorous treatment with bicarbonate and calcium is indicated when hyperkalemia is suspected.
- Most patients in ventricular fibrillation can be defibrillated. Repeated unsuccessful defibrillation attempts may be due to poor technique. Successful defibrillation involves the depolarization of a critical mass of left ventricular myocardium. One paddle should be placed to the right of the sternum below the right clavicle, and the other in the midaxillary line at the level of the nipple. If the paddles are too close together, the skin, rather than the heart, may be getting the current. Alternatively, the anteroposterior position may be used over the left precordium. Firm pressure of approximately 25 lb should be applied to each paddle, and the appropriate contact gel must be used. The chest should be in full expiration when shocks are administered, because air in the lungs can significantly add to transthoracic impedance. Repeated shocks decrease the transthoracic impedance and improve the chances of successful defibrillation; therefore, the shocks may be delivered in pairs or triplets, with only a short pause between shocks to check for a pulse and the rhythm on the monitor.
- Torsades de pointes can be mistaken for ventricular tachycardia or fibrillation. The ECG reveals cycles of QRS complexes “twisting around” the isoelectric point of the ECG. It is associated with a congenital or drug-induced prolonged QT interval, most frequently due to quinidine. Although antiarrhythmic drugs are commonly ineffective in terminating torsades, electrical cardioversion is usually successful. Further treatment with magnesium sulfate, isoproterenol, or overdrive pacing decreases the QT interval and prevents recurrence.¹⁵
- There are no good parameters that can be used to assess the effectiveness of ongoing CPR or to guide treatment during the resuscitation effort. Femoral

pulsations may reflect venous rather than arterial blood flow. Carotid pulsations may reflect some blood flow but cannot be used as a guide to decision making during resuscitation. The longer the patient remains in cardiac arrest, the worse is the prognosis for resuscitation. After 30 minutes of resuscitation attempts, the prognosis is very poor, although there are case reports of successful resuscitation after hours of CPR. Therefore, no clear guidelines can be given as to when resuscitation efforts should be stopped.

- In patients who are hypothermic, as in near-drowning victims, resuscitation efforts should continue until the patient has been adequately warmed. Strong consideration should be given to cardiopulmonary bypass for these patients. In other patients, resuscitation efforts should be continued until the patient is unresponsive to ACLS protocols as outlined.

CHAPTER 130

Acute Respiratory Insufficiency

Paul E. Pepe

[Ventilatory Support](#)
[Oxygenation Support](#)
[Identifying who Needs Ventilatory and Oxygenation Support](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation and Management](#)
[Common Pitfalls](#)
[Chapter References](#)

Acute respiratory insufficiency usually implies a failure of the breathing apparatus to maintain an adequate systemic arterial O_2 tension (PaO_2) so that hemoglobin (Hgb) in the red blood cells becomes significantly desaturated (less than 92%) or when CO_2 levels rise enough to result in significant arterial acidosis (pH less than 7.30). To some, the term may simply mean severe respiratory distress, with a respiratory rate (RR) at rest greater than 30 to 35 breaths per minute. However, it must also be emphasized that respiration refers not only to the act of breathing, but also to cellular respiration (O_2 consumption and CO_2 production).

Cellular respiration depends on systemic O_2 delivery, which, in turn, depends on an adequate Hgb level, an adequate Hgb O_2 saturation, and an adequate cardiac output. Thus, the need to maintain adequate tissue O_2 delivery directs us to the basics of emergency care: (1) Stop the bleeding or provide definitive surgical care and transfuse as necessary (preserve Hgb); (2) ensure an airway and adequate lung inflation with O_2 (facilitate an adequate PaO_2); and (3) when appropriate, provide intravascular volume or assure circulation through the use of appropriate interventions such as cardiovascular drugs and, if necessary, external cardiac compressions (to maintain cardiac output). In essence, the ABCs of emergency resuscitation (airway, breathing, and circulation) are directed at maintaining adequate cellular respiration. Therefore, acute respiratory insufficiency can be viewed as a failure of an integrated systemic mechanism to maintain tissue O_2 delivery and consumption.

In turn, if CO_2 is not cleared by the lungs as quickly as it is produced, the arterial CO_2 tension ($PaCO_2$) rises, the acidity of the blood increases, and, readily crossing the blood–brain barrier, the elevated $PaCO_2$ results in cerebral acidosis, depressing the level of consciousness and dilating the cerebral vessels. This last event, in turn, may significantly elevate intracranial pressure (ICP), a potentially serious effect in patients with serious head injury or a cerebrovascular insult. Unlike impaired O_2 delivery, however, a high $PaCO_2$ in itself may not always constitute a major acute problem. For example, patients who are chronic CO_2 retainers usually have compensated for chronic respiratory acidosis by renal bicarbonate retention and tolerate a high $PaCO_2$ quite well. A pounding headache (caused by cerebral vasodilatation) may be their only manifestation of further CO_2 retention during acute exacerbations of underlying pulmonary disease.

The removal of CO_2 is a relatively simple process in the normal lung. Simply flushing the alveoli with fresh breaths causes CO_2 to leave the bloodstream because of the significant concentration gradient. However, the more O_2 is consumed, the more CO_2 is produced. With increased CO_2 production (exercise, stress, and metabolic alterations), more fresh ventilation needs to be introduced. A shivering, awake patient undergoing the stress of acute injury or illness may require extraordinary ventilatory support to adequately remove CO_2 from the body. On the other hand, a comatose patient with a phenobarbital overdose or a hypothermic patient whose oxygenation and circulation are properly supported usually requires little ventilation because of very low metabolic rates. In apneic, pulseless patients who are receiving cardiopulmonary resuscitation (CPR) efforts, O_2 delivery to the tissues is severely compromised.¹ In turn, there eventually is diminished systemic CO_2 production, and markedly diminished venous return to the lungs, and thus a markedly decreased need for ventilation. As long as such patients receive an adequate lung inflation (10 to 15 mL/kg) with each breath, they may only require five to eight breaths per minute. If and when spontaneous circulation is restored, CO_2 production and return to the lungs will increase significantly, and the delivered RR should be increased accordingly (e.g., ten to 15 breaths per minute).

From a pragmatic viewpoint, the key aspects of emergency care can be targeted by the emergency physician by answering the following questions:

1. Does the patient need ventilatory support (a certain number of manual or mechanical breaths to remove CO_2)?
2. Does the patient need oxygenation support (hemorrhage control or transfusion, supplemental O_2 , positive-pressure lung inflations, or even positive end-expiratory pressure), with or without circulatory support?
3. What are the potential complications of these interventions (e.g., barotrauma and circulatory compromise)?

Although oxygenation and ventilation are undeniably intertwined, a critically ill or injured patient should be approached by specifically distinguishing between the need for ventilatory support and that for oxygenation support. That is, some patients may require mechanical ventilatory support for one and not the other. For example, if unoxygenated blood is shunted through gas exchange units that are not being adequately inflated, resulting in a low PO_2 , alveoli that remain well inflated still provide a route for clearance of CO_2 (Fig. 130.1). On the other hand, despite their ability to maintain adequate oxygenation, some patients may need ventilatory support for CO_2 retention (chronic lung patients) or to purposefully lower $PaCO_2$ to decrease ICP (severe head injury).^{6,7,17}

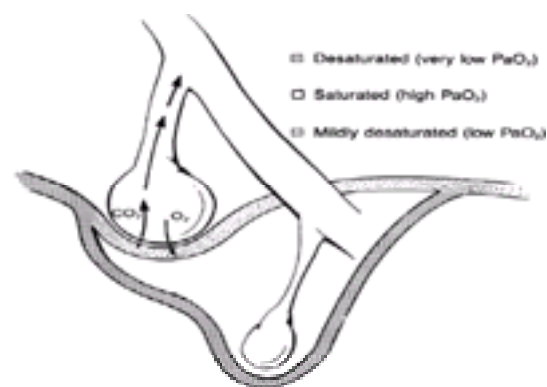

Figure 130.1. Inflated (*upper*) lung unit with intact route for gas exchange (CO_2 clearance and O_2 saturation of red blood cells), while deflated or consolidated (*lower*) lung unit leads to shunting of desaturated (*blackened*) red blood cells to the arterial side. An increased RR allows additional clearing of CO_2 in the upper zone to maintain a normal (or even low) CO_2 tension in the systemic arterial blood, but still does not achieve O_2 saturation of red blood cells when a large enough number of air spaces are closed in the lower zone. Thus, shunting may lead to significant decreases in arterial O_2 content, even when the patient is hyperventilating (i.e., low $PaCO_2$).

In summary, respiratory support involves the preservation of adequate Hgb levels and adequate circulation, adequate lung inflation and O_2 supplementation, and appropriate clearance of CO_2 .

VENTILATORY SUPPORT

Minute ventilation (V_E) is the product of tidal volume (V_T) and respiratory rate (RR). From a clinician's point of view, the patient's immediate " V_E demand" can be considered the V_T and RR required to maintain a normal blood pH. Thus, need for ventilatory support usually arises when a patient is unable to ventilate adequately to remove enough CO_2 to maintain a normal blood pH. The removal of CO_2 to compensate for excess production of metabolic acids can be considered part of the immediate demand as well. V_E demand can be increased by (1) augmented CO_2 production by body tissues, (2) metabolic acidosis, and (3) an increased amount of

wasted ventilation because of an increased ratio of dead space to tidal volume (V_D/V_T).

Most critically ill or injured patients are stressed and have an increased V_E demand, especially when there is shock and anaerobic acidosis. Most patients can briefly tolerate even large stresses in V_E demand. But like prolonged exercise, prolonged increases in V_E demand owing to injury may lead to respiratory muscle fatigue and eventual ventilatory failure, even in the healthiest of patients. All severely ill and injured patients, particularly those with respiratory system impairment, are potential (if not immediate) candidates for ventilatory support. The third mechanism of increased V_E demand, an acute increase in dead space (wasted ventilation), is usually the result of extremely shallow breathing (high V_D/V_T) or pulmonary embolism (air or thromboemboli).

Meeting ventilatory demand requires an intact bellows system, including open airways; an intact, tightly sealed chest wall; and respiratory muscles capable of generating enough negative (outward-pulling) pleural pressure to expand the lungs into an inflated state. The chest wall is a particularly important component because it anchors the respiratory muscles, including the diaphragm. The signal generator is the central nervous system, which determines the required V_E and signals adjustments in V_T and RR by way of the brainstem and spinal cord. In patients with cerebral insults or severe injuries, all of these elements may be compromised or malfunctioning, but even when these elements are intact, ventilatory support may be necessitated by overwhelming demands. Active ventilatory intervention may also be considered in cases of severe head injury to lower PaCO₂ in an intentional attempt to decrease ICP acutely.^{6,7,17}

Common reasons for inadequate ventilation are airway obstruction, high spinal cord injury, flail chest, and open pneumothorax (sucking chest wound). In the latter, air preferentially enters the thorax through the path of least resistance (the chest wound that is larger than the tracheal orifice) during inspiration. Underlying medical problems such as acute asthma or chronic lung disease can cause expiratory phase air-flow obstruction and may also result in CO₂ retention, as may narcotic and other sedative drug overdoses, stroke, head injury, and neuromuscular disorders. Hemodynamic compromise (extreme blood loss, tension pneumothorax, and pericardial tamponade) may eventually result in ventilatory failure because of inadequate perfusion of the respiratory apparatus.

OXYGENATION SUPPORT

In the absence of severe anemia or circulatory compromise, the need for tissue oxygenation support normally arises from pulmonary failure to oxygenate the bloodstream, usually when a critical number of the lung's gas exchange units fail to remain inflated.¹⁴ Although inadequate ventilation can lead to hypoxemia (by increasing the partial pressure of CO₂ relative to O₂ in the alveoli), the degree of hypoxemia is usually not great and is readily reversible once ventilatory support or supplemental O₂ is administered. On the other hand, *hypoinflation* is more likely to result in serious hypoxemia (PaO₂ less than 60 mm Hg) as blood perfuses across collapsed alveolar beds. This arterial hypoxemia may be refractory to even a high inspired O₂ fraction (FiO₂). This is a common mechanism of respiratory insufficiency in the critically ill or injured patient. Thus, tidal volume (V_T) size plays an important role in the maintenance of an adequate PaO₂ in these patients. For example, it is estimated that without intervention, 60% to 70% of patients with severe head injury have relative hypoxemia and 30% to 40% have critical hypoxemia (PaO₂ less than 60 mm Hg), despite apparently normal respiratory patterns and the absence of signs of respiratory distress.^{4,5,8,9} The reasons may include aspiration of gastric contents or concomitant lung contusion, but more often, hypoxemia occurs because of clinically inapparent changes in the respiratory pattern. This hypoxemia can often be reversed by the initiation of effective positive-pressure lung inflations alone (e.g., with V_T equal to 10 to 15 mL/kg lean body weight).^{1,2,12,17,22} The critically ill patient is recumbent in most situations and may also have a significant decrease of functional residual capacity, owing to thoracic muscle weakness and a decrease in total thoracic compliance.

Cardiac arrest patients rapidly deflate their lungs, and lung compliance diminishes by fivefold or more.¹² Endotracheal (ET) intubation is often required to guarantee reinflation, particularly after 1 or 2 minutes of CPR.¹² In patients who are conscious, lung deflation is normally not a problem; even in obtunded patients, stimulation or commands such as "take a deep breath" can often substitute for more invasive support. However, most unconscious patients must also be considered to be at high risk for aspiration (unprotected upper airway) or progressive closure of the smaller airways.

Alveolar closure can also result from physical compromise by increased abdominal pressure, a collapsed or paralyzed chest wall, or hemothorax or pneumothorax. Filling of alveoli with blood, vomitus, pus, or edema fluid blocks the movement of O₂ from the airways to the blood and also causes atelectasis. Obstruction of larger airways with distal collapse of airspaces can occur from foreign bodies. Less obvious is the diffuse alveolar closure that occurs after prolonged hypoinflation. Although V_E demand may be met by increasing RR and the flow in and out of remaining open alveoli (see [Fig. 130.1](#)), specific support measures may still be required to reverse hypoxemia (i.e., ET intubation and provision of V_T of 15 mL/kg).

Although the need for active ventilatory support and the need for active oxygenation support should be addressed independently, the means to provide these two types of support often overlap. For example, while a patient's V_E demand may be met by various combinations of mechanically delivered V_T and RR, hypoxemia secondary to shallow breaths will probably be reversed by 10 to 15 mL/kg V_T . Thus, the selected V_T could be used for both ventilatory and oxygenation support. If the V_T is increased for purposes of oxygenation, the effect on PaCO₂ and pH must then be taken into account and the RR tailored appropriately. A logical approach is to first choose an adequate delivered V_T and then adjust the RR to meet V_E demands. The need for additional oxygenation support, such as increased FiO₂ and positive end-expiratory pressure, can then be judged independently.

Although such guidelines are useful, experience and clinical judgment are still the keys to proper management. In some situations, early intervention may be warranted, despite normal arterial blood gas (ABG) analysis and clinical appearance. For example, elderly patients with rib fractures or head-injured patients with unstable neurologic status may benefit from early ET intubation and positive-pressure mechanical ventilation, particularly before undergoing extensive evaluations such as radiologic examination, peritoneal lavage, or computed tomographic scans. Such patients may experience fatigue, and their condition may deteriorate after the initial evaluation while these diagnostic studies are carried out. The same applies to patients with chronic obstructive pulmonary disease (COPD), chronic musculoskeletal disorders, pneumonia, or asthma, who may experience fatigue before other therapy (e.g., antibiotics and bronchodilators) can take full effect.

IDENTIFYING WHO NEEDS VENTILATORY AND OXYGENATION SUPPORT

In identifying which patients require ventilatory and oxygenation support, four considerations should be kept in mind: (1) Certain immediately life-threatening problems (e.g., airway obstruction, inadequate respirations or apnea, and open or tension pneumothorax) require urgent attention before other assessments; (2) some urgent problems, not obvious at first, can be detected by repeated assessments (e.g., simple pneumothorax and flail chest); (3) the risk of late pulmonary complications (e.g., adult respiratory distress syndrome [ARDS] and pneumonia) can often be predicted by initial assessments; and (4) underlying conditions (e.g., asthma, COPD, heart failure, and overdose) must be promptly addressed.

Whether a patient is breathing spontaneously or receiving manual ventilation, certain respiratory problems require immediate attention. Auscultation of the upper anterior chest bilaterally should be performed with simultaneous inspection for apnea, cyanosis, tracheal deviation, engorged neck veins, retractive respirations, accessory muscle use, ecchymoses, flail segments, and sucking wounds. With auscultation, the following observations can be made: (1) lack of air movement (obstruction or respiratory arrest); (2) tachypnea or agonal respirations (impending arrest); (3) the presence of stridor (inspiratory obstruction); (4) prolonged expiration or wheezing (expiratory obstruction); (5) asymmetric breath sounds (large hemothorax or lung collapse); and (6) abnormal quality or pattern of respirations (retractive, shallow). The initial screening is best performed over the anterior chest because the larger airways can be heard best there. Once the presence of reasonable ventilation has been ascertained by auscultation and visualization, the assessment of other systems and secondary assessments of the respiratory system can be accomplished. It must be remembered that upper airway obstruction may not be obvious at first in a patient who has had blunt trauma to the head, neck, and chest. However, the trachea may become progressively compromised by mechanical compression from an expanding hematoma deep in the throat, and such an obstruction may not be discovered until stridor develops (a late sign) or, in some cases, until the unintubated unconscious patient becomes cyanotic and apneic. Repeated assessments are the key; one must always keep one's index of suspicion high in the context of the overall picture.

Abnormal chest findings on chest examination may be perceived in the heat of an emergency, while normal examinations do not guarantee that active ventilatory and oxygenation support will not be necessary. Again, a high degree of suspicion and repeat examinations are the best tools of respiratory assessment. This rule also applies to chest radiography and ABG analysis. For example, many patients at high risk of developing ARDS after trauma have reasonable arterial oxygenation at first. Many cases of ARDS are not confirmed until several hours after injury, but physiologic (ABG) changes can evolve rapidly (usually within 3 to 4 hours), and thus close monitoring is essential in those with associated risk.^{3,11,13} Contusions, pneumothorax, and atelectasis can also have a delayed onset (6 to 48 hours after injury)^{3,11,15,19,20} and ^{and 21,23} and can occur without early signs of respiratory distress or change in physical examination. In severely ill or injured patients, ABG

measurements should probably be repeated every 1 or 2 hours, at least in the early stages, and particularly in those who are already receiving early ventilatory and oxygenation support or are noncommunicative. In those with frank shock, ABG analysis should be performed frequently. Whenever an adjustment in ventilatory therapy is made or when there is an adverse change in the patient's assessment (decreased breath sounds, new infiltrate on chest radiograph), ABG analysis should be performed promptly, but preferably after 4 to 5 minutes of equilibration time on new ventilator settings.

Pulse oximetry is now available in most ambulances and emergency facilities. It is a very useful tool for detecting desaturation of red cells, although false-positive "normal saturations" can occur (e.g., CO poisoning). On the other hand, deterioration of overall respiratory status may not always be detected by pulse oximetry, especially when supplemental O₂ is in use. For example, while O₂ saturation may be maintained in an asthma patient on supplemental O₂, a rising PaCO₂ may go undetected. Likewise, worsening oxygenation (e.g., PaO₂ of 210 mm Hg falling to 150 mm Hg), despite the same amount of supplemental O₂, will not be detected by the pulse oximeter (which will show 100% saturation at both readings). False-positive *desaturations* are more common. Hypoperfusion, excess vasoconstriction, cool skin, and mechanical problems can cause falsely low readings.

The use of an end-tidal CO₂ (E_T-CO₂) detector can be helpful in both the assessment and management of patients with acute respiratory insufficiency.^{27,28} E_T-CO₂ detection is best suited for patients who have received ET intubation. Detection of expired CO₂ can be accomplished through either a colorimetric E_T-CO₂ device (capnometer) or an E_T-CO₂ electronic graphic monitor (capnograph). *Capnometers* can be easily attached to the end of the ET tube and are commonly used to confirm proper ET tube placement by demonstrating tidal CO₂ expulsion (rising and falling of the CO₂ level with each breath). When CO₂ is not detected, this generally indicates inappropriate tube placement (e.g., in the esophagus). However, a false-negative reading (i.e., proper ET tube placement with low or no CO₂ detection) can occur. For example, patients with inadequate circulation (little CO₂ returning to the lungs) or significantly increased dead space (e.g., massive pulmonary embolus) may not show CO₂ detection despite proper tube placement.

Capnography can also be used for confirmation of proper ET tube placement, but it requires a more sophisticated electronic monitoring device (Fig. 130.2). The capnographic tracing does provide additional information, however. Even if a low CO₂ level is detected, the tidal waxing and waning of the CO₂ curve can indicate appropriate ET tube placement. The tracing can provide other important diagnostic and management information. For example, patients with severe expiratory obstruction (e.g., COPD, asthma) do not show a quick rise in the CO₂ level during expiration, but rather a more gradual upslope (Fig. 130.3). The tracing improves (quicker upslope) with improvements in airway obstruction. The E_T-CO₂ tracing can also be useful in CPR. For example, E_T-CO₂ levels may fall gradually over several minutes during CPR, indicating fatigue of the person performing chest compressions and the need to rotate rescuers (Fig. 130.4). Conversely, a sudden rise in CO₂ production during CPR may herald the return of spontaneous circulation (Fig. 130.5). Many practitioners consider capnography to be the standard of care, at least for those greater than 2 to 3 years of age. E_T-CO₂ devices are more complex in infants and are thus less useful in that population.

Figure 130.2. Normal capnograph indicating exhalation of the dead-space gas (no CO₂) in the first phase of exhalation (A-B); exhalation of mixed dead-space and alveolar gas from the air spaces with the shortest transit time (phase B-C); the alveolar plateau (phase C-D), exhalation of primarily alveolar gas; and, finally, inhalation (phase D-E), in which there is inspiration of fresh gas. Point D represents the end-tidal CO₂ value.

Figure 130.3. A capnograph of a patient with severe expiratory obstruction, showing a delay in reaching the alveolar gas plateau as reflected by a more gradual upstroke of phase B-C (see Fig. 130.2). Improvements in air-flow obstruction are reflected by a normalization of the tracing.

Figure 130.4. Capnograph indicating a gradual decrease in circulation (relatively normal tracing, but of decreasing magnitude over time).

Figure 130.5. Capnograph over an extended period of time (trended timebase), showing a low magnitude of end-tidal CO₂ during CPR, then increasing dramatically, indicating a sudden return of spontaneous circulation, with an increase in CO₂ production and a return of CO₂ via the circulation to the lungs.

DIFFERENTIAL DIAGNOSIS

When faced with a patient with difficulty breathing or signs of respiratory insufficiency, the clinician should always keep an open mind, even after formulating an initial working assessment, and should continue to reassess the patient and review a mental differential diagnostic list. Above all, one should think in terms of O₂ transport; thus, the differential diagnosis includes both pulmonary and circulatory processes (Table 130.1). Such a mental list helps the physician to better direct historical queries and the physical examination to cover all pertinent areas. It also must be remembered that multiple processes may be occurring simultaneously. For example, an exacerbation of COPD may be associated with a pulmonary embolus or pneumonia.

CARDIAC OUTPUT PROBLEMS
Bleeding, myocardial ischemia, sepsis, pericardial tamponade, tension pneumothorax, etc.
PULMONARY PROBLEMS
Airway obstruction (upper airway problems such as anaphylaxis, foreign body, inflammation, infection, trauma)
Bronchial obstruction (asthma, bronchitis, COPD)
Congestive heart failure and other forms of pulmonary edema
Drug-induced (stimulants, e.g., cocaine, vs. depressants, e.g., narcotics)
Embolic (air, thrombi)
Fractures (with or without underlying contusion)
Gross hemoptysis (usually from bronchial circulation fed from the aorta)
Hemothorax and pneumothorax (spontaneous and traumatic)
Inhalation injuries (CO, toxic fumes, near-drowning, aspiration)
"honky" lungs (pneumonia, cancer, emphysema)
"Compensation" for metabolic acidosis (shock, ketoacidosis, renal failure, toxins)
Lower (subdiaphragmatic) problems and restrictive breathing (trauma, ascites, pain, injury)
Muscle weakness (Ca ²⁺ , PO ₂ , K ⁺ , Mg ²⁺ , myasthenia, dystrophin)
Neurologic impairment (spinal or central lesion, Guillain-Barré syndrome)

TABLE 130.1. Differential Diagnosis of Acute Respiratory Problems

The chest radiograph is a critical tool in the evaluation of respiratory status. It usually reveals the source of any intrapulmonary shunt detected by ABG analysis (e.g., pulmonary edema, pneumonia, atelectasis, main-stem intubation, or pneumothorax). Aside from cardiac right-to-left shunts (congenital and traumatic), pulmonary emboli, and early hypoinflation, hypoxemia unresponsive to low levels of FiO₂ (less than 0.3) usually can be identified by a chest radiographic finding. If not obvious on initial films, in most cases follow-up films show the source or infiltrate progression within a few hours. However, while radiographic infiltrates are usually present in the patient with severe hypoxemia, the severity of hypoxemia does not necessarily correspond to the amount of infiltrate seen. The clinical picture, associated findings, ET secretions, ABG analyses, and response to positive-pressure ventilation can aid in the delineation of the causes of infiltrates seen on chest radiographs.^{10,11,14}

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

ABG values are the immediate end point of early respiratory support: The traditional aim is to deliver the V_E that will maintain normal blood pH (7.35 to 7.45) and to maintain adequate saturation of Hgb (preferably greater than 97%) by maintaining adequate arterial O₂ tensions (PaO₂ greater than 70 mm Hg).

Acutely, pH rather than PaCO₂ should be the focus of ventilatory interventions; an abnormal PaCO₂ is not necessarily harmful in itself, except for its effect on pH and ICP. The usual normal range for PaCO₂ is 35 to 40 mm Hg, but in a patient with shock whose PaCO₂ is 38 mm Hg, the pH may be less than 7.10, owing to excessive production of lactic acid. In such cases, the PaCO₂ can be temporarily lowered by increasing V_E enough to return the pH toward normal (until the underlying metabolic disturbance can be corrected). In a patient who has received excess sodium bicarbonate (e.g., during cardiac resuscitation) or in a patient with chronic CO₂ retention, a high PaCO₂ should be left untreated as long as the pH is normal. Attempts to lower PaCO₂ acutely will raise the pH and increase the risk of life-threatening complications from alkalosis.¹¹ "Permissive hypoventilation" is now considered an optional therapy to diminish mean airway pressure in selected patients, including those with "auto-PEEP" (diminished venous return and cardiac output due to overzealous positive-pressure ventilation).

Because misinterpretation of ABG values can have serious consequences, during the early hours after acute illness or injury, trends in PaO₂ (rather than a single result) should guide therapy. The variability of duplicate PaO₂ analysis can be as much as ±10%.²⁴ Artifacts in technique can affect PaO₂ measurements, such as inadvertent venous sampling (or mixed arteriovenous sampling when the needle tip is moved), laboratory error (technician error or miscalibration of the machine), and misreporting (misunderstanding over the phone, misplaced decimal point, or poor handwriting). If the sample is run within 10 or 15 minutes, air bubbles and failure to place the sample on ice are not significant problems. However, longer delays can lead to unreliable analyses. Furthermore, if too much liquid heparin is in the syringe, the measurement will be inaccurate; this seldom affects PaO₂ significantly but may cause artifactual lowering of the measured PaCO₂ (as well as pH).

Finally, one's interpretation of the ratio of PaO₂ to FiO₂ should clearly consider the O₂ delivery system and the temporally related activities surrounding the sampling. Even 100% O₂ given by a loosely fitting mask usually does not achieve much more than 50% to 70% inspired O₂; when sampling takes place during or soon after a transient removal of supplemental O₂ for transport or suctioning or when the patient continually removes the O₂ facemask, the interpretation of the degree of respiratory insufficiency will be inaccurate. When in doubt, maintaining a high FiO₂ and repeating the sampling is the safest approach.

Even when the PaO₂ is sampled, measured, and reported correctly, other factors can still interfere with oxygenation of the tissues. Above a PaO₂ of 70 to 80 mm Hg, the red blood cells are almost completely saturated. Thus, in a patient with an adequate hematocrit, a PaO₂ of 500 mm Hg does not add much to O₂ delivery. However, in a patient whose hematocrit is 15% or less, the amount of O₂ dissolved in the blood with PaO₂ equal to 500 mm Hg (about 1.5 mL O₂ per 100 mL blood) may be significant. Therefore, if severe anemia is even a slight possibility, maintaining a high FiO₂ (greater than 0.6) may be temporarily advisable to achieve the highest possible O₂ tensions, even when lung function appears adequate.

Even with an acceptable hematocrit, good cardiac output, and adequate PaO₂, adequate tissue oxygenation and utilization are not guaranteed. For example, in cyanide or CO poisoning, PaO₂ that would normally saturate Hgb would no longer be adequate. Not only are O₂-binding sites blocked on Hgb, but the poisons also interfere with O₂ utilization in the mitochondria. In addition, in CO poisoning, O₂ binds tighter than usual to Hgb, thus diminishing release at the tissues. Although CO poisoning leads to anoxic lactic acidemia, attempts to lower PaCO₂ to compensate for the acidosis should be avoided, as O₂ release to the tissues is better in an acidemic environment. PaO₂ should be kept as high as possible to compete with CO-Hgb binding and decrease the half-life of carboxyhemoglobin and also to

dissolve a certain amount of O₂ in the blood for tissue oxygenation. Hyperbaric O₂ therapy should be considered in severe cases.

In the patient with chronic lung disease who retains CO₂ and has lost the usual stimulus to breathe from elevated CO₂ levels, the much weaker “hypoxic” stimulus to breathe helps to maintain the respiratory drive to some extent. It is commonly taught that one should give these patients *only* low-flow O₂ (1 to 2 L/min). This consideration may be applicable if there is no acute exacerbation of lung disease, but when dyspnea, increasing respiratory distress, or disorientation is involved, one should not withhold liberal O₂ flows while gauging the PaO₂. During acute exacerbations, in fact, these patients are more likely to be critically hypoxic while on low-flow O₂. A pragmatic resolution may be to monitor O₂ saturation with pulse oximetry and titrate O₂ supplementation to maintain a satisfactory O₂ saturation (e.g., greater than 92%).

Even without a specific indication, supplemental O₂ should be considered in all ill or injured patients, because it provides a small but possibly critical margin of tissue PO₂ in a patient who has a sudden, unexpected setback (e.g., sudden airway obstruction, hemorrhage, or arrest). The basic modes of O₂ administration include nasal cannula, facemask, and ET tube. As discussed earlier, the use of ET intubation should be emphasized in critically ill and injured patients.^{12,18} In cases in which ET intubation or 100% inspired O₂ is not specifically indicated, low-flow O₂ (i.e., approximately 2 L/min) should be administered, preferably by nasal prongs in alert or semialert patients without obvious nasopharyngeal injury. Patients who are short of breath often become apprehensive when masks cover their faces, and they tend to pull the masks off. Communication is somewhat hampered by a mask and may also promote aspiration by the supine obtunded patient. Nasal cannulas can deliver up to 35% inspired O₂ at 6 L per minute, a level that should suffice in most noncritical cases, but may be inadequate if there is a significant intrapulmonary shunt (greater than 15%) or if nasal inhalation is impaired. In cases in which a very high FIO₂ is indicated but ET intubation cannot be readily performed, an O₂ mask should be considered along with available suction and close observation. A mask with an attached reservoir can supply nearly 100% inspired O₂ at high-flow rates. Assisted ventilation with bag-valve-mask, oral airways, and proper positioning is a mandatory adjunct to ET tube placement attempts.

Because most pH abnormalities can be controlled immediately by adaptations in ventilation, it is more advantageous in patients with severe injuries and acid–base abnormalities to manipulate acid–base status acutely by effecting changes in ventilation. Alkali should be administered only if ventilatory support is inadequate or if acidosis is persistent or refractory to transfusion, intravascular volume restoration, and other primary modes of oxygenation support.

Many clinicians have traditionally attempted to “hyperventilate” patients they believe to be acidotic or in need of lowered ICP.²³ However, more recent practices have deemphasized the use of early, aggressive hyperventilation for patients with severe head injuries.⁸ Rather, maintenance of O₂ saturation and prevention of hypoventilation have become the primary focus. In fact, overzealous ventilation may diminish cardiac output significantly, particularly in those with severe COPD and/or hypovolemia.¹⁶ This effect is difficult to recognize and may be responsible for continued cardiovascular impairment or even “pulseless electrical activity” during CPR. Transient suspension of ventilation (e.g., for 10 seconds) may be helpful in detecting its presence. Permissive hypoventilation may even be useful in such cases until the underlying problem (e.g., hypovolemia, asthma, bronchospasm) can be improved.

COMMON PITFALLS

- Assuming that an initially stable respiratory status will remain that way, particularly in the very young and the elderly
- Providing overzealous positive-pressure ventilation, which can lead to profound circulatory compromise, particularly in hypovolemic patients and those with severe COPD
- Failing to consider multiple processes in assessing respiratory failure. For example, an acute exacerbation of chronic obstructive lung disease could be caused or accompanied by a concurrent pneumonia, pneumothorax, or pulmonary embolus.
- Assuming a stable respiratory status because of a high pulse oximetry reading. Pulse oximetry does not measure CO₂ levels, nor does it always indicate worsening oxygenation when supplemental O₂ is in use.
- Failing to appreciate that patients with severe head injury may appear to be breathing normally and may even be “hyperventilating” (low PaCO₂) but still have significant hypoxemia, even while on supplemental O₂

More than 65 million Americans live with cardiovascular disease, including hypertension, coronary artery disease, rheumatic heart disease, and stroke. Approximately 45% of all deaths in the United States are due to cardiovascular disease, and nearly half of these deaths are in patients younger than age 65. More than 1.5 million patients with suspected acute ischemic heart disease (IHD) are admitted to coronary care units (CCUs) in the United States each year. At least 250,000 patients with IHD experience prehospital cardiac arrest each year, and only approximately 6% of these patients survive to be discharged from the hospital. IHD is thus a major national health concern as well as a common problem encountered in the emergency department.

Of increasing importance is the effective triage of patients with symptoms suggestive of acute IHD. Unnecessary admission to the hospital of patients with chest pain is estimated to cost more than \$12 billion annually.¹³

The coronary arterial lesion most commonly encountered in the patient with typical, stable angina pectoris is a smooth-surfaced atherosclerotic plaque that may permit sufficient coronary arterial flow at rest or with minimal exercise to meet the metabolic demands of the myocardium. The determinants of myocardial oxygen supply and the factors that determine myocardial oxygen demand are listed in [Table 131.1](#). During physical exertion or emotional stress, myocardial oxygen demand increases due to an increase in heart rate and blood pressure (the double product). To meet an increase in oxygen demand, either coronary arterial flow or myocardial oxygen extraction must increase. Because myocardial oxygen extraction is near maximal under normal circumstances, the only way to balance myocardial oxygen supply and demand is to increase coronary flow. If a fixed obstructive lesion is present, flow cannot increase sufficiently to meet augmented demands. Supply–demand imbalance ensues, with the development of ischemia, contractile dysfunction, and the classic symptoms of angina.²⁸ When supply and demand are equalized, the supply–demand imbalance ceases and symptoms subside. This pathophysiologic substrate is the basis for medical management of chronic stable angina. Nitroglycerin preparations, beta blockers, and calcium channel blockers either increase myocardial oxygen supply or decrease demand.

Oxygen Demand	Oxygen Supply
Frequency of pressure development (heart rate)	Diastolic time
Rate of pressure development (contractility)	Extravascular resistance
Ventricular volume (preload)	Perfusion pressure
Pressure developed (afterload)	Collateral resistance
	Coronary arterial tone

TABLE 131.1. Determinants of Myocardial Oxygen Supply and Demand

Unstable coronary artery syndromes encompass unstable angina pectoris and acute myocardial infarction (MI). The pathologic substrate is a complex, irregular, and thrombogenic atherosclerotic plaque that may not be flow-limiting, even during activities that increase the double product. The occurrence of chest pain is thought to result from intermittent flow limitations caused by platelet or fibrin thrombi, an increase in coronary vasomotor tone (i.e., vasospasm), or a combination of both, in the area of the unstable arterial plaque. Myocardial supply–demand imbalance, therefore, occurs because of a decrease in oxygen supply rather than an increase in demand, as in the stable coronary syndrome. Such patients may present with a history of chest pain and may have had a normal exercise stress test or coronary angiography that demonstrated noncritical coronary obstruction.^{6,31}

Myocardial ischemia can also occur in the absence of coronary atherosclerosis. Common causes of nonatherosclerotic myocardial ischemia are listed in [Table 131.2](#).

VALVULAR HEART DISEASE
Aortic stenosis
Aortic regurgitation
Pulmonary stenosis (right ventricular ischemia)
Mitral stenosis with pulmonary hypertension (right ventricular ischemia)
CONGENITAL HEART DISEASE
Congenital valvular disease
Cocurvature of the aorta
Cyanotic heart disease
NONATHEROSCLEROTIC CORONARY DISEASE
Coronary artery spasm, spontaneous or drug-induced (e.g., from use of cocaine)
Coronary artery embolus
Congenital coronary disease (anomalous anatomic origin)
Coronary dissection
Coronary artery vasculitis

TABLE 131.2. Causes of Nonatherosclerotic Myocardial Ischemia

CLINICAL PRESENTATION

History of Present Illness

No single presenting symptom is uniformly diagnostic of IHD. Chest pain or chest discomfort is the most common chief complaint. Such pain or discomfort may be described as a burning, tightness, squeezing, or heaviness, and as dull, sharp, or knifelike in character. Substernal or retrosternal chest pain may radiate to the left

shoulder or to the arm, neck, or jaw due to convergence of sympathetic and somatic afferent pathways at the spinal level. Patients with IHD may also complain of similar types of abdominal discomfort. Chest pain caused by IHD is of visceral origin and is poorly localized. Chest pain that can be localized with a fingertip is unlikely to be of ischemic cardiac origin.²¹

Chest pain caused by IHD usually occurs abruptly, increases in intensity over time, and reaches peak intensity within 2 to 5 minutes of onset. If the pain occurs during or immediately after exertion, it typically resolves gradually within minutes of cessation of physical activity. Chest discomfort that lasts for only seconds or chest pain that is constant and lasts for hours to days is not consistent with IHD. Similarly, chest pain that is pleuritic, reproduced by palpation, and is sharp, stabbing, or positional has a low likelihood of being due to IHD.²⁵ (Table 131.3).

Typical
Substernal in location
Squeezing, heavy, or burning sensation
Precipitated by exertion
Promptly (within 2–3 min) relieved by nitroglycerin
Lasting minutes (typically 5–15 min; longer with acute infarction)
Atypical
Pain described as sharp or stabbing
Fleeting (lasting seconds) or prolonged (>24 h)
Unrelated to exercise
Not relieved by rest or nitroglycerin
Positional or related to respiration ("pleuritic")
Characterized by palpitations without chest pain
Well localized to a specific point

TABLE 131.3. Characteristics of Chest Pain Typical and Atypical for Ischemic Heart Disease

Patients with IHD, usually the elderly or those who also have diabetes mellitus or hypertension, may present with symptoms other than chest pain during acute ischemia. Such patients may complain of dyspnea, early fatigue, or declining exercise tolerance, symptoms that are caused by diastolic myocardial dysfunction. Decreased ventricular compliance leads to an increase in left ventricular (LV) end-diastolic pressure and pulmonary artery pressure, resulting in an increase in pulmonary interstitial fluid.

Patients with a history of chest pain or with known medically controlled angina pectoris may present with new symptoms, such as chest pain at rest, chest pain associated with previously tolerated levels of exertion, chest pain unrelieved by a previously effective dose of a nitrate preparation, or chest pain of increasing severity, duration, or frequency. These patients should be considered to have unstable angina. Patients with typical exertional angina of less than 2 months' duration that is severe or frequent (three or more episodes per day) should also be considered to have unstable angina.³¹

Coronary artery vasospasm may produce symptoms that are atypical for classic angina pectoris. Episodes of chest pain or discomfort may occur at rest, pain may persist longer than is common for typical angina, and symptoms more commonly occur during the early morning. Such patients may also relate no risk factors for IHD.

The symptoms of an acute MI may not be distinguishable from those of a severe stable anginal episode or of unstable angina, although patients with acute MI usually have chest pain of typical anginal quality for at least 30 minutes. This consideration has served as a major entry criterion in studies of the efficacy of thrombolytic agents in acute MI.

Based on a number of epidemiologic studies, major and minor risk factors for coronary artery disease have been defined. Major risk factors include family history (MI in a first-degree relative of age less than 55 years), smoking, hypertension, hypercholesterolemia, diabetes mellitus, and male sex.

Physical Examination

Most patients with chest pain caused by IHD have one or more abnormal physical findings, but these are not specific for IHD and may occur in patients with valvular or congenital heart disease, or cardiomyopathy. If the finding of an S₄ is excluded, about 25% of patients with symptomatic IHD have a normal physical examination.

Common physical findings during myocardial ischemia are noted in Table 131.4 with their respective pathophysiologic explanations. The clinician should also seek evidence of risk factors for IHD, for example, hypercholesterolemia (xanthomas and arcus senilis) and hypertension (elevated arterial blood pressure and funduscopic changes).

Physical Sign	Underlying Pathophysiology
Soft S ₁	Decreased LV dp/dt or first-degree AV block
Paradoxically split S ₂	Prolonged LV ejection time
S ₃ and/or S ₄	Decreased LV compliance
Mitral regurgitation	Papillary muscle ischemia
Palpable precordial systolic bulge	Anterior or lateral dyskinesis
Bibasilar rales	Increased preload

LV, left ventricular; dp/dt, rate of pressure rise; AV, atrioventricular.

TABLE 131.4. Physical Signs That Occur during Ischemia

DIFFERENTIAL DIAGNOSIS

A detailed discussion of the differential diagnosis of chest pain is included elsewhere in this volume. Diseases that are life-threatening and which may be confused with IHD include aortic dissection, pulmonary thromboembolism, pneumothorax, and esophageal rupture. Pneumonia, mitral valve prolapse, pericarditis, reflux esophagitis, esophageal spasm, peptic ulcer disease, and chest wall pain should also be included in the differential diagnosis. Particular attention to the character of the pain, precipitating factors, associated symptoms, and the physical examination usually allows the clinician to rule out a number of these other causes for chest pain.

EMERGENCY DEPARTMENT EVALUATION

The emergency department evaluation, management, and triage of patients suspected of having chest pain caused by myocardial ischemia have changed dramatically in the past decade. These changes are the result of cost-containment concerns as well as the demonstration that early administration of thrombolytic agents in the setting of acute MI significantly decreases mortality.^{5,27,35}

Annually, about 1.5 million patients are hospitalized in CCUs in the United States for suspected acute MI. Only about 30% of these patients subsequently have an acute MI diagnosed by conventional standards during hospitalization. Large-scale studies have shown that emergency department chest pain units (CPUs) can quickly identify and stratify patients with chest pain of suspected ischemic origin into low- and high-risk groups in an effort to more effectively use the resources uniquely available in the CCU setting.³⁵ Diagnostic efforts in the emergency department should be directed toward *ruling in* acute IHD, not just ruling out acute MI. In

nearly all instances, patients with suspected acute IHD, not just those with acute infarction, require hospitalization.

Acute transmural MI is caused by complete occlusion of the infarct-related coronary artery by thrombus. Numerous large-scale, multicenter trials have demonstrated that dissolution of the thrombus by intravenous administration of thrombolytic agents and early reperfusion of the occluded coronary artery can preserve ventricular function and reduce mortality from acute MI by nearly 30%. This beneficial effect depends on the time from onset of symptoms to reperfusion. ^{5,11,14,34} Diagnostic techniques for the early recognition of acute MI in patients who are likely to benefit from thrombolytic therapy are an active area of investigation. ²⁸

Electrocardiography

The electrocardiogram (ECG) and clinical history are the major screening methods available in most emergency departments when acute IHD is suspected. It has been stated that the emergency department ECG is often “normal” in patients subsequently diagnosed as having acute MI. Recent data indicate that the admission ECG is rarely normal but that nonspecific findings are frequent in this group of patients.

The early ECG signs of MI are ST-segment and T-wave changes that may also be seen with transient reversible ischemia or in patients with an established diagnosis of coronary artery disease. ST-segment elevation of more than 1 mm (0.1 mV) in two contiguous limb leads or 2 or more mm in two contiguous precordial leads is reported in the setting of acute transmural (Q-wave) MI. ST-segment elevation is seen in approximately 40% to 50% of patients with chest pain and acute MI at the time of initial evaluation. This population of patients is most likely to benefit from early administration of thrombolytic agents.

ST-segment depression of a similar degree (greater than or equal to 1 mm) or T-wave inversion is most commonly seen in nontransmural (non-Q-wave) infarction. Approximately 75% of patients with non-Q-wave infarction present with ST-segment depression. As a corollary observation, about one-third of patients with chest pain who have ST-segment depression or T-wave inversion subsequently evolve a non-Q-wave infarction.

ST-segment and T-wave changes are not always due to acute IHD. Common nonischemic causes for ST and T-wave changes suggestive of acute IHD are listed in [Table 131.5](#). Although the presence of new nonspecific ECG changes increases the likelihood that chest pain is due to myocardial ischemia, the predictive value of such a finding is only about 50%.

Left bundle-branch block
Left ventricular hypertrophy
Pericarditis
Paced ventricular rhythm
Hypothermia (Osborne J waves)
Hyperkalemia
Drug-induced (e.g., tricyclic antidepressants)
Left ventricular aneurysm

TABLE 131.5. Nonischemic Causes of Precordial ST-Segment Elevation

Nonconventional surface ECG recordings are of value in some patients with suspected acute MI. The right coronary artery supplies the inferior wall of the LV as well as the right ventricle (RV) in 90% of patients. In the setting of inferior MI, a right precordial electrogram should be recorded to detect RV infarction. The right precordial electrogram is obtained by placing the V leads over the anterior right chest in a pattern that is the mirror image of the standard left-sided placement. RV infarction occurs in about 60% of patients who suffer an inferior MI and is detected by ST-segment elevation of greater than 1 mm in lead V_{3R} or V_{4R}, or both. Although RV infarction commonly accompanies infarction of the inferior wall of the LV, RV contractile dysfunction becomes hemodynamically significant in only about 10% of patients. Patients with hemodynamically significant RV infarction typically present with arterial hypotension and jugular venous distention, but clear lung fields. RV involvement with inferior infarction is associated with a greater 1-year mortality than inferior wall infarction alone.

The optimal time interval at which to perform a repeated emergency department ECG in patients with initial nondiagnostic findings has not been determined. Repeated ECGs are most commonly performed in patients who experience recurrent chest pain during emergency department observation or in those who have received a thrombolytic agent and are being monitored for ST-segment changes suggestive of reperfusion.

Chest Radiography

The most common chest film abnormality in patients with IHD is cardiomegaly, usually associated with prior infarction or chronic arterial hypertension. Additional radiographic signs of LV dysfunction may also be found (e.g., pulmonary venous hypertension, Kerley B lines, and chronic pleural effusions).

The primary value of the chest radiograph in the evaluation of the patient with chest pain and suspected IHD is in the detection of other causes of chest pain (e.g., pneumothorax, pneumonia, or a widened mediastinum suggesting aortic dissection).

Biochemical Markers

After the clinical history and 12-lead ECG, the third tool readily available to assist in the diagnosis of an acute ischemic cardiac event is the serial measurement of enzymes and proteins released into the blood during myocardial ischemia. ⁸ When myocytes are damaged, there is loss of cell membrane integrity, and these macromolecules diffuse into the interstitium and subsequently into the intravascular space and lymphatics. Their patterns of appearance in blood depends on the intracellular location, molecular weight (heavier molecules diffuse more slowly), local blood and lymph flow, and rate of elimination from the blood. The enzyme creatine kinase (CK), its myocardial subunit (CK-MB), and the proteins troponin I and T are the most readily available and most commonly used biochemical markers of cardiac ischemia. CK is typically reported as total enzyme activity (units per liter) and CK-MB as a concentration (CK-MB mass, nanograms per milliliter) or as a percentage of total CK (CK-MB activity). The former measurement of CK-MB is now available as a microparticle enzyme immunoassay based on monoclonal antibody technology. It is analytically and clinically more sensitive than the CK-MB percentage activity measured by electrophoresis. Elevations above the reference range or normal value for total CK and CK-MB mass are not specific for myocardial injury. CK and CK-MB are also present in skeletal muscle, and elevations may be seen after vigorous exercise, rhabdomyolysis, skeletal muscle trauma, dermatomyositis or polymyositis, renal failure, and cardiac contusion. Interpretation of total CK and CK-MB mass values must take this nonspecificity into consideration. Elevations of total CK and CK-MB mass are detectable 4 to 6 hours after acute infarction. Peak CK-MB mass is typically observed 12 to 18 hours after ischemia, while the peak of total CK occurs slightly later (12 to 24 hours). Both measurements return to normal values 24 to 36 hours after the ischemic event; a secondary rise suggests reinfarction. Time to peak levels of total CK and CK-MB mass vary, depending on the extent of myocardial injury. Peaks generally occur earlier with non-Q-wave or subendocardial infarction and later with Q-wave or transmural infarction.

The troponins (troponin [Tn] I and T) are proteins that regulate calcium-dependent interactions between myosin and actin. The cardiac troponins (cTnI, cTnT) are highly specific for myocardial tissue and are immunologically distinct from the skeletal muscle troponins. Due to this specificity, the concomitant use of a troponin measurement and CK-MB mass assists in differentiating myocardial from skeletal muscle injury in the presence of an elevated CK-MB measurement. Elevated cardiac Tn levels are detectable in serum within 4 to 6 hours following acute cardiac ischemia, reach peak concentrations in approximately 12 hours, and remain elevated after an ischemic event for 3 to 10 days. This temporal pattern allows detection of an acute cardiac event days after it has occurred and should replace lactate dehydrogenase (LDH) isoenzyme determinations for the diagnosis of “remote” acute myocardial injury. Due to its lower molecular weight, TnT appears earlier in the plasma than TnI. This advantage may be offset by the fact that TnT can be artificially elevated in the setting of renal failure.

At present, there is an indeterminate range of Tn values (typically 0.4 to 2.0 ng/mL) that are not normal yet are below the levels accepted for the diagnosis of acute MI. Such values may be seen in the clinical settings of unstable angina (presumably due to “microinfarction”), chronic congestive heart failure, and myocarditis, and

after cardiac surgery.

A single measurement of total CK, CK-MB mass, and Tn has a low sensitivity (30% to 40%) in ruling out acute MI, despite a specificity of 80% to 99%. Because of this low sensitivity, single normal values cannot be relied on to eliminate acute infarction as a diagnostic possibility in a patient with chest pain. Measurements should be performed serially, usually at 3- to 6-hour intervals for 12 to 18 hours. The reported sensitivities, specificities, and positive and negative predictive values for the various biochemical markers vary considerably in the literature ([Table 131.6](#)).⁸ This variation is due to the reported timing of blood sampling (from onset of symptoms or from time of emergency department arrival), the use of one marker or a panel of markers, and the populations studied (e.g., patients with diagnostic vs. nondiagnostic ECGs). In general, sensitivity increases over this time period (0 to 6 hours), while specificity remains relatively constant (greater than 90%). Within 8 to 10 hours after the ischemic event, the sensitivity of CK-MB mass and the troponins is approximately 90%.³⁶

	Myoglobin (%)	CK Total	CK-MB			Troponin I (%)
			CK-MB Mass (%)	Isoforms (%)	Troponin T (%)	
Sensitivity	50-100	NR	15-45	90-95	50-80	6-45
Specificity	75-95	NR	90-100	95-100	75-95	90-100

NR, not reported.

TABLE 131.6. Sensitivity and Specificity of Biochemical Markers of Ischemia at 0 to 6 Hours

Other biochemical markers for acute MI may facilitate the earlier diagnosis of acute infarction, particularly in the patient with a nondiagnostic ECG. Myoglobin is released from the myocardium within 2 to 4 hours of the onset of ischemia and appears earlier in the plasma than CK-MB. Serial measurements of myoglobin using newer rapid assays have been shown to be 100% sensitive, but with a specificity of approximately 80%, in detecting acute MI within 6 hours of symptom onset. Similarly, measurement of CK-MB isoforms (MB1 and MB2) has a sensitivity and specificity of greater than 90% of detecting acute MI within 6 hours of onset of symptoms. These latter markers are currently not widely used.

Noninvasive Assessment of Myocardial Perfusion and Cardiac Function in the Emergency Department

Patients who present with chest pain suggestive of acute cardiac ischemia, a nondiagnostic ECG or an ECG demonstrating “nonspecific” ST-segment or T-wave changes, and normal total CK, CK-MB, and Tn on serial measurements present a diagnostic problem. This patient population is the one most likely to have acute MI and unstable angina ruled out after hospital admission to a CCU or intensive care unit, at a cost of billions of dollars annually. These patients are also those most likely to benefit from extended observation in a CPU. The CPU has been shown to be a cost-effective alternative to hospital admission for these patients and to result in a decrease in the incidence of “missed” MI. Standard treadmill exercise stress testing (EST), myocardial scintigraphy at rest and during exercise, and stress echocardiography are standard diagnostic tests performed in patients with suspected coronary artery disease. The sensitivities, specificities, and positive and negative predictive values of these tests have been defined largely in the population of patients with a moderate-to-high probability of coronary artery disease ([Table 131.7](#)). These tests are now being applied to the broader group of patients who present to the emergency department with a chief complaint of chest pain. The diagnostic accuracy of these tests in this population has not been well established and is likely to be different from those with a greater probability of having significant coronary artery disease due to selection criteria or bias. It is likely that these tests will be more useful in risk stratification than in diagnosis.

	EST (%)	2D-Echo (%)	Nuclear Imaging (%)
Sensitivity	67-69	83-87	70-94
Specificity	79-78	74-80	43-97

EST, treadmill exercise stress test.
2D-echo includes exercise, dobutamine, and dipyridamole studies.
Imaging includes thallium and sestamibi.
Adapted from Garber and Solomon¹¹ and Kuntz et al.²²

TABLE 131.7. Reported Sensitivity and Specificity of Noninvasive Diagnostic Tests for Coronary Artery Disease (CAD) in Patients with a High Pretest Probability of CAD

Acute myocardial ischemia depletes adenosine triphosphate stores, resulting in ventricular contractile dysfunction and ventricular wall motion abnormalities that may occur in the absence of diagnostic ECG changes. Two-dimensional echocardiography with the patient at rest is sensitive in detecting regional wall motion abnormalities that accompany acute ischemia, and has been used in the screening of patients with chest pain and suspected acute ischemia. However, echocardiography cannot reliably differentiate prior infarction (with myocardial scarring) from a new ischemic event. The sensitivity and specificity of the test appear to depend on whether the test is performed during chest pain or after its resolution. Based on limited studies, it is estimated that the sensitivity of standard echocardiography in the emergency department for acute cardiac ischemia or infarction is approximately 50% to 90%, with a specificity of 50% to 100%.^{28,35}

Technetium-99m-labeled sestamibi is a radionuclide agent that is taken up by the myocardium in proportion to regional blood flow and is therefore capable of demonstrating myocardial perfusion defects. With ECG-gating, the technique can also detect wall motion abnormalities. Limited studies indicate that this method of perfusion imaging is greater than 90% sensitive for detecting coronary artery disease in an emergency department population, with a specificity of approximately 70%. The accuracy of the test does not appear to be affected by the presence or absence of chest pain at the time of imaging.³⁵

Standard treadmill EST has also been used for evaluation and risk stratification in this patient population. EST can be safely performed, requires less technical expertise than does echocardiography, and is less expensive than radionuclide imaging. Based on limited studies, EST in the emergency department assessment of chest pain has a sensitivity ranging from 29% to 90% for detecting coronary artery disease, with a specificity of 50% to 99%.^{16e,35a} As clinical experience with EST in the emergency department increases, it is likely that the reported range of sensitivity and specificity will narrow.

EMERGENCY DEPARTMENT MANAGEMENT

The initial management of all patients with chest pain and suspected acute IHD should include administration of low-flow oxygen, establishment of vascular access, and continuous cardiac rhythm monitoring combined with frequent blood pressure determinations. Continuous pulse oximetry should also be employed, if available.

Interventions in the Patient with Chest Pain and Suspected Unstable Angina Pectoris or Non-Q-Wave Infarction

Unstable angina is generally defined as a clinical syndrome falling between stable angina and acute MI. Typical presentations of unstable angina are presented in [Table 131.8](#). Clinical features usually include a history of typical chest pain or a history of stable angina or MI and two or more risk factors for coronary artery disease.

The ECG may be normal, nonspecific (ST-segment depression, 0.05 mm; T-wave flattening or inversion of less than 1 mm in leads with dominant R waves), or highly suggestive (ST-segment depression greater than or equal to 1 mm or marked symmetrical T-wave inversion in multiple leads) of ischemia. Therapeutic interventions in this clinical setting are directed toward decreasing myocardial oxygen demand and stabilizing thrombogenic atherosclerotic plaques. ^{2,31}

Angina at rest within 1 wk of presentation
New-onset angina of Canadian Cardiovascular Society Classification (CCSC) class III (pain when walking < two blocks or climbing < one flight of stairs) or IV (inability to carry on any physical activity without discomfort) within 2 months of presentation
Angina increasing in CCSC class to at least class III or IV
Non-Q-wave MI
Postinfarction angina (>24 h after acute MI)

Adapted from Braunwald et al.⁷

TABLE 131.8. Clinical Presentations of Unstable Angina

Nitroglycerin

Sublingual nitroglycerin decreases myocardial oxygen demand by decreasing ventricular preload, improves myocardial perfusion by dilating the coronary vascular bed, and has antiplatelet properties. This combination of pharmacologic effects often results in relief of chest pain. The usual starting dose is 0.3 to 0.4 mg of nitroglycerin sublingually via a tablet or spray. If chest pain persists, this dose may be repeated every 5 minutes if the systolic blood pressure remains greater than 100 mm Hg. If chest pain persists after three to five sublingual doses, the administration of intravenous nitroglycerin should be considered (50 mg of nitroglycerin in 250 mL of dextrose 5% in water). The initial infusion rate is 10 to 20 $\mu\text{g}/\text{min}$ and can be increased in increments of 5 to 10 $\mu\text{g}/\text{min}$ at 5- to 10-minute intervals until chest discomfort resolves or mean arterial pressure decreases by 10%. Most patients respond to infusion rates of 50 to 200 $\mu\text{g}/\text{min}$. At low doses, nitroglycerin acts principally as a venous and coronary vasodilator. At high doses, it acts as an arterial vasodilator as well, thereby affecting an additional component of myocardial oxygen demand.

The major complication of nitrate therapy, whether sublingual or intravenous, is hypotension. This is most likely to occur in patients who are hypovolemic at the time of emergency department presentation or in those who have suffered an RV infarction complicating inferior wall infarction. If hypotension occurs, nitrate therapy should be discontinued and intravenous normal saline administered, with careful monitoring of vital signs and lung sounds. Hemodynamically significant bradyarrhythmias have been reported during nitrate therapy; these should be treated with atropine.

Morphine Sulfate

Intravenous morphine may be administered if chest pain is not relieved with sublingual or intravenous nitroglycerin. The usual dose is 2 to 4 mg administered every 5 to 30 minutes if systolic blood pressure remains greater than 100 mm Hg.¹ Morphine may decrease venous tone and decrease ventricular preload, but the required dose for these desired pharmacologic effects may produce respiratory depression. In addition, morphine may relieve pain but not necessarily reverse or modify the pathophysiologic processes involved in acute myocardial ischemia. Other potential complications of morphine therapy are hypotension and bradycardia, which may be treated with normal saline and atropine, respectively.

Antiplatelet and Antithrombin Agents

Aspirin prevents platelet aggregation and platelet-induced coronary vasoconstriction via acetylation of platelet cyclooxygenase and prevention of the formation of thromboxane A_2 . All patients with suspected acute ischemic heart disease who have no contraindications to the use of aspirin (such as allergy or active gastrointestinal hemorrhage) should receive a dose of 80 to 325 mg as soon as possible after the onset of symptoms.¹¹ Concomitant aspirin and heparin therapy have been shown to be more effective than either agent alone.²⁴

Unfractionated heparin is a heterogeneous mixture of polysaccharides, which activates antithrombin III, which in turn inhibits thrombin and coagulation factors X to XII. It also inhibits platelet aggregation, platelet vascular adhesion, and leukocyte chemotaxis.¹¹ Heparin is often administered intravenously as a 5,000-U bolus, followed by an infusion of 1,000 U/h. The infusion rate is adjusted based on periodic measurement of the partial thromboplastin time (goal, 45 to 75 seconds).

Low-molecular-weight heparin can also be used. It does not require monitoring of coagulation times, is associated with fewer clinically significant bleeding complications, and may be more effective than unfractionated heparin in preventing infarction, recurrent pain, and the need for early revascularization.^{10,19} Similarly, the glycoprotein IIb/IIIa inhibitors, although not extensively evaluated in the emergency department, may offer benefit in preventing recurrent symptoms or acute infarction in this patient group.^{16,33}

Beta Blockers

Beta blockers reduce myocardial oxygen demand by decreasing ventricular contractility (dP/dt), heart rate, and afterload (blood pressure). These agents also have antiarrhythmic properties (class III antiarrhythmics) and may counteract the effects of catecholamines of the myocardium. These agents should be administered in the setting of suspected unstable angina or acute MI if contraindications to their use are not present.² (Dosing and contraindications are discussed later.)

Patients with chest pain suggestive of acute cardiac ischemia who have ST-segment depression or T-wave inversions on the ECG are usually treated as if they are having a non-Q-wave (subendocardial) infarction. This diagnosis is supported if the ECG findings are new or “dynamic” (change in depth or amplitude over time). These patients are treated the same as patients with unstable angina. Thrombolytic agents have not been shown to improve survival in this patient population.^{2,32}

Specific Interventions in Patients with Suspected Acute Transmural Myocardial Infarction (Q-Wave Infarction)

Acute MI is most commonly caused by abrupt thrombotic occlusion of a coronary artery at the site of a “thrombogenic” atheromatous plaque (i.e., one that is ulcerated or fissured).⁵ Clot dissolution using thrombolytic agents in acute MI is safe and effective. A number of large prospective, controlled clinical trials comparing an intravenous thrombolytic agent with placebo have shown significant reductions in mortality with minimal risk (25% to 30% mortality reduction when used early).^{5,11,34} Other trials^{10,24} have compared thrombolytic agents with and without other adjunctive interventions (e.g., aspirin, beta blockers). The latter studies have resulted in controversies regarding the thrombolytic agent of choice and the timing or method of administration. However, it is generally agreed that (1) the promptness of administration of a thrombolytic agent after the onset of symptoms is more important than the choice of agent and (2) adjunctive drugs add to the mortality reduction observed with thrombolysis alone.

The generally accepted ECG criteria for thrombolytic therapy are ST-segment elevation of more than 1 mm in two or more contiguous limb leads or greater than 2 mm of elevation in two or more contiguous precordial leads, either persisting after sublingual nitroglycerin administration. It is well recognized that left bundle-branch block (LBBB) may obscure the diagnosis of acute MI because of the secondary ST-segment and T-wave changes that accompany altered ventricular depolarization. Criteria have been reported to identify acute MI in the presence of an LBBB, but although generally highly specific, they are insensitive in making this diagnosis.^{29,30} Due to this problem with recognition of acute MI in the setting of LBBB (either old or new) and the high mortality encountered when LBBB develops during the course of acute infarction, thrombolytic administration is recommended in patients with a history suggestive of acute cardiac ischemia and LBBB, regardless of whether it is new or old.^{14,30}

large infarctions or a history of LV dysfunction appear to derive the most benefit from this intervention. The mechanism of benefit is related to the vasodilator and neurohumoral effects of these drugs. The ACE inhibitors appear to modify maladaptive ventricular remodeling, thereby decreasing LV volume, and to attenuate the effects of activation of the renin–angiotensin system during the early infarct period, and may improve collateral coronary flow. ¹ Although early use of these drugs (within 24 hours) is recommended, particularly in selected populations, they are rarely given in the emergency department.

Complications of Acute Ischemia or Infarction

Arrhythmias

Cardiac rhythm disturbances are common during unstable angina or acute infarction. ³ The most common arrhythmias are of ventricular origin. Premature ventricular contractions (PVCs) are noted in 80% to 100% of patients who experience an acute MI. Ventricular ectopy should be treated with intravenous lidocaine. One regimen consists of an initial bolus of 1 mg/kg followed by an infusion of 1 to 4 mg/min. The major side effect of lidocaine is neurotoxicity, typically manifested as altered mental status and seizures. In low cardiac output states, lidocaine metabolism is decreased, and usual therapeutic doses may be toxic. Thus, in this setting, the initial intravenous loading dose should be halved and the continuous infusion should be started at 1 mg/min.

Lidocaine should not be used prophylactically. Such use does not improve mortality and may actually contribute to the morbidity and mortality of acute MI. Indications for the use of lidocaine include frequent PVCs (more than 6 per minute), closely coupled PVCs (R-on-T phenomenon), multiform PVC, and nonsustained ventricular tachycardia.

Bradycardias or tachycardias that compromise systemic or myocardial perfusion require immediate therapy (see [Chapter 134](#) and [Chapter 135](#)).

Conduction Disturbances

Second- and third-degree AV block may occur during either inferior or anterior infarction. In the setting of inferior MI, these conduction disturbances are normally associated with an increase in vagal tone and are usually transient and responsive to atropine. The abrupt occurrence of complete heart block is rare. In anterior MI, high-degree AV block is due to ischemia of the conduction pathways, and complete heart block may occur abruptly. Bundle-branch blocks are usually associated with anterior infarction. The indications for temporary artificial pacing in the setting of acute ischemia are listed in [Table 131.12](#).

INDICATED
Mobitz II AVB
Complete AVB
New RBBB in anterior MI
RBBB plus LAFB
RBBB plus LPFB
LEBB plus first-degree AVB
Drug-resistant symptomatic bradycardia
NOT INDICATED
First-degree AVB
Wenckebach second-degree AVB
Old LBBB
Old RBBB
CONTROVERSIAL
New LBBB
New RBBB in inferior MI

AVB, atrioventricular block; LBBB, left bundle-branch block; RBBB, right bundle-branch block; LAFB, left anterior fascicular block; LPFB, left posterior fascicular block; MI, myocardial infarction.

TABLE 131.12. Indications for Temporary Pacing in Acute Myocardial Infarction

Cardiogenic Shock

LV pump failure begins to occur when approximately 40% of the ventricular muscle mass has been lost. Severe contractile dysfunction results and necessitates the use of a number of therapeutic interventions (see [Chapter 132](#)). Studies suggest that PTCA may improve both short- and long-term outcome; this intervention should be considered early in the course of management in selected patients. ⁴

DISPOSITION

All patients with suspected acute myocardial ischemic syndromes should be admitted to the hospital, typically to an intensive care unit or CCU. Recent studies have shown that a low-risk group of patients may be identified, based on clinical and ECG findings, that could be cared for in an intermediate care unit or a monitored short-term emergency department observation unit. ^{27,35}

When acute MI is suspected, the consulting cardiologist should be contacted as soon as possible to facilitate intervention therapy with intravenous thrombolytic or emergent PTCA, as indicated.

Patients in the acute phase of infarction or with unstable angina should not be transferred to another facility unless definitive care cannot be given at the institution where the initial evaluation is performed. In such an instance, transfer in an appropriately equipped vehicle is justified after initial treatment and stabilization. The transport team should include personnel trained in advanced cardiac life support. It has been demonstrated that patients having an acute MI can be safely transported to a referral center for thrombolytic or interventional therapy.

Patients discharged from the emergency department with a diagnosis of stable angina or atypical chest pain should be referred to a cardiologist for further evaluation (e.g., EST and ambulatory ECG monitoring).

COMMON PITFALLS

- Missed MI is the fourth most common cause of malpractice suits filed against emergency physicians, and it ranks first with respect to monetary awards.
- For patients in whom the diagnosis is uncertain, the threshold for admission should be low. Due to the limited diagnostic tools available in the emergency setting, only a minority of patients admitted to the hospital with suspected acute IHD (“rule out MI”) actually have an acute infarct.
- A single ECG or CK-MB determination cannot be used to rule out the diagnosis of acute MI.
- Comparison of a current ECG to a prior or baseline ECG should not be relied on to exclude acute IHD.
- If the patient meets appropriate criteria, reperfusion therapy should be administered as soon as possible. Every institution needs to address the issues of appropriate early triage of ambulatory patients with chest pain and rapid access to 12-lead electrocardiography.

CHAPTER 132

Cardiogenic Shock

Brian R. Tiffany and Robert C. Jorden

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Role of the Consultant](#)
[Indications for Admission](#)
[Transfer Considerations](#)
[Common Pitfalls](#)
[Chapter References](#)

The clinical definition of cardiogenic shock is hypotension with evidence of impaired perfusion in the setting of acute myocardial infarction (AMI). Specifically, a blood pressure less than 90 mm Hg (or a drop of more than 80 mm Hg in systolic pressure in a known hypertensive patient) with accompanying confusion; cold, moist skin; cyanosis; and oliguria defines the syndrome.^{7,22} Approximately 7.5% of all patients with AMI develop this complication, which, in historic series, carried a mortality of 80% to 90%.³ Today, despite diagnostic and therapeutic advances, cardiogenic shock remains the leading cause of death in AMI.⁷

A variety of other causes, such as myocardial contusion, myocarditis, and cardiomyopathy, can produce cardiogenic shock, but the majority of cases result from coronary atherosclerosis and AMI. Infarction can cause shock in several ways. Papillary muscle dysfunction or rupture can result in severe mitral insufficiency. An infarcted interventricular septum can rupture, resulting in a hemodynamically significant left-to-right shunt. Transmural infarction can cause rupture of the ventricular wall into the pericardium with cardiac tamponade. A right ventricular infarction can be extensive enough to impair left ventricular filling.

By far, the most common cause of cardiogenic shock, however, is extensive myocardial necrosis. When more than about 40% of the left ventricle is infarcted, the ability to maintain the systemic circulation is impaired.^{8,22} This amount of damage can result from a single massive infarction or from an acute infarction superimposed on a previous one. The compensatory mechanisms that normally act to prevent hypotension can worsen the situation. Specifically, catecholamine release produces tachycardia, vasoconstriction, and increased cardiac contractility, all of which increase the workload of the left ventricle and increase myocardial oxygen demand, potentially causing extension of the infarct and further compromising left ventricular function.

CLINICAL PRESENTATION

Often, the clinical presentation is straightforward: clinical shock associated with the characteristic pain and associated symptoms of ischemia. In some patients, however, the diagnosis may be obscured, as, for example, when the patient has an altered sensorium and cannot communicate effectively, or when chest pain is not severe or is overshadowed by other symptoms. Depending on the degree of decompensation, physical findings vary from minimal signs of shock to stupor, cyanosis, and florid pulmonary edema. Not only can signs and symptoms vary from patient to patient, but they can also rapidly deteriorate in a given patient. Hence, close observation and repeated examinations are needed whenever the diagnosis is suspected.

DIFFERENTIAL DIAGNOSIS

Massive pulmonary embolism complicated by hypotension should be considered in the differential diagnosis of cardiogenic shock, although the nature of the pain of pulmonary embolism is not commonly characteristic of ischemia. The presence of cyanosis and tachypnea could support either diagnosis, but the absence of auscultatory findings favors pulmonary embolism over a cardiac etiology. Arterial blood gas analysis is probably not helpful in distinguishing the two entities, but an electrocardiogram (ECG), a chest radiograph, and an echocardiogram may prove valuable.

Thoracic aortic dissection may be mistaken for cardiogenic shock under certain circumstances. Although hypertension is the rule with dissection, hypotension can occur if the dissection extends retrograde into the pericardial sac and causes tamponade. Rupture of the dissection into the chest or abdominal cavity also produces shock, but this complication is usually an abrupt, terminal event. Pulmonary edema is not often present with aortic dissection but can occur from aortic insufficiency induced by dissection of the aortic root and distortion of the annulus. A chest film and ECG should help to distinguish the two diagnoses; ultimately, an aortic angiogram or a transesophageal echocardiogram confirms or rules out dissection.

Esophageal perforation can cause many of the signs and symptoms of cardiogenic shock, including retrosternal chest pain, diaphoresis, and respiratory distress, but shock is not universally present. When shock does occur, it is due to septic complications, which can occur within hours but are usually more delayed in onset. Absence of pulmonary edema and the presence of a fever and precordial crunch favor esophageal perforation over cardiogenic shock. Pleural effusion with or without pneumothorax also supports the diagnosis.

Pericarditis complicated by effusion and tamponade can mimic cardiogenic shock. The more insidious course of pericarditis, the absence of pulmonary edema, and the typical ECG findings help to distinguish it from cardiogenic shock. An echocardiogram can establish or exclude the diagnosis.

Acute bacterial endocarditis complicated by severe mitral or aortic insufficiency is also a potential diagnosis. Fever, if present, and perhaps a more indolent course, support endocarditis over cardiogenic shock, but distinguishing between the two entities may be difficult. An echocardiogram showing valve vegetations can establish a diagnosis of endocarditis, but normal findings do not rule it out.

Other, less specific conditions should also be considered in the differential diagnosis. Shock of any etiology that results in coronary insufficiency and ischemic chest pain could be mistaken for cardiogenic shock. Similarly, noncardiogenic pulmonary edema with hypoxemia and secondary myocardial oxygen deprivation could suggest an early phase of cardiogenic shock before hemodynamic decompensation has occurred. A rapid response to treatment directed at the true underlying cause should distinguish these conditions from cardiogenic shock.

EMERGENCY DEPARTMENT EVALUATION

As in any critically ill patient, diagnostic evaluation of patients with cardiogenic shock is initiated during stabilization. Depending on the degree of decompensation on presentation, a variety of diagnostic investigations should be undertaken, but performing a detailed history and physical examination is an important first step. A history of pain consistent with myocardial ischemia should direct the physical examination toward findings that support a diagnosis of cardiogenic shock, such as pulmonary congestion, jugular venous distention, a mitral insufficiency murmur, decreased level of consciousness, and poorly perfused skin. The examination should be repeated frequently to detect deterioration.

Important studies to perform include an ECG (with a V_{4R} lead to detect right ventricular infarction), a portable chest radiograph, arterial blood gas analysis, and baseline complete blood count and electrolyte determination. Cardiac isoenzymes should be measured. The ECG can be helpful if it is diagnostic of an acute infarction, but it may show only a nonspecific pattern. The chest film may show early changes of congestive failure or a more fulminant picture of pulmonary edema. Cardiomegaly may or may not be present, depending on whether the patient has preexisting congestive heart failure or cardiomyopathy. Arterial blood gas values can help gauge the severity and progression of decompensation. Although they are not helpful in establishing a specific diagnosis, they can be invaluable in directing therapeutic interventions such as endotracheal intubation.

Bedside echocardiography is of enormous value in the evaluation of the shock patient.¹⁷ Identification of an akinetic or dyskinetic area of the left ventricle that corresponds to an area of ischemia or infarction on the ECG, although not specific, supports a diagnosis of cardiogenic shock. Conversely, normal results all but rule out acute transmural infarction and cardiogenic shock. The echocardiogram can also effectively diagnose surgically correctable causes of cardiogenic shock, such as

ruptured interventricular septum or ruptured papillary muscle.

EMERGENCY DEPARTMENT MANAGEMENT

The management of cardiogenic shock consists of three components: prevention, supportive care, and myocardial reperfusion. The basis for these measures is the fact that an area of infarction is not homogeneous. Rather, necrotic tissue is surrounded by and intermingled with ischemic yet potentially viable tissue. Preservation of this periinfarction zone can save enough myocardial function to prevent pump failure. Thus, interventions that favorably affect myocardial oxygen supply and demand should prove beneficial.

The most effective way to treat cardiogenic shock is to prevent it. Measures should be taken to minimize infarct size in all patients with acute infarction. Tachyarrhythmias, symptomatic bradycardia, and hypertension, conditions that increase myocardial oxygen consumption, should be aggressively treated. The routine use of beta blockers such as atenolol and metoprolol is of proven value. Large, well-controlled studies have documented the efficacy of beta blockers in limiting infarct size and improving survival.^{12,13} Even so, data from the National Registry of Myocardial Infarction suggest that a surprisingly low number of AMI patients receive beta blockers early in their treatment.¹⁶

Supportive care is geared toward maintaining oxygenation and vital organ perfusion. In the early stages, supplemental oxygen may be sufficient to accomplish the first goal. However, if the patient deteriorates and tires, active airway management may be necessary. The usual clinical and blood gas parameters are used to determine when intubation is indicated.

Maintaining an adequate blood pressure is far more complex. The measures normally used to restore pressure can adversely affect myocardial oxygen consumption, and thus worsen the underlying problem. To complicate matters further, emergency physicians do not usually have ready access to measurements of cardiac output and left heart pressures. As a result, the clinician must decide between administering empiric therapy that could be deleterious, taking the time to place a Swan-Ganz catheter, or transferring an unstable patient to an intensive care unit. The patient's condition, however, may force the issue and mandate immediate treatment without the benefit of hemodynamic measurements. Newer noninvasive modalities, such as measurement of cardiac output by thoracic electrical bioimpedance, may be of great value in making these decisions.²⁰

Under these circumstances, it is reasonable to attempt volume expansion by giving small boluses of normal saline solution. Some patients in cardiogenic shock have normal or low left ventricular end-diastolic pressures, and although most do not respond to volume expansion, it is nevertheless acceptable to initiate careful incremental saline infusions as a first step. If the patient is already in pulmonary edema, one can presume an elevated wedge pressure and avoid a fluid bolus.

If fluid challenge is ineffective, a vasopressor is used. Dobutamine, considered the drug of choice by many authorities, has the advantage of increasing cardiac output and lowering left ventricular filling pressure while not increasing the pulse rate or otherwise increasing oxygen demand. Dobutamine decreases vascular resistance, improving cardiac output without increasing blood pressure. This property is problematic at lower pressures, when coronary blood flow is jeopardized. If the blood pressure remains low despite adequate doses of dobutamine, dopamine is added to the regimen. Both vasopressors are titrated to the desired clinical effect. Amrinone and milrinone, bipyridine derivatives that cause vasodilation and have positive inotropic effects, have also been effective in improving cardiac output. Published experience with these drugs in cardiogenic shock to date is limited, however.

If a Swan-Ganz catheter and arterial line can be inserted, more precise management is possible. An optimal filling pressure of 18 to 24 cm H₂O should be achieved through volume expansion before considering vasopressors. Vasodilators such as intravenous nitroglycerin and nitroprusside can be added to decrease afterload, and thus left ventricular work and oxygen consumption. Extreme caution must be exercised when using these potent drugs because of their hypotensive effects. All hemodynamic parameters must be monitored continuously and drugs titrated carefully.

Furosemide and morphine may also be of help. The anxiolytic effect of morphine relieves apprehension and may help to reduce tachycardia. However, the preload and afterload reduction caused by morphine, although potentially helpful, may be detrimental. Similarly, furosemide may cause deterioration by reducing preload excessively through venodilatation and diuresis. Because of these hazards, it is probably wise to avoid these drugs unless left-sided heart pressures can be monitored.

For patients who remain hemodynamically unstable despite all of these interventions, insertion of an intraaortic balloon pump (IABP) can be considered. IABP supports the diastolic blood pressure, thus improving coronary perfusion, and it reduces afterload and therefore myocardial oxygen consumption. However, in spite of the widespread acceptance and use of this modality, only limited evidence supports its benefit in cardiogenic shock patients,¹ unless in conjunction with a revascularization strategy.¹⁸

Other circulatory assist devices, such as the Hemopump (a device placed by means of the femoral artery and threaded across the aortic valve into the left ventricle), percutaneous cardiopulmonary bypass, and various surgically implantable ventricular assist devices, have also been used as temporizing measures.¹⁹ Unfortunately, neither pharmacologic manipulation nor the use of these devices has lowered the mortality of AMI complicated by cardiogenic shock.⁹ Nevertheless, both interventions can be helpful or even essential in maintaining patients until more definitive treatment can be instituted.

Although data are equivocal, it appears that reperfusion of the infarct zone is the only therapy that improves survival.¹⁴ Toward that end, thrombolytic therapy has had disappointing results in patients who develop cardiogenic shock in the setting of AMI, showing no significant reduction in mortality.^{5,6,11} The reason appears to be a low rate (less than 50%) of reestablishing patency of the infarct-related vessel.⁵ The low reperfusion rate is probably related to the low perfusion pressure inherent in the shock state.⁶ Patients in whom thrombolysis is successful demonstrate a substantial reduction in mortality.

In contrast to thrombolysis, percutaneous transluminal coronary angioplasty (PTCA) has been more effective. Several studies have demonstrated a reperfusion rate of about 70% to 90% and a 6-month mortality rate in the range of 30% to 50% when the procedure is successful.^{2,11} This is a vast improvement over the 80% mortality rate for noninvasive management. A large-scale, randomized trial of PTCA and emergency coronary bypass grafting in cardiogenic shock is underway (the SHOCK trial).¹⁰

In summary, cardiogenic shock is a highly lethal condition, with an 80% mortality rate that is usually unaffected by supportive measures. Reestablishing perfusion to the infarcted area is the only intervention with demonstrated efficacy. The role of emergency physicians in salvaging these critically ill patients lies in early recognition, prompt application of stabilizing and supportive measures, administration of thrombolytic agents where appropriate, and early involvement of a cardiologist to consider revascularization strategies.

DISPOSITION

Role of the Consultant

The role of the cardiology consultant in patients with cardiogenic shock is crucial. Difficult decisions must be made quickly about additional resuscitative efforts, invasive monitoring, and the feasibility of coronary angiography and reperfusion. Therefore, once the diagnosis is seriously considered, consultation should be requested immediately.

Indications for Admission

There is no difficulty in deciding whether admission is needed for these patients, but determining disposition within the hospital is more challenging. Depending on the resources and policies of the institution, the patient should go either to the cardiac care unit or directly to the cardiac catheterization laboratory. Regardless of the destination, transport must be expeditious, and the patient must be monitored and accompanied by appropriate resuscitative equipment and capable physician personnel.

Transfer Considerations

Transfer of patients from one institution to another is hazardous and doomed to failure unless some hemodynamic stability has been achieved. Ideally, transport should be done by a specialized team, including physicians capable of transporting and inserting a balloon pump and of instituting and maintaining supportive care and invasive monitoring. Transport under less favorable conditions carries a significant risk of a less favorable outcome.

COMMON PITFALLS

- Failing to diagnose cardiogenic shock promptly in its early stages is probably the most significant management error. Not recognizing the diagnosis until decompensation is severe may preclude any meaningful intervention, due to irreversible deterioration in cardiac function.
- Failing to recognize right ventricular infarction or surgically correctable causes of cardiogenic shock is also a serious error. The former condition requires more vigorous volume expansion; the latter ones require surgery. Because the prognoses for both entities, however, are better than for shock related to extensive left ventricular necrosis, patient survival is seriously affected if these conditions are not accurately diagnosed.
- Liberal use of morphine and diuretics, as might be implemented for patients with pulmonary edema, may produce untoward hemodynamic effects. Morphine can also cause respiratory depression or a deterioration in mental status, which makes aspiration more likely. These drugs should be used cautiously, preferably while monitoring left-sided heart pressures and cardiac output.
- Applying medical antishock trousers (MAST trousers) to treat cardiogenic shock should be avoided. MAST trousers cause an increase in afterload that further taxes the compromised left ventricle.

CONGESTIVE HEART FAILURE (LEFT HEART FAILURE)

Congestive heart failure (CHF) is not a single disease but a symptom complex. The pathophysiologic definition of heart failure is “that condition or state in which an abnormality of cardiac function is responsible for failure of the heart to pump blood at a rate commensurate to meet the requirements of the metabolizing tissues.” The clinical definition is broader in its scope; that is, it is “a condition in which ventricular dysfunction is accompanied by reduced exercise capacity.” The latter definition incorporates less severe forms of ventricular dysfunction that are manifest only during exercise.²²

The incidence and prevalence of CHF have increased in recent years, despite an overall decrease in cardiovascular mortality in the United States. It has been estimated that more than 3 million Americans have CHF. Approximately 30% to 40% of patients with CHF are hospitalized every year, and CHF is the leading diagnostic-related group among hospitalized patients over the age of 65.⁹ CHF is associated with increasing age, and these numbers are likely to increase as the number of elderly persons in the United States continues to increase. Prognosis after onset of clinical symptoms and signs of CHF is poor.¹⁹ When all New York Heart Association (NYHA) classes are considered, the 5-year mortality rate after diagnosis is approximately 60% in men and 45% in women. However, the 1-year mortality rate for NYHA class IV is about 50%. The cause of death may be the result of disease progression or may be the sudden result of ventricular arrhythmias. In the overwhelming majority of these studies, CHF was attributed to left heart failure (LHF). In this section, only LHF is discussed.

The symptoms and signs of LHF are produced by a variety of primary heart diseases as well as systemic diseases that alter left ventricular (LV) anatomy and result in mechanical dysfunction, myocardial contractile failure, or impaired LV filling. The causes of LHF are listed in [Table 133.1](#). Systolic dysfunction, characterized by a low ejection fraction, is the most common form of CHF. Diastolic dysfunction with impaired LV filling has been increasingly recognized as a cause of LHF and is present in 30% to 40% of patients with CHF.²¹

CONTRACTILE DYSFUNCTION
Ischemic heart disease
Idiopathic cardiomyopathy
Myocarditis
SYSTEMIC PRESSURE OVERLOAD
Aortic stenosis
Systemic hypertension
SYSTEMIC VOLUME OVERLOAD
Aortic regurgitation
Mitral regurgitation
RESTRICTED DIASTOLIC FILLING
Mitral stenosis
Left atrial myxoma
Hypertrophic cardiomyopathy
HIGH-OUTPUT STATES
Hypothyroidism
Anemia
Arteriovenous fistula

TABLE 133.1. Functional Classification and Causes of Left Heart Failure

With the advent of early and effective therapy for hypertension in the 1970s, ischemic heart disease (IHD) has become the major cause of acute or chronic LHF in the United States. LHF caused by IHD may have multiple causes, such as loss of ventricular muscle, intermittent ischemia and contractile dysfunction (e.g., papillary muscle dysfunction), ventricular aneurysm formation with paradoxical expansion and increased wall stress, and decreased ventricular diastolic compliance. The cardiomyopathies (dilated, hypertrophic, and restrictive) of both primary (idiopathic) and secondary origin are also becoming an increasingly more frequent cause of heart failure, especially among younger patients.

A decrease in effective cardiac output (CO) at normal LV filling pressures is the hemodynamic hallmark of LHF. When CO falls because of such factors as loss of muscle and obstruction to outflow, there are three principal compensatory mechanisms that maintain systemic perfusion: (1) the Frank-Starling principal relating preload to contractile force or CO, (2) ventricular hypertrophy, and (3) central neural and peripheral neurohumoral responses to maintain systemic perfusion pressure and effective intravascular volume.⁷

An increase in systemic vascular resistance and maintenance of effective intravascular volume are accomplished by means of complex neurohumoral compensatory mechanisms. Hormonal changes that occur during LHF are summarized in [Table 133.2](#). Based on measurements of neurohumoral agents in LHF, hemodynamic profiles of LHF patients, and the response to pharmacologic agents that attenuate neurohumoral responses to a decrease in CO, it has become evident that compensatory mechanisms may be maladaptive; that is, reflex responses further impede ejection of blood from the compromised ventricle. Manipulating the compensatory response to a fall in CO (e.g., use of vasodilators and angiotensin converting enzyme inhibitors) has become a therapeutic focus in the management of chronic CHF.^{4,5}

Increased circulating catecholamines
 Increased angiotensin
 Increased aldosterone
 Increased arginine vasopressin
 Increased atrial natriuretic factor
 Increased prostaglandin E2 and prostacyclin

TABLE 133.2. Neuroendocrine Changes in Left Heart Failure

CLINICAL PRESENTATION

The typical patient with LHF presents with dyspnea at rest, decreased exercise tolerance, shortness of breath when supine (orthopnea or paroxysmal nocturnal dyspnea), and ankle swelling and weight gain.¹¹ In acute LHF (acute pulmonary edema), shortness of breath is the major presenting symptom. Clinical findings usually include (1) rales, caused by pulmonary venous hypertension and extravasation of fluid into the pulmonary interstitium and alveoli; (2) a third heart sound, caused by decreased LV compliance; (3) a fourth heart sound, caused by forceful atrial contraction to overcome the rise in LV diastolic pressure (not heard in atrial fibrillation); (4) peripheral edema, the consequence of renal sodium and water retention initiated by hormonal responses; and (5) jugular venous distention (JVD), owing to pulmonary venous hypertension, restricted right ventricular (RV) output, and fluid retention.¹⁸

No single feature or physical examination finding reliably distinguishes patients with CHF due to systolic dysfunction (decreased ejection fraction, typically less than 40%) from those with diastolic dysfunction (increased left heart filling pressures, pulmonary capillary wedge pressure [PCWP] typically greater than 18 mm Hg). Patients with systolic dysfunction often have increased filling pressures due to a decrease in compliance as well as a decrease in ejection fraction. In addition, many of the clinical symptoms of LHF (e.g., exercise intolerance and pedal edema) may be caused by isolated right heart failure, primary pulmonary disease, obesity, or poor physical conditioning.³

Four highly specific clinical findings suggesting a cardiac cause for dyspnea and pedal edema are pulsus alternans; reduced proportional blood pressure (BP) (defined as [systolic BP – diastolic BP]/systolic BP less than 0.25); abnormal BP response to the Valsalva maneuver; and jugular venous distention at rest or during the hepatojugular reflex test.^{2,21}

DIFFERENTIAL DIAGNOSIS

Common causes of LHF are listed in [Table 133.1](#). Constrictive pericarditis and cardiac tamponade are also characterized by impaired diastolic filling and can mimic LHF.

Although systemic hypertension and coronary artery disease are the major causes of LHF in the United States, valvular heart disease (see [Chapter 137](#)), especially aortic stenosis and mitral regurgitation, should be considered in the elderly and immigrant populations.

Cardiomyopathies are becoming an increasingly recognized cause of LHF. Patients with a dilated or restrictive cardiomyopathy most commonly present with progressive symptoms. Cardiomegaly is noted on chest radiograph, and electrocardiogram (ECG) findings of four-chamber enlargement and intraventricular conduction defects are commonly seen. Only about 10% of patients with dilated cardiomyopathy have an underlying cause determined after extensive evaluation. Most patients are classified as idiopathic; secondary causes of dilated cardiomyopathy are listed in [Table 133.3](#). Common causes for restrictive cardiomyopathy are listed in [Table 133.4](#); this entity is also commonly idiopathic in origin.¹⁷ In both dilated and restrictive cardiomyopathy, definitive diagnosis typically requires an extensive evaluation, which often includes endomyocardial biopsy. These distinctions are unimportant in acute management, however, if the patient's presentation is that of acute LHF.

Idiopathic
 Connective tissue disease (e.g., systemic lupus erythematosus, scleroderma)
 Neuromuscular disorders (muscular dystrophies)
 Infection (viral, parasitic, bacterial)
 Metabolic (e.g., beriberi, hyperthyroidism or hypothyroidism)
 Toxic (alcohol, daunorubicin, cocaine)
 Miscellaneous (postpartum)

TABLE 133.3. Causes of Dilated Cardiomyopathy

Idiopathic
 Amyloidosis
 Hemochromatosis
 Sarcoidosis
 Scleroderma
 Metastatic malignancy
 Hypereosinophilic syndrome

TABLE 133.4. Causes of Restrictive Cardiomyopathy

Patients with hypertrophic cardiomyopathy rarely present with LHF. Dyspnea on exertion, chest pain that may be anginal in character, palpitations, and syncope are the major symptoms and are caused by a combination of diastolic dysfunction, functional outflow obstruction, and a propensity to dysrhythmias. If LHF does occur, it is most commonly the result of a tachyarrhythmia.

Myocarditis is an uncommon cause for LHF but should be considered in the patient who presents with subacute signs and symptoms of heart failure and who relates a history of an antecedent “viral infection.” Coxsackievirus A and B are most commonly implicated. These patients often have elevated serum creatine kinase MB levels

because of active myocardial inflammation and necrosis.¹⁵

Common causes of sudden worsening of symptoms in patients with chronic stable CHF are listed in [Table 133.5](#).

Lack of medications (noncompliance)
Dietary indiscretion (increased sodium intake)
Arrhythmias
Myocardial infarction
Infection (increased metabolic demand)
Pulmonary embolism
Anemia
Thyroid disease

TABLE 133.5. Exacerbation of Chronic Congestive Heart Failure: Precipitating Factors

EMERGENCY DEPARTMENT EVALUATION

Other than a carefully obtained history and physical examination, there are few other diagnostic aids available to the emergency physician. The posteroanterior chest radiograph is usually the only readily available ancillary test of value.² Radiographic stages that reflect the severity of LHF have been described, but the classic radiographic progression is not always seen. In addition, the chest radiograph may not correlate temporally with the patient's immediate condition; that is, there may be as long as a 12-hour diagnostic lag from the onset of LHF, and a posttherapeutic lag of up to 4 days after clinical resolution.

The earliest radiographic finding is redistribution or "cephalization" of flow. Normally, more blood flow occurs to the dependent portions of the lungs. When PCWP increases to 12 to 18 mm Hg, flow to the lower lung fields is reduced because of the vasoconstriction, and flow to the upper lung fields increases. Redistribution is best detected on an upright film and is most commonly seen in the setting of chronic LHF. When the PCWP is 18 to 25 mm Hg, fluid accumulates in the interstitial spaces, producing Kerley B lines, and the pulmonary vessels are enlarged and their radiographic shadows become blurred. Alveolar edema occurs when the PCWP acutely rises above 25 mm Hg and is recognized by the classic butterfly pattern of bilateral perihilar infiltrates. In all stages, the cardiac silhouette is typically enlarged (cardiothoracic ratio more than 50%), and, in chronic LHF, pleural effusions are common.

The ECG is of limited diagnostic value. In chronic LHF, the ECG usually shows enlargement or hypertrophy of one or more chambers. Intraventricular conduction defects are frequent, and secondary ST-T wave changes caused by ventricular hypertrophy or bundle-branch blocks often preclude accurate diagnosis of acute ischemia or infarction.

Arterial blood gas analysis predictably shows hypoxemia caused by ventilation–perfusion mismatch, but it is of no value in diagnosis and of limited use in guiding therapy. Other blood tests show typical but nondiagnostic abnormalities (e.g., abnormal liver function tests caused by passive hepatic congestion, and hyponatremia caused by retention of excess free water).

EMERGENCY DEPARTMENT MANAGEMENT

All patients with LHF should receive supplemental oxygen, an intravenous line should be placed, heart rate and rhythm should be continuously monitored, and the head of the bed should be elevated. Continuous pulse oximetry should also be used, if available. Treatment is directed primarily toward reducing LV preload or filling pressure, and secondarily toward improving myocardial contractility or decreasing afterload. The sequence of drug therapy and the pace of acute intervention depend on the severity of symptoms.

Patients with mild-to-moderate LHF usually have typical symptoms of varying duration. On examination, patients are normotensive or hypertensive and have bibasilar rales, JVD, third and fourth heart sounds, and pedal edema. Murmurs caused by underlying valvular disease may also be heard. Emergency department therapy would include intravenous furosemide (80 mg) to decrease preload and induce diuresis and sublingual (0.8 to 1.2 mg) or oral (20 to 40 mg) nitroglycerin to increase venous capacitance and lower preload. Urine output and BP should be monitored to detect the response to diuresis as well as any complications of excessive preload reduction (e.g., hypotension). Due to renal vasoconstriction caused by decreased CO, an increase in urine output after diuretic administration may not be immediate and may be delayed for 30 to 60 minutes. If a supraventricular tachyarrhythmia other than sinus tachycardia is present, controlling the ventricular response rate to facilitate ventricular filling also decreases preload and improves CO. The most common supraventricular tachyarrhythmia encountered in LHF is atrial fibrillation, which probably occurs because of atrial distention. In most instances, immediate cardioversion is not necessary, and the ventricular response rate can be controlled quickly with an intravenous calcium channel blocker (e.g., diltiazem).²⁰ If premature ventricular contractions (PVCs) are present and treatment is indicated, lidocaine can be given (1 mg/kg intravenous bolus, followed by a continuous infusion at a rate of 1 mg/min). A low infusion rate is recommended because of depressed CO and the resulting decrease in the hepatic clearance of lidocaine. Mild hypertension caused by neural and hormonal compensatory responses is common in the mildly to moderately symptomatic patient and usually responds to diuresis and preload reduction alone. Aggressive afterload reduction (e.g., nitroprusside infusion) is usually required only when acute CHF is the result of a hypertensive crisis.

Acute pulmonary edema is LHF in its most extreme form and is a life-threatening emergency. The typical patient is anxious, severely dyspneic, diaphoretic, pale, cool, and clammy. Inspiratory rales and wheezes may be heard over all lung fields. A summation gallop may be heard on cardiac auscultation, and JVD is common. Hypertension is usual and is due to intense vasoconstriction. Other peripheral signs (e.g., pedal edema and hepatomegaly) may be present if acute decompensation is superimposed on chronic LHF.

Immediate therapy in the normotensive or hypertensive patient should include furosemide (80 mg intravenously) and intravenous nitroglycerin (5 to 200 µg/min).^{6,16} The transdermal route (e.g., nitroglycerin paste or patch) should not be used, because there is limited skin perfusion in acute pulmonary edema. Morphine sulfate administered in small intravenous doses (2-mg increments) is a time-honored therapeutic agent in acute pulmonary edema. Although morphine is a venodilator, its effects on venous capacitance have not been well established in the setting of acute pulmonary edema caused by LHF, and respiratory depression may occur at doses that do not affect hemodynamic variables. An inhaled selective beta agonist can be used if severe bronchospasm is present. Theophylline preparations should be avoided because of their arrhythmogenicity. If BP remains severely elevated after initial improvement in symptoms, afterload reduction with nitroprusside, infused at a rate titrated to desired response, or enalaprilat, 1.25 mg every 6 hours, can be used.¹ If the patient is hypotensive at the time of presentation, inotropic agents should precede the use of venodilators and diuretics.¹⁶ Dopamine (initial infusion rate of 10 µg/kg/min) or a combination of dopamine and dobutamine (each infused at an initial rate of 7.5 µg/kg/min) can be used. If a sustained supraventricular tachyarrhythmia (e.g., atrial fibrillation) is present and is judged to be a major cause of hypotension, electrical cardioversion should be attempted. PVCs can be treated with lidocaine, as discussed. Endotracheal intubation may be required if pulmonary edema is accompanied by severe hypoxemia that does not improve during early treatment. The most reliable indication of life-threatening hypoxemia is a decreasing level of consciousness, although it is a relatively insensitive sign. Continuous or bilevel positive airway pressure (CPAP, BiPAP) may reduce the need for intubation.¹⁴

DISPOSITION

Role of the Consultant

Acute pulmonary edema is a medical emergency, and therapy should be instituted immediately, even before consultation with the patient's personal physician or the on-call cardiologist. Initial therapy and symptomatic response should be carefully documented to assist the admitting physician in planning further therapy. In the patient with mild-to-moderate LHF, early consultation after initial assessment is appropriate.

Indications for Admission

All patients with acute pulmonary edema should be admitted to an intensive care unit. Invasive hemodynamic monitoring may be required in patients who do not respond to emergency department therapy. Patients with chronic LHF and a mild worsening of symptoms who respond to intravenous diuretics may be discharged after adjustments in the chronic drug regimen (e.g., an increase in the furosemide dose), consultation with the patient's physician regarding medication changes, and assurance of follow-up within 24 to 48 hours. Patients with more severe symptoms or other complicating factors (e.g., new rhythm disturbances, poorly controlled hypertension, or a suspected acute myocardial ischemic event) should be admitted for observation, evaluation, and optimization of drug therapy.¹² All patients with new onset of LHF of uncertain origin should be admitted for evaluation. If an interfacility transfer is required, the patient should be stabilized first.

COMMON PITFALLS

- The signs and symptoms of cor pulmonale and acute respiratory failure are similar to those of LHF, and, in some cases, it may not be possible to distinguish between them by physical examination alone.
- In the patient with CHF atrial fibrillation with a rapid ventricular response, digoxin alone should not be used. Slowing of the ventricular response rate is usually not seen for approximately 8 hours after administration.
- RV infarction should always be considered in the patient with an acute inferior wall infarction who has clear lung sounds, JVD, hypotension, and a normal heart rate and rhythm. Increasing venous capacitance in this setting decreases RV filling pressures and further decreases CO. RV infarction can be diagnosed with a right precordial ECG. ST-segment elevation is typically seen in leads V_{3R} and V_{4R} (see [Chapter 131](#)).
- If the cardiac silhouette is not enlarged, but other radiographic findings of LHF are seen, the failure is most likely to be of acute onset and caused by valvular disease (e.g., aortic insufficiency due to endocarditis, papillary muscle rupture in patients with mitral valve prolapse, valvular dysfunction in patients with prosthetic valves, or acute myocardial infarction). Noncardiogenic pulmonary edema should also be considered.
- CHF is a complex physiologic state. There are a number of drugs that can alleviate symptoms, improve quality of life, and increase long-term survival. However, these drugs have well-described complications. Altering a patient's medical regimen by adding a new medication prior to discharge from the emergency department should not be undertaken without consultation with the patient's primary physician, in order to assure follow-up monitoring of drug effect.

CHRONIC COR PULMONALE (PULMONARY HEART DISEASE)

Chronic cor pulmonale has been defined as a combination of RV hypertrophy and dilatation caused by increased resistance of the pulmonary circulation due to intrinsic pulmonary disease, inadequate function of the chest bellows, or inadequate ventilatory drive from the respiratory centers. Implicit in this definition is the exclusion of congenital heart disease and LHF as causes.⁸ Although cor pulmonale may be acute (most commonly caused by pulmonary thromboembolism), only the chronic form is discussed. Causes of chronic cor pulmonale are listed in [Table 133.6](#). In the United States, chronic bronchitis and emphysema are the major causes of chronic cor pulmonale, and the yearly incidence of these diseases is approximately ten per 1 million persons. At autopsy, cor pulmonale is estimated to occur in 40% of patients with emphysema or bronchitis. Cor pulmonale is estimated to account for 7% to 10% of all heart disease.

DISEASES THAT PRIMARILY AFFECT AIR PASSAGES
Chronic bronchitis/emphysema
Bronchial asthma
Pulmonary fibrosis (e.g., pneumoconiosis)
Gangliomas and infiltrates (e.g., sarcoid)
Pulmonary resection
Congenital cystic disease
High-altitude hypoxia
DISEASES THAT PRIMARILY AFFECT CHEST BELLOW
Kyphoscoliosis
Thoracoplasty
Pleural fibrosis
Chronic neuromuscular weakness
Obesity
DISEASES THAT PRIMARILY AFFECT PULMONARY VASCULATURE
Primary pulmonary hypertension
Pulmonary embolism
Polycytemia, redness
Other arteritides

TABLE 133.6. Causes of Chronic Cor Pulmonale

The hemodynamic hallmark of cor pulmonale is pulmonary hypertension (elevated pulmonary artery pressure), which may either manifest at rest and worsen with exercise or occur only during exercise. Increased pulmonary vascular resistance is the result of a reduction in the size of the effective cross-sectional area of the pulmonary vascular bed because of obstruction or destruction and is usually combined with active vasoconstriction. Hypoxemia is a potent pulmonary vasoconstrictor, and concurrent hypercapnia and acidemia are synergistic. Most causes of cor pulmonale are accompanied by these gas exchange and acid-base abnormalities. The rise in pulmonary vascular resistance impedes RV ejection, and a compensatory response results in hypertrophy or dilatation and increased preload.

CLINICAL PRESENTATION

The clinical manifestations of cor pulmonale are largely determined by the underlying disease process, and symptoms of pulmonary dysfunction most often precede manifestations of right heart failure.

Common symptoms include dyspnea at rest or with minimal exertion, weight gain, ankle swelling, and, in severe cases, abdominal swelling due to ascites. Physical signs usually include bibasilar crackles and scattered wheezes (caused by lung disease, not interstitial fluid accumulation) on auscultation. The pulmonic component of the second heart sound may be palpable, and the jugular vein may fill paradoxically during inspiration or exhibit no respiratory fluctuations. Tricuspid insufficiency may be present, manifested by a systolic murmur heard best at the lower left sternal border and increasing with inspiration; this is often accompanied by the finding of a pulsatile liver edge.

DIFFERENTIAL DIAGNOSIS

The signs and symptoms of cor pulmonale may mimic those of LHF, constrictive pericarditis, and cardiac tamponade. Severe and advanced mitral stenosis may present with predominant right heart failure or "silent mitral stenosis." When signs and symptoms of cor pulmonale are of abrupt onset, acute pulmonary thromboembolism should be considered.

EMERGENCY DEPARTMENT EVALUATION

The chest radiograph usually shows only evidence of the underlying pulmonary disorder, but it may be helpful in diagnosing the cause of an acute exacerbation (e.g., pulmonary infiltrate). The ECG is not a sensitive test for detecting RV hypertrophy or dilatation, but some findings are reasonably specific. These include a P-pulmonale pattern (P-wave amplitude of at least 2.5 mm in lead II), right-axis deviation, R/S amplitude ratio in V₁ of greater than 1, low-voltage QRS, and right bundle-branch block pattern.¹⁰ Failure to detect radiographic or ECG evidence of RV hypertrophy or dilatation does not rule out the diagnosis. Arterial blood gas analysis usually shows some combination of hypoxemia, hypercapnia, and acidemia. Liver function tests may be abnormal because of passive hepatic congestion. Pulmonary function tests are always abnormal, and the typical patient has a forced expiratory volume in 1 second of less than 1 L.

EMERGENCY DEPARTMENT MANAGEMENT

Most patients who present with an acute exacerbation of chronic cor pulmonale have acute respiratory failure caused by the worsening or progression of the underlying lung disease. Therapeutic efforts should be directed toward reversing reactive pulmonary vasoconstriction (i.e., improving oxygenation, decreasing hypercarbia, and normalizing pH). Therapy is usually the same as that employed in acute respiratory failure resulting from emphysema or chronic bronchitis. Such

therapy should include administration of low-flow oxygen, corticosteroids, and antibiotics and inhaled and systemic bronchodilation (see [Chapter 147](#)).

DISPOSITION

Role of the Consultant

An acute worsening of chronic cor pulmonale is usually caused by acute respiratory failure. Acute respiratory failure is a life-threatening emergency, and immediate treatment should be instituted before consultation.

Indications for Admission

Indications for admission for an exacerbation of chronic cor pulmonale are usually the same as for acute respiratory failure (see [Chapter 130](#)).

COMMON PITFALLS

- The clinical symptoms and signs of LHF and cor pulmonale overlap. Administering high-flow oxygen to a patient with suspected LHF who has cor pulmonale may result in worsening of clinical status, because the hypoxic drive is suppressed and hypercapnia worsens.
- The diagnosis of cor pulmonale cannot be ruled out simply by the absence of ECG or radiographic findings of RV hypertrophy or dilatation. ¹⁰
- Emergency treatment should be directed toward improving pulmonary function and decreasing pulmonary vascular resistance, rather than toward alleviating signs of right heart failure (e.g., aggressive diuresis, which may decrease RV preload and worsen left heart outflow).
- Patients with obstructive sleep apnea typically present with manifestations similar to those of chronic cor pulmonale. ¹³ A careful history is helpful in suggesting the diagnosis and appropriate referral.

[Common Pitfalls](#)

[Chapter References](#)

The cardiac conduction system consists of pacemaker cells, conducting cells, and contractile cells. *Pacemaker cells* possess the capacity to spontaneously depolarize. The sinus (sinoatrial) node, normally the predominant pacemaker of the heart, is located at the junction of the right atrium and the superior vena cava and has an intrinsic basal rate of 60 to 100 beats per minute.

The atrioventricular (AV) node, located beneath the right atrial endocardium above the insertion of the septal leaflet of the tricuspid valve, can also function as a pacemaker, with an intrinsic rate of 45 to 60 beats per minute. It fires in the absence of sinus node impulses, or it may itself usurp control from the sinus node. Other cells in the bundle branches and Purkinje network can function as pacemakers as well, but their intrinsic rate is quite low, approximately 30 to 40 beats per minute.

Electrical impulses in the heart travel over a network of *conducting cells*. Impulses normally originate in the sinus node. Passage through the AV node is relatively slow, accounting for a normal physiologic delay in ventricular depolarization. The AV node blends into the bundle of His, which divides into bundle branches. They, in turn, arborize into a network of Purkinje fibers that transmit impulses to the ventricular myocardial *contractile cells*. Contractile cells in the atria and the ventricles do not spontaneously depolarize.

The electrocardiographic (ECG) P wave represents atrial depolarization. The P-R interval (normally 0.12 to 0.20 second in the adult) reflects intraatrial, AV nodal, and His-Purkinje conduction. The QRS complex, representing ventricular depolarization, has a normal duration of 0.04 to 0.10 second, and the following T wave represents ventricular repolarization. The U wave is seen in a variety of circumstances, such as hypokalemia. Its electrophysiologic basis is uncertain.

Two basic pathophysiologic mechanisms underlie the production of both tachyarrhythmias and bradyarrhythmias: disorders of impulse formation and disorders of impulse conduction. Depressed *automaticity* may result in bradyarrhythmias such as sinus bradycardia or sinus arrest. If sinus node automaticity is sufficiently depressed, escape rhythms originating elsewhere in the heart may assume control. Depressed *impulse conduction* may lead to AV or fascicular blocks.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

In the approach to the patient with bradyarrhythmia, as with any patient, the priorities of airway, breathing, and circulation must be addressed first. The urgency and means of treating bradyarrhythmias depend on how symptomatic the arrhythmia is, the clinical setting in which the arrhythmia occurs, the propensity for the arrhythmia to progress, and concurrent drug therapy.

Bradyarrhythmias may produce light-headedness, dizziness, fatigue, syncope, or even convulsions. Prompt therapy is required for these symptoms and for hypotension, congestive heart failure, mental status changes, and angina. However, many arrhythmias are asymptomatic and require no treatment. An arrhythmia that occurs during an acute myocardial infarction often mandates a different treatment approach than an arrhythmia that is incidentally discovered during a routine physical examination. Electrolyte imbalances and the use of certain drugs (e.g., digitalis, beta blockers, and calcium channel blockers) may also be the cause of bradyarrhythmias, and each has its own implications for treatment. General supportive measures, such as oxygenation, ventilation, and correction of electrolyte abnormalities, are usually the first step. Specific drug therapy or artificial cardiac pacing are also required in many instances.

Among drug therapy, the cornerstone is atropine sulfate, a vagolytic agent that enhances sinus node automaticity and AV nodal conduction. The usual adult dose is 0.5 to 1.0 mg intravenous push every 3 to 5 minutes to a total maximum dose of 0.04 mg/kg (3 mg) in the adult. Atropine is effective when administered by the endotracheal route; the suggested dose is 2.0 to 2.5 times the recommended intravenous dose diluted in 10 mL of normal saline.³ Because it can increase myocardial oxygen consumption, atropine should be used with caution in the presence of myocardial ischemia. Adverse effects include sinus tachycardia, ventricular tachycardia, or ventricular fibrillation, as well as manifestations of anticholinergic toxicity. In the patient with high-degree AV block, one may see, in rare instances, a marked reduction in the heart rate after atropine use.³

Isoproterenol, a beta-adrenergic sympathomimetic drug with potent inotropic and chronotropic effects, may be useful as a temporary measure in the treatment of bradycardia unresponsive to atropine. It is, however, gradually being relegated to a position behind pacing in this situation.⁴ It is administered as an infusion at a rate of 2 to 10 µg/min. Isoproterenol markedly increases myocardial oxygen demand and, like atropine, may cause significant adverse effects, including ventricular tachycardia or fibrillation.

Glucagon has been found to be beneficial in treating bradyarrhythmias secondary to beta-adrenergic blocking agents and calcium antagonists. The drug appears to be effective in both the toxic and nontoxic patient. Glucagon has been shown to stimulate the sinoatrial node, resulting in a modest increase in the heart rate. It increases automaticity at the AV node, which may be helpful in slow junctional rhythms. It has also been shown to increase cardiac contractility, thereby increasing coronary perfusion. The peak action of glucagon occurs approximately 5 to 10 minutes after intravenous administration. Suggested initial dosing ranges are 0.05 to 0.10 mg/kg in children and 0.05 to 0.15 mg/kg in adults. This may be repeated based on the clinical situation and the characteristics of the offending medication.¹

When drug therapy is ineffective artificial pacing should be instituted.

DISORDERS OF IMPULSE FORMATION

ATRIAL BRADYARRHYTHMIAS

Sinus arrhythmia is a physiologic finding commonly seen in healthy young people in which the sinus discharge rate decreases with expiration and increases with inspiration. It is thought to be due to changes in vagal tone during respiration. P-wave morphology and P-R intervals are usually constant. No treatment is indicated.

Sinus bradycardia, arbitrarily defined as a sinus rhythm of less than 60 beats per minute, may be the result of organic heart disease, and may cause symptoms, but is also a common finding in healthy patients and particularly in conditioned athletes. Studies have found that 50% to 85% of conditioned athletes have benign sinus bradycardia, compared with 23% in the general population.² The significance of sinus bradycardia depends on the clinical setting. It is common during drug therapy with digitalis and beta blockers, and may not warrant intervention. The following findings should suggest possible nonphysiologic vagotonia: (1) profound bradycardia in an individual not engaged in strenuous endurance training, (2) sinus pauses longer than 3 seconds on a Holter monitor, or (3) syncope or near-syncope at rest or after strenuous exercise.² When sinus bradycardia is associated with symptoms, treatment with atropine is usually successful. Use of cardiac pacing and other drug

therapies is sometimes necessary.

The *sick sinus syndrome* encompasses a spectrum of conditions, including severe sinus bradycardia, sinoatrial block, sinus arrest, and the bradycardia–tachycardia syndrome. The latter refers to the intermittent occurrence of bradyarrhythmias and tachyarrhythmias (e.g., atrial fibrillation, flutter, or paroxysmal supraventricular tachycardia) in the same patient. Bradyarrhythmia typically occurs immediately after resolution of an episode of tachycardia. Symptoms such as syncope or chest pain may result from either the tachycardia or the bradycardia. Effective pharmacologic therapy for tachycardia can exacerbate the bradycardia, so cardiac pacing must often be initiated before pharmacologic therapy.

ATRIOVENTRICULAR NODAL BRADYARRHYTHMIAS

An *AV junctional rhythm* may be a physiologic escape rhythm initiated by the AV node in the absence of an adequate sinus stimulus, or may result from an abnormally rapid AV junctional focus that usurps control from the sinus node (e.g., accelerated junctional rhythm). Junctional rhythms usually exhibit the same QRS morphology as the patient's sinus rhythm. The P waves are usually inverted if they are conducted in a retrograde manner, and can fall before, during, or after the QRS complex, depending on the location of the focus within the AV junction and the degree of retrograde AV block. When the P wave occurs before the QRS complex, the P-R interval is, usually, less than 0.12 second. The absence of P waves may be due to obliteration by the QRS complex or to retrograde block.

AV junctional escape beats occur singly or multiply in the absence of stimuli arriving at the AV node ([Fig. 134.1](#)). Their hallmark is occurrence *after* an interval longer than the dominant cycle. The underlying disorder may be sinus bradycardia, sinus arrest, sinus exit block, or AV block. Digitalis or beta-blocker therapy may also be responsible. Junctional escape rhythms may also be incidental findings in otherwise healthy people with increased vagotonia. Treatment is not indicated for asymptomatic patients with infrequent escape beats. If symptoms occur, the clinician should treat the underlying rhythm rather than attempt to obliterate the escape beats. Treatment involves withholding offending drugs or using atropine, artificial pacing, or isoproterenol.

Figure 134.1. Junctional escape rhythm.

VENTRICULAR BRADYARRHYTHMIAS

A ventricular rhythm with a rate of less than 50 beats per minute is termed a *ventricular escape rhythm*, or idioventricular rhythm. Ventricular escape rhythm represents a physiologic safety mechanism that arises in the absence of stimuli from above, as in sinus bradycardia, sinus arrest, or, more commonly, AV block. Most patients with ventricular escape are symptomatic, because the heart rate is low. Treatment is directed at the underlying arrhythmia (i.e., use of atropine, isoproterenol, or, most often, cardiac pacing). Lidocaine, which may abolish the ventricular rhythm, is contraindicated, because it has the potential for causing cardiac standstill.

Also known as idioventricular tachycardia or slow ventricular tachycardia, *accelerated idioventricular rhythm* has a rate of 50 to 100 beats per minute. It is one cause of isorhythmic dissociation, with occasional fusion beats demonstrating the continued presence of an intact AV node ([Fig. 134.2](#)). It may be associated with acute myocardial infarction (particularly after thrombolysis,¹² but may also be seen in otherwise healthy patients. In the absence of symptoms, specific therapy is not warranted.

Figure 134.2. Idioventricular rhythm, with isorhythmic dissociation and fusion beats.

DISTURBANCES OF CONDUCTION

DISORDERS OF SINOATRIAL CONDUCTION

The tissue surrounding the sinus node may delay or prevent conduction of sinus node impulses to the atria and AV node. Such conduction disorders are termed *sinoatrial block* and are classified in a manner analogous to AV block. However, because of the limitations of the surface ECG, their precise diagnosis is more difficult than the varieties of AV block.

In *first-degree sinoatrial block*, there is a delay in the propagation of the sinus node impulse out to the atrial myocardium. Every beat is transmitted, however, and no abnormality is detected on the surface ECG.

Like AV block, *second-degree sinoatrial block* may be divided into types I and II. In *type I* (Wenckebach), there is, with each succeeding beat, a progressive delay in conduction from the sinus node to the atria, until conduction is totally blocked and a P wave is dropped ([Fig. 134.3](#)). The P-P interval progressively shortens before the dropped P wave, analogous to the situation in second-degree AV block, in which the R-R interval shortens before the dropped QRS complex.

Figure 134.3. Type I (Wenckebach) sinoatrial block.

In *type II* second-degree sinoatrial block, there is intermittent failure of the sinus impulse to reach the atria, resulting in a missing P wave and a sudden lengthening of the P-P interval. The resulting P-P interval is usually a multiple of the previous one, which is doubled in the case of 2:1 block ([Fig. 134.4](#)). This disorder can be mimicked by blocked premature atrial contractions, in which the P wave is obscured by the preceding T wave ([Fig. 134.5](#)).

Figure 134.4. Type II sinoatrial block 2:1.

Figure 134.5. Blocked premature atrial contractions mimicking AV or sinoatrial block.

Third-degree sinoatrial block, in which there is a failure of any sinus node impulses to be conducted to the atria ([Fig. 134.6](#)), is usually indistinguishable from sinus arrest, in which there is a failure of impulses to arise from the sinus node.

Figure 134.6. Third-degree sinoatrial block, with escape rhythm.

DISORDERS OF ATRIOVENTRICULAR CONDUCTION

Traditionally, AV blocks have been divided into first, second, and third degree. However, AV block is a relative phenomenon, and the physiologic delay normally present in the AV node is one end of a continuum. For example, in the patient with atrial flutter “normal” AV conduction usually results in 2:1 block. In addition, the degree of block is rate dependent. One patient with mild AV disease may exhibit second-degree block at a particular supraventricular rate, while another patient with more advanced AV nodal disease may exhibit 1:1 conduction if the supraventricular rate is slower.

A P-R interval of more than 0.20 second defines *first-degree AV block*. All P waves are conducted, 1:1 AV conduction is maintained, and the P-P and R-R intervals are consistent. Most commonly, the delay in AV conduction is within the AV node, and the QRS complex is of normal duration. Delays within the His bundle or His-Purkinje system are less common and are usually associated with widened bundle-branch block QRS patterns, but can be localized conclusively only by intracardiac recordings.

First-degree AV block may be associated with electrolyte disturbances or the use of digitalis, beta blockers, or calcium channel blockers. It may be a finding during acute myocardial infarction, particularly inferior myocardial infarction. Treatment includes correction of electrolyte abnormalities or removal of an inciting agent. During acute myocardial infarction, close observation is warranted to detect progression to higher degrees of block. Otherwise, specific treatment is not indicated.

Second-degree AV block can be divided into Mobitz types I and II. Interestingly, Wenckebach distinguished between these two in the pre-ECG era, using only

physical observation.¹²

Mobitz type I (Wenckebach) second-degree AV block is characterized by repeated cycles of progressively slowing AV conduction until conduction is totally blocked. This pattern is manifested electrocardiographically by a progressive prolongation of successive P-R intervals, until there is a nonconducted P wave, after which the cycle repeats itself (Fig. 134.7). The cycle is referred to by the ratio of P waves to QRS complexes (i.e., 4:3, 3:2, and so on). Classically the R-R interval shortens as the P-R interval lengthens.

Figure 134.7. Mobitz type I (Wenckebach) second-degree AV block.

Type I block usually results from conduction delay in the AV node, although delays may occur in the bundle of His, bundle branches, or Purkinje system. For this reason, the QRS complex in type I block is most often of normal duration. It may be associated with inferior myocardial infarction or the use of digitalis, beta blockers, and calcium channel blockers. Mobitz type I AV block is usually transient and asymptomatic and has a good prognosis. If it is symptomatic, atropine can be given to enhance AV nodal conduction, but pacing is usually not necessary. Offending drugs may need to be withheld.

Mobitz type II second-degree AV block is less common. The site of blockage is usually within the His-Purkinje system, and, thus, a bundle-branch block QRS pattern is usually seen. In type II block, the P-R intervals are constant until single or multiple beats are suddenly dropped (Fig. 134.8).

Figure 134.8. Mobitz type II second-degree AV block.

Type II block is usually symptomatic and has a high likelihood of progressing to complete AV block. If associated with acute anterior myocardial infarction, it carries an ominous prognosis. Most authorities agree that Mobitz type II second-degree AV block requires permanent cardiac pacing. Because emergency treatment with atropine or isoproterenol is often ineffective, temporary pacing may be necessary as a stabilizing measure.

A particular clinical problem is presented by the patient with 2:1 AV block. Although it is often assumed that such patients have type II block, type I block can, and does, present as 2:1 block, and, in fact, is more common than type II. The distinction is important, given the difference in prognosis and treatment between the two entities. Although definitive proof may require intracardiac recordings, the following principles may aid in the clinical distinction¹³:

- Type I block is more common than type II.
- A narrow QRS complex usually reflects a type I block (although not all type I blocks have a narrow QRS complex). Type II block usually has a wide QRS complex.
- Coexistent acute inferior myocardial infarction suggests type I block, while anterior myocardial infarction suggest type II.
- Digitalis, beta-blocker, or calcium channel blocker therapy tends to be associated with type I block.
- Other areas of the rhythm strip may reflect other patterns of type I conduction, such as 3:2 or 4:3.

In *third-degree (complete) AV block*, no atrial impulses reach the ventricles, and a subsidiary, escape pacemaker usually emerges. AV dissociation results, with constant but independent P-P intervals and R-R intervals. The P-R interval is variable, and P waves have no discernible relation to QRS complexes (Fig. 134.9). The site of block may be within the AV node, His bundle, bundle branches, or Purkinje system. In general, the lower the site of the block, the more severe the symptoms.

Figure 134.9. Third-degree AV block.

Third-degree AV block may be intermittent or self-limited. If it complicates digitalis, beta-blocker, or calcium channel blocker therapy, it usually resolves on withdrawal of the offending agent. It may be associated with acute myocardial infarction, but, occasionally, it is an asymptomatic finding in an otherwise healthy person.

Like other bradyarrhythmias, the emergent treatment of third-degree AV block depends on symptomatology and clinical setting. Symptomatic patients may improve with atropine, particularly if the block is within the AV node. Symptomatic patients who are unresponsive to pharmacologic therapy require emergent pacing. Stable patients with acute inferior infarction may require only a prophylactic pacemaker. Acute anterior infarction complicated by third-degree AV block is more ominous and

requires emergent pacing.

The term *AV dissociation*, although commonly used interchangeably with the term *third-degree AV block*, encompasses a much broader range of rhythms. AV dissociation implies that the atria and ventricles are beating independently, a situation that includes not only complete AV block, but also accelerated junctional and idioventricular rhythms (including ventricular tachycardia). In *isorhythmic dissociation* (Fig. 134.10), the sinus rate and the escape or ectopic rate are nearly identical, producing an ECG pattern characterized by varying P-R intervals as the sinus and ectopic foci slowly change their relative firing rates. Occasional fusion beats are an indication that the cause is not complete AV block.

Figure 134.10. AV dissociation, with isorhythmic dissociation due to a junctional focus.

ARTIFICIAL PACEMAKERS

Temporary cardiac pacemakers are normally used in emergent or urgent circumstances, whereas most permanent pacemakers are placed electively. The emergency physician should be familiar with the indications and use of temporary pacemakers, and with the principles of permanent pacemakers and their complications.

TEMPORARY PACEMAKERS

Therapeutic emergent cardiac pacing is indicated in any hemodynamically unstable bradycardia that fails to respond to pharmacologic therapy. In addition, prophylactic emergent cardiac pacing may be indicated, even without symptoms, for patients with acute myocardial infarction in the following circumstances:

- First-degree AV block with new-onset bundle-branch block
- Second-degree AV block type II
- Third-degree AV block
- Right bundle-branch block with left anterior fascicular block or left posterior fascicular block (either new or old)
- Left bundle-branch block (old or new) and placement of a Swan-Ganz catheter (because of the risk of inducing iatrogenic right bundle-branch block, and hence complete block)

Emergent pacing may also be indicated in bradysystolic cardiac arrest, if initiated early. It appears that pacing is of no benefit if it is initiated more than 20 minutes after arrest.³

Transcutaneous cardiac pacing involves the application of cutaneous electrodes to the chest and delivery of electrical impulses through the chest wall to the myocardium. Interestingly, transcutaneous pacemakers, developed in the early 1950s, were the first modern cardiac pacemakers. They were largely replaced by other devices until “rediscovered” in the early 1980s.^{6,10} Transcutaneous pacing is now the technique of choice for emergent pacing in the emergency department, and it is the only option available for prehospital use.

The advantages of transcutaneous pacing are its ease and speed of use and the absence of serious side effects. Its disadvantages include an inability to capture in some patients and the discomfort experienced by conscious patients due to chest wall contractions. The latter can usually be treated satisfactorily with analgesics or sedation. Because the possibility of myocardial tissue damage from prolonged transcutaneous pacing has not been extensively investigated, the transcutaneous pacer should be considered a stabilizing device, to be replaced by another pacing technique when possible.

Transthoracic cardiac pacing involves the placement of a pacing wire through the skin directly into the right ventricular cavity. Because significant complications have been reported, such as pericardial tamponade, pneumothorax, and coronary vessel injury, transthoracic pacing should usually be considered only if transcutaneous pacing is unsuccessful or unavailable. *Transvenous cardiac pacing* involves the placement of the pacing electrode into the right ventricle by way of a central vein, often the subclavian or internal jugular. Thus, it carries the risk of central venous catheterization, but it is the temporary modality that most closely approximates the function of a permanent pacemaker. It does not involve painful muscle contractions or the hazard of direct cardiac puncture, and it can be used for relatively prolonged periods. Unfortunately, emergent transvenous pacemaker placement in the emergency department setting is often a lengthy and unsuccessful procedure associated with a high incidence of noncapture. Ideally, transvenous pacemaker placement is performed under fluoroscopic guidance. With the advent of transcutaneous pacing, transvenous pacing has been relegated to those situations in which fluoroscopy is available, in which stabilization has been achieved by another modality, or in which attempts at transcutaneous pacing have been unsuccessful.

Once capture has been achieved, regardless of the device used, the pacemaker settings will be dependent on the clinical situation. An initial rate of 80 to 100 beats per minute is appropriate for the majority of the patients. The mode should initially be asynchronous (sensitivity off) in those patients requiring emergency pacing for cardiac arrest. The initial output setting should be at maximum and then decreased after capture is achieved.

PERMANENT PACEMAKERS

Permanent cardiac pacemakers (see also [Chapter 136](#)) are classified using a three-letter code. The first letter (A, V, or D) indicates the chamber being paced (atrium, ventricle, or dual). The second letter indicates the chamber being sensed. The third letter (I, T, D, or O) indicates the mode of response (inhibited, triggered, dual, or not applicable). Optional fourth and fifth letters can indicate programmability and antitachycardia functions. Patients often carry identification cards indicating the type and settings of their particular unit.

Many permanent pacemakers currently in use are of the VVI type, which pace the ventricle, sense intrinsic ventricular activity, and inhibit pacemaker output if ventricular complexes are sensed at a rate greater than that of the pacemaker setting. Increasingly common are AV sequential (DDD) units and units that are externally programmable.

Owing to improvements in pacemaker design and function, pacemaker malfunction requiring emergency intervention is uncommon but still occasionally occurs. Pacemaker malfunction can be classified as failure to pace, failure to capture, or failure to sense.

Failure to pace is indicated by a lack of appropriate pacer spikes on the ECG. Apparent failure to pace may be caused by the presence of a faster intrinsic rate than that of the pacemaker or by problems with the ECG recording equipment. True failure to pace is the result of battery or lead wire problems or of oversensing (e.g., sensing T waves as QRS complexes, or mistakenly sensing external, noncardiac activity).

Failure to capture is indicated by appropriate pacer spikes without corresponding QRS complexes. This may be due to fibrosis about the electrode tip, local

myocardial changes (such as infarction), migration or displacement of the lead tip, battery malfunction, or lead wire malfunction.

Failure to sense is indicated by the inappropriate delivery of pacer spikes, usually during the patient's intrinsic cardiac complexes. Such undersensing may be due to battery or lead failure or to a decrease in the intrinsic QRS amplitude, as may occur with infarction or electrolyte disturbance.

Most pacemakers may be temporarily converted to the nonsynchronized firing mode by placing a magnet directly over the subcutaneous generator. This maneuver is particularly helpful when pacemaker malfunction is suspected in the patient whose intrinsic rhythm is, for the moment, fast enough to suppress pacemaker activity.

With improvements in technology, most forms of pacemaker malfunction do not require emergent treatment. However, the emergency physician should still be able to recognize dysfunction in order to arrange appropriate management.

DISPOSITION

Virtually all patients with symptomatic bradyarrhythmia require admission to the hospital. Patients with type II second-degree AV block and complete AV block warrant admission even if asymptomatic. Admission should be to a monitored bed in a unit with the capability of initiating emergent pacing.

If transfer to another facility is necessary, pacing should first be initiated, if indicated and available. En route, the patient should have continuous cardiac monitoring and access to advanced cardiac life support. Transcutaneous pacing capability en route is also desirable.

COMMON PITFALLS

- Automatically assuming that a 2:1 second-degree AV block is of the Mobitz type II variety, possibly leading to unnecessary treatment and intervention
- Not taking rate into account when evaluating AV and fascicular blocks
- Misdiagnosing blocked premature atrial contractions as significant AV block, possibly leading to unnecessary treatment and intervention
- Mistakenly blocking an escape rhythm, with the potential for causing cardiac standstill

The truism that we must treat patients and not electrocardiograms (ECGs) or laboratory results is perhaps nowhere more relevant than in the emergency management of tachyarrhythmias. Decisions must be guided principally by the clinical presentation, and rhythm interpretation should be subservient to the goal of prompt appropriate management. Hemodynamic abnormalities are more typically dependent on the heart rate produced by any arrhythmia than they are on the arrhythmia's source. Ventricular tachycardia (VT), for example, conjures up images of imminent catastrophe, and supraventricular tachycardia (SVT) is usually assumed to be benign. However, some patients with VT are relatively stable, at least in the short run, whereas, in other patients, SVT can be acutely life-threatening.

Types of Tachyarrhythmias

Under normal circumstances, the sinoatrial (SA) node is the pacemaker for the heart. Depolarization is initiated in the SA node, and the impulse is conducted down the atrium to the atrioventricular (AV) node. Atrial depolarization corresponds to the P wave on the ECG. Conduction is slowed in the AV node, which provides a measure of protection against hemodynamically unstable tachycardias, because even in the presence of atrial tachycardias, ventricular rates will remain relatively slow. The normal slowing in the AV node is seen on the ECG as the PR interval. After the impulse traverses the AV node, it is conducted first down the His bundle, followed by the left and right bundle branches, and is then dispersed to the ventricular myocardium via the Purkinje fibers. Ventricular depolarization corresponds to the QRS wave on the ECG. The His-Purkinje system is made up of specialized myocardial cells that conduct impulses very rapidly. Normal impulse conduction thus produces a narrow QRS complex. Disease of the AV node causes heart blocks; disease of the His-Purkinje system produces bundle-branch blocks.

Tachycardias can be generated from any focus in the heart, because essentially all myocardial tissue has intrinsic pacemaker activity. There are two principal mechanisms by which tachyarrhythmias arise: reentry and enhanced automaticity. *Reentry* is a phenomenon in which an initial depolarizing impulse travels a closed-loop path that returns cyclically to its point of origin, and, in doing so, generates a regular sustained tachyarrhythmia.

The requirements for a reentrant tachyarrhythmia are (1) a closed-loop conduction path; (2) slower conduction and prolonged refractoriness in one limb of the loop; (3) propagation of the initiating impulse down the faster limb of the loop, with antegrade conduction down the slower limb blocked; and (4) retrograde excitation of the initially blocked slower limb, returning the impulse to its point of origin, where depolarization is reinitiated. Repetition of this cycle sustains the arrhythmia. A premature beat is the typical precipitant. Reentry can occur at a microscopic or a macroscopic level. Most reentry circuits occur with both limbs within the AV node, producing paroxysmal supraventricular tachycardia (PSVT). Reentry is often a common mechanism in VT as well, with the reentrant circuit typically contained entirely in a local area of abnormal ventricular tissue.

Enhanced automaticity is an increase in the rate of the spontaneous depolarization of myocardial cells above their electrical threshold. Sinus tachycardia is the physiologic response to enhanced automaticity of the SA node. When enhanced automaticity results in more rapid depolarization of extranodal myocardial cells, these foci can produce ectopic tachyarrhythmias. Examples include paroxysmal atrial tachycardia (PAT) and junctional tachycardia. Enhanced automaticity often occurs as a result of increased sympathetic tone (e.g., with fever, thyrotoxicosis, or sympathomimetic overdose). Treatment of these arrhythmias generally should be directed at removing the underlying stressor.

In adults, SVT generally does not generate a ventricular response of more than 180 beats per minute because of the damping effect of the AV node. In the presence of a bypass tract, however (e.g., the atrial tissue bundle of Kent found in Wolff-Parkinson-White [WPW] syndrome), rates of 200 or more beats per minute may be attained. VT, on the other hand, particularly when due to a reentry mechanism, may reach rates as high as 250 to 300 beats per minute, but is usually less than 220 beats per minute.

Tachycardias that originate below the AV node produce wide QRS complexes; therefore, any tachycardia with a narrow QRS complex can be presumed to originate from the AV node or above. On the other hand, SVTs and nodal tachycardias can produce wide QRS complexes in several circumstances: underlying bundle-branch block, rate-related bundle-branch block induced by the tachycardia itself, and anterograde conduction from the atrium to the ventricle through a bypass tract that circumvents the AV node. Thus, wide-complex tachycardias can be of either ventricular or supraventricular origin.

Although VT is more likely than SVT to produce hemodynamic decompensation, and thus more likely to initiate an episode of ventricular fibrillation (VF), VT is not always immediately life-threatening, nor is every episode of SVT benign.²¹ VT tends to be more worrisome, both because of the lack of atrial systole and, more important, the generally faster ventricular rate it produces. However, very rapid atrial or junctional tachycardias can produce hemodynamic instability, and efforts to distinguish between SVT and VT based purely on symptomatic effects produced by the arrhythmia are frequently inaccurate.²¹ The configuration of the QRS complexes seen during an episode of tachycardia is less important as a clue to the origin of the rhythm disturbance than as a guide to choosing between several possible therapeutic approaches.

TREATMENT MODALITIES

Electrical Cardioversion

With the exceptions of sinus tachycardia and multifocal atrial tachycardia (MFAT), any tachycardia that produces significant end-organ hypoperfusion can be treated in the same manner, regardless of its mechanism. Patients with tachyarrhythmia and hypotension, altered mental status, significant chest pain, or significant congestive heart failure generally require emergency electrical cardioversion. Expedient sedation and analgesia should precede electrical cardioversion in awake patients.

The amount of electrical energy required depends on the mechanism of the tachycardia. Fibrillatory rhythms, including both atrial fibrillation (AF) and VF, normally require significantly more energy than tachycardias such as PSVT or VT. Atrial flutter is the most electrosensitive rhythm and usually responds to energies in the range of 10 to 50 J. PSVT and VT both respond in at least 80% of cases to energies of 10 to 20 J; an initial energy of 50 J achieves successful conversion in more than 90% of cases. By contrast, AF and VF often require 100 to 200 J, or more. Initial doses should be as low as can reasonably be expected to succeed in converting the rhythm. If conversion fails on the initial attempt, energy levels can be serially increased until cardioversion is achieved.

Antiarrhythmic Agents

Drug therapy (Table 135.1) is reserved for patients who are clinically stable despite the tachyarrhythmia (or in whom cardioversion is either not indicated [MFAT, torsade de pointes] or has been tried unsuccessfully). The standard classification of antiarrhythmic agents provides a useful scheme for the treatment of tachycardias. Class I agents stabilize cell membranes and decrease the slope of phase zero of the action potential. Class II agents, the beta-adrenergic blockers, depress the SA and AV nodes. Class III agents decrease the entire duration of the action potential in all cardiac tissues, and thus have effects on all types of arrhythmias. Class IV agents, the calcium channel blockers, affect primarily the SA and AV nodes.

Class	Drug	Indications	Contraindications
Class I	Class IA	Procainamide, Quinidine, Disopyramide	QT prolongation, hypotension, lupus-like syndrome
	Class IB	Lidocaine, Phenytoin	None
	Class IC	Flecainide, Encainide	Myocardial infarction, heart failure
Class II	Beta-blockers	Propranolol, Metoprolol, Sotalol	Heart failure, asthma, bradycardia
	Calcium channel blockers	Diltiazem, Verapamil	Heart failure, hypotension
Class III	Amiodarone, Bretylium	Refractory VT and VF	Hypotension, heart block, QT prolongation
	Ibutilide	Refractory AF	None

TABLE 135.1. Drugs for Tachyarrhythmias

Three subclasses of class I are distinguished by their independent effects on repolarization. Although all these drugs slow phase zero of the action potential, and thus indirectly lengthen repolarization, the clinical effects of the various subclasses differ because they each have separate direct effects on repolarization. Class IA drugs directly prolong repolarization, class IB drugs independently shorten it, and class IC drugs have little independent effect on repolarization. The total effect on repolarization is thus minimal for class IB drugs, whereas prolongation of repolarization is moderate for class IC agents and pronounced with class IA drugs.

These properties are clinically important, because delayed repolarization (which is reflected on the ECG as a prolonged QT interval) can result in reentrant-type ventricular arrhythmias. This is of particular concern in the presence of ischemia, when the difference between the refractory periods of normal and ischemic cells is enhanced. Clinically, prolonged QT intervals associated with class IA antiarrhythmic agents are linked to the development of VT of the torsade de pointes variety. Class IA agents are contraindicated if the tachycardia manifests a prolonged QT interval.

The most important class IA agent is *procainamide*. Procainamide is probably more effective for the treatment of VT than is lidocaine, and it is also effective for many SVTs. In cases of regular wide-complex tachycardias of uncertain type, it is particularly useful because it treats both VT and SVT with aberrancy. It is also of use in patients with WPW and AF because it reduces conduction speed in the accessory pathway. It does, however, increase conduction through the AV node, so it should be used in conjunction with an AV node blocking agent in these cases. It is given in a dose of 17 mg/kg at not more than 50 mg/min. Procainamide may cause hypotension and QRS widening, particularly if given rapidly, and serial assessment of the ECG is required. Long-term therapy is associated with a lupus-like syndrome.

Quinidine and *disopyramide* are class IA agents seldom used in the emergency department (ED). Tricyclic antidepressants share the same electrophysiologic properties, and tricyclic antidepressant poisoning is associated with prolonged QT intervals (as well as prolonged QRS complexes). Emergency physicians should be familiar with these drugs, because many patients use them and because, in some patients, tachyarrhythmias may be due to their proarrhythmic effects.¹⁹ *Lidocaine*, the prototype parenteral class IB agent, has long been considered the drug of first choice in the acute treatment of ventricular arrhythmias. More recent studies suggest that it is not as effective in this role as previously believed; conversion rates for VT may be as low as 30%.⁸ It continues to be used, however, in the ED in the treatment of VT in clinically stable patients (i.e., those without signs of end-organ hypoperfusion), to protect against recurrent VF after resuscitation from cardiac arrest, and to treat significant ventricular ectopy in acute ischemia. However, there is no evidence that lidocaine is valuable in the primary prophylaxis of ventricular arrhythmias in acute myocardial infarction, and its utilization in this manner is widely discouraged.³ Lidocaine is safe when used appropriately. Toxicity, which is primarily related to the central nervous system, can be avoided if appropriate total doses (typically less than 225 mg in adults) are given at rates no faster than 50 mg/min for the initial 1-mg/kg bolus and 50 mg/5 min for further loading doses.

Phenytoin is another class IB drug, but like several newer oral lidocaine analogues, such as mexiletine and tocainide, it is seldom used in the ED as an antiarrhythmic agent.

Class IC agents, including *encainide* and *flecainide*, effectively suppress premature ventricular complexes (PVCs). They are not as effective at preventing propagation of whatever ectopic beats continue to occur, and thus are not useful in the suppression of ventricular tachyarrhythmias. They have powerful proarrhythmic effects and actually increase mortality when given chronically to patients who have suffered myocardial infarction.⁷ Although class IC agents have little current role in the ED, there have been sporadic reports of utility in the initial treatment of AF.

Class II agents (beta blockers) play only a secondary role in the acute treatment of tachycardias. They have negative dromotropic and chronotropic effects, and thus are sometimes used to treat sinus tachycardia when the elevated heart rate is associated with significant hemodynamic consequences. They are also occasionally used as adjunctive therapy for tachycardias involving the AV node.²⁰ Because of the superior efficacy and safety of adenosine and calcium channel blockers, however, even esmolol, a very short acting beta blocker, is, in most cases, only a second-line agent in this circumstance. A possible exception to this general rule is the presence of an acute coronary syndrome, in which the use of beta blockers is generally beneficial, and where there are concerns about the overall effects of calcium channel blocking agents. Although these concerns probably do not apply to the long-acting nondihydropyridine agents such as verapamil and diltiazem, some experts believe that beta blockers should be preferred over calcium channel blockers in this setting.

Sotalol is a noncardioselective beta-adrenergic blocker that, unlike other beta blockers, prolongs the duration of the action potential, increases the refractory period, and lengthens the QT interval. As a result, sotalol is an effective antidysrhythmic agent and has been marketed for the treatment of life-threatening ventricular dysrhythmias. Although sotalol also has demonstrated efficacy in the prophylaxis and treatment of AF and PSVT, its role in the emergency management of these conditions remains poorly defined.

Class III agents include *amiodarone* and *bretylum*, as well as *ibutilide*, which is not yet approved in the United States but has been studied in Europe. Amiodarone is a complex antiarrhythmic with multiple effects. Although previously available only in oral form, an intravenous preparation of amiodarone was approved by the Food and Drug Administration in 1996 for the treatment of refractory VT and VF. Amiodarone is probably superior to lidocaine and bretylium for this indication, as well as for the treatment of stable VT. Amiodarone has also been moderately effective in the treatment of AF for rate control and conversion to sinus rhythm. Amiodarone can cause hypotension, heart block, and QT prolongation leading to torsade de pointes. Usual doses for VT and VF are 150 mg intravenously (i.v.) over 10 minutes, followed by 1 mg/min for 6 hours and then 0.5 mg/min. An additional bolus of 150 mg can be given for breakthrough arrhythmias. Similar doses can be used for unstable AF.¹⁷

Bretylum has been widely used in emergency medicine, particularly in the setting of cardiac arrest. However, in light of the greater safety and efficacy of other agents, bretylium should be considered, at best, a second- or third-line option.

Calcium channel blockers, particularly *diltiazem* and *verapamil*, continue to have a role in the therapy of tachycardias that involve the AV node. These drugs, which constitute class IV, dramatically decrease conduction through the AV node, thus slowing the ventricular response in conditions such as AF and interrupting reentry in PSVT (both when the circuit is contained entirely in the AV node and when one of its limbs is in the AV node and the other is in a bypass tract, such as occurs with WPW syndrome). Despite the popularity of adenosine, verapamil remains an excellent choice for the treatment of stable patients with regular narrow QRS complex tachycardia (usually PSVT), although it is contraindicated when the QRS complex is wide.¹³ VT is the most common cause of a regular wide-complex tachycardia, and

it cannot be ruled out with certainty on clinical or electrocardiographic grounds; calcium channel blockers may cause fatal degeneration to VF if given to patients with VT. Diltiazem has effects on the AV node similar to those of verapamil, but fewer vasodilatory and negative inotropic effects. The primary indication for intravenous diltiazem is for prompt control of the ventricular response rate in patients with rapid AF, particularly in the presence of mild-to-moderate congestive heart failure. ¹¹

Because of their vasodilatory and negative inotropic effects, calcium channel blocking agents can cause significant hypotension. They are contraindicated in the presence of severe hypotension and should also be used with caution in the presence of significant congestive heart failure. They are contraindicated in the presence of SA and AV nodal disease. Intravenous calcium blocking agents should be used cautiously in the presence of oral beta blockade, and are relatively contraindicated when intravenous beta blockers have recently been used. They are also relatively contraindicated in the presence of digitalis toxicity (but not merely because a patient is on digitalis) because of their effect on the AV node. Calcium, in doses as low as 100 mg of calcium chloride, can ameliorate the vasodilatory and negative inotropic effects of verapamil without diminishing its negative dromotropic effects on the AV node. ¹²

Several drugs with important antiarrhythmic effects do not fit easily into this classification scheme. *Adenosine* is a naturally occurring nucleotide, which, like verapamil and diltiazem, exerts its principal antiarrhythmic effects by slowing conduction at the AV node. Adenosine also shares the potentially adverse cardiovascular effects of vasodilation, negative inotropy, and potentially excessive blockade of the AV node. The unique pharmacokinetic properties of adenosine, however, which has a serum half-life of less than 10 seconds, set it apart from the calcium channel blockers. In the treatment of reentrant AV nodal tachycardia (which makes up the vast majority of cases of PSVT), in which only a transient slowing of AV nodal conduction is necessary to interrupt the reentrant impulse and thus effect conversion to sinus rhythm, the shorter duration of action is particularly attractive, because side effects, even when momentarily severe, resolve so quickly that they are typically of minimal clinical consequence. On the other hand, the short half-life may also be responsible for the higher rate of recurrence of PSVT that is seen following conversion with adenosine than with verapamil.⁵ The ultrashort duration of action also precludes the use of adenosine for control of the ventricular response in AF or atrial flutter.

In addition to its use in the termination of PSVT, adenosine is probably safe in regular wide-complex tachycardias of uncertain origin, and has been used diagnostically in this patient group. This practice should not be routine in patients with a high likelihood of VT (known coronary artery disease, ECG with evidence of AV dissociation) in whom benefit is unlikely. Adenosine is contraindicated in patients with an irregular wide-complex tachycardia (often due to AF with WPW) in whom VF may be induced.

Although the side effects of adenosine are generally too transient (less than 10 to 30 seconds) to be clinically significant, the drug is uniquely capable of causing brief but sometimes severe chest pain. The cause of this pain, which mimics myocardial ischemia, is uncertain, but it may be related to cardiac afferent innervation. It is not a sign of myocardial ischemia. Reassuring the patient of the benign nature of the pain is the only treatment necessary.

Because of its rapid degradation, adenosine must be given by rapid bolus injection, preferably in a more proximal venous access site (e.g., antecubital fossa), followed by a flush of normal saline. In the treatment of PSVT, an initial dose of 6 mg (0.01 mg/kg) can be followed by a 12-mg dose if the first dose is ineffective. Heart transplant patients are very sensitive to adenosine and require reduced doses, starting at 1 to 2 mg. Adenosine is potentiated by carbamazepine and dipyridamole and is antagonized by the methylxanthines (theophylline and caffeine). Contraindications include AV block, significant hypotension, and known WPW with AF.

Digoxin slows conduction through the AV node and has long been used for the control of the ventricular response in acute and chronic AF. Although digoxin may still have a role in the long-term management of AF, it has largely been supplanted by diltiazem for acute rate control. Digoxin is no more effective than placebo in converting AF to sinus rhythm, and it is less effective in this regard than a number of other drugs. Digoxin has a low toxic–therapeutic index and can induce arrhythmias at concentrations only minimally above therapeutic.

Magnesium appears to be an effective antiarrhythmic agent, although clinical and research experience with it is relatively limited. Magnesium is a necessary cofactor in the energy-dependent transmembrane sodium–potassium adenosine triphosphatase pump, and it is important in correcting intracellular hypokalemia (which greatly increases the risk of serious arrhythmias in the setting of acute ischemia). It also has antiarrhythmic effects in a variety of circumstances in which repolarization abnormalities exist. Clinically, magnesium has been demonstrated to be effective in the treatment of ventricular arrhythmias, particularly torsade de pointes, for which it is the drug of choice, and stable monomorphic VT.

Magnesium slows the ventricular rate in AF by blocking the AV node and may increase the rate of conversion to sinus rhythm. Magnesium can terminate MFAT and is marginally effective in PSVT. Usual doses of magnesium are 2 to 4 g i.v. over 5 minutes, followed by an infusion of 1 g per hour. At these dosages, magnesium is a safe agent that produces few side effects. At excessive doses or rates of administration, hypotension, loss of reflexes, and respiratory depression can occur. Infusions should be avoided in patients with renal failure, as accumulation can result in respiratory failure.

Automated Implantable Cardioverter–Defibrillators

Automated implantable cardioverter-defibrillators (AICDs) are being used in a growing number of patients with recurrent ventricular tachyarrhythmias who are at increased risk of sudden death. These devices have a computerized pulse generator, typically implanted in the abdominal wall, and both afferent and efferent cardiac leads. They are designed to recognize malignant rhythms and deliver a countershock to the heart. ²⁴

AICD failure can take several forms, each of which may result in emergent problems. The device may fail to fire when necessary, or may fire inappropriately (randomly, or in response to a nonmalignant tachycardia). When the AICD fails to fire, a patient can present in cardiac arrest (in VT or VF) or with recurrent bouts of tachycardia-related symptoms (palpitations, light-headedness, syncope). During an arrest, the AICD should be deactivated by placing a standard pacemaker magnet over the upper right corner of the pulse generator for at least 30 seconds, until the QRS-synchronous beeps are replaced by a single continuous tone. Although the AICD poses no threat to the resuscitation team, it can interfere with the resuscitation. A cardiologist expert in the use of these devices should analyze the reason for AICD failure (sensing problems, lead problems, or pulse generator failure) in an intensive care unit.

Patients may present because the AICD has fired. This could represent an appropriate (and lifesaving) response to a malignant arrhythmia, or an inappropriate shock due to device malfunction. These patients should be seen by their cardiologist in the ED, and almost all (even those in whom the shock was ostensibly appropriate) should be admitted to a monitored setting to evaluate the underlying arrhythmia, to monitor antiarrhythmic drug therapy, and to ensure that the AICD is working properly. If the device continues to fire intermittently in the ED in the absence of malignant arrhythmic stimuli, it must be deactivated. This should be done only after ensuring that appropriate resuscitation equipment is immediately available; all such patients require admission to an intensive care unit.

EMERGENCY DEPARTMENT MANAGEMENT

In the ED, where diagnostic data are often limited and the patient's condition warrants prompt action, tachyarrhythmias are most successfully managed using an algorithmic diagnostic and therapeutic schema that is easily remembered and applied. The following approach is broadly applicable to the emergency management of tachyarrhythmias.

Step 1. Be Prepared for a Cardiopulmonary Arrest

Any patient with a tachyarrhythmia is at risk for deterioration, due either to the arrhythmia or to its treatment. Being prepared for a cardiopulmonary resuscitation by having advanced airway equipment and a defibrillator at the bedside minimizes the patient's risk.

Step 2. Determine Stability

Determine what hemodynamic effect the rhythm is having on the patient. In this context, *unstable* is defined as a heart rate and blood pressure inadequate to maintain vital organ perfusion and function, manifested clinically by significant chest pain, pulmonary edema, altered mental status, syncope, or severe hypotension. Categorizing a patient as stable or unstable is complicated by the innumerable gradations on the continuum from asymptomatic health to cardiopulmonary arrest. The most important feature in determining a patient's stability is the state of perfusion. Altered mental status and ischemic chest pain with ECG changes of ischemia are convincing evidence of instability. Electrical cardioversion should be used to treat unstable patients with any tachyarrhythmia except sinus tachycardia and MFAT.

It is important to note that although up to 70% of patients with a tachyarrhythmia complain of chest pain, the majority of these people do not have myocardial ischemia

and are not really unstable. Chest pain associated with a tachyarrhythmia in a young healthy patient, in the absence of other evidence of hypoperfusion, is rarely clinically important. On the other hand, if the patient has a reasonable chance of underlying coronary artery disease, the chest pain must be taken seriously. Similarly, arbitrary blood pressure cut-offs for defining stable or unstable do not take into account the patient's baseline blood pressure. A systolic blood pressure of 80 mm Hg is of far more concern in a hypertensive elderly patient than in a young and healthy 20-year-old. It should be emphasized that stability is subject to change on a minute-to-minute basis, and therapy must be adjusted accordingly.

After clinical stability is assessed, the ECG should be rapidly and systematically evaluated. Although most therapeutic decisions can be made on the basis of a rhythm strip, a rapid search for evidence of acute ischemia (particularly ST-segment elevation or depression) is necessary and appropriate.

Step 3. Determine the Rate

The more extreme the ventricular rate, the more likely the patient is to become unstable. Sinus tachycardia rarely reaches 160 to 80 beats per minute in adults. Although SVTs typically have rates slower than 180 beats per minute, they can be faster in the presence of a bypass tract. VT is not slowed by passage through the AV node and can thus be much faster (250 to 300 beats per minute), but is usually less than 220 beats per minute.

Step 4. Determine the QRS Complex Width

When emergent cardioversion is not required, subsequent decisions can be based on the duration of the QRS complex. In an adult, a QRS width of greater than 0.12 milliseconds is considered "wide." In many adults with a wide-complex tachyarrhythmia, the QRS duration is substantially greater than 0.12 milliseconds. In children, the QRS duration is age-dependent, but any QRS duration over 0.10 milliseconds is considered prolonged.¹ It is usually possible to determine if a rhythm is wide or narrow from a rhythm strip alone, but if there is uncertainty, the widest QRS complex in the 12-lead ECG should be used as the measure.

Narrow-complex tachycardias can be assumed to be supraventricular. Wide-complex tachycardias are the result of any of three distinct pathophysiologic processes:

1. The rhythm originates in the ventricle and does not use the normal conduction pathway.
2. There is a block of the normal conduction pathway below the AV node (bundle-branch block).
3. The origin of the tachycardia is supraventricular, but there is an accessory conduction pathway that bypasses the normal conduction pathway.

With rare exceptions, a wide-complex tachycardia should be treated as VT for three reasons: (1) VT is the most common cause of a wide-complex tachycardia; (2) despite the existence of diagnostic criteria, VT cannot be reliably distinguished from SVT with aberrancy in the clinical setting, and treating VT as SVT can be fatal (while treating SVT as VT is not harmful); and (3) even if the tachycardia has a supraventricular origin, there may be an associated bypass tract, in which case, standard SVT treatment (e.g., verapamil) is contraindicated. It is never safe to assume that a wide-complex tachycardia is due to aberrancy.

Most important treatment decisions can be made on the basis of the foregoing process. Some, usually less critical, decisions require the following steps as well.

Step 5. Assess the Regularity of the RR Intervals

An irregular narrow-complex tachycardia is usually caused by AF, although it can occasionally be due to MFAT. Because VT is usually regular except during the first few beats, an irregular wide-complex tachycardia should raise the suspicion of AF with a bypass tract, for which the treatment of choice is cardioversion, even in a stable patient.

Step 6. Determine the Presence or Absence of P Waves

Determine whether P waves are present, their morphology, whether they are regular, and how they are related to the QRS complexes. Regular uniform P waves preceding the QRS complex help distinguish sinus tachycardia from other SVTs. Although similar P waves may be present with the much rarer PAT, an abnormal P-wave axis or morphology should alert one to the ectopic origin of that rhythm. An irregular narrow QRS complex rhythm with more than three P wave morphologies is indicative of MFAT. One should, in addition, look for the regular sawtooth deflections of the ECG baseline that characterize atrial flutter waves.

Application of this scheme organizes arrhythmias into a limited number of categories, each with a specific management strategy. Unstable patients sometimes need treatment initiated before analysis of the rhythm can be completed. Once the rhythm is stabilized, the patient may require additional pharmacologic treatment to prevent recurrent arrhythmias.

NARROW-COMPLEX TACHYCARDIAS

Regular, P Waves Present

Sinus tachycardia makes up the vast majority of these cases. PAT is a rare alternative diagnosis. Therapy for sinus tachycardia is usually directed at the rhythm's underlying cause rather than at the rhythm itself. However, there are exceptions. In the setting of acute myocardial ischemia, slowing the heart rate with beta blockers diminishes myocardial oxygen demand and improves mortality.²⁵ Beta blockers are also important in thyroid storm to counteract the adverse consequences of extraordinary increases in sympathetic drive. In cocaine overdose, beta blockade may be appropriate for control of heart rate, but only once simultaneous alpha blockade has been begun to avoid the greater danger of unopposed alpha-adrenergic stimulation.

Regular, No P Waves

PSVT (Fig. 135.1) makes up the majority of cases in this category. Although the rhythm strips of patients having atrial flutter with a consistent degree of AV nodal block can appear similar, careful inspection of a 12-lead ECG usually reveals flutter waves. Patients with PSVT who have severe signs of end-organ hypoperfusion should be cardioverted; more than 90% convert with small doses of electrical energy (10 to 50 J).

Figure 135.1. Paroxysmal supraventricular tachycardia.

Treatment of PSVT, typically a reentrant tachycardia in which the AV node is part of the circuit, is directed at blockade of the AV node. Vagal maneuvers may be tried first: carotid massage, the Valsalva maneuver, and ice-water immersion work well in many patients. However, because many patients with recurrent PSVT are familiar with vagal maneuvers, they often present for treatment only when these maneuvers have failed; thus, these maneuvers are often not useful in the ED.

Pharmacotherapy for stable patients with PSVT involves blockade of the AV node. Treatment options include adenosine, verapamil, diltiazem, and beta blockers. Adenosine, due to its brief duration of action and its resultant lack of sustained hemodynamic effect, has become the drug of choice. The recommended initial dosage of adenosine is a 6-mg bolus over 1 to 3 seconds, followed by a 20-mg flush of normal saline. If there is no response in 1 to 2 minutes, a 12-mg dose can be administered in the same manner. It is important that the drug be given as a rapid bolus, so as to achieve high levels in the heart.

In the absence of any of the standard contraindications to calcium channel blockers (hypotension, congestive heart failure, sinus or AV nodal disease, or the previous use of i.v. beta blockers), verapamil is a safe and effective alternative. The standard initial dose is 0.075 to 0.150 mg/kg. In adults, an initial dose of 5 mg is usually appropriate. Most patients convert to sinus rhythm within about 2 minutes, and incremental doses to a maximum of 15 to 20 mg are usually successful in those who do not. Diltiazem is also effective in a dose of 10 mg i.v., repeated up to a total of 50 mg in the first 30 minutes. Calcium may be used to prevent or treat the hypotensive effects of verapamil and probably diltiazem.

Verapamil is safe when used in patients with narrow QRS complex tachycardias, particularly when calcium is used to prevent or treat transient hypotension. Nevertheless, there is a substantial incidence of adverse effects when contraindications are present, so they should not be ignored.¹³ Many pediatric cardiologists consider it unsafe to use verapamil in children under 1 year of age, and so use adenosine exclusively in this age group.

Esmolol, an extremely short-acting beta-blocking agent with a half-life of less than 10 minutes, is moderately effective in treating PSVT, although success rates are significantly lower than with either adenosine or verapamil and the incidence of hypotension is higher. Esmolol is, therefore, a secondary drug in the treatment of PSVT.²³

Atrial Flutter

Atrial flutter is the most electrosensitive tachycardia, and electrocardioversion is the treatment of choice in most cases. The calcium channel blockers (verapamil and diltiazem), as well as digitalis, are capable of slowing the ventricular response in atrial flutter, and verapamil will convert perhaps 15% to 20% of cases to sinus rhythm.² Adenosine, while capable of slowing conduction for a few seconds, rarely results in cardioversion and has no role in the management of atrial flutter, although it can occasionally be of diagnostic value in distinguishing atrial flutter and PSVT. Unless cardioversion is contraindicated, pharmacologic therapy to slow heart rate is a secondary approach. Cardioversion, which occasionally results in AF rather than sinus rhythm, can be done semielectively in most patients in flutter. Given the small amount of current needed and the availability of excellent sedative agents, cardioversion should be possible with minimal discomfort.

While the diagnosis of atrial flutter is often fairly easy, some patients with flutter at first glance appear to be in other rhythms. Therefore, it is important to consider and exclude flutter before using any drug (such as procainamide) that speeds conduction through the AV node. This is because atrial activity in flutter is typically much faster than ventricular response, and such drugs can change the conduction from 2:1 or 3:1 to 1:1, with serious hemodynamic consequences. Vagal maneuvers can sometimes slow the ventricular rate enough to bring out flutter waves (if they are present), but adenosine is particularly effective in this regard.

Irregular, P Waves Present

Multifocal Atrial Tachycardia. MFAT is characterized by P waves of varying morphologies and by changing PR intervals. Because it originates in the atria, it is associated with narrow QRS complexes, except in the presence of underlying bundle-branch block. MFAT occurs primarily in patients with chronic lung disease, and within this group it is most common in patients with high or toxic levels of theophylline.

Because MFAT has been thought to occur due to the hypoxic effects of the underlying lung disease, treatment has been considered futile. The recognition that theophylline toxicity may contribute to this arrhythmia,¹⁴ and several small series demonstrating slowing or conversion of MFAT with magnesium or verapamil, suggest that a nihilistic approach is inappropriate. Although MFAT is seldom life-threatening, the ability to control it can provide symptomatic benefit.

Irregular, No P Waves

Atrial Fibrillation. An irregular narrow-complex tachycardia is almost invariably AF or atrial flutter with variable block ([Fig. 135.2](#)). Occasionally, the P waves of MFAT are overlooked and that rhythm is confused with AF.

Figure 135.2. AF or atrial flutter with variable block.

Although many patients with AF are seen in the ED, not all require emergency therapy. For example, those with chronic AF whose ventricular response rate is well controlled do not require immediate treatment. At the other extreme are patients with extremely rapid heart rates associated with hemodynamic deterioration, who require emergent cardioversion regardless of whether the AF is new or old. Because chronic AF is much less likely to convert to (or remain in) sinus rhythm regardless of the therapy used,¹⁵ pharmacologic intervention to control the ventricular response rate is extremely important. Nevertheless, if there is evidence of severe end-organ hypoperfusion, cardioversion should always be tried.

For patients presenting with AF and a rapid ventricular response, treatment is directed at slowing the ventricular rate, and conversion to sinus rhythm is, at best, a secondary consideration. In the majority of these patients, the tachycardia itself (which profoundly decreases the time available for diastolic filling of the ventricles as well as coronary artery perfusion), rather than the loss of atrial systole, is responsible for the hemodynamic consequences. Patients with hypertrophic cardiomyopathy, as well as other patients with significant diastolic dysfunction of the heart, are an exception, because their stiff ventricles fill slowly and poorly during the passive phase of early diastole, and they thus rely on active atrial systole for an inordinate proportion of their end-diastolic ventricular volume.

At the other extreme, a slow ventricular response in new-onset AF is worrisome (unless the patient is already taking medications that slow conduction in the AV node), because it implies sinus node or AV node dysfunction (the “tachy-brady syndrome”). Such patients are rarely acutely unstable and may not require immediate treatment at all. In fact, attempted cardioversion may lead to asystole or prolonged bradycardia, and even if successful, it is typically followed by early reversion to AF.⁴ Patients with spontaneously slow ventricular response to new-onset AF generally need to be admitted for consideration of long-term measures, including, in some cases, insertion of a permanent pacemaker.

Calcium channel blockers, in particular diltiazem, have supplanted digoxin as the drug of choice for AF with a rapid ventricular response in stable patients. This change in practice is the result of evidence that, although digoxin is no more effective than placebo in slowing ventricular response¹⁶ in the first few hours, calcium channel blockers slow ventricular response within the first few minutes of i.v. administration. Neither digoxin nor calcium channel blockers are particularly effective at producing cardioversion to sinus rhythm. In stable patients, diltiazem can be given at a dose of 5 to 10 mg over 2 minutes, repeated as necessary every 5 minutes to a total dose of 50 to 60 mg in the first 30 minutes. To reduce hypotension, patients can be pretreated with calcium as described earlier. Following bolus injection, rate

control can be maintained with an i.v. infusion of 5 to 15 mg per hour.

Alternative agents include verapamil, magnesium, beta blockers, and digoxin. Verapamil and magnesium are given in the same doses as for regular tachyarrhythmias. Beta blockers such as atenolol or metoprolol can be given in doses of 5 mg intravenously, repeated up to a total of 15 mg. Beta blockers are about as effective as calcium channel blockers for rate control, but are seldom used because of a higher incidence of hypotension. Beta blockers are indicated for rapid AF associated with thyrotoxicosis, a catecholamine excess state for which calcium channel blockers are minimally effective. Digoxin may be given as 0.5 mg i.v. or orally, followed by 0.25 mg 4 and 8 hours later. Even when using these loading regimens, rate control is no better than with placebo for at least several hours. Diltiazem or verapamil may be given i.v. at the same time as digoxin, in the absence of other contraindications. There may be some advantage to diltiazem in patients with mild hypotension or congestive heart failure, because of its less pronounced negative inotropic effect.¹¹ Calcium channel blockers should be avoided in the presence of digitalis toxicity.

The therapy of unstable patients with narrow-complex AF is one of the most challenging situations in all of arrhythmia management. Many AF patients have dilated atria and decreased ejection fractions. These patients do not easily cardiovert to sinus rhythm or remain in sinus rhythm if converted. In addition, cardioversion to sinus rhythm does not produce mechanical atrial contraction for hours to days. For this reason, cardioversion should be considered a form of rapid rate control and not a therapy that immediately restores atrial systole. Finally, if the patient has been in AF for more than 2 to 3 days, intraatrial thrombus may have formed and may embolize following cardioversion. For these reasons, cardioversion is considered by many a therapy of last resort.

If the patient is truly unstable, however, electrical cardioversion is required. Although some authorities suggest higher levels, 100 J is the usual starting dose, increasing to 200 J and 300 J as required. For unstable patients in whom electrical cardioversion fails and for somewhat more stable patients, rate control can be achieved by using repeated small boluses of diltiazem following pretreatment with calcium. Intravenous magnesium is a reasonable alternative. Amiodarone has been used in unstable atrial fibrillation in a number of small case series and in one randomized trial in which it was found to be inferior to magnesium.¹⁷ Amiodarone slows ventricular rate and increases the frequency of conversion to sinus rhythm. In rare cases, the cautious use of dopamine may be required to maintain blood pressure. The seriousness of this clinical situation cannot be overemphasized, and no therapy is without significant risk.

New-onset AF has many causes, from the benign to the extremely serious. It has long been standard practice to admit almost all patients with new-onset AF in order to evaluate the possibility of serious underlying disease (e.g., acute myocardial infarction, mitral valve disease, pulmonary embolism, thyrotoxicosis, or drug effect) as its cause. However, 80% to 95% of stable patients with new-onset AF do not prove to have an acutely critical etiology, and those who do almost always have other worrisome clinical findings besides the arrhythmia itself.²⁰ Thus, the traditional policy is being questioned. Nevertheless, given the limited data on this subject to date, it remains reasonable to discharge only those patients with new-onset AF who do not have evidence of underlying heart disease or other acute instability, who convert easily in the ED back to sinus rhythm, and who are reliable and have good follow-up. Patients with chronic AF should be admitted to the hospital if they have signs of hemodynamic decompensation that requires cardioversion, or if hemodynamic effects and rapid ventricular response are not easily controlled.

Several agents have been the subject of limited testing in the pharmacologic cardioversion of new-onset AF, and they may prove to be of use in the future. These include flecainide, amiodarone, sotalol, clonidine, ibutilide, dofletanide, propafenone, and magnesium. The earlier rates of conversion of these drugs are offset by a high rate of proarrhythmia and hypotension and the fact that by 8 hours there is little difference from placebo in conversion rates.⁶ For these reasons, the chemical conversion of recent-onset AF in the ED remains controversial. Magnesium given as an i.v. bolus of 2 to 4 g over 5 minutes, followed by an infusion of 1 to 2 g per hour, has been associated with a prompt reduction in heart rate and a 64% rate of conversion to sinus rhythm.¹⁷ The fact that risks and benefits must be carefully explained to the patient, and that a trial of "time" may be very effective by itself, has led some authorities to suggest that attempts at chemical conversion should be performed only in the inpatient setting. The exact roles, if any, that these agents will play in the future management of new-onset AF await further study.

Anticoagulation is an important management issue for patients with AF. Not only are patients with AF that lasts more than several days at risk for systemic embolization, but recent evidence suggests that even shorter periods of AF may carry a risk of embolization, particularly following conversion to sinus rhythm. Even if accurate, a history of a brief duration of AF may fail to preclude the possibility of embolization due to intraatrial clot formation during the period of atrial stand-still that follows conversion to sinus rhythm. For this reason, some authorities suggest that all patients with acute AF be anticoagulated at the time of diagnosis and for 12 to 24 hours after conversion to sinus rhythm.

On the other hand, recent studies of transesophageal echocardiography (TEE) in ruling out an intraatrial thrombus prior to conversion of AF suggest that a negative TEE reduces the risk of embolization enough to obviate the need for anticoagulation. However, until additional studies more fully define the risks and benefits of these new management strategies, the standard of care is to anticoagulate all patients with AF of more than 72 hours' duration prior to elective electrical or chemical cardioversion. Of course, if it is necessary, cardioversion should never be withheld because of hemodynamic instability. In addition, all patients with chronic AF, except, perhaps, those less than 60 years old who have no other evidence of heart disease, should be on maintenance anticoagulant therapy unless there are substantial contraindications.²²

Patients with chronic AF are usually taking antiarrhythmic medications. Digitalis has long been used for chronic rate control. Cardioversion in patients taking digoxin is a risk because of the potential for asystole. If cardioversion is required due to extreme hemodynamic compromise, it should initially be attempted at lower energy levels, such as 50 J. Many experts now prefer calcium channel blockers to digoxin for chronic rate control, because they control rate not only at rest, but also during exercise. There are also several recent reports suggesting a role for other drugs, including, particularly, amiodarone and sotalol, in chronic AF, although the overall safety of long-term therapy has been questioned.

WIDE-COMPLEX TACHYCARDIAS

As with narrow-complex tachycardias, tachycardias manifesting wide QRS complexes must be managed primarily according to their hemodynamic effects. Patients with wide-complex tachycardias are more likely to require cardioversion, because most have VT, which is more likely to be associated with end-organ hypoperfusion. Nevertheless, many such patients are relatively stable at presentation and respond to pharmacologic therapy.²¹

Regular, No P Waves

Diagnostic possibilities include VT, PSVT with aberrancy (bundle-branch block), and antidromic WPW syndrome. Several clinical and ECG criteria have been devised to enable clinicians to distinguish between VT and SVT when the QRS complex is wide. Useful indicators that make VT more likely include a history of heart disease, fusion and capture beats, and the presence of AV dissociation. Although such criteria are relatively accurate in predicting the source of tachycardia in series of patients, no single sign or combination of signs can definitively identify the origin of tachycardia.¹⁰ For this reason, wide-complex tachycardia should virtually always be treated as VT. Thus, drugs contraindicated in VT (e.g., verapamil) are almost never used to treat wide-complex tachycardia.^{16,21} Adenosine may be used to treat regular wide-complex tachycardia of uncertain etiology, because it is probably safe (if only very rarely effective) in VT and will convert most episodes of PSVT, including antidromic WPW syndrome.

Ventricular Tachycardia. VT is usually a life-threatening medical emergency. Although some patients have intermittent asymptomatic bouts of VT (usually episodes of less than 10 beats), patients who present to an ED with VT are usually either suffering from significant hemodynamic effects or experiencing other acute cardiac problems, including, particularly, myocardial ischemia, that require emergent treatment. Essentially, all patients with VT require consultation with a cardiologist and admission after ED therapy of the arrhythmia.

The typically very rapid heart rate of sustained VT usually causes hemodynamic deterioration.¹⁶ Such patients require emergent electrical cardioversion. Fifty joules is a reasonable initial energy, because about 90% of episodes of VT respond to 10 to 50 watt-seconds of energy. Cardioversion is performed in the synchronized mode to avoid precipitating VF. Lidocaine, procainamide, and bretylium are standard agents used to prevent recurrence of VT after successful cardioversion or to treat patients with recurrent VT. Recent evidence suggests that magnesium and amiodarone may also be efficacious.

Sometimes, patients with sustained VT show no signs of hemodynamic instability in the short term. These patients can be treated with lidocaine, procainamide, magnesium, or amiodarone. The medical literature does not provide a clear basis for preferring one agent over another. Lidocaine, which is only moderately effective for VT, is given as an initial 100-mg i.v. bolus and may be repeated in 75-mg boluses up to 3 mg/kg. Procainamide, an effective therapy for both VT and PSVT, is given as a 17-mg/kg i.v. bolus at a rate of not more than 50 mg/min. Procainamide can cause QRS widening and hypotension. Magnesium is effective for VT and moderately effective for PSVT. Usual doses of magnesium are 2 to 4 g i.v. over 5 minutes, followed by an infusion of 1 g per hour. Amiodarone can be given as 150 mg i.v. over 10 minutes, followed by an infusion of 1 mg/min over the next 6 hours. An additional 150-mg i.v. bolus can be given for breakthrough VT. Amiodarone can

cause hypotension (treated with fluid bolus) and AV nodal block.

Wide-Complex PSVT. PSVT can manifest with wide QRS complexes when bundle-branch block (either underlying or rate-related) is present (Fig. 135.3). The duration of the QRS complex in this circumstance is not likely to exceed 0.14 second, and heart rates usually range between 130 and 200 beats per minute. Nevertheless, it is virtually impossible to be certain that a wide-complex tachycardia represents PSVT with bundle-branch block, rather than VT; therefore, treatment should almost never be based on this assumption.¹⁰

Figure 135.3. Wide-complex paroxysmal supraventricular tachycardia.

Wide QRS complexes are also seen in PSVT in association with the WPW syndrome when anterograde conduction occurs down the bundle of Kent and retrograde conduction occurs through the AV node. It may be possible to make this diagnosis from the ECG in patients with known WPW syndrome, although confusion with VT may still occur. When faced with a stable patient with a regular wide-complex tachycardia of uncertain etiology, adenosine is the preferred antiarrhythmic. Neither verapamil nor digoxin is recommended in this circumstance.

When adenosine fails to convert regular wide-complex tachycardia or when VT is considered more likely, procainamide is a rational choice. Procainamide has antiarrhythmic effects on both atrial and ventricular tissue, and it is safe and useful in most cases of wide-complex tachycardia, whether VT or PSVT with anterograde conduction through the bundle of Kent. Wide-complex tachycardia in the setting of possible drug overdose, however, suggests cyclic antidepressant toxicity, in which case, procainamide is absolutely contraindicated. Lidocaine, the first-line pharmacologic agent for treatment of known VT (in the absence of hemodynamic consequences), can occasionally speed conduction through bypass tracts in experimental models; thus, lidocaine is less attractive than procainamide when wide-complex tachycardia is suspected to be due to WPW-related PSVT.

Irregular, No P Waves

Diagnostic possibilities include AF with bundle-branch block, AF with the WPW syndrome, torsade de pointes, and VF.

Wide-Complex AF. A few patients with AF present with wide QRS complexes, owing to an underlying or rate-related bundle-branch block or to the WPW syndrome. In the presence of known underlying bundle-branch block, treatment can be similar to that for routine narrow-complex AF (i.e., cardioversion for unstable patients and a calcium channel blocker for rate control in stable patients).

Patients with rate-related bundle-branch block often demonstrate both wide complexes (in beats that follow short RR intervals) and narrow complexes (in beats that follow longer RR intervals), but patients with AF and the WPW syndrome may also have both wide and narrow QRS complexes, depending on the conduction path followed by each depolarization. It is critical to recognize this latter entity, because agents that slow conduction through the AV node are absolutely contraindicated.⁹

WPW is a relatively rare syndrome that involves accessory pathway connections between the atrium and the ventricles. The presence of these rapidly conducting pathways predisposes to a number of arrhythmias, of which AF is the most dangerous. AF generates impulses at 300 to 600 per minute. The accessory pathways of WPW, which bypass the AV node and its protective slowing, conduct impulses to the ventricle at rates exceeding 250 beats per minute. The ventricle will fail or undergo fibrillation if these excessively rapid atrial impulses are conducted for more than a short time. Many patients are aware that they have WPW. Among patients who give no history of WPW, the possibility should be considered when the irregular rhythm is wide and very fast, and the QRS complexes are variable and bizarre.

Drugs such as verapamil, diltiazem, and digitalis are contraindicated in WPW syndrome with wide-complex AF, because they can actually increase the speed of conduction through the bypass tract. More importantly, relative blockade of the AV node causes preferential conduction through the bypass tract, resulting in much higher ventricular response rates; an extremely rapid ventricular response to AF can then deteriorate into VF. With calcium channel blockers, other hemodynamic effects, such as decreased inotropy and vasodilation, in the absence of any therapeutic effect, can add to the potentially catastrophic consequences of such therapy.

Although procainamide is unlikely to be harmful in WPW-related AF, it may not be particularly effective in the acute setting. Therefore, even in the absence of acute hemodynamic deterioration, patients with WPW-related AF are best treated with electrical cardioversion. After cardioversion, procainamide is given to prolong the refractoriness of the accessory pathway and to prevent recurrence of AF. Because procainamide can increase AV nodal conduction, some authorities suggest the addition of an AV node blocking agent.

Torsade de Pointes. Torsade de pointes is an unusual form of polymorphic VT characterized by the peculiar spiral pattern it produces on the surface ECG. The most common cause is the use of type IA antidysrhythmic agents (e.g., quinidine, procainamide, and disopyramide) that prolong the QT interval, a factor central to the development of this dysrhythmia. Other drugs (most prominently, the phenothiazines), drug interactions, and many other conditions (especially hypocalcemia and hypokalemia) are also associated with torsade.

Although most episodes of torsade are self-limited, they are nevertheless life-threatening, because any episode can precipitate VF. Because torsade usually converts spontaneously to sinus rhythm but then recurs, treatment is directed at preventing recurrences rather than terminating a given episode. In the long term, this often requires only withdrawal of the offending agent. In the ED, however, antidysrhythmic therapy is mandatory.

Magnesium, given as an i.v. infusion of 2 to 4 g over 30 minutes to 1 hour, is highly effective and is the treatment of choice for torsade. Alternately, overdrive electrical pacing can be used to speed the heart rate and thus decrease the dispersion of refractoriness that is the underlying basis for this arrhythmia. Infusions of isoproterenol have also been used with the same goal, although the proarrhythmic effect of isoproterenol is worrisome.

Ventricular Fibrillation. VF is the chaotic firing of the ventricle from multiple foci and never results in effective myocardial contraction. It is the most common rhythm found early in cardiac arrest. The only therapy proven to improve the outcome of patients with VF is electrical defibrillation. When a defibrillator is available, no other activity should take precedence: No time should be spent starting i.v. lines, securing an airway, performing cardiopulmonary resuscitation, or giving drugs, as these delay the performance of electrical defibrillation. Immediate defibrillation in the nonsynchronized mode with a dose of 200 J provides the greatest likelihood of success. Increasing energy levels probably does not improve the likelihood of defibrillation and may, in fact, be detrimental. Good contact with the chest, use of conduction gel, and firm pressure are all important to reduce transthoracic impedance and improve energy transfer to the heart.

Several adjunctive drugs are widely used when initial defibrillation is not successful. Although these drugs are considered standard therapy in this situation, it is important to remember that none of them has been definitively shown to increase the success of defibrillation or to improve long-term outcome in human beings with cardiac arrest. Thus, administration of these agents should never interfere with the rapid use of electrical defibrillation, the only intervention that has been definitively shown to affect outcome.

Specifically, no study has confirmed a positive effect of epinephrine use at either standard or high doses. Indeed high-dose epinephrine use is associated with increased costs from the small but significant increase in severely neurologically impaired survivors. Similarly, there is little evidence that lidocaine, bretylium, or

amiodarone significantly improves outcome in refractory VF. Lidocaine remains the drug of choice in the current American Heart Association advanced cardiac life-support guidelines, but there is evidence that amiodarone may be marginally more effective.

Intravenous lidocaine, bretylium, or amiodarone is used, however, to help prevent recurrence of VF after successful defibrillation. Comparative studies have failed to show any major differences between lidocaine and bretylium in this regard, but trends in several studies have favored lidocaine, which probably has fewer adverse effects. The role of amiodarone in arrhythmia prophylaxis following successful cardioversion is, as yet, undefined.

Although sodium bicarbonate and calcium chloride may worsen outcome if used routinely in cardiac arrest, they still have a role in specific circumstances. Sodium bicarbonate may be lifesaving in tricyclic antidepressant overdose, and i.v. calcium is often an effective antidote for calcium channel blocker overdose.

DISPOSITION

In most cases, the disposition of patients with tachyarrhythmia is obvious. The patient resuscitated from cardiac arrest due to VF obviously must be admitted to the intensive care unit. Similarly, there should be little controversy about discharging a healthy young patient with a brief, minimally symptomatic episode of PSVT that readily converted to sinus rhythm. In the few patients with a problematic disposition, the physician should remember that ED care involves only initial therapy and not definitive management of the tachyarrhythmia. Several categories of patients should be admitted:

- Patients who are symptomatic after acute onset of tachycardia and who have failed appropriate therapy or responded only transiently
- Patients who were clinically unstable as a result of a tachycardia, including all patients who require cardioversion because of end-organ hypoperfusion
- Patients who were treated successfully before the development of serious symptoms but who have the potential for decompensation if the tachyarrhythmia recurs

The basis of the arrhythmia also plays a role in disposition decisions: Any patient with a realistic likelihood of a dangerous etiology (e.g., possible acute myocardial infarction) should be admitted, even if the arrhythmia itself was benign.

Finally, it may be appropriate to admit a stable patient for continuous ECG monitoring during initiation of chronic drug therapy.

COMMON PITFALLS

- Failure to be prepared for deterioration of the patient's condition. All arrhythmias and their therapies have the potential to cause the patient to decompensate. A defibrillator and advanced airway equipment should be ready at the bedside.
- Failure to use a systematic approach to tachyarrhythmias based on the clinical status at presentation
- Being overly concerned with "diagnosis." One should concentrate more on the hemodynamic effects of the rhythm than on its origin. An apparently benign narrow-complex rhythm should not be treated conservatively in the face of end-organ hypoperfusion. Patients who are unstable in the face of any very rapid tachycardia (except for sinus tachycardia or MFAT) require electrical cardioversion. Conversely, stable patients can often be managed without electrical cardioversion, even if their tachycardia appears ominous from the standpoint of its cause or morphology.
- Reliance on ECG and clinical findings to identify the likely source of an arrhythmia. ECG and clinical findings are suggestive but not infallible guides.
- Use of verapamil to treat a wide-complex tachycardia. Verapamil is appropriate for many narrow-complex tachycardias but can precipitate VF in wide-complex tachycardias. This is true not only when the rhythm is VT, but also for other wide-complex tachycardias originating above the AV node, such as AF with anterograde conduction down a bypass tract in WPW.
- Treatment of symptoms rather than the tachyarrhythmia precipitating those symptoms. In patients having symptoms related to a very rapid tachycardia, controlling the ventricular rate usually ameliorates the symptoms.
- Failure to seek and, if possible, correct the factors that precipitated a tachyarrhythmia. Examples of specific precipitants include hypoxemia, infectious or inflammatory processes (e.g., endocarditis, myocarditis, pericarditis), and endocrine or metabolic abnormalities (e.g., thyrotoxicosis, hypokalemia or hyperkalemia, hypomagnesemia). Arrhythmias can also be caused by intoxications, such as intentional overdose (e.g., tricyclic antidepressants), drug abuse (e.g., cocaine, alcohol), or therapeutic misadventure with prescribed medications (e.g., digoxin, theophylline). In patients taking antidysrhythmic agents, an acute dysrhythmia may be the result of subtherapeutic drug levels, a dysrhythmogenic effect of the drug at therapeutic or toxic levels, or simply a failure of the drug to prevent a preexisting dysrhythmia.
- Failure to consider myocardial ischemia in all patients. Myocardial infarction must be ruled out whenever it seems a reasonably likely cause of the arrhythmia, or when the arrhythmia has itself produced a substantial period of ischemia as suggested by ECG changes or symptoms.

[The Patient with a Pacemaker](#)[Clinical Presentation and Differential Diagnosis](#)[Emergency Department Evaluation](#)[Pacemaker Malfunction and Pacemaker-Associated Disorders](#)[Emergency Department Management](#)[Disposition](#)[The Patient with an Implantable Cardioverter–Defibrillator](#)[Clinical Presentation and Differential Diagnosis](#)[Patient Evaluation and Emergency Department Management](#)[Disposition](#)[Common Pitfalls](#)[Chapter References](#)**THE PATIENT WITH A PACEMAKER**

The first permanent cardiac pacemakers were implanted in the late 1950s, and since that time, advances in microprocessor technology have led to the production of compact pacemakers that adapt to changes in patient physiology.¹¹ While the earliest models had only single-chamber, asynchronous pacing capability, with less than a 2-year battery life, current dual-chamber pacemakers are rate-responsive to increased patient activity and are powered by lithium batteries that may last more than 10 years.³

Given that over 1 million Americans currently have pacemakers,¹¹ the emergency physician will undoubtedly care for many patients with these devices. While detailed knowledge of the myriad complexities of pacemaker programming and operation is unnecessary, the emergency physician must understand the basics of pacemaker terminology and function and must be familiar with the presentation, evaluation, and treatment of the common pacemaker-related problems.

Central to the understanding of basic pacemaker function are the five-letter codes used by the North American Society of Pacing and Electrophysiology–British Pacing and Electrophysiology Group (NASPE/BPEG) to characterize the modes of operation of current pacemakers ([Table 136.1](#)). In everyday practice, description of the mode of pacing is limited to use of the first three code letters: position I, chamber(s) paced; position II, chamber(s) sensed; and position III, pacemaker response to sensing. A VVI pacemaker thus paces the ventricle only, senses only ventricular depolarizations, and inhibits pacemaker output in response to a sensed ventricular depolarization. The more versatile DDD pacemaker, which is currently the most frequently implanted type of pacemaker,¹¹ may pace the atria, the ventricles, or both; sense atrial depolarizations, ventricular depolarizations, or both; and either inhibit or trigger pacemaker output to the atria and ventricles in response to sensed depolarizations. Intrinsic ventricular depolarizations will inhibit both atrial and ventricular output; intrinsic atrial depolarizations will inhibit atrial pacemaker output and will trigger ventricular output if the ventricle itself does not respond after a programmed time interval.

1st position indicates the chamber paced:
W = ventricle
A = atrium
D = dual
0 = no pacing
2nd position indicates the chamber sensed:
W = ventricle
A = atrium
D = dual
0 = no sensing
3rd position indicates the response to a sensed event:
I = inhibited
T = triggered/backup
D = dual
0 = no response
4th position indicates programmability & rate response:
0 = not programmable
P = single programming (three functions or less)
M = multiprogrammable (more than three functions)
C = communicating (telemetry capabilities)
R = rate responsive
5th position indicates anti-tachycardia functions:
0 = none
P = pacing
S = shock
D = dual (shock and pacing)

TABLE 136.1. NASPE/BPEG (NBG) Codes

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Syndromes of pacemaker malfunction can generally be divided into those that cause underpacing, with associated bradycardia, hypotension, light-headedness, and syncope; and those that produce overpacing, manifested by tachycardia and palpitations with or without ischemia or hypotension symptoms. The differential diagnosis of these nonspecific presenting complaints is broad, however, encompassing multiple other disorders, including dysrhythmias, vasovagal phenomena, anemia, hypovolemia, and non–rate-related syndromes of low cardiac output. Before attributing presenting symptoms to pacemaker malfunction, the physician must first determine whether the device is truly malfunctioning. Patient history, electrocardiogram (ECG) analysis, and determination of the current programming and specifications of the pacemaker are the keys to making this evaluation.

EMERGENCY DEPARTMENT EVALUATION

In addition to elucidating standard history about the symptoms, time course, and precipitants related to the presenting complaint(s), the physician should also seek the following information regarding the pacemaker: pacemaker model, current programming, date of implantation, indication for implantation, history of pacemaker malfunction, and dates of last interrogation and battery check. Some of this vital information may be obtained from the pacemaker identification card, which the patient should carry at all times. If this card is unavailable, a chest x-ray may reveal the pacemaker's identifying serial number or code.¹² For technical support or to find out other information about the pacemaker, the physician may call the pacemaker manufacturer's assistance department.

The emergency physician should also ask about exposure to potential sources of environmental electromagnetic interference with pacemaker function. While most everyday appliances and devices pose virtually no risk to current pacemakers, electric toothbrushes, cellular telephones, induction ovens, and stove plates can markedly alter their operation. Most modern airport security gates pose minimal risk, but antitheft systems in stores emit signals of variable intensity, with unpredictable effects on pacemaker function.⁸

Because right ventricular (RV) pacemakers produce left bundle-branch block (LBBB) patterns of depolarization, the ECG diagnosis of myocardial ischemia or infarction (MI) may be difficult. Discordant T waves after paced beats are the norm; minor ST-segment elevations inferiorly and anteriorly (leads V₁ to V₃) and ST-segment depression leads 1, V₁, V₅, and V₆ also commonly occur in the absence of ischemia.² Pacing may even induce marked ST-segment and T-wave abnormalities when the patient's native, spontaneous rhythm emerges.²

Applying the criteria used in the evaluation of patients with intrinsic LBBB, however, the physician may still occasionally diagnose MI in the patient with a pacemaker.² Concordant ST-segment elevations and markedly elevated (greater than 5 mm) discordant ST-segments are highly indicative of MI, especially when the T waves associated with these segments are of opposite polarity.^{2,16} ST-segment depression in leads V₁, V₂, and V₃ also suggests ischemia or infarction, as does late notching of the ascending QRS limb in the left precordial leads.^{2,16} A qR pattern after the pacemaker spike in leads 1, V₁, and V₅ has low sensitivity but very high specificity for

anteroseptal MI.² Finally, serial ECGs may demonstrate progressive ST-segment and T-wave changes that lead to the diagnosis of MI. The emergency physician should certainly look for these patterns, but their absence does not, by any means, rule out ischemia or infarction.

Evaluating the utility of an ECG algorithm based on these patterns for the detection of MI in patients with intrinsic LBBB, investigators found that the algorithm had poor sensitivity (less than 10%) for MI prediction.¹⁸ If the results of this study can be generalized to pacemaker patients with LBBB depolarization patterns, then the emergency physician must not base decisions about thrombolysis and other interventions for pacemaker patients with suspected ischemia or infarction solely or even primarily on the ECG.

Pacemaker Malfunction and Pacemaker-Associated Disorders

Pacemaker malfunction leading to a slow pulse arises from noncapture, pacemaker output failure, and/or pacemaker oversensing. *Noncapture* refers to an absence of ventricular or atrial depolarization after a pacemaker spike (Fig. 136.1). The most common cause of this condition is pacemaker lead dislodgement, which typically occurs within a few weeks of implantation.⁸ Other mechanical causes include insulation breaks, lead fracture, and inflammatory reaction at the lead tip.⁸ Reversible metabolic abnormalities, such as hyperkalemia, and drug effects should also be considered. Of note, if a pacemaker spike occurs within 300 milliseconds of a prior ventricular depolarization, the ventricle may be in its refractory period and lack of capture is expected.⁶ The pacemaker may be firing early because of undersensing of the prior depolarization, but it is not truly malfunctioning with regard to pacing (Fig. 136.2).

Figure 136.1. Noncaptured pacemaker spike between two captured spikes.

Figure 136.2. Pacemaker undersensing.

Absent or inappropriately delayed ventricular pacemaker spikes on the ECG of a bradycardic pacemaker patient indicate primary pacemaker output failure, battery depletion, or output failure secondary to oversensing (reading other signals as ventricular depolarizations).⁸ Causes of primary output failure include lead fracture or disconnection and various pulse generator component failures. Oversensed signals may be of cardiac (P and T waves) or extracardiac (myopotentials) origin and lead to inappropriate inhibition of pacemaker ventricular output.⁸

These causes may be distinguished by performing a magnet test of the pacemaker. Application of a ring magnet over a normally functioning pacemaker disables sensing and induces asynchronous pacing at model-specific rates, which may be determined by checking the patient's records or calling the pacemaker manufacturer.^{8,12} If the problem is oversensing, the magnet will induce asynchronous pacing at that model's characteristic rate. If battery depletion is the cause, asynchronous pacing will occur at a different, generally slower rate.⁸ If the malfunction is due to lead displacement or some other primary cause, no pacing response to the magnet will be seen.

Pacemakers may produce inappropriate tachycardia by several mechanisms. When a pacemaker fails to sense intrinsic ventricular depolarizations, it will fail to inhibit pacemaker output, potentially causing a pacemaker-driven tachycardia; that is, "undersensing leads to overpacing."¹² In dual-chamber systems, the pacemaker circuit may act like an accessory pathway similar to those seen in Wolff-Parkinson-White syndrome, thus propagating a reentrant tachycardia known as pacemaker-mediated tachycardia or "endless-loop tachycardia."¹² This dysrhythmia may be terminated by vagal maneuvers, external magnet suppression of sensing, intravenous adenosine, or external cardiac pacing with 10 to 20 mA of output.^{6,12}

A final pacemaker-related tachycardia that occurs only rarely with current pulse generators is "runaway pacemaker," a potentially lethal disorder in which battery depletion or other component failure causes extremely rapid pacing, with rates restricted only by the pacemaker's upper rate limit.⁹ This disorder generally does not respond to conservative treatment measures, and, in the setting of hemodynamic instability, the emergency physician should attempt to disable the runaway pacemaker by incising over the pacemaker pocket and disconnecting the pulse generator leads.^{6,9}

Pacemaker syndrome, a classic example of a pacemaker operating correctly according to its programming yet still causing bothersome symptoms, results from a loss of atrioventricular synchrony in the VVI pacing mode.¹² Fatigue, light-headedness, and syncope due to decreased cardiac output (loss of atrial kick), and disturbing neck pulsations related to regurgitant cannon A waves (atria contracting against closed atrioventricular valves) are the predominant symptoms. While this disorder is largely limited to patients with VVI pacemakers and is usually ameliorated with a change to synchronized dual-chamber pacing, it can occasionally occur in patients who have DDD pacemakers.¹⁷

In addition to the rhythm and hemodynamic problems associated with pacemakers, foreign-body-related complications also occur. Infections of pacemakers and associated hardware occur in approximately 6% to 15% of patients, with staphylococcal species being the most common pathogens.⁶ In the patient presenting with fever and redness and tenderness over the pulse generator pocket, the diagnosis of pacemaker infection is obvious.

Subtler presentations are common, however, and the emergency physician should consider pacemaker-related infection as a potential cause of unexplained fever in any patient with a pacemaker. Notably, without superimposed endocarditis, embolic phenomena and murmurs are generally absent. Nuclear medicine scans may provide ancillary evidence of infected pacemaker hardware. Confirmed pacemaker infection mandates a course of parenteral antibiotics, and most authorities agree that removal of the device is indicated.¹³

Pacemaker-associated thrombosis of the upper extremity vessels is uncommon (less than 5% by venography), but it should be considered in the patient with unilateral arm swelling, erythema, and/or pain.⁵ Ultrasound or venography may be used to distinguish this entity from similar-appearing arm cellulitis. Anticoagulation without

pacemaker removal has been reported to successfully treat the thrombosis.⁵

EMERGENCY DEPARTMENT MANAGEMENT

As with other emergency department (ED) problems, patient stability determines the urgency of intervention in the patient with a pacemaker. The cardiac arrest patient should receive standard advanced cardiac life support (ACLS)–guided resuscitation. During defibrillation or cardioversion, however, the physician should avoid placing pads or paddles directly over the pulse generator.⁷ Pacemakers of resuscitation survivors should be evaluated for damage and/or reprogramming arising from countershocks. In nonsurvivors, the pacemaker may continue to produce ECG spikes without associated ventricular capture, which represents isolated pacemaker activity and not true pulseless electrical activity.

The pacemaker patient with hypotensive bradycardia requires the usual emergent therapeutic measures (chronotropic support with medications, external pacing, and/or transvenous pacing). The physician may attempt to temporarily asynchronously pace the patient's rate with higher current by placing a ring magnet over the pacemaker, as described earlier in this chapter.⁸ This maneuver may be helpful if the pacemaker is oversensing, and thereby suppressing output (absent or inappropriately slow pacemaker spikes on ECG), or if low pacemaker current is leading to noncapture.

During the ED management of pacemaker patients, the physician must recognize the multiple potential sources of electromagnetic interference with pacemaker function, especially magnetic resonance imaging (MRI) and electrocautery. Given that MRI may induce complete block of pacemaker output, severe pacemaker-driven tachycardias, and other potentially disastrous effects on pacemaker operation, MRI is contraindicated for patients with pacemakers.⁸ If MRI is absolutely essential to patient management, some authorities have suggested switching the pacemaker to its "off" mode, turning pacemaker output down so that it will not capture, or surgically removing the device.^{1,3} These maneuvers must be undertaken with the help of an electrophysiologist, and patient informed consent should be obtained. Electrocautery may also induce any of a number of hazardous abnormalities in pacemaker function; precautions and steps to minimize risk during surgical procedures may be found in other reference texts.³

DISPOSITION

Disposition of the patient with a pacemaker-related problem largely depends on the severity of signs and symptoms, and should be determined collaboratively with the patient's electrophysiologist. Patients with pacing malfunction, such as failure to capture or battery depletion, should be admitted to monitored settings. Patients requiring a higher level of care may occasionally need interhospital transfer. ACLS units should be used, and the patient's rhythm and hemodynamics obviously must be stabilized prior to transfer; backup pacing modalities (transthoracic and/or transvenous) should be in place during transit.

THE PATIENT WITH AN IMPLANTABLE CARDIOVERTER–DEFIBRILLATOR

The first implantable cardioverter-defibrillator (ICD) was placed in 1980, and, as with pacemakers, technologic improvements have produced smaller, "smarter" defibrillators that are more easily placed.⁴ Early models were nonprogrammable shock or no-shock devices that required open thoracotomy for epicardial patch placement. Current programmable devices have defibrillator leads that are inserted transvenously and utilize improved rhythm analysis algorithms to deliver tiered therapy.

For example, slow ventricular tachycardia (VT) may be first treated with overdrive pacing; if it fails to convert the VT, low-energy shocks are delivered. If they also fail, higher energy shocks are given.¹² Some new ICDs also incorporate antiarrhythmia (pacing) functions that may be activated if cardioversion or defibrillation results in a bradycardic or asystolic rhythm. Major trials demonstrating increased mortality with pharmacologic antiarrhythmic therapy and markedly decreased mortality with ICDs have led to broader indications for ICD use.⁴ Currently, there are approximately 400,000 ICDs in operation worldwide.¹⁵

NASPE/BPEG descriptive codes also characterize the types and functions of ICDs¹²: position I, chamber(s) shocked; position II, chamber(s) for antitachycardia pacing; position III, method of tachycardia detection; and position IV, chamber(s) for bradycardia pacing ([Table 136.2](#)). However, in everyday practice, these codes are less commonly used than are pacemaker codes.

1st position indicates the chamber shocked: V = ventricle A = atrium D = dual O = no shock therapy
2nd position indicates the chamber for antitachycardia pacing: V = ventricle A = atrium D = dual O = no antitachycardia pacing
3rd position indicates the method of tachycardia detection: T = electrogram H = hemodynamic
4th position indicates chambers for bradycardia pacing* V = ventricle A = atrium D = dual O = no bradycardia pacing
* Sometimes the three or four letter NBD pacing code may be used following the first three letters of the NBD code (e.g., VVT/VVR indicating ventricular shock, ventricular ATP, electrogram detection and VVR pacing capability).
From Lown G, ed. <i>Handbook of Cardiac Pacing</i> . Georgetown, TX: Landes Bioscience; 1998, with permission.

TABLE 136.2. NBD Codes (for Implantable Defibrillators)

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Patients with ICD malfunction generally present with either defibrillation–cardioversion failure or frequent ICD discharge. Defibrillation–cardioversion failure may result from failure to deliver a shock, analogous to pacemaker output failure, or from failure of delivered shock(s) to convert the dysrhythmia, analogous to pacemaker noncapture. ICD discharge for rhythms other than ventricular fibrillation (VF) or VT is common, occurring in 22% of patients over 2 years of follow-up in one case series.¹⁰ Although the potential lethality of inappropriate ICD discharge is lower than that of ICD failure to discharge, repeated shocks may cause myocardial injury, temporary ventricular dysfunction, and rapid battery depletion.¹⁴ Furthermore, they may be very painful and anxiety-provoking. The most common causes of recurrent discharges are dysrhythmias (supraventricular tachycardias and nonsustained VT) that fall into the ICD's window of treatment.¹²

PATIENT EVALUATION AND EMERGENCY DEPARTMENT MANAGEMENT

When treating the patient in cardiac arrest or with unstable hemodynamics, determination of the exact cause of ICD failure is, at least initially, unimportant. Resuscitation is the obvious priority and should generally follow ACLS protocols.¹⁴ Most ICDs analyze and shock VF or VT within 30 seconds; therefore, if a patient presents in these rhythms, the physician should assume that ICD defibrillation–cardioversion has been unsuccessful and should immediately proceed with external countershocks.⁷ However, to prevent ICD absorption of current, defibrillator pads or paddles should not be placed directly over the device and, when feasible, should be positioned anteroposteriorly.⁷ Chest compressions should be given in the standard fashion. Without rubber gloves, the rescuer may feel a slight, harmless shock if an ICD discharges during compressions.⁷

After successful resuscitation, the emergency physician should investigate the events surrounding the arrest, focusing on the few causes of ICD failure (electrolyte imbalance, myocardial ischemia or MI, and drug effects) that may be treated without ICD reprogramming or surgery. When feasible, the physician should ask the patient if he or she recalls chest pain, palpitations, or ICD discharges. As with the pacemaker patient, the emergency physician should use direct history, the patient's ICD card, medical records and telephone calls to the ICD manufacturer to gather information about reasons for and date of ICD implantation, most recent ICD interrogation, and prior ICD malfunction. The emergency physician should ask about exposures to the sources of environmental electromagnetic interference described earlier in regard to pacemakers. There are many etiologies of ICD malfunction, and these may be explored later by the electrophysiologist, who may interrogate the ICD for detailed analysis of dysrhythmias and ICD response. Additionally, referral to an electrophysiologist is essential to evaluate the ICD for lead

fracture or displacement caused by chest compressions and for pulse generator damage or reprogramming arising from external countershocks.¹⁴

When rapid atrial fibrillation triggers frequent ICD discharge, the physician should attempt to slow the ventricular rate with the usual pharmacologic agents.¹⁴ If, after a period of close monitoring, it is determined that frequent ICD discharges are not occurring as appropriate responses to significant dysrhythmias, or if frequent ineffective ICD discharges are interfering with resuscitation, the physician may disable the ICD by applying a ring magnet to the chest wall over the device.¹⁴ Occasionally, two magnets, stacked one on top of the other, are required to deactivate the ICD in markedly obese patients.¹⁴ While the magnet suspends all antitachycardia functions (i.e., the ICD will not deliver a shock for VT), back-up pacing functions of the ICD may persist. Attention to hemodynamics, close monitoring, and sedation or analgesia for the anxious patient are other keys to ED management of frequent ICD discharges. The emergency physician must understand that although a ring magnet generally causes changes in pacemaker function only during application of the magnet (i.e., the pacemaker resumes its normal function after removal of the magnet), a magnet may reset some ICD models to the “off” mode indefinitely.¹⁴ Thus, if a magnet is either intentionally or inadvertently applied to an ICD, the physician should assume the device has been deactivated and should arrange for ICD interrogation and reprogramming.

The presentation and management of infectious and thrombotic complications of ICDs parallel those of pacemakers, except that ICD infections may be more serious and difficult to treat.¹³ Hospital admission for administration of parenteral antibiotics and hardware removal is recommended for all infected ICDs.¹³ If the patient has an older model with epicardial patches, computed tomography imaging of the heart and mediastinum is warranted to determine the extent of mediastinal involvement.

DISPOSITION

Given the potentially catastrophic consequences of ICD failure, urgent referral to an electrophysiologist is recommended for essentially all types of ICD malfunction. ICD patients should be observed in or admitted to monitored settings until specialist evaluations are completed. If specialist evaluation or higher level of care issues mandate transfer to another facility, ACLS units should be used, and transthoracic (anteroposterior) defibrillation and pacing pads should be applied to the patient prior to transit.

COMMON PITFALLS

- Misdiagnosing pacemaker or ICD malfunction because of inadequate information about the current programming and operation of the device. The physician should gather as much information about the pacemaker or ICD as possible from patient history, device identification cards, pacemaker or ICD registration departments, and patients' cardiologists or electrophysiologists.
- When evaluating the pacemaker patient for MI, failing to understand both the utility and the limits of 12-lead ECG interpretation. Several ECG patterns are reliable indicators of ischemia or infarction during RV pacing, but a normal LBBB pattern of pacing does not rule out infarction or ischemia.
- In a patient with cardiac arrest, allowing the presence of a pacemaker or ICD to change resuscitation procedures. Other than anteroposterior positioning of paddles and avoiding shocks over the devices, resuscitation should generally follow the usual ACLS protocols.
- Assuming that, after magnet application over an ICD or after cardioversion or resuscitation of a patient with an ICD or a pacemaker, the device has reverted to its normal programming and operation. The ICD or pacemaker must be reevaluated after these procedures.
- Failing to make disposition decisions for most pacemaker problems and for essentially all cases of ICD malfunction in collaboration with an electrophysiologist.

CHAPTER 137 Valvular Heart Disease

Joseph P. Ornato

[Common Clinical Presentations](#)
[Emergency Department Evaluation](#)
[Prosthetic Valves](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

A wide variety of common diseases and conditions can affect the heart valves ([Table 137.1](#)). In the 1950s, virtually all patients with clinically significant valvular disease suffered from complications of acute rheumatic fever or syphilis, or congenital heart disease. Since then, the pattern of disease responsible for valvular dysfunction in adults has changed dramatically.^{1,22,24} The major reasons for this shift are a marked decline in the incidence and better early treatment of acute rheumatic fever and syphilis; the wide availability of invasive and noninvasive testing to detect valvular heart disease; the development and perfection of surgical techniques for the repair or replacement of diseased valves; the increased longevity of the general population, allowing even normal valves to be subjected to more years of wear and tear; and sociocultural changes in our society (e.g., intravenous drug abuse).

Cause	Specific Disease	Valves Affected	Murmur
Congenital	Bicuspid valve	A	S, R
Rheumatic	Rheumatic fever	M, A, T, P	S, R
Infectious	Endocarditis	A, M (rheumatic) A, M, T, P (ix drugs)	R
Myxomatous degeneration	Prolapse	MT	R
Degenerative aging	Aortic root dilatation	A	R
	Sclerosis	A	S

A, aortic; M, mitral; P, pulmonary; T, tricuspid; S, stenotic; R, regurgitant; ix, intravenous

TABLE 137.1. The Most Common Causes of Valvular Heart Disease in Adults

Regardless of the cause, significant acute or chronic valvular dysfunction has predictable hemodynamic consequences. Regurgitant lesions (e.g., mitral or aortic regurgitation) cause volume overload of the affected atrium or ventricle. Although massive acute regurgitation can lead to shock and pulmonary edema rapidly, mild-to-moderate volume overload is usually well tolerated until after months or years, when the ventricle will often dilate and fail, leading to signs and symptoms of heart failure. Stenotic lesions above, at, or below the valve can cause pressure overload of the affected atrium or ventricle. Pressure overload is metabolically more costly to the myocardium than volume overload, and leads to myocardial hypertrophy and eventual heart failure.

The combined hemodynamic effect of multiple valvular lesions is often complex.¹⁶ Some compound lesions (e.g., combined aortic regurgitation and stenosis) impose a tremendous burden on the myocardium by producing both volume and pressure overload of a single chamber (in this example, the left ventricle). Other combination lesions may be “protective” of a given chamber (e.g., in aortic stenosis combined with mitral stenosis, the volume of blood reaching the left ventricle is decreased, thereby “protecting” it from heart failure). However, the net effect may be to decrease forward, and thus net, cardiac output.

Some valvular lesions produce a rapidly downhill course. For example, acute, severe mitral or aortic regurgitation can lead rapidly to pulmonary edema, shock, or both, which can usually be remedied only by immediate valve replacement.^{6,8,17,28} Other lesions, such as chronic mitral or aortic regurgitation, can be tolerated well for decades.^{1,15,17} A structurally abnormal valve puts the patient at increased risk of developing infective endocarditis, which can further impair valvular function. Other concomitant diseases (e.g., coronary atherosclerosis, myocarditis), arrhythmias (e.g., atrial fibrillation), or valvular calcification can also unfavorably influence the patient’s symptoms and length of survival.

COMMON CLINICAL PRESENTATIONS

Patients with valvular heart disease may present to the emergency department (ED) with a complication of previously known disease, or they may challenge the emergency physician to evaluate a previously undetected and undiagnosed heart murmur. If complex congenital heart disease, such as tetralogy of Fallot, is excluded, complications of adult valvular heart disease are most often the result of left heart lesions ([Table 137.2](#)).

Valvular Lesion	Common Complication(s)
Mitral stenosis	Pulmonary edema, atrial fibrillation, systemic embolism
Mitral regurgitation	Heart failure, endocarditis
Aortic stenosis	Angina, syncope, heart failure, arrhythmias, sudden death, endocarditis
Aortic regurgitation	Heart failure, endocarditis

TABLE 137.2. Common Complications of Left Heart Valvular Disease in Adults

When a patient with a heart murmur presents to the ED with symptoms that could be due to valvular heart disease, an immediate question is whether the heart murmur is *causing*, *unrelated to*, or *caused by* the symptom complex. For example, if a 70-year-old man with dyspnea and moderate pulmonary edema on chest x-ray has a grade 3/6 systolic ejection murmur at the left upper sternal border and cardiac apex, the murmur may be due to aortic stenosis or mitral regurgitation, either of which could cause heart failure. The patient’s heart failure could be caused by an unrelated problem, such as ischemic heart disease, cardiomyopathy, myocarditis, or a congenital shunt lesion (e.g., atrial septal defect). Finally, left ventricular (LV) failure and dilatation could be causing a “functional” murmur due to dilatation of the mitral valve and its supporting structures (papillary muscle dysfunction).

Myocardial ischemia (e.g., during angina) can also increase the murmur of papillary muscle dysfunction. “Functional” tricuspid regurgitation can be caused by right ventricular dilatation secondary to left heart failure. In practice, it is sometimes impossible to determine the relationship between the murmur and the patient’s symptoms without further diagnostic evaluation, such as echocardiography or cardiac catheterization.

The most frequent pathologic conditions affecting the heart valves in adults presenting to the ED are (1) mitral valve prolapse (MVP); (2) aortic valve sclerosis in the

elderly, with or (more typically) without significant stenosis; (3) valvular aortic stenosis due to congenital bicuspid aortic valve; (4) mitral regurgitation due to papillary muscle dysfunction, rheumatic heart disease, infectious endocarditis, or ruptured chordae tendineae; (5) aortic regurgitation due to rheumatic fever, infectious endocarditis, bicuspid aortic valve, or aortic root disease; and (6) mitral stenosis due to rheumatic fever.

EMERGENCY DEPARTMENT EVALUATION

A careful cardiovascular physical examination, beginning with the pulse and blood pressure, often identifies the cause of a heart murmur. ⁴ A wide pulse pressure accompanied by a brisk (often bifid) carotid upstroke and a bounding (“water-hammer”) peripheral pulse is common in moderate-to-severe aortic regurgitation; a narrow pulse pressure with a slow, delayed carotid upstroke (“pulsus parvus et tardus”) is seen in severe aortic stenosis. When a harsh systolic murmur suggesting valvular aortic stenosis is accompanied by a brisk carotid upstroke (and *no* aortic regurgitation), idiopathic hypertrophic subaortic stenosis (IHSS) should be suspected. In a young person (especially male), hypertension in the upper extremities and a *lower* arterial pressure in the legs with a weak femoral pulse and a basal systolic murmur suggests coarctation of the aorta (which is associated with congenital bicuspid aortic valve in 40% to 80% of cases).

All normal and abnormal heart sounds should be carefully noted. A loud first heart sound (S₁) at the apex and/or an opening snap after the second heart sound halfway between the left sternal border and apex are clues to the presence of mitral stenosis with a mobile valve. Paradoxical splitting of the second heart sound (S₂) (i.e., widening of the split on *expiration*) is seen in moderate-to-severe aortic stenosis. A widely (“fixed”) split S₂ that fails to close fully during normal expiration in the upright position suggests atrial septal defect.

A high-pitched, early systolic click that is heard best along the left sternal border and that is followed by a systolic murmur usually signifies valvular pulmonic or aortic stenosis with a pliable, noncalcified valve. Systolic clicks heard later than the carotid upstroke or multiple systolic (“machine gun”) clicks suggest mitral valve prolapse.

A third heart sound (S₃) is often heard in normal, healthy children, adolescents, and young adults without heart or valvular disease. When the heart rate is rapid, the third heart sound is usually termed an S₃ gallop. In a person with heart disease, it usually indicates left ventricular failure. Chronic or acute mitral regurgitation is often accompanied by an S₃,⁶ but its presence in this condition does *not necessarily* indicate heart failure, because its presence may indicate only the torrential inflow of blood from the left atrium into the left ventricle in early diastole.

A fourth heart sound (S₄) is abnormal in a young person; it can occur with hypertension or aortic stenosis.^{4,16} A loud S₄ accompanying mitral regurgitation indicates that the lesion is acute and substantial, the sound being caused by the left atrium's valiant attempt to cope with overwhelming volume overload. With time, the left atrium dilates and the S₄ disappears.

The timing of heart murmurs should be studied carefully and characterized as systolic, diastolic, or continuous ([Table 137.3](#)). Innocent murmurs are virtually *never* accompanied by a thrill. In an older individual, a harsh, musical, vibratory murmur with a thrill at the base is usually due to valvular aortic stenosis. A similar murmur with the thrill at the apex can be seen with mitral regurgitation. A new-onset musical “cooing-dove” murmur at the apex is almost always caused by rupture of the mitral valve chordae tendineae due to underlying mitral valve prolapse, Marfan syndrome, or trauma.⁴ It is interesting that, although mitral valve prolapse occurs slightly more often in young women than men, most complications (infective endocarditis, mitral regurgitation, and ruptured chordae), though unusual, occur disproportionately more often in men.⁷

SYSTOLIC MURMURS	
Aortic stenosis (valvular, supra-aortic, and subaortic)	
Mitral regurgitation, including MVP	
Tricuspid regurgitation	
Pulmonic stenosis	
IHSS	
Coarctation of the aorta	
Ventricular septal defect	
Atrial septal defect	
Intense systolic murmur	
DIASTOLIC MURMURS	
Mitral stenosis	
Tricuspid stenosis	
Aortic regurgitation	
Pulmonic regurgitation	
CONTINUOUS MURMURS (EXTENDING THROUGH S2 WITHOUT RELATIONSHIP TO AORTIC OR PULMONIC VALVE CLOSURE)	
Patent ductus arteriosus	
Mammary souffle	
Ruptured sinus of Valsalva aneurysm	

TABLE 137.3. Classification of Common Murmurs by Timing

The response of murmurs to “provocative” maneuvers, spontaneously occurring extrasystoles, change in body position, brief exercise, and pharmacologic intervention can help emergency physicians to differentiate among causative entities.⁴ Virtually all systolic murmurs—except that caused by IHSS—get softer or disappear during the strain phase of the Valsalva maneuver ([Table 137.4](#)). After the Valsalva strain is released, right-sided systolic heart murmurs (such as pulmonic stenosis and many innocent murmurs) usually return during the next 1 to 4 beats as blood rushes back into the right side of the heart. Left-sided systolic heart murmurs (mitral regurgitation, valvular aortic stenosis) are usually not well heard for 8 to 10 heartbeats, until the right heart and pulmonary circulation have refilled.

Murmur	Timing	Pitch	Location	Quality	Other
AS	Systolic	High	Base, neck	Decr	Slowly
IHSS	Systolic	High	Base	Inc	Mildly
MR	Diastolic	Low	Apex, axilla	Decr	Water-hammer pulse
MS	Diastolic	Low	Apex	Decr	OS
MR, decubitus	Systolic	High	Apex, axilla	Decr	Increase
MR, W/prop	Systolic	High	Apex, axilla	Decr	Systolic click
PS	Systolic	High	Pulmonic area	Decr	No late systolic ejection click
PI	Diastolic	High	Base, CR	Decr	Slight delay from S ₂ to murmur
TS	Diastolic	Low	CR or RL	Decr	Increase on inspiration
TR	Systolic	High	CR	Decr	Systolic pulsation of jugular pulse

AS, aortic stenosis; CR, carotid; Decr, decrescendo; Inc, increase; IHSS, idiopathic hypertrophic subaortic stenosis; MR, mitral regurgitation; MS, mitral stenosis; MVP, mitral valve prolapse; OS, opening snap; PI, pulmonic insufficiency; PS, pulmonic stenosis; RL, right lower lung; TR, tricuspid regurgitation; TS, tricuspid stenosis; W/prop, with prominent pulmonary flow murmur.

TABLE 137.4. Differentiation of Common Heart Murmurs in Adults

The isometric handgrip (squeezing two of the examiner's fingers tightly for 30 to 60 seconds) increases the systemic vascular resistance and typically increases the intensity and duration of mitral or aortic regurgitation. If the patient has extrasystoles or an irregular rhythm as in atrial fibrillation, the murmur of valvular aortic stenosis usually becomes much louder in the beat following a long pause because of increased LV stroke volume and flow across the valve. In contrast, the murmur of mitral insufficiency generally does not change in intensity with the change in cardiac cycle length.

Listening to murmurs with the patient in different body positions may also be helpful. For example, most innocent systolic murmurs decrease or disappear in the sitting or standing position. These murmurs are often soft and blowing in quality, are heard best along the left sternal border without radiation, and are unaccompanied by any other abnormal clinical findings or symptoms. The diastolic rumble of mitral stenosis is heard best in the left lateral decubitus position with the bell of the stethoscope placed lightly over the apex (see [Table 137.4](#)). The high-pitched, early diastolic decrescendo murmur of aortic insufficiency is heard best along the left sternal border with the patient leaning forward and holding a maximal expiration. This murmur is virtually always louder to the left of the sternum when aortic regurgitation is due to rheumatic heart disease or a bicuspid valve. If it is louder to the right of the sternum, one should suspect that aortic regurgitation is due to aortic

root dilatation caused by aortic dissection, hypertension, syphilis, ruptured sinus of Valsalva aneurysm, or Marfan syndrome.

Prosthetic Valves

Surgically implanted prosthetic valves present special diagnostic problems in the ED.^{23,26} Patients with such devices are at risk for (1) endocarditis (which may present with fever, chills, or peripheral embolic complications, including stroke^{12,13,27}); (2) embolization due to clot formation (which may present as a new stroke, transient ischemic attack, or occluded peripheral artery); and (3) prosthetic valve dysfunction due to dehiscence of suture lines, thrombosis of the valve, valve degeneration (porcine heterografts or human homografts), hemolysis, or structural failure (disc devices). Patients with prosthetic valve dysfunction may gradually develop heart failure or fatigue, or may present suddenly with syncope or pulmonary edema.

The sounds and murmurs that should be heard after valve replacement vary from device to device.^{13,14,23,26} Mechanical disc valves should produce clicking or metallic opening and/or closing sounds. Most implanted mechanical valves are relatively stenotic compared with native valves, so it is common and permissible to have a short systolic murmur with a prosthetic aortic valve or a short diastolic rumble with a prosthetic mitral valve. Short whiffs of aortic regurgitation, common after aortic valve replacement, are often due to a small periprosthetic leak at the suture line. Prominent mitral regurgitant murmurs are usually not present following mitral valve replacement unless there is a mechanical problem with the valve.

Because severe mitral or aortic regurgitation due to prosthetic valve dysfunction occasionally produces no audible murmur, the development of heart failure or the appearance of other potential indicators of valve failure always warrants immediate investigation as to the valve's integrity, even in the absence of a murmur. Thrombolysis is a highly effective treatment in resolving prosthetic thrombosis. However, because it carries a significant risk of embolization, it should be limited to patients with hemodynamic deterioration in whom surgery could also entail a significant risk of death.²⁵

Catheter balloon valvuloplasty²⁰ is now being performed for pulmonary, mitral, and aortic valve stenosis. Following a successful procedure, it is common to have a persistent stenotic murmur or a new murmur due to valve regurgitation. Complications of this procedure include valve regurgitation, inadequate opening of the stenosis, endocarditis, arrhythmias, embolization, or atrial septal defect (mitral valvuloplasty only).

EMERGENCY DEPARTMENT MANAGEMENT

All patients with a previously undiagnosed heart murmur should, of course, receive a thorough cardiovascular physical assessment, as described previously. A high-quality posteroanterior and lateral chest x-ray and an electrocardiogram (ECG) complement the physical examination. Specific chamber enlargement (e.g., LV dilatation due to aortic or mitral regurgitation, left atrial enlargement due to mitral stenosis, regurgitation, or both) or poststenotic dilatation of the aorta or pulmonary artery on x-ray, or chamber hypertrophy on ECG (LV hypertrophy in aortic stenosis, left atrial enlargement in mitral stenosis, right ventricular hypertrophy in pulmonic stenosis) can help to disclose the cause of a murmur. Cardiomegaly, pulmonary vascular congestion, pulmonary edema, and/or pleural effusions on chest x-ray can detect or confirm heart failure.

Two-dimensional echocardiography with Doppler is a sensitive and precise means of detecting and evaluating the severity of valvular lesions noninvasively.^{2,3,19} It should be performed in the ED or ordered electively on any patient who is being referred to a cardiologist for follow-up evaluation of a murmur that is suspected to be due to valvular disease. It can often detect vegetations or intracardiac thrombi in patients with suspected endocarditis and/or evidence of systemic embolization.^{12,13,26,27} and can be used to evaluate prosthetic valve motion and function.^{12,13} and ^{14,23,26}. If transthoracic echocardiography cannot provide clear enough resolution to adequately define the anatomy, transesophageal echocardiography can be performed. The latter technique can produce spectacular images of the heart and great vessels.

Specific complications of valvular heart disease, such as heart failure, cardiogenic shock, embolization, or arrhythmias, should be managed in the normal fashion.^{1,6,8,16,17} Severe heart failure, hypotension, and shock due to massive acute aortic or mitral regurgitation may be refractory to medical therapy.^{1,6} In such cases, it is often preferable to use dobutamine or low-to-medium doses (5 to 15 µg/kg/min) of dopamine, or both, rather than potent alpha vasoconstrictors (e.g., high-dose dopamine or norepinephrine), because increases in afterload will only worsen valvular regurgitation. Intraaortic balloon counterpulsation or other LV mechanical assist devices may be required for stabilization prior to cardiac catheterization and/or surgery.

In general, antibiotic prophylaxis against infective endocarditis should be offered to all patients with significant valvular lesions who are about to undergo procedures that may result in bacteremia.¹⁰ It is not clear whether all patients with MVP, which occurs in approximately 5% of the population, require such prophylaxis,⁹ but those patients who have a systolic murmur or echocardiographic evidence of mitral regurgitation are 35 times more likely to develop endocarditis than are those who have no systolic murmur or other evidence of mitral regurgitation.¹¹ Thus, all patients with prolapsing and leaking mitral valves, evidenced by audible clicks and murmurs of mitral regurgitation or by Doppler-demonstrated mitral insufficiency, should receive prophylactic antibiotics.⁵ Whether to provide coverage to other MVP patients is a decision that should be made, in most cases, by the patient's cardiologist.

DISPOSITION

Absolute indications for immediate ED consultation by a cardiologist while hospital admission is being arranged include (1) known or suspected valvular lesions that are accompanied by hemodynamic instability (heart failure and/or shock), fever, arrhythmia, or embolization; and (2) new onset or progression of these symptoms; or (3) significant hemolysis following valve surgery or valvuloplasty. Admission to the intensive care unit is usually indicated for significant arrhythmia (particularly in new-onset cases and/or those causing hemodynamic compromise), pulmonary edema, hypotension, or when there are other concomitant life-threatening medical problems. Immediate cardiac catheterization and surgical intervention are indicated for new-onset severe valvular regurgitation, prosthetic valve malfunction, systemic embolization in the face of adequate anticoagulation, valve ring abscess, intractable heart failure, or shock.

If transfer to another facility is required, the emergency physician should consult by telephone with the receiving cardiologist to get advice on initial treatment and stabilization and to discuss the appropriate means of transportation and the patient's care en route. If available, an advanced cardiac life-support team with monitoring and resuscitation equipment should always accompany the patient. Air transport by helicopter or pressurized fixed-wing aircraft may be indicated if the patient is in need of urgent cardiac catheterization and operative intervention.

Most asymptomatic patients in whom a previously undetected heart murmur is found incidentally should be referred electively to a cardiologist for further evaluation. Pregnant patients with newly detected murmurs or abnormal heart sounds should also be referred for further cardiac evaluation if there is any question of the finding not being physiologic during pregnancy, or if there is the slightest possibility that the patient may have structural heart disease.

COMMON PITFALLS

- It is easy to be misled by the physical findings when a patient is seen for the first time. For example, the severity of valvular disease is always underestimated during periods of severe heart failure, shock, or tachycardia, because the decreased cardiac output leads to a decrease in the intensity of heart murmurs under such conditions.^{8,15,16,18} The elderly patient presents a special problem, because the presence of concomitant atherosclerosis with rigid vessels may either mask or amplify pulse or blood pressure changes due to valvular disease. In addition, the location and radiation of murmurs are notoriously unreliable diagnostic indicators in older patients.
- A common error is to mistake a normal heart sound (such as the physiologic S₃) or an innocent murmur in a young person for the presence of structural heart disease. Children or young adults may have a cervical venous hum, heard best in the upright position, at the base of the neck and occasionally in the upper chest. The murmur is continuous, extending throughout the second heart sound, and can mimic a patent ductus arteriosus murmur. It can be correctly diagnosed by proving that it can be obliterated by having the patient lie down, applying pressure at the base of the neck with the stethoscope while listening, and by turning the patient's head away from the examiner.
- Murmurs are difficult to evaluate during pregnancy.^{4,21} They may suddenly appear or disappear as the cardiac output, blood volume, and vascular resistance change during each trimester and in the postpartum period. A continuous, innocent "mammary souffle" murmur can often be heard along the right or left chest during late pregnancy or during lactation following delivery. This murmur is caused by the increased flow of blood through the mammary arteries due to the hypertrophied breast tissue. It can often be eliminated by direct chest wall pressure or with changes in body position.
- Finally, perhaps the most important pitfall is the failure to consider infectious endocarditis as a possibility in a patient with known or suspected heart valve

pathology who presents with suspicious signs or symptoms (e.g., unexplained fever, anemia, heart failure, hypotension, signs of systemic embolization). Emergency physicians should maintain a relatively high index of suspicion in such cases. When in doubt, consider infectious endocarditis to be present until proven otherwise.

CHAPTER 138

Acute Pericarditis and Cardiac Tamponade

Franklin D. Pratt and Howard A. Bessen

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Complications](#)
[Emergency Department Management and Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Acute pericarditis is a diagnostic challenge because its presentation is similar to that of several other disorders, and it may have life-threatening complications. Management ranges from symptomatic, supportive treatment to lifesaving invasive procedures.

The common causes of acute pericarditis are listed in [Table 138.1](#). In many cases, the cause is unclear (idiopathic pericarditis). Viral pericarditis is frequently diagnosed presumptively in a patient who presents with pericarditis after a virus-like syndrome. Other infectious causes (bacterial, fungal, and parasitic) are less common, but pericarditis may occur as a complication of another systemic or intrathoracic infection.

Idiopathic	Connective tissue disease
Infectious	Rheumatoid arthritis
Viral	Systemic lupus erythematosus
Bacterial	Scleroderma
Tuberculosis	Drug-related
Fungal	Anticoagulants
Parasitic	Procainamide
Malignancy	Hydralazine
Metastatic disease	Methyldopa
Radiation-induced	Cardiac injury
Uremia	Postmyocardial infarction
	Postsurgical
	Postinstrumentation
	Cardiac trauma
	Aortic dissection

TABLE 138.1. Causes of Acute Pericarditis

Patients with human immunodeficiency virus (HIV) infection may develop pericarditis and pericardial effusions.³ A wide variety of viral, bacterial, mycobacterial, and other opportunistic infections can cause pericarditis in these patients. Pericarditis may also be associated with acquired immunodeficiency disease syndrome (AIDS)-related malignancies such as Kaposi's sarcoma.

Pericarditis is the most prominent cardiac complication of neoplastic disease, and nontraumatic pericardial tamponade is usually of metastatic origin.^{9,15} Lymphoma, leukemia, melanoma, and breast or lung carcinoma cause most pericardial metastases. Patients receiving radiation treatment may develop postirradiation pericarditis.

Pericarditis may occur as a complication of chronic renal failure, or of connective tissue diseases such as systemic lupus erythematosus, scleroderma, or rheumatoid arthritis. Medications, including anticoagulants and those associated with a drug-induced lupus syndrome (e.g., hydralazine, methyldopa, and procainamide), may also be implicated.

Pericarditis frequently occurs during the first few days after acute myocardial infarction^{4,22}; it is unclear whether there is also a late-onset postinfarction pericarditis syndrome.¹³ Aortic dissection, cardiac trauma, invasive procedures that involve the great vessels and the heart (central venous pressure catheter insertion and cardiac catheterization), and intrathoracic surgery may also cause pericarditis and pericardial tamponade within hours to weeks.

CLINICAL PRESENTATION

Most patients with acute pericarditis present with chest pain. The pain is usually sharp and often pleuritic, but it may also be dull, constrictive, or aching. It may radiate to any part of the chest and back and to the trapezius ridge.¹¹ Typically, the chest discomfort is eased by sitting up and leaning forward. The pain is frequently associated with shortness of breath, which may be caused by coexisting pleuritis or by cardiac tamponade. Patients may also present with hypotension and other signs and symptoms of tamponade.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes other conditions that cause chest pain and dyspnea, such as acute myocardial infarction (MI), congestive heart failure (CHF), pulmonary embolism, pneumonia, pneumothorax, pneumomediastinum, pleuritis, and aortic dissection. Cardiac tamponade may be confused with CHF and cardiogenic shock.

Acute pericarditis is frequently mistaken for acute MI. In contrast to MI patients, patients with pericarditis may present with fever and typically have sharper pain that increases with body motion and varies with position. The ST-segment elevation in patients with acute MI is typically focal, with ST-segment depression in reciprocal leads. In pericarditis, ST-segment elevation is more diffuse, without reciprocal ST depression,² and the Q waves often seen in acute infarction do not develop. Patients with pericarditis (even with tamponade) have clear lung fields, as opposed to those with CHF or pneumonia.

On the electrocardiogram (ECG), a normal early repolarization variant may mimic pericarditis (discussion follows).

EMERGENCY DEPARTMENT EVALUATION

Initial assessment and therapy consist of measures appropriate for any patient who presents with shortness of breath and chest pain: supplemental oxygen administration, intravenous access placement, cardiac monitoring, and a 12-lead ECG.

The classic diagnostic physical finding is the pericardial friction rub, which may consist of one, two, or three components. Frequent careful auscultation allows recognition of a rub in most patients with pericarditis.²¹ The rub may be transient or intermittent, and can be confused with a heart murmur. The ECG can be virtually diagnostic. Typically, the ECG changes of acute pericarditis evolve through four stages^{2,20}:

- Stage 1 is the most characteristic and will probably be seen when the patient presents with acute symptoms. Concave-upward ST-segment elevation is seen in most of the leads; PR segment depression may also be seen ([Fig. 138.1](#)).

Figure 138.1. Electrocardiogram of a 35-year-old man with acute pericarditis. Note the diffuse, concave-upward ST-segment elevation.

- In stage 2, the ST segments return to baseline, and the T-wave amplitude decreases; the PR segment may be depressed.
- T-wave flattening and then inversion in the leads with previous ST-segment elevation defines stage 3.
- In stage 4, the ECG normalizes.

The ECG findings in acute pericarditis are diffuse changes that are seen in most leads, rather than the focal abnormalities seen in acute MI. ^{2,20}

Although the ECG is usually abnormal, diagnostic changes may be absent in patients with clinically evident pericarditis. ^{14,20} Patients with post-MI pericarditis (diagnosed by the presence of a pericardial friction rub) frequently have no ECG changes. ¹⁴

Early repolarization, a normal ECG variant characterized by ST-segment elevation, can be difficult to distinguish from pericarditis. ^{2,18} If the clinical presentation suggests pericarditis, serial ECGs may be required to differentiate pericarditis from the benign early repolarization variant. On a single ECG, an ST/T ratio (the amount of ST-segment elevation divided by the height of the T wave) of 0.25 or more in lead V₆ suggests pericarditis, not early repolarization. ⁸

The chest radiograph is often normal. The cardiac silhouette may be enlarged secondary to a pericardial effusion, but the heart size may be normal, even if an effusion is present. ⁶ In addition, radiographic cardiomegaly is a nonspecific finding, and may represent significant myocarditis or many other types of heart disease.

The white blood cell count can range from normal to markedly elevated, and is usually not helpful in making or excluding the diagnosis. Similarly, the erythrocyte sedimentation rate is usually elevated, but this is a nonspecific finding. Cardiac enzyme levels are often normal or minimally elevated, but may be significantly elevated because of associated myocarditis. ¹²

Echocardiography can provide useful information in suspected pericarditis. In the absence of significant associated myocarditis, most patients with pericarditis have normal cardiac wall motion. In contrast, patients with chest pain caused by cardiac ischemia often have focal wall motion abnormalities. Echocardiography is also the best method for detecting and monitoring pericardial effusions (discussion follows).

COMPLICATIONS

The major complications of acute pericarditis are pericardial effusion (potentially leading to cardiac tamponade), recurrent pericarditis, and chronic constrictive pericarditis. Dysrhythmias are unusual in pericarditis but may occur in patients with associated myocarditis or other underlying heart disease.

Cardiac tamponade is an acutely life-threatening complication. The presentation may be subtle, potentially leading to a delayed or missed diagnosis and a poor outcome. Close attention to physical findings is essential to make the diagnosis.

Cardiac tamponade results from the accumulation of fluid within the pericardial space, causing an impairment of cardiac filling and thus a decrease in cardiac output. Tamponade is often mistaken for CHF because patients present with dyspnea, orthopnea, jugular venous distention, and hepatic enlargement.

The classic findings of cardiac tamponade are muffled heart sounds, diminished arterial pressure, and elevated venous pressure. However, these findings are seen only with fully developed tamponade and are much more likely to occur when pericardial fluid accumulates quickly, precluding pericardial distention. ^{7,9}

An important clue to the diagnosis is the presence of pulsus paradoxus, an inspiratory decrease in systolic blood pressure of more than 10 mm Hg. ^{5,16} Other clinical entities associated with pulsus paradoxus include emphysema, asthma, obesity, pulmonary embolism, cardiogenic shock, right ventricular infarction, and restrictive cardiomyopathy. Patients with acute traumatic tamponade may not have a pulsus paradoxus.

Patients with tamponade may have relatively normal ECGs. With large effusions, reduction of the QRS amplitude or electrical alternans (alternating beat-to-beat variation in QRS amplitude) may be seen. Central venous pressure measurements reveal an elevation of right-sided pressures and help confirm the diagnosis.

Clinical decompensation can be rapid. If time allows, definitive diagnosis using echocardiography is indicated. Echocardiography can detect small amounts of pericardial fluid; in cardiac tamponade, it may demonstrate diffuse hypokinesis, right atrial collapse, and right ventricular diastolic collapse. ^{7,11,19} If possible, echocardiography should be performed emergently in any patient with suspected tamponade, because delays in evaluating the presence and size of a pericardial effusion can be disastrous. ¹⁵

The diagnosis of tamponade can also be definitively established by measuring pressures in the cardiac chambers. Right atrial, right ventricular diastolic, pulmonary artery diastolic, and pulmonary capillary wedge pressures are equalized in this condition.

Occasionally, after recovering from the acute illness, patients suffer one or several episodes of recurrent *pericarditis*, weeks to months after the initial episode. ¹ Evaluation and management of recurrences are, for the most part, the same as for a first presentation of acute pericarditis.

Constrictive pericarditis, an uncommon complication of acute pericarditis, results when healing of acute pericarditis leads to encasement of the heart in fibrous tissue, impeding ventricular filling. ^{11,17} Patients often present with dyspnea on exertion, ascites, peripheral edema, and hepatic enlargement. The lung fields are clear, in contrast to patients with CHF. The presence of distended neck veins in constrictive pericarditis helps to separate these patients from those with severe liver disease, who may appear clinically similar. Pericardial calcification on the chest radiograph and pericardial thickening on echocardiography may also provide clues to this diagnosis. The definitive treatment is resection of the pericardium.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Once the diagnosis of acute pericarditis is made or strongly suspected, most patients should be admitted. The admitting consultant can coordinate the diagnostic evaluation, perform echocardiography and pericardiocentesis, as needed, and arrange proper follow-up care.

Whether all patients with acute pericarditis require admission is controversial. Some young patients with uncomplicated idiopathic or viral pericarditis may be appropriately managed as outpatients. However, pericarditis may occur as a complication of MI, and, in any patient with pericarditis, development of a pericardial effusion and cardiac tamponade may be subtle. Obtaining an echocardiogram before discharge ensures that a pericardial effusion is not missed. Patients who are not admitted require close, careful follow-up.

The therapy for uncomplicated pericarditis is largely symptomatic, but specific therapy is available for a few causes of pericarditis. Nonsteroidal antiinflammatory

agents give excellent results in viral and idiopathic pericarditis. Recurrent pericarditis may respond to colchicine. ¹ Bacterial pericarditis must be treated with drainage and appropriate antimicrobial therapy. Uremic pericarditis is usually an indication for dialysis.

The definitive treatment of pericardial tamponade is pericardiocentesis. However, to “buy time” until pericardiocentesis can be performed, volume infusion is the treatment of choice. Ideally, pericardiocentesis should be done with echocardiographic and ECG guidance, but emergent “blind” pericardiocentesis may be necessary for hypotensive patients who do not respond to volume infusion.

The procedure for emergent pericardiocentesis is fully described elsewhere. ¹⁰ The pericardium may be approached by a left parasternal or subxiphoid puncture. In the parasternal approach, the needle is inserted perpendicular to the skin in the fifth intercostal space, just lateral to the sternum. In the subxiphoid approach, the puncture is made about 2 cm below and 1 cm to the left of the xiphoid process; the needle enters the skin at a 30-degree to 45-degree angle and is aimed toward the sternal notch or the left shoulder. The needle is advanced with constant syringe aspiration. As much fluid is aspirated as is needed to improve the clinical condition or to obtain specimens for diagnostic use.

After completing the procedure, a chest radiograph is obtained to look for complications such as pneumothorax or pleural effusion secondary to laceration of the lung or myocardium. Serial physical examinations and central venous pressure monitoring are done to detect reaccumulation of fluid. The admitting consultant may choose to observe the patient for fluid reaccumulation, place a soft catheter in the pericardial space for continued drainage, or perform surgical drainage in the operating room.

COMMON PITFALLS

- Failing to consider pericarditis in the differential diagnosis of chest pain
- Mistakenly diagnosing pericarditis in patients with other causes of chest pain, such as MI, pulmonary embolism, or aortic dissection
- Misdiagnosing acute pericarditis as acute MI, potentially leading to the inappropriate administration of thrombolytics.
- Failing to consider the etiology of pericarditis. Many of the causes listed in [Table 138.1](#) require specific therapy.
- Failing to rule out the presence of a pericardial effusion in patients with pericarditis
- Failing to consider cardiac tamponade in the differential diagnosis of hypotension, especially in patients with cancer

TABLE 139.2. Differential Diagnosis of Deep Venous Thrombosis

EMERGENCY DEPARTMENT EVALUATION

The clinical evaluation of the patient with possible DVT focuses both on identifying findings consistent with DVT and on identifying other conditions that explain the patient's presentation. It is important to question the patient about risk factors for DVT, including a family history (see [Table 139.1](#)). Perhaps one-fourth of patients with acute DVT have a history of prior DVT.³

The physical examination can provide useful findings, but must be interpreted with caution. Though patients with cellulitis and other infections often have a fever, DVT can also result in temperature elevations, although usually only low-grade. Unilateral warmth and erythema are common with DVT, but also with cellulitis. The presence of an abscess, enlarged lymph nodes, and ulcerations can be clues to an infectious etiology. A difference of 1 cm in the circumference of the calves, or 2 cm in the thighs, measured from a reference point such as the patella, is clinically significant and one of the most specific findings for DVT. The presence of palpable "cords" is generally thought to be fairly specific but quite insensitive for thrombosis. In the popliteal fossa, they can be confused with Baker's cysts. Homan's sign was classically taught as being important in the evaluation of DVT, but it is now well known that its sensitivity and specificity are only about 50%.

DVT is a difficult diagnosis to make clinically; between 50% and 75% of patients suspected of having DVT will not have the diagnosis confirmed by objective tests. Therefore, patients in whom the diagnosis is expected must undergo further diagnostic studies. The only blood test of relevance is the serum D-dimer level, which is elevated in the presence of clot breakdown. Early enthusiasm for this test has been tempered with time, however. The test is 93% to 98% sensitive for DVT, but only 40% to 80% specific.^{2,12} False negatives are particularly common in chronic or recurrent DVT. The D-dimer should not be used to replace imaging studies in patients in high- or medium-risk groups. In patients without significant comorbidity and in a "low-risk" group, a negative D-dimer result may be sufficient evidence to avoid further studies.¹⁶ Only the sensitive but more time-consuming ELISA test or the SimplicRed test should be used, not the less sensitive latex agglutination.

The primary imaging study for patients with DVT is now ultrasonography. It is relatively inexpensive, noninvasive, and widely available. Though a number of techniques are used, B-mode looking at compressibility of the vein is the standard for confirming the diagnosis. Ultrasound is considered 95% to 99% sensitive for acute thrombi above the knee, and it can also occasionally identify other conditions, such as tumor, cysts, aneurysms, and so forth. However, scans can be reader-dependent, and some institutions lack individuals with sufficient expertise or experience. In addition, the test is less accurate in the second half of pregnancy and for suprainguinal vein thrombus, in which case, the Doppler mode of the duplex ultrasound scan can be helpful. In these situations, or in patients felt to be at high risk for DVT, it may not be appropriate to end the evaluation with a single negative ultrasound examination. Use of additional tests or close follow-up with serial outpatient studies is recommended.⁵

Although venography is considered the gold standard for the diagnosis of DVT, it has a number of problems. Approximately 10% of the studies are technically inadequate, and radiologists often disagree on interpretation. Some patients develop phlebitis from the procedure, and there are occasional cases of anaphylaxis from the radiographic contrast material. Patients often report the procedure to be painful. For all of these reasons, the role of venography has largely been supplanted by ultrasound. Its main role is in patients with a history of prior DVT in whom ultrasound is equivocal. It can better distinguish between acute and chronic changes.

Impedance plethysmography (IPG) measures changes in lower extremity venous volume in response to selected maneuvers and draws comparisons between the legs. Though relatively inexpensive and noninvasive, IPG has been shown to be very operator-dependent, and its sensitivity is only 65% to 85%.¹¹ It is not recommended for use in ED patients. Likewise, radiolabeled fibrinogen studies, which are designed to identify growing thrombus, are relatively insensitive, take prolonged periods to perform, and are not useful in ED patients.

Magnetic resonance imaging (MRI) is developing a growing role in the evaluation of DVT. Its sensitivity (97%) and specificity (95%) are the equal of ultrasound. In addition, it is particularly useful in identifying thrombus in the pelvis, an area where ultrasound has limitations. It is also approved as safe for use during pregnancy and is the test of choice in that population.¹⁷ It can distinguish mature from recent clot and also has applications for identifying pulmonary thrombi. However, it is relatively expensive, not widely available, and requires greater patient cooperation, somewhat limiting its use.

Though much less common, DVT can also develop in the upper extremities, usually in the subclavian or axillary veins.¹ The use of diagnostic imaging studies in such cases is less well studied. Because of differences in the anatomy, ultrasound may not be as sensitive as it is in the thigh, but it is still recommended as the first-line study. However, inadequate examinations or negative examinations in high-risk patients should be followed with contrast venography.

EMERGENCY DEPARTMENT MANAGEMENT

Patients with isolated DVT rarely require immediate lifesaving interventions. However, many of these patients have occult PEs, and all are at risk for new emboli. In patients in whom PEs are strongly suspected, starting heparin prior to imaging studies is appropriate. In addition, occasional patients can present with complete venous obstruction and the condition referred to as "phlegmasia dolens." These patients should also undergo immediate heparinization and fluid resuscitation prior to imaging studies when the diagnosis is suspected. They also often require thrombolytics and, occasionally, urgent thrombectomy ([Table 139.3](#)).

Deep Venous Thrombosis Heparin load (80 U/kg) and infusion (18 U/kg/h) Warfarin on first day Admit to hospital (floor bed) Consider outpatient protocol using LMWH in selected patients IVC filter if heparin contraindicated or fails anticoagulation therapy
Superficial Venous Thrombosis Ultrasound to exclude DVT Outpatient care with elevation, NSAIDs; consider compression
Cell Thrombi Same as DVT Or treat like superficial phlebitis, but with serial outpatient studies to detect propagation
Phlegmasia Dolens Immediately heparinize Fluid resuscitate Admit to ICU Consider thrombolysis Vascular surgery consult
<small>NSAIDs, nonsteroidal antiinflammatory drugs; ICU, intensive care unit.</small>

TABLE 139.3. Disposition and Treatment

In the vast majority of patients, the initial treatment for DVT is anticoagulation with heparin. Those with absolute contraindications to anticoagulation require vena caval interruption, usually with an IVC filter.⁶ Filters are approximately 95% effective in preventing further PEs, but they have a 10% complication rate on insertion. However, this complication rate is not appreciably higher than that of full anticoagulation.

Heparin blocks extension of thrombus and reduces the risk of further emboli. It does not actively break down clot, but allows the body's own fibrinolytic mechanism to operate over a period of several days to weeks.⁸ Heparin has a relatively narrow therapeutic index and is noteworthy as the most common cause of drug-related deaths in the hospital. Significant bleeding occurs in up to one-fourth of patients; the elderly and those on aspirin are at greatest risk. However, these complications rarely occur during the first few hours of treatment or during the time the patient is in the ED. Though heparin is commonly given as a 5,000-U bolus (often 10,000 U if PE is expected), this "standard dosing regimen" often results in inadequate anticoagulation at 24 hours. It has been shown that more accurate dosing occurs when heparin is given as an 80-U/kg bolus and then as a drip of 18 U/kg/h.¹⁶ The rate is then titrated, with the goal of prolonging the partial thromboplastin time by 1.5 to 2.5 times that of normal. Contraindications to heparin include active internal bleeding, malignant hypertension, central nervous system neoplasm, very recent surgery or significant trauma, or a history of heparin-induced thrombocytopenia. Relative contraindications include gastrointestinal bleeding or prior hemorrhagic stroke. Once

heparin has been initiated, warfarin (10 mg PO) may be begun, although this is generally not administered in the ED.

Recently, there has been growing interest in the low-molecular-weight heparins (LMWHs) for the treatment of DVT. These are fractionated versions of standard heparin that have a more predictable effect (and therefore do not require close monitoring) and fewer side effects or complications. Most studies comparing these with standard heparin show that LMWHs have advantages but higher costs for the drug itself. Because they can be given subcutaneously once a day, however, and do not require repeated blood tests, home treatment of DVT is possible.¹³ Some health systems have protocols for discharge from the ED of selected stable patients with DVT for home LMWH therapy.

Although occasionally recommended, there is no clear role for thrombolytic therapy in patients with isolated DVT, and it should not be initiated independently by the EP. There is some weak evidence that thrombolytics may decrease the incidence of subsequent complications, but these are balanced by an increased rate of acute complications. Therefore, its routine use is not recommended.⁷

There is some controversy regarding recommended management of DVT below the knee. Historically, most of these cases have been treated conservatively, with elevation and antiinflammatory drugs. More recently, however, it has been recognized that these DVTs often propagate and, in as many as one-third of patients, eventually embolize. Therefore, it is generally recommended that these DVTs be treated in a manner similar to that for iliofemoral DVTs. For those patients in which the decision is not to acutely anticoagulate, there should be close follow-up and serial noninvasive studies to document clot regression and absence of propagation, generally with ultrasound.

Similarly, there has been some controversy regarding the ideal treatment of superficial thrombophlebitis of the leg. Here, the danger of acute embolism is less than for calf DVT. However, it must be confirmed that propagation to the deep system has not occurred at the time of the ED visit, and, again, close follow-up must be arranged. Compression bandages, antiinflammatory drugs, and elevation are standard recommendations. If the patient is an intravenous drug user or appears toxic, septic thrombophlebitis must be ruled out. Treatment guidelines are outlined in [Table 139.3](#).

DISPOSITION

Historically, all patients with proximal lower extremity or upper extremity DVT required admission to the hospital. However, some institutions have now initiated protocols by which a select subset of patients (stable symptoms, no comorbid diseases, and reliable compliance) are being discharged directly home from the ED on a subcutaneous LMWH protocol with close outpatient follow-up. This should not be initiated by the EP, other than as part of a hospital or health-care system protocol.

Conversely, the treatment of patients with DVT distal to the knee was historically similar to that of superficial thrombophlebitis. Now, with increasing concerns that these patients have risks for embolization that are only moderately lower than those with proximal DVT, it is recommended they be hospitalized or entered into a close follow-up protocol.

There is one group of patients that requires a more aggressive approach, namely those with phlegmasia dolens. This condition represents a life-threatening emergency and requires admission to an intensive care unit. These patients also require vascular surgery consultation for consideration of thrombectomy in those situations in which there is risk of loss of the limb without urgent intervention. Fortunately, phlegmasia dolens is a very uncommon complication, but, in this situation, the lack of vascular surgery capability would be the one indication for transport to a higher level of care.

COMMON PITFALLS

- Patients with a painful or swollen leg should be considered to have DVT until proven otherwise. Clinical evaluation alone is not sufficient to rule out the diagnosis.
- The traditional physical examination findings of DVT are notoriously inaccurate. The Homan test should be abandoned, and the presence of a palpable cord should not be relied on.
- A negative D-dimer test is useful only in patients with a clinical low risk of DVT. It should not be used to exclude the diagnosis in moderate- or high-risk patients.
- Although ultrasound examination is generally an excellent test for DVT, it is somewhat operator-dependent, and there are false negatives. Patients with a very high clinical suspicion for DVT but a negative ultrasound should either undergo additional studies or be admitted for serial evaluations.
- Traditional loading doses of heparin result in under-anticoagulation of many patients. Weight-based dosing is more effective.
- Isolated DVT distal to the knee is not as benign as previously thought. It should be treated more like proximal DVT in terms of therapeutic aggressiveness.

[Chapter References](#)

Infectious endocarditis (IE) is an infection of the endothelial lining of the heart, usually including the valvular endothelium. The disease has been described since the 1600s and continues to evolve and change. Because of a dramatic surge in intravenous (i.v.) drug use and the increased use of prosthetic heart valves, the number of cases of IE is increasing.

IE has classically been divided into two forms: a relatively insidious, chronic disease—subacute bacterial endocarditis (SBE)—and a more abrupt-onset, fulminant form—acute bacterial endocarditis (ABE).

Endocarditis is now more likely to be encountered in patients with prosthetic heart valves, i.v. drug users and the elderly, and less likely to be seen in patients with a history of rheumatic heart disease.^{1,2} (Table 140.1). The most common organisms causing IE have also changed. As IE has evolved, the frequency of *Streptococcus viridans* has decreased, while the incidence of *Staphylococcus* species has risen.^{1,9,13,14}

Patients with valvular or structural heart disease
Intravenous drug abusers
Patients with prosthetic heart valves
Patients with indwelling devices, especially hemodialysis shunts
Elderly patients who have recently undergone an invasive procedure

TABLE 140.1. Emergency Department Patients at Highest Risk for Endocarditis

There are four steps in the development of SBE: (1) A hemodynamically defective valve produces turbulent blood flow and endothelial disruption; (2) a sterile platelet–fibrin thrombus forms on the damaged valve lining; (3) transient bacteremia infects the thrombus; and (4) high titers of antibodies to the infecting organism are produced. Bacterial endocarditis may also develop on previously normal native and prosthetic heart valves. In these cases, the only necessary measure is an inoculum of a highly invasive organism.^{1,2}

Once endocarditis develops on a valve, the clinical manifestations are attributable to the following series of events: (1) local destruction and malfunction of the cardiac valve; (2) invasive infection of contiguous structures in the heart; (3) continuous bacteremia, leading to distant infections; (4) embolization of vegetations that break off from the valve; and (5) an antigen–antibody response, leading to immune-mediated complications.

IE is often classified into one of four distinct clinical groups: (1) patients with a damaged native valve; (2) i.v. drug abusers (IVDAs); (3) patients with prosthetic valves who develop early-onset prosthetic valve IE (PVE); and (4) patients with late-onset PVE.⁷ Early-onset PVE is defined as infection that presents less than 2 months after valve replacement surgery; late-onset PVE presents more than 2 months after surgery.⁷

Damaged Native Valve

Any condition causing cardiac valve damage (e.g., rheumatic, degenerative, and congenital cardiac abnormalities) can predispose the patient to IE. Patients with rheumatic valvular disease and those with mitral valve prolapse with documented valvular redundancy and incompetence are, by far, the two highest risk groups for native valve IE.⁹ Patients with native valve IE are most likely to develop a syndrome similar to the classic SBE, a relatively chronic infection with only left-sided cardiac involvement, often with a streptococcal organism.^{1,2} The mitral valve is the most common valve to be infected in the native valve group. Isolated mitral involvement occurs in 35% to 45% of cases, isolated aortic valve involvement in 15% to 35%, and involvement of both valves in 15% to 30%.⁴ Tricuspid valve IE is unusual in this group and accounts for only 1% to 5% of cases.⁴ Pulmonic involvement is rare in native valve IE, occurring in less than 1% of cases.^{1,2,7}

Native valve IE is caused by streptococcal pathogens in approximately two-thirds of cases (Table 140.2).^{1,2,7} *S. viridans* is by far the most common *Streptococcus* species causing IE.^{1,7,13} *S. viridans* bacteremia and subsequent valvular seeding traditionally have been attributed to dental procedures in patients with preexisting valvular heart disease.¹⁸ This presumed cause-and-effect relationship has been questioned, and it is no longer clear whether dental procedures are the cause of a significant number of cases of IE.²⁰ *Streptococcus bovis* (up to 15% of cases of native valve IE) and *Streptococcus fecalis* (more than 10%) are more commonly introduced by bowel and urologic infections or procedures, especially in the elderly.^{5,23} Coagulase-positive *Staphylococcus* (up to one-third of all cases of native valve IE) and coagulase-negative *Staphylococcus* (less than 5%) are probably introduced via the skin and are most likely to cause infection in patients who have diabetes or chronic obstructive pulmonary disease, and in those who are elderly or are otherwise debilitated.²³ Central venous and arterial catheterizations are relatively high-risk procedures for causing IE.¹⁶ Indwelling devices, especially hemodialysis shunts, also increase the risk for IE.¹⁹ Gram-negative organisms, fungi, and diphtheroids seldom occur in native valve IE.³

be responsible.

Emboli and Immunologic Responses

Besides the brain and heart, other important areas of embolization are the splenic, renal, mesenteric, and extremity vasculature. The emboli result in endarteritis, mycotic aneurysm, local infection, and distal infarction. It is not clear how many of the signs and complications of IE are immune complex-mediated. It is thought that glomerulonephritis, aseptic arthritis, and most of the classic skin manifestations are immune-related.^{1,2,7}

EMERGENCY DEPARTMENT EVALUATION

Patients with IE often have numerous nonspecific complaints. Most complain of fever, malaise, anorexia, and weakness.^{2,23} Approximately one-half of patients report headache, weight loss, nightsweats, arthralgias, and myalgias.^{1,2,7} A history of back pain, rash, dyspnea, or a spectrum of neuropsychiatric symptoms is not uncommon in IE.^{1,2,7} Clinicians seldom initially attribute these less common symptoms to IE, however. Patients should be asked about recent dental, gastrointestinal, and urologic procedures. Elderly patients in particular may not volunteer or may forget to relate these high-risk procedures. Young patients who are being evaluated “for the flu” seldom volunteer information about i.v. drug use unless specifically questioned.

Physical findings suggestive of endocarditis are listed in [Table 140.3](#). Patients with IE may appear acutely or chronically ill. Nearly all nonimmunosuppressed patients have fever.⁹ Other abnormal vital signs, especially tachycardia, are relatively common.²³

A careful cardiac examination is important in patients suspected of having IE. Approximately 85% of patients with IE have a murmur.⁷ Patients most likely to lack murmurs are those with acute IE. Thus, lack of a murmur in an IVDA should never decrease the suspicion of IE. On the other hand, a new regurgitant murmur in a febrile patient is very strong evidence for the disease.⁹ Rarely, a large (usually fungal) vegetation may block the outflow tract, resulting in a new stenotic murmur.²¹ The cardiac examination should also seek any findings suggestive of heart failure.

A variety of skin lesions are considered classic for IE, but are relatively uncommon. Petechial lesions may be found in different locations. Splinter hemorrhages are tiny red, purple, brown, or black splinter-like lesions that appear under the fingernails. They are seen in up to 20% of patients with IE, but are also found in approximately 8% of all hospitalized patients.⁷ Osler's nodes are small, painful, tender erythematous nodules that are most commonly seen in the distal finger pads; they occur in 5% to 20% of patients.^{7,9} Janeway lesions are small, flat, nontender red spots on the palms and soles; they occur in only about one in ten patients with IE.⁹ Conjunctival petechiae may occur in approximately 10% of patients. Roth spots are retinal petechial hemorrhages with central pallor, which may be seen in 10% to 25% of patients with IE.^{6,9} The remainder of the physical examination may reveal abnormal abdominal or neurologic findings. Splenomegaly is a common finding, and a tender, enlarged liver is often noted. Neurologic examination may reveal signs consistent with meningitis, encephalitis, embolic stroke, or a leaking aneurysm.¹² Some patients present with subtle mental status changes or behavioral symptoms that appear to be psychiatric in nature.

There are numerous nonspecific laboratory findings in IE ([Table 140.4](#)). Normochromic, normocytic anemia occurs in up to 75% of patients, and microscopic hematuria in nearly 50%.^{14,16} Leukocytosis is seen in about half of cases, and, thus, its absence should not be used to rule out the diagnosis. An elevated sedimentation rate is typical, but it may be normal in up to one-third of patients.²³

BLOOD	ECHOCARDIOGRAM
Positive blood cultures	Vegetations
Anemia	Valve dysfunction
Microscopic or gross hematuria	Chamber enlargement
Leukocytosis	Pericardial effusion
Uremia	
CHEST RADIOGRAPH	V/Q SCAN
Cardiomegaly	Multiple pulmonary infarcts
Pulmonary infiltrates	
Pulmonary infarcts	CEREBROSPINAL FLUID
Pulmonary effusions	Purulent meningitis
Chamber enlargement	Aseptic meningitis
Abnormal movement of prosthetic valve	Bleeding aneurysm
Stimson's sign	
ELECTROCARDIOGRAM	COMPUTED TOMOGRAPHY
Conduction defect	Mycotic aneurysm
Acute myocardial infarction	Cerebral abscess
Pericarditis	Subarachnoid hemorrhage

TABLE 140.4. Laboratory Findings in Endocarditis

The most important part of the laboratory evaluation is the blood culture. Approximately 20 mL of blood (not 5 to 10 mL) should be drawn for each set of blood cultures and sent for aerobic and anaerobic cultures. The diagnosis of “possible endocarditis” should appear on the specimen label so that the laboratory will hold the specimen for at least 3 weeks to ensure detection of slow-growing organisms. If at all possible, blood cultures should be from three separate sites and should be drawn over a period of approximately 1 hour.

Blood cultures may be positive in up to 98% of patients with IE.¹⁶ Unfortunately, some recent series have reported positivity rates as low as 60% to 80%.^{9,14} To maximize the chances of a positive culture and to minimize the confusion caused by contaminants, three to five sets of cultures drawn at least 1 hour apart should be obtained before antibiotics are initiated. Recent antibiotic use by the patient and infection with fastidious or slow-growing organisms are the two major reasons for negative IE cultures.²³ The patients that most commonly have negative cultures are drug abusers, patients with prosthetic valves, and those who have recently received antibiotics.³

The chest radiograph of patients with IE is usually normal. Signs of congestive heart failure, including cardiomegaly, isolated chamber enlargement, and abnormal vascular patterns, provide valuable information regarding abnormal valvular or cardiac function. The chest radiograph may also reveal pneumonia, especially in IVDA patients. Multiple pulmonary infarcts or nodules suggest right-sided disease, usually tricuspid valve endocarditis.¹⁶ In PVE, a double shadow of a mechanical valve, known as Stimson's sign, indicates movement of a valve that has undergone partial dehiscence.⁴

Although usually normal, the ECG should always be carefully examined for evidence of pericarditis, ischemia, infarction, conduction delay, or any degree of heart block. These changes may be indirect evidence for the coexistence of myocarditis, myocardial abscess, pericarditis, or coronary artery embolism.²⁵

Echocardiograms are almost always performed in patients who are suspected of having IE. The finding of a vegetation is very strong evidence for the diagnosis of IE.⁹ However, a negative echocardiogram should never be used as the definitive test to rule out IE, as up to one-third of patients with IE have nondiagnostic echocardiograms.¹⁵ Transesophageal echocardiography (TEE) is more sensitive than transthoracic echocardiography (TTE), though it is probably more appropriate to begin with a TTE.¹¹ Echocardiographic detection of valve malfunction, chamber enlargement, or an associated pericardial effusion may also be helpful in the clinical management of IE. Mechanical valves are too echo-dense for TTE to be of significant value, and valvular function should instead be evaluated by either TEE or cinefluoroscopy.^{4,15}

EMERGENCY DEPARTMENT MANAGEMENT

Definitive therapy for IE is guided by the infecting organism's sensitivity to specific antimicrobial agents. Once blood culture and sensitivity data are available, optimal therapy can usually be decided on easily. The choice of optimal empiric therapy for presumed IE prior to culture results is guided by the expected sensitivity of the bacteria that cause infection in a specific type of patient.

Antibiotics Based on Known Organism

Most experts recommend a combination of aqueous penicillin (12 to 18 million U/d) and gentamicin (1 mg/kg i.v. q8h) for IE in native valve endocarditis due to *S. viridans* or *S. bovis*.^{10,26} Single daily dosing of gentamicin is not appropriate in treating IE.^{10,26} A combination of high-dose penicillin and gentamicin is also recommended for enterococcal IE.^{7,10,26} Nafcillin (2 g i.v. q4h) and gentamicin are often recommended for *S. aureus* infections on native valves.^{10,26} Vancomycin is recommended when *Staphylococcus* species are methicillin-resistant.²⁶ Because *Staphylococcus* is the single most common organism in IVDAs, broad antistaphylococcal coverage is essential in this population.^{17,18} Routine antipseudomonal coverage is not routinely recommended in IVDAs because of the rarity of this once more common organism.^{10,18,26}

PVE occurring within 1 to 2 months of valve surgery is due to *S. aureus* in approximately 50% of cases and to *Staphylococcus epidermidis* in another 20%.^{4,7} Gram-negative organisms and fungi are also common in patients who develop IE soon after surgery. Thus, coverage usually includes vancomycin, gentamicin, and rifampin.^{7,10,26} PVE occurring more than 2 months after valve replacement is similar to native valve IE, in that *S. viridans*, *S. bovis*, and *S. aureus* are the most common organisms.⁷ Most experts recommend the same initial coverage for early and late PVE, as coagulase-negative *Staphylococcus* species and gram-negative organisms may also be the causative agents.^{7,10,26}

If a stable patient presents to emergency department (ED) with the possibility of IE, it is best to obtain at least three sets of blood cultures from separate sites over a period of 1 hour. The patient should then be admitted to an inpatient area and subsequent care and additional culturing performed at the direction of the patient's physician or infectious disease consultant. Antibiotics should, however, be started in the ED if the patient appears septic; is elderly, debilitated, or immunocompromised; has concomitant pneumonia; is in heart failure; or is hemodynamically unstable.

Empiric Antibiotic Coverage

There is no universal agreement on optimal therapy. However, ED physicians can begin therapy by choosing an antibiotic regimen that provides broad-spectrum bactericidal coverage for the most common organisms causing IE. The authors' recommendations for empiric therapy to be begun in the ED appears in [Table 140.5](#).

Patients with Native Valves (Including Intravenous Drug Abusers)		Patients with Prosthetic Valves	
Nafcillin ^a	2 g i.v. q4h	Rifampin	300 mg PO q8h
and Gentamicin ^b	1 mg/kg i.v. q8h	and Gentamicin ^b	1 mg/kg i.v. q8h
and Vancomycin	1 g i.v. q12h or 15 mg/kg	and Vancomycin	1 g i.v. q8h

^aConsider ceftriaxone 2 g i.v. in penicillin-allergic patients.
^bUse q8h dosing and not single daily dosing in infective endocarditis.

TABLE 140.5. Empiric Emergency Department Therapy for Presumed Endocarditis prior to Culture Results

The recommendations attempt to provide broad coverage divided into two regimens: one for presumed IE in a seriously ill patient with native valves, and a second for presumed IE in a patient with one or more prosthetic valves. The regimens are designed to be easily remembered, and do not address whether the patient may have developed IE in association with i.v. drug abuse or how long ago the prosthetic valve was implanted. In addition, *Staphylococcus* species are assumed to have the potential to be of the methicillin-resistant type. Thus, patients with the possibility of IE should receive nafcillin, gentamicin, and vancomycin. Patients with prosthetic valves who require that therapy be initiated on an emergent basis should receive rifampin, gentamicin, and vancomycin. The regimen should be adjusted after the patient is admitted to the hospital, based on inpatient physician preference and culture and sensitivity data. Consultation with the patient's physician should be accomplished at the earliest possible time.

Anticoagulants

Anticoagulation is contraindicated in patients with native valve IE because of the greatly increased risk of intracranial bleeding that occurs in patients with IE who have cerebral emboli.^{1,7} The exception is the patient who develops massive life-threatening pulmonary emboli.⁷ Patients with PVE who are already maintained on anticoagulation should probably continue the medication and be closely monitored for complications.⁴

Surgery

Valve replacement has become much more widely accepted as a therapy for complicated IE.⁴ Although there is agreement on the indications for surgery, the timing and specific details are debated. The following are general indications for valve replacement: heart failure as a result of new valve malfunction, major embolic complications, continued infection despite administration of appropriate antibiotics, arrhythmia or new conduction defect, or a fungal cause.^{1,2,4,7} It is not clear to what extent the size of the vegetations seen on the echocardiogram determines the prognosis and need for valve replacement.

DISPOSITION

Because of the frequency of serious complications and the need for parenteral antibiotic therapy, all patients who are strongly suspected of having IE should be admitted to the hospital. Patients with overwhelming sepsis, serious embolic complications, or any degree of heart failure or conduction block require admission to an intensive care setting. In addition, intensive care unit admission is mandatory for PVE patients with any evidence of paravalvular leak.

Two to three sets of blood cultures (20 mL of blood for each set) should be obtained in patients suspected of having IE, but in whom the diagnosis is thought to be unlikely. Outpatient follow-up for these patients is appropriate if the patient is reliable and can be readily contacted and if the patient's private physician agrees.

When IE is strongly suspected, a cardiologist should be consulted for possible echocardiographic examination. TEE must be done as soon as possible in any patient with a prosthetic valve in whom the possibility of IE is considered. Patients with PVE or those who may need valve replacement should have a cardiac surgeon involved early to ensure that the timing of surgery is optimal. For patients with possible brain abscess or aneurysm, a neurosurgeon should be consulted promptly.

ENDOCARDITIS PROPHYLAXIS

The aim of antibiotic prophylaxis is to prevent bacteremia from occurring during procedures in patients who have conditions that predispose them to IE. Decisions regarding appropriate prophylaxis depend on knowing which patients are at risk, which procedures predictably cause bacteremia, and which are the most common organisms involved in each organ system ([Table 140.6](#) and [Table 140.7](#)).⁵

HIGH RISK
Prosthetic valves: all types History of infectious endocarditis Congenital cyanotic heart disease Surgically constructed pulmonary vasculature
MODERATE RISK
Most other congenital cardiac malformations Acquired valvular dysfunction, including rheumatic heart disease Hyperplastic cardiomyopathy Mitral valve prolapse with regurgitation
PROPHYLAXIS NOT RECOMMENDED
Prior coronary artery bypass surgery Mitral valve prolapse without valvular regurgitation Cardiac pacemakers Physiologic murmurs History of rheumatic fever without valvular dysfunction History of Kawasaki disease without valvular dysfunction Surgically repaired ASD, VSD, or PDA Isolated secundum-type ASD

ASD: atrial septal defect; VSD, ventricular septal defect; PDA, PDA.

TABLE 140.7. Prophylaxis for Dental, Oral, Respiratory, and Esophageal Procedures

There is increasing debate over the efficacy of prophylactic antibiotics in preventing IE caused by instrumentation or other outpatient procedures. Prophylactic antibiotics may, in fact, not confer any significant protection from IE.²² More importantly, dental procedures and perhaps most other outpatient procedures may not be significant causes of IE.^{8,22}

The American Heart Association has revised its recommendations for prophylactic antibiotic administration.⁵ The 1997 recommendations are simpler and much easier to follow. Now, only a single oral dose of amoxicillin is recommended 60 minutes prior to dental procedures. For patients who cannot take oral medications, a single i.v. dose of antibiotics within 30 minutes of the procedure is recommended. Previous, more complicated regimens were followed by only about one in four physicians.⁸

Patients with heart disease at highest risk for developing IE are listed in [Table 140.6](#). [Table 140.7](#) lists the prophylactic regimen for dental, oral, and upper respiratory procedures required for these patients.⁵ Guidelines for preprocedure prophylaxis for gastrointestinal and genitourinary tract procedures are provided in [Table 140.8](#).⁵

Antibiotic	Dosage	Timing
ANTIBIOTICS FOR HIGH-RISK PATIENTS		
Ampicillin or Cloxacillin	2 g i.v. or i.m. (50 mg/kg up to 2 g in children) 5.5 mg/kg i.v. or i.m. (40 mg/kg in children)	Within 30 min of procedure
Amoxicillin or Ampicillin	2 g i.v. or i.m. (50 mg/kg in children) 5.5 mg/kg i.v. or i.m. (40 mg/kg in children)	60 min before
ANTIBIOTICS FOR MODERATE-RISK PATIENTS		
Amoxicillin or Ampicillin	2 g PO (50 mg/kg in children) 2 g i.v. or i.m. (50 mg/kg in children)	1 h before procedure Within 30 min of procedure
HIGH-RISK PATIENTS ALLERGIC TO PENICILLIN		
Vancomycin or Clindamycin	1 g i.v. over 1-2 h (20 mg/kg in children) 5.5 mg/kg i.v. or i.m. (40 mg/kg in children)	Complete intravenous infusion within 30 min of procedure
MODERATE-RISK PATIENTS ALLERGIC TO PENICILLIN		
Vancomycin	1 g i.v. over 1-2 h (20 mg/kg in children)	Complete intravenous infusion within 30 min of procedure

TABLE 140.8. Prophylaxis for Genitourinary and Nonesophageal Gastrointestinal Procedures

COMMON PITFALLS

- Not asking about risk factors in patients who present with nonspecific symptoms consistent with IE
- Missing the diagnosis in the elderly by attributing a cardiac murmur to chronic heart disease
- Failing to remember that IVDAs are at high risk for endocarditis
- Not asking specifically about i.v. drug use in patients who present with nonspecific symptoms consistent with endocarditis
- Failing to remember that IE in drug abusers often presents without a murmur
- Failing to consider the embolic and immune-mediated complications of IE as the underlying cause of stroke, meningitis, myocardial infarction, septic arthritis, or renal failure
- Failing to recognize that, in patients with a mechanical valve, a regurgitant murmur is a sign of impending heart failure or valve dehiscence
- Failing to consult a cardiac surgeon in cases of IE that have only mild-to-moderate heart failure
- Forgetting that mild degrees of heart block and conduction delays are signs highly suggestive of myocardial abscess or myocarditis
- Not asking about risk factors for IE in patients about to undergo a procedure prone to cause bacteremia
- Failing to learn the new, simplified single-dose amoxicillin regimen for prophylaxis prior to dental procedures

heart (producing bradycardia) in susceptible individuals. [7,21](#)

The finding that vasovagal syncope occurs in individuals following cardiac transplantation, as well as information from animal studies, has led to recognition that a purely cardiac mechanoreceptor mechanism is inadequate to explain the physiologic changes of reflex-mediated syncope. Increasingly, the importance of neurohumoral factors, including the renin–aldosterone–angiotensin system, vasopressin, serotonin, pancreatic polypeptides, endogenous opioids, and nitric oxide, is being recognized. The exact contributions of each of these factors and the nature of their interaction remain to be elucidated. [7,21](#)

Syncope may be a manifestation of psychiatric illness. Studies have documented a high prevalence of psychiatric illness among patients with syncope, particularly patients with syncope of unknown origin. Psychiatric disorders included somatoform disorders, mood disorders (including major depressive disorder), anxiety disorders (including panic attacks), and substance abuse.

Psychiatric disease may be associated with syncope by several mechanisms, including exacerbation of coexisting medical illness, by leading to hyperventilation, by triggering a vasovagal response, or as a presenting complaint in a somatic disorder. Syncope may also be the result of volume depletion or cardiac ischemia produced by alcohol or cocaine abuse, respectively. [22](#)

True seizures also cause a transient loss of consciousness. Distinguishing a seizure disorder from other causes of syncope is usually straightforward by history. Postictal disorientation is the most reliable discriminator, occurring in most patients with seizures and very rarely in patients with syncope. Brief (usually less than 10 seconds) tonic–clonic seizure activity can accompany syncope of any etiology, especially vasodepressor syncope. This activity is not accompanied by postictal disorientation, and it does not represent true seizure activity.

Transient ischemic attacks and stroke rarely cause syncope. [14](#) For cerebrovascular disease to cause a loss of consciousness, either both cerebral hemispheres or the brainstem must be deprived of blood flow. In a patient with a prior hemispheric infarction, marked ischemia or infarction on the contralateral side may cause a loss of consciousness, but it is unlikely that this alteration in consciousness would be transient and resolve spontaneously. Similarly, vertebrobasilar ischemia may cause syncope, but not in isolation. Other manifestations of brainstem dysfunction (diplopia, vertigo, or nausea) are required to make this rare diagnosis. Most investigators agree that syncope is rarely a manifestation of neurologic disease, except for seizures. [14](#)

Subarachnoid hemorrhage can produce syncope, presumably as a result of a sudden increase in intracranial pressure and a sudden transient decrease in cerebral metabolism. The complaint of headache or the appearance of focal neurologic findings in a patient with syncope raises this possibility.

Medications can produce syncope by several mechanisms: by producing volume depletion, causing orthostasis, promoting gastrointestinal hemorrhage, or depressing left ventricular function, or by virtue of having proarrhythmic effects. Medications and the interaction of multiple medications, particularly in the elderly, are important considerations in the evaluation of syncope.

Other causes of syncope include orthostasis secondary to acute blood loss, dehydration, and third-spacing of fluid, as well as disorders of autonomic function, including peripheral neuropathies and central nervous system disease.

EMERGENCY DEPARTMENT EVALUATION

The emergency physician should have several goals in the evaluation of patients presenting with syncope. First, the clinician must identify the subgroup of syncope patients presenting with life-threatening or other causes of syncope requiring emergent or urgent diagnosis and treatment (e.g., subarachnoid hemorrhage, abdominal aortic aneurysm, myocardial infarction). Second, the clinician must be able to identify other recognizable causes of syncope that will benefit from specific treatment or other intervention (e.g., volume depletion, adverse effects of medications). Third, in the patients who remain without a diagnosis despite a thorough emergency department evaluation, the emergency physician must identify those who require further evaluation. Finally, the physician must determine whether the most appropriate setting for that evaluation is as an inpatient or outpatient.

History, physical examination, and the initial electrocardiogram (ECG) are the crucial elements in determining a cause of syncope and in stratifying the risk of those patients in whom it is not possible to make a diagnosis during the emergency department visit. These three components established the diagnosis in 88% of patients who eventually received a diagnosis in two large studies. [3,11](#) In addition, specific abnormalities revealed in this evaluation led to the performance of other tests, which established the diagnosis in another 5% of patients, resulting in a net yield of 93% from a directed emergency department evaluation. A history of exercise-induced syncope, for example, suggests hypertrophic cardiomyopathy or aortic stenosis and justifies echocardiography, while a history of sudden-onset headache with syncope suggests an intracranial hemorrhage and justifies computed tomography of the brain and lumbar puncture.

Physical examination may reveal asymmetric upper extremity blood pressures and lead to consideration of aortic dissection or subclavian steal. Similarly, dysrhythmias on ECG direct the evaluation down another path. Screening laboratory studies have been shown to add little in establishing a cause of syncope (hypoglycemia was clinically suspected, abnormal electrolytes never accounted for a loss of consciousness, and anemia from bleeding was clinically evident). [3,17](#) There is, therefore, no “standard” emergency department workup for syncopal patients beyond history, physical examination, and ECG; further studies are indicated only for selected patients as determined by the initial evaluation.

The history should focus on the events and sensations before, during, and after the syncopal episode, as well as on the medical and medication histories. Physical examination focuses on vital signs and a careful cardiovascular (murmurs, pulses, signs of congestive heart failure) and neurologic evaluation. The ECG is analyzed for arrhythmias, conduction abnormalities, and signs of ischemia or infarction.

Although orthostatic vital signs are a part of the physical examination for a patient with syncope, there is little agreement on the definition of orthostatic hypotension. An increase in the heart rate of 30 beats or more on standing correlates with an acute blood loss of 1000 mL, but smaller degrees of volume loss do not reliably correlate with orthostatic changes. [1,13,19,20 and 21](#) Even symptoms of dizziness on standing correlate poorly with orthostatic changes or volume depletion. Thus, the diagnosis of postural syncope is probably best made by a history of syncope on arising (unless hypovolemia is profound, in which case the orthostatic vital signs will be reliably abnormal).

Although there are reports of syncope as the initial complaint of elderly patients with acute myocardial infarction, there are no convincing reports of acute myocardial infarction presenting solely with syncope. [2](#) Of ten patients whose painless infarction was “ushered in by a syncopal attack,” all had other symptoms or signs (acute severe dyspnea or cardiovascular collapse) or ECG changes that were diagnostic of myocardial infarction at the time of their first evaluation.

More recent reports of syncope as the initial symptom of myocardial infarction in the elderly have also stressed that these patients are often pain-free on presentation. Diagnoses were made nevertheless on the basis of other symptoms, signs, and ECG findings available to the initial examining physician. Thus, admission to the hospital to “rule out myocardial infarction” for the patient whose syncope is unexplained is not warranted (unless indicated for other reasons).

Somewhat similarly, syncope has been described as the initial symptom in patients with aortic dissection, ruptured aortic aneurysm, pulmonary embolism, subarachnoid hemorrhage, and ruptured ectopic pregnancy. However, careful evaluation directed by findings on initial history, examination, and ECG was sufficient to make the diagnosis in all cases.

Attributing syncope to transient arrhythmias, unless they are identified on the initial ECG or monitor strip, can be problematic. Long-term, continuous ECG (Holter) monitoring has inadequate specificity to provide useful results; the vast majority of abnormalities detected cause no symptoms and are of no particular significance. [6,11](#) Invasive electrophysiologic studies may be indicated for a small group of patients who are at high risk for sudden death (those with a history of ventricular tachycardia or fibrillation, myocardial infarction, congestive heart failure, or valvular or hypertrophic heart disease). [4,12](#) Consultation with a cardiologist is desirable when deciding on disposition in this setting.

Upright tilt-table testing has become a useful adjunct in the further evaluation of patients with suspected vasovagal or neurocardiogenic syncope. Tilt-table testing reveals abnormalities in 20% to 70% of patients whose ED evaluation leaves them without a diagnosis. A positive test in patients with a recurrent syncope may guide therapy with a beta blocker, anticholinergic agent, or fludrocortisone. Treatment has been shown to be effective in preventing recurrence of syncope in the majority of

patients with positive tests.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

As with the emergency department evaluation, the management of patients with syncope also requires a tiered approach. For patients presenting with symptoms that allow identification of a cause of the syncopal episode, management is directed toward that entity. For patients who remain without a diagnosis at the end of the emergency department visit, disposition is predicated on an assessment of risk.

Large cohort studies in the 1980s stratified risk based on the etiology of syncope. Patients eventually found to have cardiac causes of syncope were found to have increased rates of mortality, cardiovascular mortality, and sudden death, compared with patients who had syncope of noncardiac origin or in whom an explanation for syncope was not found.^{3,5,11} Often, however, this information is of little help to the emergency physician when the etiology of syncope remains undefined.

The job of the emergency physician is further complicated by other deficiencies in the available medical literature. First, no information is available concerning the risk of adverse outcome (significant arrhythmia or cardiovascular mortality) in the time typically covered by hospitalization surrounding an acute syncopal episode. Second, no literature supports the conclusion that hospital admission results in a benefit to patients or a change in outcome.

Despite these shortcomings, some guidance is available concerning the question of disposition in patients with syncope. Left ventricular function is a clear determinant of outcome. Studies have documented left ventricular function as a significant predictor of arrhythmia, cardiovascular mortality, and sudden death.^{16,19} and ²⁰ In populations matched for age and comorbid illnesses, syncope was not a risk factor for overall and cardiac mortality or for cardiovascular events. Rather, age, male sex, and congestive heart failure were the factors predictive of these end points.⁹

More recently, one emergency department study¹⁸ found that the risk of arrhythmia and 1-year mortality could be stratified by the presence of the following: (1) age greater than 45 years, (2) a history of congestive heart failure, (3) a history of ventricular ectopic activity, and (4) an abnormal ECG, defined as any finding other than sinus tachycardia, sinus bradycardia, or nonspecific ST and T-wave changes. Arrhythmias and death within 1 year occurred in 4% to 7% of patients without any risk factors and in 57% to 80% of patients with three or four risk factors.¹⁸ However, no combination of variables available to the emergency physician identifies a cohort of patients with syncope who have no risk of an adverse outcome.

Given this perspective, it becomes apparent that the decision to hospitalize a patient presenting to the emergency department with syncope, in whom the history, physical examination, and initial ECG are unrevealing, must be made on a case-by-case basis. This decision must be predicated on a careful assessment of the risk of adverse outcome and the potential benefit to the patient of inpatient evaluation. Factors that should be considered include (1) a history of congestive heart failure or left ventricular dysfunction; (2) a history of ventricular arrhythmias; (3) historical factors, physical examination findings, or ECG findings suggestive of structural heart disease, left ventricular dysfunction, arrhythmia, or conduction system disease; (4) the patient's age; (5) the use of medications that may predispose to arrhythmia; and (6) the occurrence of syncope related to exertion.^{15,18}

A clear recommendation for admission can be made for any patient with syncope and known or suspected left ventricular dysfunction or a history of ventricular arrhythmias. Patients with no suspicion of structural heart disease and a single episode of syncope may often be closely followed without other testing, while those with recurrent episodes should be referred for tilt-table testing, event monitoring, or psychiatric evaluation.¹⁵

In patients for whom emergency department discharge is considered, the ability of the patient to provide for basic needs, the safety of ambulation, and the availability of necessary supports following discharge should be assured.

COMMON PITFALLS

- Attributing syncope to a vasovagal or unknown cause because of a failure to take a detailed history of the syncopal event
- Attributing syncope to an incidentally found, asymptomatic arrhythmia
- Attributing syncope to a transient ischemic attack
- Attributing syncope to any finding when the causal relation is tenuous
- Failure to take seriously the finding of an aortic outflow murmur in a patient with syncope
- Admission of patients with isolated syncope of unknown cause to "rule out myocardial infarction"
- Failure to recognize the following catastrophic scenarios: syncope with headache (subarachnoid hemorrhage), syncope with chest pain (myocardial infarction, aortic dissection, pulmonary embolism, pulmonary hypertension), syncope with exertion (aortic stenosis, hypertrophic cardiomyopathy), and syncope with abdominal pain (leaking aortic aneurysm, ruptured ectopic pregnancy)

Although the acute complications of hypertension are less common today than in previous years, they must be recognized and treated promptly and effectively when they occur.^{15,20} Elevations of blood pressure may be divided into hypertensive emergencies, in which the blood pressure must be lowered within hours, and asymptomatic hypertension, in which the blood pressure can be lowered over a period of days to weeks.

A true hypertensive emergency is a severe elevation in arterial blood pressure that represents a threat to life or vital organ function unless treatment is initiated immediately.^{3,23} The diagnosis of hypertensive emergency should never be made solely on the basis of the blood pressure measurement; rather, the patient's response to the blood pressure and the immediate risk to the cardiovascular system are of primary importance.⁹ Many patients with hypertension tolerate high blood pressure levels chronically without acute end-organ damage.^{3,9} In more recent years, the terms *nonemergent hypertension* and *asymptomatic hypertension* have come into favor. Generally, a systolic blood pressure greater than 140 mm Hg and a diastolic blood pressure greater than 90 mm Hg for two or more readings are considered significant and help define asymptomatic hypertension.^{1,18}

HYPERTENSIVE EMERGENCIES

EMERGENCY DEPARTMENT MANAGEMENT

The goal of therapy in hypertensive emergencies is to control the blood pressure to a level that will prevent end-organ damage. The exact level depends on the clinical situation. It is important not to lower the blood pressure too quickly or to levels that produce cerebral or myocardial ischemia, especially in patients with atherosclerosis.³ If the patient has been hypertensive and poorly controlled for years, the cerebral autoregulation curve may be shifted to the right, and rapid reduction of blood pressure may not be well tolerated. A safe goal is to bring the diastolic blood pressure down to 100 to 110 mm Hg over a period of hours, with the higher level being more appropriate in atherosclerotic or elderly patients.^{9,17} The patient should be closely monitored for symptoms of cerebral or coronary insufficiency.

True hypertensive emergencies require parenteral therapy, ideally in an intensive care setting where cardiac and blood pressure monitoring are available. Diuretics should be avoided unless necessary to treat fluid overload. Intravenous furosemide is a relatively ineffective antihypertensive when used alone; moreover, patients with malignant hypertension may be volume contracted and may deteriorate when given diuretics because of stimulation of the renin-angiotensin system and increased sodium retention. In addition, diuretics can cause hypotensive episodes, especially when given in the presence of vasodilating drugs.

The agents most commonly used in hypertensive emergencies are either direct vasodilators (e.g., nitroprusside, nitroglycerin, hydralazine) or inhibitors of the sympathetic or adrenergic system (e.g., labetalol, phentolamine, esmolol).¹⁸ [Table 142.1](#) provides a guide to pharmacologic management. The agent chosen depends on the clinical situation, the availability of immediate close monitoring, and the physician's familiarity and experience with the drugs available.

Drug	Indications	Dose/Route	Pitfalls
Nitroprusside	All hypertensive emergencies except pregnancy	0.2-0.5 µg/kg/min up to 1 µg/kg/min i.v.	Avoid in pregnancy
Nitroglycerin	Myocardial infarction/ischemia, acute left ventricular failure	5-20 µg/min i.v.	Preferential use in CHF or MI
Esmolol	All hypertensive emergencies	50 µg bolus, then 50-200 µg/kg/min	Avoid in asthma, COPD, heart block
Labetalol	All hypertensive emergencies	10-20 mg i.v. over 1-2 min, or 2 mg/min i.v. drip	Avoid in asthma, COPD, heart block
Magnesium	Eclampsia	4-8 mg i.v. over 15-20 min	Use with magnesium sulfate
Phentolamine	Pheochromocytoma, MAO inhibitor crisis	5-10 mg i.v.	Use alpha blocker before beta blocker

CHF, congestive heart failure; MI, myocardial infarction; COPD, chronic obstructive pulmonary disease; MAO, monoamine oxidase.

TABLE 142.1. Pharmacologic Management of Hypertensive Emergencies

Nitroprusside is the drug of choice in many hypertensive emergencies, including malignant hypertension, hypertensive encephalopathy, and aortic dissection (combined with a beta blocker). Nitroprusside is a direct arteriovenous vasodilator that decreases both preload and afterload. Its onset of action is 1 to 2 minutes, and its effect lasts for only 2 to 5 minutes after the drug is discontinued. It is given as an intravenous drip, starting at a dosage of 0.2 to 0.5 µg/kg/min and increasing every 5 minutes to a maximum of 8 µg/kg/min, or until the desired effect is achieved. Nitroprusside should be given with close hemodynamic monitoring of the blood pressure and pulse to prevent inadvertent hypotension. There is no tachyphylaxis, but thiocyanate toxicity may occur if the drug is used over a period of days, particularly in patients with renal failure. It is contraindicated in pregnancy. Nitroprusside is light-sensitive, so bottles and tubing must be kept covered. Because there is no oral form, the patient must be switched to another antihypertensive once control is achieved.^{3,15}

Nitroglycerin functions via stimulation of the cyclic GMP pathway and is a potent peripheral arterial and venous vasodilator. It has both afterload and preload reducing properties. As such, it is especially useful in pulmonary edema and states of high peripheral resistance. Nitrates are also thought to effect coronary artery vasodilatation, making them first-line agents in the treatment of hypertension with associated cardiac ischemia. Nitrates can be administered sublingually in bolus doses of 0.4 mg as tablets or sprays. Nitroglycerin drips start at 5 µg/min and are titrated upwards to effect. The usual dose ranges from 5 to 200 µg/min.¹⁸

Labetalol, a combined alpha and beta blocker, has been used in certain hypertensive emergencies as an alternative to nitroprusside. In certain instances, such as aortic dissection, it can be used in conjunction with nitroprusside; its beta-blocking effects reduce the abrupt rise in pressure during early systole, helping to decrease shear forces at the dissection site. Labetalol is also useful in acute cocaine-associated hypertension because its alpha-blocking effects prevent the unopposed alpha vasoconstriction that may occur when pure beta antagonists are given. Labetalol can be given either intravenously or orally and has the advantage of not causing reflex tachycardia.⁸ The ratio of alpha- to beta-blocker activity is 1:7, but the antihypertensive effects of alpha blockade are felt first. The onset of action averages 30

minutes, and its duration is 3 to 4 hours. Labetalol can be given intravenously in 10- to 20-mg boluses every 5 to 10 minutes. An alternative is to infuse 2 mg/min to a total dose of 300 mg. Patients already taking other antihypertensive agents may require a smaller dose of labetalol to control the blood pressure. Advantages of labetalol include the absence of reflex tachycardia and the ease of converting to the same agent orally once blood pressure is controlled. Labetalol should not be used in patients with contraindications to beta blockade.

Esmolol is a beta-blocking agent with a very rapid onset and offset. It is used in similar situations as labetalol but can be more easily titrated, and can be used as a drip. The initial dose is a bolus of 500 µg/kg, and the drip is titrated between 50 and 200 µg/kg/min. As with labetalol, esmolol should not be used in patients with asthma, chronic obstructive pulmonary disease (COPD), or other contraindications to beta blockade.¹⁸

Hydralazine as an agent for immediate blood pressure control has found application principally in eclampsia, because it has been shown to be safe in pregnancy. Using a dose of 10 to 20 mg, the onset of action is 10 to 30 minutes when given intravenously; its duration of action is 3 to 8 hours.^{3,14} The drug produces marked reflex tachycardia. The advantage of hydralazine over beta blockers is that it can be used in bradycardic patients without concern about further decreases in heart rate.

Phentolamine, an alpha-receptor blocker, is particularly useful in pheochromocytoma, monoamine oxidase (MAO) inhibitor reactions, and antihypertensive drug withdrawal states. The dose is 5 to 10 mg intravenously, and the effect lasts only 15 minutes, requiring repeated dosing. Once the patient is adequately alpha blocked, oral phenoxybenzamine can be begun. Beta blockers should be used only for tachycardia and dysrhythmias, and only after alpha blockade has been achieved.¹⁵

CLINICAL PRESENTATIONS

Malignant Hypertension

Malignant hypertension, the prototype of the hypertensive emergency, occurs in 2% of patients with essential hypertension. It is more common in young Black men and in patients with underlying renal parenchymal disease or renovascular disease. The diagnosis is usually a clinical one based on the marked elevation of the blood pressure and characteristic eyeground changes, including papilledema, which most authors believe is a *sine qua non* of the diagnosis.

Pathologically, malignant hypertension is a physical vasculitis.²¹ Flame-shaped hemorrhages occur around the optic disk due to the high intravascular pressure; “soft” exudates are due to ischemic infarction of the nerve fibers secondary to occlusion of supplying arterioles. However, eyeground changes of increased arteriolar light reflex, arteriovenous nicking, arteriolar tortuosity, and hard exudates are all chronic changes and cannot be used to establish the diagnosis of malignant hypertension.

Common symptoms of malignant hypertension are headache (85%), visual blurring (55%), nocturia (38%), weakness (30%), and weight loss (25%).²¹ Laboratory evaluation reveals progressive azotemia, proteinuria, microscopic or gross hematuria, and cylindruria. Additional findings are microangiopathic hemolytic anemia, thrombocytopenia, and increased fibrin degradation products. Hypokalemia and metabolic alkalosis commonly result from stimulation of the renin–angiotensin system.²¹

If untreated, malignant hypertension carries a 90% 1-year mortality, usually from uremia, cerebrovascular accident (CVA), or congestive heart failure (CHF). With treatment, 1-year survival is increased to 85%.

Hypertensive Encephalopathy

Hypertensive encephalopathy is characterized by significant alteration in cerebral function that improves with lowering of the blood pressure.²¹ It is believed to be due to a loss of normal cerebrovascular autoregulation that results in overperfusion and forced dilatation of the cerebral vessels and the development of multiple areas of cortical edema. Patients complain of headache, nausea, vomiting, confusion, and blurred vision.^{15,21} On physical examination, there is a marked elevation of blood pressure (usually greater than 130 mm Hg diastolic), altered mental status, and, commonly, papilledema. Focal neurologic deficits are sometimes noted, as are seizures.¹⁵

The differential diagnosis is vast, but no other condition resolves with lowering of the blood pressure. Cerebral infarction usually has a more rapid onset (minutes to hours); the headache is typically mild, and neurologic deficits are fixed. Cerebral embolism has a sudden onset, and usually causes minimal or no headache or mental status change. With intracerebral or subarachnoid hemorrhage, neurologic deficit or alteration of consciousness is also of rapid onset; sudden severe headache is also characteristic, particularly with subarachnoid hemorrhage. To differentiate among these entities, a computed tomography (CT) scan of the head must be done immediately while other supportive measures are being initiated.

Lowering the blood pressure is the key to managing hypertensive encephalopathy, but if it is lowered too rapidly, hypoperfusion may result. A rough guideline is that the diastolic blood pressure should be lowered only 20% to 30% during the first 24 hours. The patient's mental status should be followed closely. Any medications that may change the neurologic examination are to be avoided. Drugs of choice include nitroprusside, labetalol, and esmolol.

Aortic Dissection

Aortic dissection usually presents with sudden, severe, tearing chest pain that radiates into the midscapular region of the back. CT scan of the chest with intravenous contrast, transesophageal echocardiography, or aortography can show the intimal flap. More than 90% of patients with aortic dissection are hypertensive by history, even if they are not hypertensive on presentation. Patients with known aortic dissection must have their blood pressure aggressively managed. Stabilization and control of the blood pressure is crucial, because propagation of the dissection depends on the instantaneous slope of the intraaortic pressure curve and the resulting stress on the aortic wall. The goal of therapy is to lower the blood pressure to 100 to 120 mm Hg systolic over a few hours in order to decrease this pressure head. This is accomplished with medications that decrease cardiac inotropy and chronotropy and decrease peripheral resistance. The typical emergency department (ED) regimen includes nitroprusside in conjunction with a beta blocker such as esmolol or labetalol.¹⁵ Medications that cause reflex tachycardia, such as hydralazine, should be avoided. Surgery is the definitive treatment for proximal dissections, whereas distal dissections can often be managed medically.

Ischemic Heart Disease and Myocardial Infarction

In patients with severe coronary artery disease, hypertension may have an immediately deleterious effect by increasing resistance to left ventricular emptying, leading to increased ventricular wall tension and increased myocardial oxygen demand. Excessive blood pressure reduction should be avoided so as not to compromise coronary artery perfusion. The degree of blood pressure reduction should be based on the hemodynamic effect rather than on a predetermined blood pressure end point, and hemodynamic monitoring should be available to avoid excessive pressure lowering. To control ischemic pain, the usual antianginal drugs should be used first because they are often effective in treating the hypertension as well. Intravenous nitroglycerin is an excellent immediate agent. Beta blockers such as metoprolol, atenolol, or propranolol are indicated in the tachycardic patient, as decreasing the heart rate reduces myocardial oxygen demand and has been shown to decrease morbidity and mortality following myocardial infarction. As mentioned previously, hydralazine causes reflex tachycardia and should be avoided.

Acute Left Ventricular Failure

Untreated hypertension can lead to acute CHF. More commonly, however, acute pulmonary edema triggers a catecholamine release, which increases peripheral vascular resistance and further reduces forward flow. The initial therapy for pulmonary edema with hypertension is to treat the pulmonary edema in the usual manner; nitroglycerin is the drug of choice. Nitroprusside can be added in individuals who have low cardiac output in conjunction with high peripheral vascular resistance. Both drugs decrease peripheral vascular resistance and therefore help to increase cardiac output. Hydralazine should be avoided because of reflex stimulation of myocardial contractility and heart rate.

Hypertension with Cerebrovascular Accident

In managing patients with hypertension and CVA, the major concern is to avoid hypoperfusion of already ischemic tissue. For a chronically hypertensive patient, the

mean arterial blood pressure necessary to maintain cerebral blood flow is higher than normal. If the blood pressure is brought below the lower limit of autoregulation, cerebral blood flow will fall, possibly leading to further neurologic damage.^{9,15,19} Thus, cautious lowering of the blood pressure may be indicated, and the use of a short-acting, titratable agent such as nitroprusside or labetalol is advised.⁶ A reasonable target is to lower the diastolic pressure to 100 to 110 mm Hg. A rapid rise in blood pressure can increase the intracranial pressure, while a rapid fall can cause brain tissue ischemia. Therefore, it is safer to aggressively control fluctuations in blood pressure and to aim for blood pressure stability rather than simply lowering the rapid blood pressure rapidly.

Some experts advocate not treating hypertension in patients with nonhemorrhagic CVAs.⁹ This is based on a lack of data showing a benefit of acutely reducing blood pressure in these patients, as well as case reports of morbidity and mortality that have resulted from this practice.^{2,17} In the case of patients with subarachnoid hemorrhage, treating with the calcium channel blocker nimodipine during the first 2 days may improve outcomes. This is thought to be a result of the antivasospastic effects and not specifically due to the antihypertensive effects of this medication.^{11,12}

Catecholamine Excess

Hypertension due to catecholamine excess occurs in patients with pheochromocytoma, in patients taking MAO inhibitors who eat tyramine-containing foods or ingest sympathomimetic drugs, and in patients who are withdrawing from certain antihypertensive agents.

Pheochromocytoma is rare and typically presents with a history of paroxysms of headache, anxiety, diaphoresis, pallor, palpitations, nausea, and abdominal discomfort. The blood pressure can be markedly elevated (systolic greater than 300 mm Hg),¹⁵ although only 50% of cases have sustained hypertension. In suspected cases, therapy should be started before a biochemical diagnosis is made. The drug of choice is intravenous phentolamine, an alpha-adrenergic blocker. Beta blockers should be used only after alpha blockade to avoid paradoxical hypertension; they are usually necessary only if tachyarrhythmias are present.¹⁵

In patients taking MAO inhibitors, severe hypertension can be precipitated by the ingestion of tyramine-containing foods and drinks (e.g., unpasteurized cheeses, certain beers, wines, pickled herring, chicken liver, broad beans, and certain milk products). Drugs such as ephedrine, phenylpropanolamine, and amphetamines can cause a similar elevation. The onset of symptoms is within 15 minutes to 2 hours of ingestion; the peak effect is normally in 2 to 4 hours, and symptoms usually abate by 6 hours. The drug of choice is phentolamine, which should be continued until hypertension and symptoms resolve.¹⁵

Rapid withdrawal from clonidine can cause a syndrome consisting of nausea, palpitations, anxiety, sweating, and headaches, similar to that seen with pheochromocytoma. These effects are thought to be due to enhanced sympathetic activity after discontinuing the drug.¹⁵

Hypertension in Pregnancy

Because blood pressure normally falls during pregnancy, the threshold for the diagnosis of hypertension in pregnancy is at a lower level than in the nonpregnant person. A pressure above 140/90 mm Hg or an increase of more than 30/15 mm Hg from baseline is abnormal. Intravenous magnesium sulfate is first-line therapy. It has smooth muscle relaxation properties and increases the seizure threshold. As such, it has mild antihypertensive effects as well as tocolytic and antiepileptic properties. If the diastolic pressure remains over 100 mm Hg despite adequate magnesium therapy, hydralazine can be used. Nitroprusside should be avoided because of possible resulting cyanide toxicity in the fetus,³ and diuretics should be avoided because of their volume-depleting effect. The definitive treatment for medication-resistant preeclampsia and eclampsia is delivery of the fetus.

ASYMPTOMATIC HYPERTENSION

A common problem facing the emergency physician is the chronically hypertensive patient who presents to the ED for an unrelated reason and is found to have a significant but asymptomatic elevation of blood pressure. Not uncommonly, the patient has run out of medications, and usually has minimal or no complaints.^{1,13,18} The physical examination may reveal signs of chronic hypertension but no evidence of acute end-organ damage in the cardiovascular, neurologic, and renal systems. On funduscopic examination, there may be evidence of retinopathy, but there are no acute changes of papilledema or flame hemorrhages.

If the blood pressure is significantly elevated (greater than 120 to 130 mm Hg diastolic), many clinicians prefer to initiate a treatment regimen for chronic blood pressure control in the ED and have the patient follow up in 2 to 3 days to continue management. The goal is often to begin the process of chronic blood pressure control, while avoiding a potentially dangerous precipitous drop. Oral medications are usually sufficient.

Controversy has arisen as to the need to treat asymptomatic hypertension acutely. There is no scientific basis for believing that immediately reducing an asymptomatic blood pressure elevation reduces complications. There is, on the other hand, a finite risk associated with rapid correction of asymptomatic hypertension. Several case reports document the occurrence of cerebral infarction, myocardial ischemia or infarction, or deterioration in renal function with rapid correction of the blood pressure in patients with asymptomatic hypertension.^{2,10,22} The frequent use of sublingual nifedipine in the early 1990s, and the subsequent criticism of this practice because of such case reports, highlights this problem.^{5,10,22} In addition, the current widespread use of sildenafil citrate (Viagra) has resulted in significant symptomatic hypotensive episodes and cases of hemodynamic collapse after antihypertensive therapy is instituted by practitioners who are unaware their patients are taking this drug.^{4,16} Finally, there is no proof that initiation of maintenance therapy in the ED leads to sustained reductions in blood pressure or better long-term outcomes.²

EMERGENCY DEPARTMENT MANAGEMENT

Because asymptomatic hypertension does not represent a threat to life or vital organ function, it does not require the aggressive therapy appropriate for hypertensive emergencies. Before receiving any medications, the patient with elevated blood pressure should be placed in a quiet room for 30 to 60 minutes. The pressure should then be rechecked to ensure that hypertension is still present, because many people have labile blood pressures ("white coat hypertension") that respond readily to such nonpharmacologic interventions.^{1,7} In addition, hypertensive patients tend to experience a spontaneous decline in their blood pressures because of "regression to the mean."^{1,13} Nonpathologic causes of elevated blood pressure include stress, anxiety, pain, and drug withdrawal. If the blood pressure remains elevated and it is judged that long-term therapy will be necessary (e.g., in a patient with a well-defined history of hypertension who has run out of medications), it is reasonable to begin oral treatment with an agent that is judged to be appropriate as part of the patient's long-term blood pressure regimen.

The emergency physician can choose from several oral antihypertensive agents in this situation. ([Table 142.2](#).) The choice of medication should be tailored to the patient's medical history. Generally, diuretics and beta blockers are considered the primary initial agents. Beta blockers have been shown to reduce morbidity and mortality in patients with coronary artery disease. They may also help in patients with migraines. They should be avoided in patients with asthma or COPD, depression, and, possibly, insulin-requiring diabetes mellitus because of the risk of blunting the hypoglycemic catecholamine response. Diuretics such as thiazides are useful in that they offer blood pressure reduction with little change in heart rate. They should be used in CHF. Blacks tend to be more responsive to diuretics and angiotensin converting enzyme (ACE) inhibitors than beta blockers or calcium channel blockers. ACE inhibitors have beneficial effects in patients with CHF and mild-to-moderate renal insufficiency. They are contraindicated in the rare patient with bilateral renal artery stenosis. Certain patients cannot tolerate the side effect of cough, and ACE inhibitor-associated angioedema is well documented. Calcium channel blockers are effective in patients with atrial fibrillation to help control ventricular response, and they also have antianginal properties. They should be used with caution in patients already on AV nodal blocking agents such as beta blockers. The centrally acting alpha antagonist clonidine should not be a first-line agent in the ED for asymptomatic hypertension. It is a potent antihypertensive than can cause significant hypertension in withdrawal states in poorly compliant patients. It is indicated in clonidine withdrawal syndromes.

Drug Class	Appropriate Patient Groups	Contraindications
Dihydropyridines, long-acting	CHF Dialysis Stroke	Contraindicated in severe aortic stenosis
Calcium channel blockers	Coronary artery disease Aortic stenosis	Heart block Contraindicated in beta-blockers
Beta blockers	Coronary artery disease Aortic stenosis Nigral insufficiency	CHF COPD/asthma Severe depression STEMI Heart block
Alpha and beta blockers	Same as for beta blockers	Same as for beta blockers
ACE inhibitors	CHF Coronary artery disease Aortic stenosis Stroke	Bilateral renal artery stenosis Hypokalemia
Central alpha blockers (clonidine)	Clonidine withdrawal Drug-resistant patients with DRD	Non-compliant patients Not a first-line agent

TABLE 142.2. Antihypertensive Agents for Asymptomatic Patients

Patients with asymptomatic hypertension do not require any acute therapy in the ED. In patients who have documented elevated blood pressures on more than one visit, the ED physician may choose to begin an antihypertensive regimen and refer them to their primary physicians. Effective long-term treatment of hypertension requires intensive patient education, the prescription of an appropriate medical regimen, compliance with that regimen, and reliable follow-up. Acutely lowering the blood pressure of chronically hypertensive patients does little to change their morbidity and mortality and, in fact, may cause cardiovascular morbidity. A more gradual lowering of the blood pressure allows the resetting of the cerebral autoregulation curve.⁹

DISPOSITION

All hypertensive emergencies require admission to an intensive care setting or a monitored bed. Close blood pressure monitoring, preferably with an arterial line, is indicated. Patients with hypertensive encephalopathy or a CVA may require neurologic consultation if the diagnosis is in question. Aortic dissection requires immediate cardiothoracic surgical evaluation while blood pressure is acutely controlled. Eclamptic patients require emergent obstetric consultation.

Patients with asymptomatic hypertension do not require hospital admission. Blood pressure control can be initiated, and close medical follow-up is required.

COMMON PITFALLS

- Diagnosing a hypertensive emergency when one does not exist. Many patients who present to the ED have blood pressure elevations related to stress, anxiety, drug withdrawal, or pain, or have chronic asymptomatic hypertension. Patients with hypertensive emergencies have evidence of acute end-organ dysfunction.
- When treating a hypertensive emergency, reducing the blood pressure too quickly or to too low a level. In patients with chronic hypertension whose autoregulation curve has been reset, this can lead to cerebral or cardiac ischemia.
- In patients with CHF and hypertension, failing to treat fluid overload first.
- Failing to diagnose hypertension in pregnant patients with blood pressures above 140/90 mm Hg, or with an increase in blood pressure of more than 30/15 mm Hg. These patients should be referred urgently for obstetric care.
- Attempting to decrease the blood pressure to a certain absolute number in every patient, or attempting to normalize the blood pressure completely in the ED. This often leads to many episodes of hypotension and the sequelae of hypoperfusion.

Common Pitfalls

Chapter References

Adult respiratory distress syndrome (ARDS; noncardiogenic pulmonary edema) results from the nonspecific response of the lung to various noxious insults. The clinical presentation depends on the underlying cause. The most common antecedent is sepsis, but ARDS must be considered in any patient with acute respiratory failure who has sustained any of a number of local or systemic insults associated with development of the condition ([Table 143.1](#)).

TABLE 143.1. Agents and Conditions Predisposing to the Development of ARDS

ARDS is a form of pulmonary edema, but, unlike cardiogenic pulmonary edema, is not caused primarily by increased pulmonary capillary hydrostatic pressure. Rather, ARDS results from a disequilibrium among all the factors that affect total lung water, including pulmonary arterial tone, osmotic pressure, alveolar epithelial permeability, surfactant integrity, and the efficiency and rate of lymphatic drainage.⁹ This disequilibrium is due to the influence of toxic agents from exogenous sources (such as inhaled gases), bacterial toxins, endogenous mediators, or any of these combined. These agents or mediators are responsible for increased pulmonary microvascular permeability, major disruption in alveolar epithelial integrity, and interstitial edema. Air spaces become filled with edema fluid, causing loss of surfactant and microatelectasis. Airway closure, decreased alveolar ventilation, shunting of blood flow, and hypoxia follow.

Studies indicate that the mortality rate for ARDS ranges from 40% to 60%.¹⁰ Only 15% of patients die of respiratory failure; most die of multisystem organ failure.¹³

CLINICAL PRESENTATION

The ARDS patient may already be acutely ill, with respiratory failure a prominent component of the clinical condition, or may be a previously healthy person with rapidly progressive respiratory failure. Clinical criteria for the diagnosis of ARDS include a ratio of the partial pressure of arterial oxygen (PaO_2) to the fraction of inspired oxygen (F_iO_2) of less than 200, regardless of the amount of positive end-expiratory pressure (PEEP) used; new diffuse bilateral infiltrates (all lung fields involved) on chest x-ray; a pulmonary arterial wedge pressure below 18 mm Hg; and the absence of other entities that might be responsible for these findings (i.e., no evidence of congestive heart failure, pleural effusion, atelectasis, or bacterial pneumonia).² A decrease in static lung compliance is also noted.

Initially, patients complain of shortness of breath and exhibit mild tachypnea. Scattered rales may be heard, and arterial blood gas values reflect an increased alveolar–arterial oxygen gradient. As the course progresses, the patient becomes more tachypneic, dyspneic, and cyanotic, and diffuse rales are noted on auscultation. Serial arterial blood gas values usually reveal progressive hypoxemia refractory to increasing levels of inspired oxygen.

[Table 143.1](#) lists conditions that predispose to or have been associated with the development of ARDS. Clinical symptoms usually become evident with 2 to 24 hours of the inciting event.

Sepsis

Sepsis and the systemic inflammatory response syndrome SIRS, especially with gram-negative organisms, is the most common—and the most commonly fatal—cause of ARDS. Although there is a 20% incidence of clinically evident lung injury after sepsis, it is unknown why sepsis results in ARDS in some patients and not in others, or why some patients with ARDS recover and others do not. ARDS is thought to result from toxic effects of neutrophil-based inflammatory mediators in the lung. Sustained hypotension and thrombocytopenia place a septic patient at greater risk for lung injury. Most often, in the septic patient with ARDS, death does not result from respiratory failure but from the underlying illness.

Trauma

The association of trauma and pulmonary dysfunction has long been recognized, although the exact mechanisms involved are not well understood. ARDS has been noted in 5% to 10% of patients with multiple fractures and in 5% to 34% of patients receiving multiple transfusions.¹² Hemorrhagic shock alone probably does not result in ARDS, and massive blood transfusions, especially when given through micropore filters, do not necessarily result in pulmonary dysfunction.⁵ Still, a clear relation between the injury severity score and the likelihood of developing ARDS has been consistently noted.⁴ Respiratory dysfunction after trauma is probably the consequence of a variety of insults, including direct pulmonary trauma, embolism, and associated soft-tissue injury.³

Aspiration

Aspiration of liquids can disrupt surfactant (freshwater and petroleum distillates), produce an osmotic gradient favoring fluid movement into the lungs (saltwater), or cause an inflammatory response in the alveoli (water, saline solution, gastric contents). The inflammatory response to acidic gastric contents is particularly rapid and severe. Patients who are unconscious or chronically debilitated or who have neurologic lesions are those most likely to aspirate gastric contents.

The diagnosis of aspiration rests on the clinical history of drowning or ingestion, or on the sudden onset of choking, coughing, or shortness of breath while eating or during emesis. An overt history of the aspiration event may not be obtained. Clinically, the patient may appear well or may be coughing, choking, or wheezing.

Respiratory dysfunction usually becomes symptomatic within the first hour, but may take up to 24 hours to develop. The degree of hypoxemia is quite variable initially and should be assessed by arterial blood gas analysis. Respiratory function may improve spontaneously or may rapidly deteriorate as inflammation and pulmonary edema develop.

Inhalation Injury

Inhalation injuries can produce pulmonary dysfunction by thermal damage and by direct chemical irritation or destruction of lung tissue. Steam can reach the parenchyma of the lung and cause direct thermal injury. Some gases (e.g., nitrogen dioxide, ammonia, chloramine, sulfur dioxide, hydrochloric acid fumes) liberated from the combustion of building materials and fabrics are direct pulmonary irritants. Pulmonary edema may occur immediately or days later.

Phosgene has been used by the military and by industry. Exposure results in irritation of the mucous membranes, chest pain, nausea, and vomiting, but these initial symptoms do not correlate with the potentially fatal pulmonary edema that may develop hours to days later.³ Ammonia, nitrous oxides, and chlorine are also used in manufacturing and can cause severe pulmonary edema.

Drugs

Various drugs cause pneumonitis and pulmonary hypersensitivity reactions that result in ARDS. These include methotrexate, cytarabine, mitomycin, protamine, hydrochlorothiazide, nitrofurantoin, lidocaine, haloperidol, chlordiazepoxide, terbutaline, and amphotericin B.^{6,8} Opiates, aspirin, colchicine, iron, and ethchlorvynol cause pulmonary injury only after overdose.⁶ Symptoms occur within minutes to hours and can result from any route of exposure.⁶ The prognosis in drug-induced pulmonary edema is better than for many other causes of ARDS, presumably because the presence of the offending agent is temporary.

Neurogenic Causes

Neurogenic pulmonary edema has long been recognized as a cause of death in the head-injured patient. With all head injuries, there is an increase in extravascular lung water. Pulmonary edema has been noted to result from head trauma, intracranial infection, acute hydrocephalus, subarachnoid hemorrhage, brain tumor, cerebrovascular accident, and seizures, and has also been noted after hanging.⁶ Neurogenic pulmonary edema may be mediated by way of alpha-adrenergic pathways, and can develop acutely within minutes to hours after a central nervous system insult, or in a delayed manner over 12 hours to several days.⁶

High-Altitude Pulmonary Edema

Rapid ascent without acclimatization results in the development of high-altitude pulmonary edema (HAPE) in about 5% to 10% of persons. It is currently believed that exaggerated pulmonary vasoconstriction, coupled with pulmonary capillary membrane leaks, is responsible for the development of HAPE.¹ Symptoms occur 1 to 4 days after ascent to altitudes above 8,000 ft. The onset is often insidious and commonly occurs at night. The patient complains of dyspnea, a dry cough, weakness, fatigue, headache, nausea, and vomiting. As pulmonary edema progresses, the patient may produce frothy or blood-tinged sputum. Symptoms are worsened by exercise, which increases pulmonary vascular resistance.

Supplemental oxygen is the most rapid treatment for HAPE, but descent is the definitive treatment; nifedipine has been used if descent is delayed.¹ The prognosis is good if the patient is brought down from altitude, and pulmonary dysfunction may resolve without requiring aggressive intervention.

DIFFERENTIAL DIAGNOSIS

Because the signs and symptoms of respiratory distress may initially be quite subtle, the clinician must have a high index of suspicion to identify respiratory compromise before it develops into frank pulmonary edema. A detailed history may prompt the physician to consider the possibility of ARDS, as well as the more common entities in the differential diagnosis of respiratory failure, such as pneumonia and cardiogenic pulmonary edema.

The diagnosis is relatively easy when a clear history of an insult to the lung, such as near-drowning or exposure to high altitude, is known. Other patients may present a greater problem. In the septic patient, one must determine whether tachycardia and tachypnea are due to hypoxia secondary to bacterial pneumonia, or secondary to early ARDS. Patients with ARDS do not normally have purulent sputum or a localized infiltrate on chest radiography. Diagnosis is also difficult in the hypoxic patient with diffuse pulmonary infiltrates, when cardiogenic pulmonary edema must be differentiated from ARDS. The ARDS patient usually does not have a history of cardiac disease, orthopnea, paroxysmal nocturnal dyspnea, nocturia, or chest pain, nor will signs of heart failure such as pedal edema, jugular venous distention, hepatojugular reflex, or S₃ gallop be present on examination.

In the trauma patient, pulmonary contusion is usually symptomatic within minutes of injury. It is often apparent on the initial chest radiograph and is commonly confined to one area of the lung fields. It should begin to clear by 48 hours. ARDS, in contrast, develops 24 to 72 hours after trauma and involves the lungs diffusely.

The chest radiograph is an extremely valuable tool for differentiating ARDS from other entities. Full progression to diffuse, bilateral alveolar infiltrates can take place within 4 to 24 hours after the first abnormal radiographic signs appear.¹⁰ In contrast to the patient with pulmonary contusion, aspiration, or bacterial pneumonia, the ARDS patient has more diffuse infiltrates on chest radiograph. Radiographic evidence of enlargement of the right-sided heart chambers and pulmonary artery often appears early in ARDS, and is presumably related to the increased pulmonary vascular resistance that is a common feature of the syndrome. The heart may be of normal size, however. Enlargement of only the left-sided heart chambers, as is often seen in cardiogenic pulmonary edema, is not noted in ARDS. Hilar blurring, an early sign of cardiogenic pulmonary edema, occurs only late in ARDS. A peripheral distribution of edema is specific for ARDS and is more common early in its course. Other signs of interstitial fluid accumulation, such as peribronchial and perivascular cuffing and septal lines, which are common in cardiac failure, are uncommon in patients with ARDS, as is pleural effusion. Rarely, differentiating cardiogenic pulmonary edema from ARDS requires pulmonary artery catheterization.

The radiographic appearance of ARDS has been correlated with its clinical severity: Peripheral or extensive white density of the lung field on chest radiograph indicates severe lung involvement.

Computed tomography (CT) in ARDS often reveals more patchy areas of infiltrate interspersed with normal lung. The degree of lung involvement on CT correlates with gas exchange efficiency and compliance of the lung. It can reveal barotrauma and localized emphyemas or abscesses not evident on plain films.¹⁰

EMERGENCY DEPARTMENT EVALUATION

Emergency department evaluation has two goals. The first is to establish the presence of respiratory distress and determine its magnitude. If possible, the patient must be questioned about the severity of respiratory distress, the nature of its onset, the duration of symptoms, the presence of sputum, and any medical history. On physical examination, attention is directed to the vital signs and cardiopulmonary system. The chest radiograph and arterial blood gas analysis add important information.

The second priority is to establish a specific cause. The clinician must be aware of the wide range of predisposing conditions and events. Although investigation directed toward establishing a specific cause for ARDS may be initiated in the emergency department, it is usually accomplished after the patient has been admitted.

Pertinent laboratory tests include a complete blood count with white cell differential and a coagulation profile. Serum chemistries and a blood lactate level may be helpful as well. A urinalysis, chest radiograph, and electrocardiogram are obtained. Blood gases may guide treatment. Measurement of cytokines in a bronchoalveolar lavage specimen predicts ARDS with good specificity,⁷ but it is impractical in the emergency department.

EMERGENCY DEPARTMENT MANAGEMENT

Close observation of the patient's respiratory status is the essential component. Because the hallmark of this syndrome is hypoxemia that is increasingly refractory to increased concentrations of inspired oxygen, supplemental oxygen is mandatory. However, the progressive derangement of respiratory function limits the value of increasing percentages of inspired oxygen (F_iO₂). As extravascular lung water accumulates, lung compliance decreases and the work of breathing increases. With

progressive atelectasis, pulmonary arterial blood is shunted through nonventilated alveoli. Because of the danger of oxygen toxicity and of absorption atelectasis, the F_{iO_2} should be limited to 0.5 if possible. Intubation and mechanical ventilation are indicated when signs of clinical respiratory fatigue supervene. Other indicators are a ratio of PaO_2 to an F_{iO_2} of less than 200, or a $PaCO_2$ above 50 mm Hg and a pH below 7.3. An arterial line may be placed to facilitate monitoring of arterial oxygen tension.

The use of PEEP may initially decrease the oxygen requirement in ARDS, but it has not improved the mortality rate, even if used prophylactically.¹⁰ Although PEEP increases functional residual capacity, allowing alveoli to remain open and to participate in gas exchange, it may also depress cardiac output, overdistend alveoli, and cause pulmonary barotrauma. The optimum level of PEEP is usually between 0 and 15 cm H_2O , but, in each patient, it may need to be defined by hemodynamic indices obtained during intensive care monitoring.¹³ Adding PEEP in small increments (2 to 3 cm H_2O) allows careful titration. The use of PEEP in neurogenic pulmonary edema is limited by its deleterious effect on intracranial pressure.⁶

Other oxygenation strategies currently being used or studied include pressure control ventilation,¹¹ inverse-ratio ventilation, high-frequency jet ventilation, permissive hypercapnia (allowing gradual increases in $PaCO_2$ in order to improve oxygenation),¹⁰ extracorporeal membrane oxygenation,⁴ and lateral decubitus or prone positioning of ARDS patients.¹⁰

Steroids are not recommended in the treatment of ARDS. Several clinical trials have demonstrated that steroids are of no benefit in reversing respiratory failure or improving survival in ARDS; in fact, steroid-treated groups had a greater incidence of subsequent infections.^{3,10} Other agents, such as nonsteroidal antiinflammatory drugs and antiendotoxin antibodies, have not been shown to be of benefit.^{10,13} Ibuprofen is of some overall benefit in the sepsis syndrome but does not improve oxygenation.^{9,10,13} Surfactant replacement therapy is not currently recommended.¹⁰ The use of vasodilators or vasoconstrictors should be limited to patients with hemodynamic instability.¹⁰ Pentoxifylline, ketoconazole, inhaled nitric oxide, and cytokine inhibitors are being studied and may show promise.^{9,10,13}

DISPOSITION

The diagnosis of ARDS should be entertained, if only briefly, in all patients with a condition known to be associated with ARDS. Asymptomatic patients (e.g., those with a narcotic overdose, HAPE, mild near-drowning, or possible aspiration) may be observed for 6 to 12 hours in the emergency department; if they are asymptomatic after this period, they may be discharged, with follow-up scheduled for the next day. Patients with other indications for admission (e.g., head trauma) must have their respiratory status followed closely while in the hospital.

All symptomatic patients must be admitted, because they are at greatest risk for rapid deterioration. Most require intensive care, and an intensivist should be involved early in their care.

If transfer to another facility is necessary to provide the required level of care, transport should be expeditious and the transferring personnel must be skilled in advanced life-support techniques, including airway management. Associated illnesses make the transfer of a patient with possible or proven ARDS even more hazardous.

COMMON PITFALLS

- Failing to associate certain conditions with the potential for the development of ARDS
- Failing to appreciate these risks in emergency department patients may lead to their premature or inappropriate discharge, or may lead the physician to disregard early signs of pulmonary dysfunction.
- Failing to recognize the degree of respiratory insufficiency in the frankly symptomatic patient exposes the patient to the risks of prolonged unsuspected hypoxemia and delays the institution of mechanical ventilation, if necessary.
- Failing to appreciate the potential for rapid progression
- Failing to pick up subtle early cases
- Failing to intubate early enough

In the United States, more than 3 million persons contract community-acquired pneumonia annually, resulting in about 500,000 hospital admissions. Pneumonia is the sixth leading cause of death in the United States, and the most common infectious cause. Most deaths occur in the elderly or immunosuppressed, but pneumonia occurs in otherwise healthy persons as well. To manage patients with pneumonia successfully, the emergency physician must be knowledgeable about a number of constantly changing factors, including an expanding spectrum of pathogens, changing antibiotic-resistance patterns, and the availability of newer antimicrobial agents. Although several noninfectious diseases may cause pneumonia, this discussion focuses on infectious etiologies, because they are by far the most common in emergency medicine practice.

Traditional pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Mycoplasma pneumoniae*, and viruses continue to be important causes of community-acquired pneumonia. Less common etiologies include *Staphylococcus aureus*, gram-negative bacilli, and oral anaerobes. Organisms such as *Legionella* species and *Chlamydia pneumoniae* are being increasingly recognized as pathogens in a significant number of cases of community-acquired pneumonia. *Pneumocystis carinii* and *Mycobacterium tuberculosis* are important as pathogens related to pulmonary infections in acquired immunodeficiency disease (AIDS) patients. Knowledge of local prevalence patterns for pathogens of community-acquired pneumonia is important to make appropriate choices regarding evaluation and treatment.

CLINICAL PRESENTATION

“Typical” and “Atypical” Pneumonias

Pneumonia is often divided into “typical” (pyogenic bacterial) and “atypical” categories, but this division is somewhat artificial. Prediction of these etiologies based on clinical and radiographic findings is inaccurate.⁷ The classic presentation of typical pyogenic bacterial pneumonia is the abrupt onset of fever and chills, followed by development of cough that is productive of purulent sputum and pleuritic chest pain. Elderly or debilitated patients may present with nonspecific complaints, such as altered mental status. Tachypnea and tachycardia are usually present. Examination of the chest may reveal signs of consolidation, such as dullness to percussion, coarse rales, bronchial breath sounds, or increased tactile fremitus.

The atypical pneumonia syndrome is caused by organisms such as *M. pneumoniae*, *C. pneumoniae*, viruses, *Legionella*, or rickettsial organisms such as *Coxiella burnetii*. Patients with this type of pneumonia generally present with a subacute onset of systemic complaints, such as fever, headache, malaise, and myalgias, associated with cough that is often nonproductive. Although mucopurulent sputum generally indicates the presence of pyogenic bacterial pneumonia or bronchitis, it may also be present with mycoplasmal or viral pneumonia. Chest examination often reveals scattered rhonchi or rales. Signs of consolidation are less common.

The high degree of overlap between the clinical and radiographic features of typical pyogenic and atypical pneumonia makes it impossible to definitively identify a specific type of pneumonia without the results of microbiologic or serologic tests. Typical and atypical pathogens sometimes coexist in the same patient, and bacterial infections often follow viral respiratory infections. Although one may not be able to determine with certainty the specific etiology of pneumonia within the time frame of an emergency department evaluation, certain clinical factors may suggest a likely etiology and can help guide empiric therapy. The clinical characteristics of several types of pneumonia are noted next.

Common Etiologies

S. pneumoniae is the single most common etiologic agent in community-acquired pneumonia. About 40% of healthy adults carry this organism in the nasopharynx. Patients with a history of diabetes, cardiovascular disease, alcoholism, or malignancy, or with other immunosuppressing illness, are at increased risk of pneumococcal infection. The classic presentation of pneumococcal pneumonia is the abrupt onset of a single shaking chill, followed by fever, cough productive of rust-colored sputum, and pleuritic chest pain. Not all patients exhibit this pattern. Many have had a preceding upper respiratory illness, and the onset of pneumonia may be insidious, especially among the elderly or those with underlying lung disease. Patients with a history of asplenia, sickle cell disease, AIDS, multiple myeloma, or agammaglobulinemia are at increased risk of pneumococcal bacteremia and sepsis. Extrapulmonary complications such as meningitis, endocarditis, or arthritis occasionally develop.

H. influenzae is a common pathogen in adults with chronic obstructive pulmonary disease (COPD), alcoholism, malnutrition, malignancy, or diabetes. The organism is a pleomorphic gram-negative rod that can be encapsulated; among serotypes a through f, type b most commonly leads to serious illness with bacteremia. In several studies, *H. influenzae* has been found to be the second most frequently isolated organism in community-acquired pneumonia among adults. Nontypeable strains (once thought to be benign) are a frequent cause of lower respiratory tract infection in patients with chronic lung disease. Such patients typically present with an insidious worsening of baseline cough and sputum production, and bacteremia is rare. *Moraxella catarrhalis* is another gram-negative rod that can be found in patients with COPD, but it appears to be associated with exacerbations of chronic bronchitis much more frequently than it is associated with pneumonia.

Intravenous (i.v.) drug users may develop hematogenous spread of *S. aureus* that involves both lungs and presents as multiple small infiltrates. This type of pneumonia is often associated with tricuspid valve staphylococcal endocarditis. *S. aureus* may also cause a primary bacterial pneumonia that may be clinically indistinguishable from other bacterial pneumonias. Staphylococcal pneumonias are often necrotizing, with cavitation and pneumatocele formation. An increased incidence of staphylococcal pneumonia has been noted during epidemics of influenza.

Klebsiella pneumoniae rarely causes disease in the normal host and accounts for a very small percentage of community-acquired pneumonias, but it may cause severe pneumonia in debilitated patients with alcoholism, diabetes, or other chronic illness. Sputum is often described as resembling currant jelly because of the necrotizing, hemorrhagic nature of the infection. Abscess formation, empyema, and bacteremia are common, and mortality is high. A chest radiograph characteristically demonstrates a dense lobar infiltrate with a bulging appearance of the fissure, but this finding is nonspecific and most cases present as a more subtle bronchopneumonia. Because the organism is often hospital-acquired, there is a high incidence of antibiotic resistance. *Pseudomonas aeruginosa* is also uncommon as an etiology of community-acquired pneumonia, but it may be present in patients with underlying lung disease, such as bronchiectasis or cystic fibrosis, or in patients who have recently been in a hospital or nursing home.

Seroprevalence studies demonstrate that virtually everyone is infected with *C. pneumoniae* at some time, and that reinfection is common. Most infections in young adults cause a minor, self-limited upper respiratory illness that is subacute in onset. This organism has also been associated with bronchitis, wheezing, sinusitis, pharyngitis, and atherosclerosis. Development of radiographically evident pneumonia is more common in the elderly, in contrast to the common perception that atypical pneumonias occur in the young.⁹ *C. pneumoniae* is a relatively common etiology of community-acquired pneumonia, accounting for at least 8% of cases; however, this is probably an underestimate, due to the difficulty in diagnosing infection with this organism.

M. pneumoniae is regarded as one of the most common causes of community-acquired pneumonia in previously healthy patients less than 40 years of age. Although

most studies have found it to be uncommon among hospitalized pneumonia patients, one study found it to be a common etiology among hospitalized older adults.¹¹ Infection usually begins as a flulike illness with headache, malaise, and fever. Cough is usually nonproductive, but may sometimes produce clear or even purulent sputum. Skin lesions, including maculopapular, vesicular, urticarial, or erythema multiforme-type rashes, are not uncommon, especially in younger patients. Many patients complain of sore throat or ear pain, but the classic finding of bullous myringitis is less common and is also nonspecific. Common physical findings include pharyngeal erythema, cervical adenopathy, and scattered rales and rhonchi. Rare extrapulmonary manifestations include pericarditis, glomerulonephritis, aseptic meningitis, and Guillain-Barré syndrome. Patients generally do not appear toxic, and the vast majority can be treated as outpatients.

At least 30 species of *Legionella* have been isolated since the 1976 outbreak in Philadelphia from which the organism derives its name. Up to 20% of community-acquired pneumonia cases may be due to this organism.² *Legionella* is an intracellular organism that lives in aquatic environments. There is no person-to-person transmission. Although it has often been implicated in point-source outbreaks related to cooling towers and similar aquatic sources, the organism also lives in ordinary tap water and has probably been underdiagnosed as an etiology of community-acquired pneumonia. It may account for as much as 19% of community-acquired pneumonia. Some patients present with a mild, self-limited atypical pneumonia, but older patients, smokers, and those with chronic disease or immunosuppression are at risk for developing the more acute manifestations of a severe systemic illness, with malaise, lethargy, and high fever. There is usually a dry cough, which is accompanied by pleuritic chest pain in 25% to 30% of patients. Purulent sputum often develops later. Gastrointestinal symptoms such as diarrhea and abdominal cramping are often prominent. Patients may appear toxic, with high fever and altered mental status.

Viral pneumonia is common in infants and young children, and has been recognized as an important cause of pneumonia in adults as well. Respiratory syncytial virus (RSV) and parainfluenza viruses are the most common seasonal causes of pneumonia in small children. Influenza viruses are the most common cause of viral pneumonia in adults. Winter influenza outbreaks, usually due to influenza type A, cause an average of 20,000 deaths yearly in the United States, mostly among persons age 65 or older.⁴ Symptoms of upper respiratory infection, such as rhinitis or sore throat, usually precede the onset of viral pneumonia in adults. The onset of pneumonia may be insidious. Cough is usually nonproductive, and pleuritic chest pain is less common than with bacterial pneumonia. Cytomegalovirus (CMV) can cause pneumonia in persons with severe immunosuppression (e.g., transplant recipients). Varicella zoster virus (chickenpox) may cause pneumonia; this appears to be more common in adults, and factors such as smoking or pregnancy are predisposing conditions.

Although *P. carinii* does not cause pulmonary disease in normal hosts, the possibility of opportunistic infection and unrecognized AIDS must always be considered. *P. carinii* pneumonia (PCP) is the most common presentation leading to a diagnosis of AIDS, and many patients who present with this pneumonia are unaware of their human immunodeficiency virus (HIV) status. All patients who present with pulmonary complaints should be questioned about HIV risk factors, and clinicians should search for signs of HIV-related immunosuppression, such as weight loss, lymphadenopathy, and oral thrush. PCP typically presents subacutely with fatigue, exertional dyspnea, nonproductive cough, pleuritic chest pain, and fever.

Lower respiratory infection due to anaerobic organisms generally results from the aspiration of oropharyngeal contents. These infections are typically polymicrobial, including *Peptostreptococcus* spp., *Bacteroides* spp., *Fusobacterium* spp., *Prevotella* spp., and several other organisms. Presentation is often subacute or chronic, and may be difficult to distinguish clinically from other etiologies of pneumonia. Clinical factors that suggest an anaerobic infection include risk factors for aspiration (e.g., central nervous system depression or swallowing dysfunction), severe periodontal disease, fetid sputum, and radiographic appearance (e.g., location in posterior segment of right upper lobe or superior segment of lower lobe, lung abscess).

Fungal infections due to organisms such as *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis* commonly present as pulmonary disease. These organisms are present in the soil in various geographic areas of the United States: *H. capsulatum* in the Mississippi and Ohio river valleys, *B. dermatitidis* in a poorly defined area extending beyond that of *H. capsulatum*, and *C. immitis* in desert areas of the Southwest. These infections should be considered in persons in appropriate geographic areas, especially in persons who are near activities that disturb the soil (e.g., construction, dirtbike riding). The clinical presentation ranges from an acute or chronic pneumonia to an incidental finding of asymptomatic granulomas on chest radiography.

Unusual Causes of Pneumonia

Q fever is an acute febrile illness, caused by the rickettsial organism *C. burnetii*, that may present as pneumonia. It is most common in persons with occupational exposure to animals. Fever is present in all patients, and a severe headache occurs in about 75% of cases. This infection is rarely fatal.

Plague (caused by *Yersinia pestis*) is endemic in many parts of the world. It occurs in the southwestern states of the United States in persons bitten by fleas from infected rodents or carnivores. Hematogenous spread may lead to pneumonia that is highly contagious and has a high mortality. It typically presents with cough, chest pain, purulent sputum, and hemoptysis, and is associated with fever and adenopathy.

Hantaviruses have recently been associated with a syndrome of severe respiratory distress and shock that has occurred in persons in several areas of the United States. Infection appears to occur from inhalation of aerosols of material contaminated with rodent urine and feces. Patients typically present with a prodrome of fever, myalgia, and malaise, followed in several days by the onset of respiratory distress. Hypoxia may progress rapidly, requiring ventilatory support. Chest radiographs demonstrate bilateral interstitial lung infiltrates that are more pronounced in dependent areas.

Tularemia is a febrile illness, caused by the bacterium *Francisella tularensis*, that is spread by contact with body fluids of infected mammals (especially rabbits) or the bite of an infected arthropod. The illness usually begins with an ulcerated skin lesion and painful regional lymphadenopathy. Some patients have a typhoidal form, with only fever, malaise, and weight loss. Pneumonia may occur with either form, presenting as a nonproductive cough and patchy infiltrates on the chest radiograph.

Psittacosis is a chlamydial infection that can be spread to humans from infected birds. It may occur in owners of pet birds, petshop employees, or others exposed to birds, or workers in poultry-processing plants. Illness often begins rapidly with chills, high fever, myalgias, and malaise; severe headache is often the major complaint. Cough is usually nonproductive. Splenomegaly is often present. Radiographic findings are variable, but patchy perihilar or lower lung field infiltrates are most common.

DIFFERENTIAL DIAGNOSIS

Several noninfectious etiologies may result in inflammatory lung processes. These include exposure to mineral dusts (e.g., silicosis), chemical fumes (e.g., chlorine, ammonia), toxic drugs (e.g., bleomycin), radiation, thermal injury, or oxygen toxicity. Immunologic diseases such as sarcoidosis, Goodpasture syndrome, Wegener's granulomatosis, collagen vascular disease, or hypersensitivity to environmental agents (e.g., farmer's lung) may also result in pneumonia. Tumors may sometimes be confused with pneumonia radiographically, or may present initially as a postobstructive infection or adenopathy with peripheral infiltrates. Pulmonary embolism must be considered in patients who present with tachypnea, hypoxia, tachycardia, or chest pain in the appropriate clinical setting. Cardiac illness often presents with respiratory complaints such as dyspnea. Aspiration of a foreign body must also be considered as an etiology of pulmonary infiltrates, especially in younger children.

In many studies of community-acquired pneumonia, no microbial etiology can be determined in one-third to one-half of cases, even after thorough investigation. To a great extent, the likely etiologies must be predicted based on epidemiologic considerations and prevalence of pathogens in careful research studies. In general, the likelihood of *S. pneumoniae* is related to the severity of illness, having been identified in as many as 50% of intensive care unit (ICU)-admitted and fatal cases. In studies of adults with community-acquired pneumonia who were hospitalized, traditional pathogens such as *S. pneumoniae* and *H. influenzae* accounted for about one-fourth of cases. *Legionella*, *M. pneumoniae*, and *C. pneumoniae* together accounted for 15% to 40%.^{7,11} Another large study, in which serologic testing was done for common viral agents, revealed a viral etiology in about 17% of cases, with influenza and parainfluenza viruses the most common.¹⁰ Studies of patients with more severe illness who required ICU admission have shown the prevalence of *S. pneumoniae* to be as high as 38% and that of *Legionella* to be as high as 22%, although the "unknown" category still accounts for 30% to 50% of cases.^{15,17} Atypical organisms such as *Mycoplasma* appear to account for a relatively higher proportion of pneumonias in those who have milder illness amenable to outpatient therapy. Nevertheless, it is important to be aware of how frequently atypical organisms are identified in patients with severe illness requiring hospitalization.

EMERGENCY DEPARTMENT EVALUATION

The emergency department evaluation should focus on establishing the diagnosis of pneumonia, determining the presence of clinical features associated with specific infectious etiologies, and identifying host factors that will influence decisions regarding the need for hospitalization and choice of antibiotics.

Chest Radiograph

The chest radiograph is generally the most important test to determine the presence of pneumonia. A number of predictive models have been developed to optimize chest x-ray use in patients with cough in whom pneumonia is suspected. Factors found to be associated with a positive chest x-ray are fever, tachycardia, and tachypnea; rales or decreased breath sounds, sputum production, and absence of rhinorrhea or sore throat have also been predictive in some models. Although use of predictive models may reduce the number of unnecessary chest x-rays, they appear to be less sensitive than physician judgment.⁶ Because of its relatively low cost and risk, chest x-ray is appropriate when management will be affected by the result (e.g., hospital admission, antimicrobial use, exclusion of other diagnoses). Chest x-ray may be particularly useful in groups such as the elderly (who may have subtle clinical signs of pneumonia), patients with serious underlying disease or severe illness, or those at risk for tuberculosis (TB) (to quickly establish the need for isolation). Young healthy adults who will receive outpatient treatment with empirical antimicrobials may have the chest radiograph deferred unless there is suspicion of immunosuppression or other unusual features of disease. Routine chest radiography for patients with exacerbation of chronic bronchitis or COPD has been shown to be of low yield and can be limited to those with other signs of infection or congestive heart failure.¹⁹

Although the causative agent cannot be determined solely by the results of chest radiography, certain radiographic patterns tend to be associated with specific pathogens. In pyogenic bacterial pneumonias, radiographs usually show an area of segmental or subsegmental infiltration and air bronchograms. Lobar consolidation is present in a minority of cases of bacterial pneumonia, and is often due to pneumococcus or *Klebsiella*. Bronchopneumonia resulting from spread of infection along the intralobular airway causes fluffy or patchy infiltrates in the involved areas of the lung. A wide variety of bacteria may cause this pattern, as well as agents such as *C. pneumoniae*, *M. pneumoniae*, *Legionella*, and even viruses. An interstitial pattern on the chest radiograph is typically caused by *M. pneumoniae*, viruses, or *P. carinii*. Tiny nodules disseminated throughout both lungs represent a miliary pattern typical of granulomatous pneumonias such as TB or fungal disease. The location of infiltrates may also give a clue to the etiology. Aspiration pneumonia occurs in dependent areas of the lung, most commonly the superior segments of the lower lobes or the posterior segments of the upper lobes.³ Pneumonia produced by hematogenous spread (such as staphylococcal) tends to be multifocal and peripheral. Apical infiltrates suggest TB.

Additional radiographic features associated with infiltrates may suggest specific etiologies. An infiltrate associated with hilar or mediastinal adenopathy suggests the presence of TB or fungal disease, or may indicate pneumonia associated with a neoplasm. Cavitation is most commonly present with infections caused by anaerobes, gram-negative organisms, fungi, or *S. aureus*; cavitation may also be present in fungal disease or TB. Pneumatoceles or spontaneous pneumothorax may be seen in AIDS patients with PCP. Pleural effusions can be seen with a wide variety of organisms, including many types of pyogenic bacterial pneumonia, *C. pneumoniae*, *Legionella*, and TB. Anaerobic infections associated with an effusion are especially prone to the development of empyema.

Radiographic findings are nonspecific for a particular infectious etiology. For example, *M. pneumoniae* pneumonia may present with a dense infiltrate, and pneumococcal pneumonia with diffuse interstitial infiltrates. Immunocompromised patients are particularly likely to have atypical radiographic appearances. Occasionally, patients with a clinical picture strongly suggestive of pneumonia have a normal chest radiograph. The absence of findings on the chest radiograph should not preclude the use of antimicrobial therapy in patients thought to have pneumonia on clinical grounds.¹³

Other Tests

Laboratory studies are also nonspecific for identifying the etiology of pneumonia. Although an elevated peripheral white blood cell (WBC) count may increase the likelihood of a pyogenic bacterial etiology, this finding is of limited value in making decisions regarding therapy in an individual patient and must be considered in light of other clinical features. A WBC count may be helpful if it yields evidence of immunosuppression, such as neutropenia, or if it reveals lymphopenia that may indicate immunosuppression from HIV infection.³ Serum chemistry studies may be helpful in identifying patients with metabolic acidosis or renal–hepatic dysfunction associated with sepsis or with underlying disease. Such findings may be helpful in predicting a complicated course and may influence decisions regarding disposition, choice of antimicrobial agents, and dosages. These ancillary tests are not necessary in patients with mild illness.

Assessment of respiratory function with arterial blood gas measurements or pulse oximetry must also be part of the evaluation. Hypoxia is a clear indication for hospital admission.

Although a Gram stain of the sputum is often recommended as a means to identify a bacterial pathogen, the use of the Gram stain as a basis for empiric therapy in the emergency department can be problematic for several reasons. Many patients cannot provide an adequate sputum specimen. Induction of sputum without adequate isolation facilities can put patients and staff at risk if sputum is induced from persons with unrecognized TB. Moreover, the correlation between the identification of pneumococcus on Gram stain and by sputum culture is often poor, even when commonly used criteria for an adequate sputum specimen are applied (fewer than five squamous epithelial cells and more than 25 WBCs per high-power field).¹⁸ The Gram stain is even less likely to demonstrate gram-negative pathogens such as *H. influenzae*, and should not be relied on to rule out a gram-negative etiology. Sputum Gram stains are less accurate when done by less experienced physicians outside the microbiology laboratory and may lead to erroneous conclusions regarding which pathogens are present. Effective empiric antimicrobial therapy can be selected on the basis of clinical information, even if a sputum Gram stain is not done.

The utility of routine blood cultures has been questioned, because studies of nonimmunocompromised adults with pneumonia have demonstrated a low prevalence of noncontaminant bacteremia, and management is rarely changed based on the results.⁵ Blood cultures should be obtained from immunocompromised patients, those with severe sepsis or shock, or those with risk factors for endovascular infection (e.g., prosthetic valves or i.v. drug use). When positive, blood cultures reflect the etiologic agent more accurately than do sputum cultures. Bacteremia occurs in about 25% to 30% of cases of pneumococcal pneumonia. Routine blood cultures are not indicated for outpatients.

Serologic tests are available for the diagnosis of a number of organisms, including *C. pneumoniae*, *Legionella*, and fungi. Serologic tests to determine the etiology of pneumonia may be helpful retrospectively, but both acute and convalescent serum titers are usually required, and are therefore of little use to the emergency physician. *M. pneumoniae* pneumonia is associated with the presence of serum cold hemagglutinins in up to 60% of cases, but they may also be present in a number of viral infections. The diagnosis of the exact etiology of viral pneumonia is made difficult by the nonspecific nature of the presentation and the lack of widely available rapid tests. Rapid diagnostic tests for viral antigens are available for several viruses, including RSV and influenza. Improvements in therapy for specific viral pneumonias (such as newly developed neuraminidase inhibitors for influenza) are likely to make these tests more useful. In the future, rapid testing, using technology such as the polymerase chain reaction, may provide emergency physicians with a reliable method for determining the specific etiology of pneumonia.

EMERGENCY DEPARTMENT MANAGEMENT

As with any seriously ill patient in the emergency department, initial attention should focus on ensuring adequate ventilation, oxygenation, and perfusion. Hypoxic patients with pneumonia should receive supplemental oxygen. Those with severe respiratory compromise may require endotracheal intubation. Patients with underlying asthma or COPD who present with wheezing may benefit from bronchodilator therapy. Seriously ill patients who present with volume depletion or septic shock will require fluid resuscitation and may require vasopressors.

It is usually necessary to begin empiric antimicrobial therapy for pneumonia before a definite microbiologic etiology is established. Antimicrobials should be started in the emergency department for patients who are being admitted to the hospital; deferring treatment until arrival on the ward can sometimes cause significant delays. Mortality has been shown to be reduced among elderly pneumonia patients who receive initial antimicrobials within 8 hours of presentation, as compared with later.¹² The antibiotics chosen must provide coverage of the likely etiologies based on clinical, laboratory, radiologic, and epidemiologic information. Though care must be taken not to miss possibly dangerous pathogens, the regimen should be as selective as possible to avoid problems with drug toxicity, emergence of resistance to broad-spectrum agents, and excessive cost.

The prevalence of drug-resistant *S. pneumoniae* (DRSP) has increased steadily over the past decade. In the United States, among outpatient pneumococcal sputum isolates collected between 1997 and 1998, approximately 36% were resistant to penicillin, with 14% having high-level resistance.²⁰ Isolates that are resistant to penicillin are also very likely to be resistant to other b-lactams as well as macrolides, tetracyclines, and trimethoprim–sulfamethoxazole (TMP/SMX). A number of extended-spectrum fluoroquinolones have been introduced, such as levofloxacin, gatifloxacin, sparfloxacin, and trovafloxacin, and others such as moxifloxacin, clinafloxacin, and gatifloxacin, are expected. These agents have enhanced activity against DRSP as well as other typical and atypical organisms that commonly cause pneumonia, and may offer additional alternatives to vancomycin if DRSP is a concern. However, it is not clear that *in vitro* resistance is related to adverse clinical outcome; in one study, patients infected with resistant pneumococcal isolates had no greater mortality than those with susceptible organisms, even when treated with

antibiotics to which the organism was resistant.¹⁶

Guidelines have been issued for empirical antibiotics for patients with community-acquired pneumonia.^{1,14} For patients whose illness is severe enough to require hospital admission and parenteral antibiotics, options include a combination of a second- or third-generation cephalosporin and a macrolide (e.g., i.v. erythromycin or azithromycin, or oral azithromycin), or an extended-spectrum fluoroquinolone alone. These regimens will treat the most common bacterial pathogens, such as *S. pneumoniae*, *M. catarrhalis*, and *H. influenzae*, as well as atypical pathogens such as *Mycoplasma*, *Chlamydia*, and *Legionella*. Intravenous azithromycin alone is another option, though this drug does not achieve significant serum levels and lacks significant activity against many aerobic gram-negative bacilli and DRSP. Azithromycin alone might be an appropriate choice for persons with milder illness who are less likely to be bacteremic. If anaerobic organisms are suspected (e.g., aspiration), clindamycin or metronidazole could be added to the regimen, or a b-lactam–b-lactamase inhibitor antibiotic such as ampicillin–sulbactam or piperacillin–tazobactam could be used. Some of the newer quinolones, such as moxifloxacin, clinafloxacin, and gatifloxacin, are also active against anaerobes.

Severely ill and compromised patients (e.g., neutropenic, recent nursing home or hospital stay) are at relatively greater risk of infection due to *S. pneumoniae*, aerobic gram-negative bacilli, *S. aureus*, and, in some areas, *Legionella* spp. Empirical therapy should include extended gram-negative activity, including *P. aeruginosa* with drugs such as ceftazidime, piperacillin–tazobactam, ciprofloxacin, or an aminoglycoside. Vancomycin and erythromycin may be combined with these agents for DRSP and *Legionella* spp., respectively, or an extended-spectrum fluoroquinolone may be included.

For patients with AIDS, it is important to treat *P. carinii* as well as bacterial pathogens such as *S. pneumoniae*. TMP/SMX is the treatment of choice; the usual regimen is 20 mg/kg of TMP and 100 mg/kg of SMX in four divided doses (3 amps i.v. q6h for most adults), to be continued for 21 days. For patients allergic to sulfa, pentamidine can be given in a dose of 4 mg/kg over 1 hour. Because pentamidine has no activity against *S. pneumoniae* or other bacterial pathogens, it is important to add a cephalosporin or other antibacterial agent to the initial empiric regimen. Other options include clindamycin 900 mg i.v. q8h plus primaquine 15 mg PO qd, TMP plus dapsone, atovaquone, or trimetrexate. The addition of steroids (prednisone 40 mg PO b.i.d.) has been shown to reduce mortality and clinical deterioration in patients with PaO₂ less than 70 or A-a gradient greater than 35.

A number of antimicrobials are available for outpatient therapy of community-acquired pneumonia. Appropriate agents for outpatient treatment of adults include macrolides (erythromycin, clarithromycin, azithromycin), fluoroquinolones with enhanced activity against *S. pneumoniae*, or doxycycline. Alternative options that would be appropriate in those patients with a higher likelihood of a “typical” bacterial etiology include amoxicillin–clavulanate or a second-generation cephalosporin such as cefuroxime axetil, cefpodoxime, or cefprozil. These b-lactam agents do not have activity against atypical pathogens. In patients properly identified at low risk for complications and who are evaluated for careful outpatient follow-up, use of a macrolide or doxycycline is reasonable, even when there is concern over DRSP. Use of more expensive agents, such as the newer fluoroquinolones, may be justified based on convenience, avoidance of side effects and drug interactions, or concern over DRSP in patients with a higher likelihood of bacterial etiology. Use of ampicillin or amoxicillin is not generally recommended due to the high incidence of b-lactamase production in pneumonia pathogens, although these have been used successfully in higher doses (e.g., amoxicillin 1 g t.i.d.) in other conditions with a high prevalence of DRSP. TMP/SMX has also been largely abandoned for treatment of pneumonia because of concern about increasing resistance. Except for the administration of fluoroquinolones, these recommendations also apply to school-aged children and adolescents, in whom *Mycoplasma* is common.

The antiviral agents amantadine and rimantadine can decrease the duration and severity of influenza A if started within 48 hours of symptom onset.⁴ They are also useful as prophylaxis to control outbreaks within families or group settings such as nursing homes. Because they are not effective against other respiratory viruses, they should be used only if influenza A virus is confirmed with a rapid test or is highly likely based on the season and epidemiology. The usual adult dose for both amantadine and rimantadine is 100 mg PO b.i.d. Dosage should be reduced to 100 mg once daily for debilitated or elderly patients to reduce side effects such as confusion (less common with rimantadine). New antiviral agents are being developed that may improve the treatment of influenza. Neuraminidase inhibitors have been shown to be effective against both influenza A and B viruses and appear to have fewer side effects.

Many emergency departments initiate outpatient therapy in moderately ill patients, who previously might have been hospitalized, with an initial parenteral dose of a long-acting antibiotic such as ceftriaxone, and employ extended observation (i.e., 12 to 24 hours) while administering supportive care such as hydration, antipyretics, and bronchodilators before discharge on an oral regimen. Certain patients may also be brought back to the emergency department for follow-up in 24 hours and receive a second parenteral or observed oral dose of antibiotics. Extended-spectrum fluoroquinolones are another option that may be employed in this strategy, and they have additional activity against atypical pathogens and DRSP. Oral administration of these agents results in blood and tissue levels similar to those with i.v. therapy, provided that normal intestinal absorption exists.

Empiric therapy for pneumonia is summarized in [Table 144.1](#).

TABLE 144.1. Empiric Therapy for Pneumonia

DISPOSITION

The disposition of patients with pneumonia is dictated by the patient's underlying medical conditions, the severity of illness and likelihood of clinical deterioration, and the feasibility of home care and outpatient follow-up. Outpatient treatment is 15 to 20 times less expensive than inpatient treatment, and most patients prefer the home environment. The decision to hospitalize a patient with pneumonia is not necessarily a commitment to prolonged inpatient care. Twelve- to 24-hour emergency department or hospital ward observation may allow the early discharge of certain moderate-risk patients.

A prospectively validated prediction rule for mortality among immunocompetent adults with community-acquired pneumonia suggests a two-step approach to assess risk.⁸ Patients in the lowest risk class are those less than age 50, without significant comorbid conditions (neoplasm, congestive heart failure, cerebrovascular disease, renal disease, liver disease), and without the following findings on physical examination: altered mental status, pulse greater than or equal to 30 beats per minute, systolic blood pressure less than 90, and temperature less than 35°C or greater than or equal to 40°C. Patients who do not fit the lowest risk category are classified into categories based on a scoring system that accounts for age, comorbid illness, physical examination findings, and laboratory abnormalities. Hospitalization is recommended for those in moderate- to high-risk categories. Although this method of assessing the likelihood of successful outpatient management is helpful in establishing general guidelines, it has not been modeled to predict acute life-threatening events, does not take into account dynamic evaluation over time, and has not been prospectively compared with physician judgment. Additional discharge criteria could include improving and stable vital signs over a several-hour observation period, ability to take oral medications, an ambulatory pulse oximetry greater than 90%, home support, and ability to follow-up.

Most patients with community-acquired pneumonia do not need respiratory isolation. Those who are suspected of having an etiology of pneumonia that could pose a threat of transmission to other patients (e.g., influenza, varicella, TB, plague) should be isolated. Neutropenic patients are generally placed in reverse isolation. HIV-infected patients who present with pneumonia ideally should be isolated until TB can be ruled out by sputum AFB smears, particularly those with other risk factors for TB. The chest radiograph cannot be relied on to rule out TB in AIDS patients, because it often does not have the typical appearance of TB. Isolation should be strongly considered for others at high risk for TB, such as inner-city homeless persons or i.v. drug users.

COMMON PITFALLS

- Failure to recognize pneumonia in a patient with exacerbation of underlying lung disease, such as asthma or COPD
- Delaying initiation of antibiotics for seriously ill patients
- Failure to question patients who present with respiratory complaints about HIV risk factors
- Failure to consider other possible etiologies of lung infiltrates, such as aspiration of foreign body
- Failure to recognize TB and initiate respiratory isolation in a patient with HIV infection or other TB risk factors

vessels, impeding drainage of the pleural space.

There are three stages in the development of a parapneumonic effusion and empyema. First, there is an accumulation of sterile pleural fluid characterized by low lactate dehydrogenase (LDH), normal pH and glucose level, and low white blood cell (WBC) count. If this is not treated, or if therapy fails, bacteria invade the pleural space; bacteria, WBCs, debris, and large pleural effusions accumulate. Fibrin sheets line the pleural surfaces, with a tendency to form loculations. The pleural fluid LDH concentration, and WBC count rise, while the pH and glucose level fall. Finally, fibroblasts grow into the exudate to form an inelastic pleural coating, or peel, encasing the lung and causing pulmonary restriction.^{7,8}

Various authors have developed criteria for the definition of *empyema*. Light⁷ suggests that the term *complicated parapneumonic effusion* be used to designate those that do not resolve without tube thoracostomy. *Empyema* is reserved for describing those effusions that have the gross appearance of pus.^{7,8}

Young, otherwise healthy, patients with parapneumonic effusion or empyema most often have *Staphylococcus aureus*, *Streptococcus pneumoniae*, or *Streptococcus pyogenes* infection. Elderly and infirm individuals with aspiration pneumonia more often have anaerobic infection. Postoperative thoracotomy patients are more likely to be infected with *S. aureus*.³ In children, *S. pneumoniae* and *S. aureus* are the most common causes, with *Haemophilus influenzae* now the third most common.^{2,3,5} Other pathogens include enteric gram-negative organisms, *Klebsiella*, *Enterococcus*, *Pseudomonas*, *Legionella*, *Mycobacterium tuberculosis*, *Chlamydia*, *Mycoplasma*, viruses, rickettsiae, and fungi. Infection with *Pneumocystis*, *Nocardia*, and *Cryptococcus* may cause effusion in the immunocompromised patient.

Other infectious processes may also lead to pleural effusion. Virtually any abdominal infection or inflammatory process may lead to a sympathetic effusion. Such processes include pancreatitis, hepatitis, perihepatitis, cholecystitis, hepatic amebiasis, splenic abscess, pyelonephritis, glomerulonephritis, peritonitis, and abdominal abscess.

The most common types of malignant effusions are those due to lung, breast, lymphoma, ovarian, and stomach tumors.¹⁷ This type of effusion may be secondary to lymphatic obstruction, superior vena cava syndrome, postobstructive atelectasis, or pleural metastases.

A pulmonary embolus may produce either a transudative or an exudative effusion. The mechanism is probably infarction of a portion of lung and visceral pleura, with resultant loss of interstitial fluid across the membrane.

EMERGENCY DEPARTMENT EVALUATION

Effusions are most frequently diagnosed by chest radiography. Because freely flowing fluid follows gravity to the most dependent region of the thorax, small effusions manifest as blunting of the costophrenic angle on the upright posteroanterior (PA) film. Experimentally, at least 175 mL of fluid is required to produce this appearance.⁴ Larger effusions appear to assume a meniscus configuration (a purely radiographic phenomenon).⁷ The lateral upright radiograph will reveal a smaller effusion than the PA film, with an air–lung interface evident in the posterior costophrenic recess.

Effusion is more difficult to detect on supine anteroposterior (AP) films. The only evidence that fluid is present may be a diffuse homogeneous density of the affected hemithorax, compared with the contralateral side. Bilateral lateral decubitus films should be a routine part of the evaluation of every patient with newly diagnosed or suspected effusion. This aids in differentiation between effusion and pulmonary infiltrate, tumor, pleural thickening, or eventration or rupture of a hemidiaphragm. With the affected side down, fluid layers along the lateral wall of the thorax. More than 10 mm of fluid thickness in this view is considered significant.⁷ With the opposite side dependent, the fluid layers along the mediastinum, allowing clearer visualization of the underlying lung parenchyma and allowing one to exclude pulmonary infiltrate, atelectasis, or mass.

Once the presence of a pleural effusion is confirmed, further emergency department (ED) evaluation should be directed at answering the following questions:

1. Is the effusion new or previously diagnosed?
2. If new, is the effusion a transudate or an exudate?
3. Is the effusion causing respiratory compromise such that therapeutic thoracentesis is indicated?
4. Is chest tube thoracostomy indicated?

In general, a previously diagnosed effusion does not require a new diagnostic workup, unless there is evidence that a complication has arisen (e.g., a patient with a known effusion secondary to CHF who presents with sepsis and is suspected of having an infected effusion).

To narrow the differential diagnosis, a new effusion should be characterized as a transudate or an exudate. (The exception to this rule is effusion in the setting of CHF. In that scenario, the underlying CHF should be treated, and thoracentesis should be performed only if the effusion does not resolve with therapy.) Although several sets of criteria have been proposed for such differentiation, Light's criteria are the most reliable⁹ (Table 145.3). Fluid that meets any one of the three following criteria is an exudate:

Pleural fluid-serum protein ratio >0.5
Pleural fluid-serum LDH ratio >0.6
Pleural fluid LDH >two-thirds of upper limit of normal for serum LDH

Source: From Light R, MacGregor M, Luchsinger P, et al. Pleural effusions: the diagnostic separation of transudates and exudates. *Ann Intern Med* 1972;77(4):507-513.

TABLE 145.3. Light's Criteria

1. Pleural fluid–serum protein ratio greater than 0.5
2. Pleural fluid–serum LDH ratio greater than 0.6
3. Pleural fluid LDH greater than two-thirds of the upper limit of normal for serum LDH

If the effusion proves to be a transudate, therapy is directed at the underlying process. Exudates, however, require further fluid analysis, including glucose, pH, amylase, fluid hematocrit, cell count with differential, Gram stain, culture, and cytology (Table 145.4). (Pleural biopsy may be necessary for the diagnosis of malignancy or tuberculosis. Pleural biopsy should be considered at the time of initial thoracentesis, because it is best accomplished before complete evacuation of the pleural fluid.)

Chemical	Significance	Normal Range	Abnormal	pH	Comments
Adenosine deaminase	Normal or slightly elevated	0-10 U/L	>10 U/L	>7.2	Chronic disease, TB, HIV, sarcoidosis
Cholesterol	Normal	<200 mg/dL	>200 mg/dL	>7.2	Chronic disease, TB, HIV, sarcoidosis
Glucose	Normal	>60 mg/dL	<60 mg/dL	<7.0	Parapneumonic effusion, empyema, malignancy, rheumatoid disease, tuberculosis
Lactate	Normal	<2.0 mmol/L	>2.0 mmol/L	<7.0	Parapneumonic effusion, empyema, malignancy, rheumatoid disease, tuberculosis
LDH	Normal	<200 U/L	>200 U/L	<7.0	Parapneumonic effusion, empyema, malignancy, rheumatoid disease, tuberculosis
Protein	Normal	>3.0 g/dL	<3.0 g/dL	<7.0	Parapneumonic effusion, empyema, malignancy, rheumatoid disease, tuberculosis
pH	Normal	7.35-7.45	<7.35	<7.0	Parapneumonic effusion, empyema, malignancy, rheumatoid disease, tuberculosis
Triglycerides	Normal	<100 mg/dL	>100 mg/dL	<7.0	Parapneumonic effusion, empyema, malignancy, rheumatoid disease, tuberculosis
Urea nitrogen	Normal	8-20 mg/dL	>20 mg/dL	<7.0	Parapneumonic effusion, empyema, malignancy, rheumatoid disease, tuberculosis
White blood cells	Normal	<10,000/mm ³	>10,000/mm ³	<7.0	Parapneumonic effusion, empyema, malignancy, rheumatoid disease, tuberculosis

TABLE 145.4. Fluid Analysis of Exudates

A pleural fluid glucose level less than 60 mg/dL, although not a sensitive indicator of any particular etiology, suggests either a parapneumonic effusion–empyema or malignancy, rheumatoid disease, or tuberculosis.^{7,10} A pleural fluid pH less than 7.0, or a glucose less than 40 mg/dL, indicates a complicated parapneumonic effusion–empyema, and the need for chest tube thoracostomy.^{7,11} An elevation of the pleural fluid amylase narrows the differential diagnosis to pancreatitis, malignancy, and esophageal rupture.^{7,10} A pleural fluid hematocrit greater than half that of the patient's blood defines a hemothorax and indicates the need for a chest tube.⁷

Additional routine workup should include a complete blood count, urinalysis, and serum electrolyte, blood urea nitrogen, and creatinine levels. If diagnostic thoracentesis is anticipated, serum glucose, protein, LDH, and amylase levels should be ordered to allow calculation of the necessary indices. If there is a history of coagulopathy, a prothrombin time can help to assess the risk associated with the invasive procedure. Continuous pulse oximetry should be used to monitor oxygenation status, particularly during thoracentesis.

An electrocardiogram may reveal an associated pericarditis or manifestations of underlying heart disease, or may suggest pulmonary embolus. Extreme QRS deviation mimicking myocardial infarction has been reported with pleural effusion.¹⁴ Additional diagnostic tests (e.g., liver or thyroid function tests, tests for collagen vascular disease, ventilation–perfusion scan, or arteriography) may be ordered as indicated by findings on the history, physical examination, and initial laboratory evaluation.

Ultrasound can be used as a guide to thoracentesis in order to decrease the risk of complications. Computed tomography may also help to localize effusion and can identify pleural masses

EMERGENCY DEPARTMENT MANAGEMENT

As for all patients who present with acute signs or symptoms, the first priority is evaluation and stabilization of the airway, optimization of oxygenation and ventilation, and circulatory support. Treatment of life-threatening conditions such as pulmonary edema should be initiated.

Diagnostic evaluation of a pleural effusion, as described, is often undertaken on an inpatient basis. For some patients (e.g., those who are likely to have parapneumonic effusion–empyema, esophageal rupture, or sepsis), ED thoracentesis may be indicated for rapid diagnosis, drainage, and institution of specific treatment. Patients with chronic pulmonary disease and the elderly may have diminished cardiopulmonary reserve, and are likely to require urgent therapeutic thoracentesis. It is wise to obtain specialty consultation early in the course, to determine whether thoracentesis is best performed in the ED or after admission to the hospital.

A number of techniques for thoracentesis have been described. The size and location of the effusion should be determined by radiography and by physical examination. Examining for tactile fremitus and percussion of the chest determine the upper limit of the fluid level. The patient is usually placed in a seated position, leaning slightly forward. For small effusions, or if the patient cannot tolerate sitting, the lateral decubitus position may be used. A small or loculated effusion is best evacuated under fluoroscopy or ultrasound guidance. If a difficult thoracentesis is anticipated, early consultation with an invasive radiologist or pulmonologist may be the most appropriate course of action.

Clotting abnormalities and anticoagulant therapy represent relative contraindications to thoracentesis, although safe thoracentesis is reported with thrombocytopenia (platelet count as low as 50,000/ μ L), or prolonged prothrombin time and partial thromboplastin time (up to twice the midrange of control) in the absence of active bleeding.¹⁵ Likewise, chest wall infection is a contraindication unless the infected site can be avoided. Thoracentesis should also be avoided when there is diaphragmatic rupture on the side of effusion.

After sterile preparation of the aspiration site, local anesthesia is injected. A small-gauge needle, a catheter and needle, a commercial thoracentesis apparatus, or a pigtail catheter using the Seldinger technique may be used. The usual site for the insertion of the needle is in the midscapular line posteriorly, in the highest appropriate intercostal space. The needle is directed over the inferior rib to avoid the intercostal vessels. The catheter is advanced into the chest, and the fluid is removed under sterile conditions. In most cases, removal of the largest possible amount of fluid, until respiratory distress is alleviated or a limit of 1,500 mL is reached, is advisable. Removing larger amounts of fluid may increase the likelihood of developing postexpansion pulmonary edema,¹² a syndrome that can carry a mortality rate as high as 20%.¹³ Less fluid should be withdrawn in the hypoalbuminemic patient.

After evacuation of the effusion, the catheter is removed and a chest radiograph is obtained to rule out iatrogenic pneumothorax. If a moderate or large pneumothorax has been inadvertently created, a thoracostomy tube is usually necessary. Other complications of thoracentesis include hemothorax, hemoperitoneum, shearing of the catheter tip, and infection.

DISPOSITION

The presence of a pleural effusion, in and of itself, does not necessitate admission. A patient with a stable effusion of known etiology may be sent home if the clinical situation allows. For most other cases, however, discussion of the timing and setting of thoracentesis with the primary physician or pulmonologist is appropriate. A clear exception is when the clinical situation demands urgent drainage. If thoracentesis is performed, hospital admission is usually indicated for further treatment of the underlying disease and for observation for procedural complications. In all other cases, the patient's condition and underlying disease process dictate the need for admission. Patients may be admitted to a bed on a regular floor or observation unit, unless cardiovascular or respiratory instability warrants admission to a monitored bed.

When definitive care is available only at another institution, patient transfer may be indicated. If thoracentesis was performed, transfer can be accomplished safely once a follow-up chest radiograph reveals no complications and provided the usual criteria for stability are satisfied.

COMMON PITFALLS

- Failure to recognize the presence of an effusion by failing to order a chest radiograph or, once taken, by misreading it. Effusion may be misdiagnosed as thickened pleura or infiltrate. This leads to inadequate or delayed evaluation and treatment, which might be particularly critical in cases of empyema, esophageal rupture, or intrathoracic hemorrhage.
- An incorrect presumptive diagnosis of the cause of the effusion or an incorrect presumption that an effusion is old and unchanged can likewise result in an inadequate evaluation or treatment. Comparison with old radiographs is essential.
- A misdiagnosis of pleural effusion may lead to inappropriate attempts at thoracentesis, with complications such as puncture of an intrathoracic mass (e.g., malignancy) or abdominal contents (in diaphragmatic rupture).
- Failure to recognize the potential need for pleural biopsy before thoracentesis. This makes subsequent biopsy more difficult if only a small effusion remains.

- Complications such as pneumothorax (from piercing the lung parenchyma or from leaving the needle or catheter hub exposed to the air); laceration of the liver, spleen, or intercostal vessels; and shearing of the catheter tip by withdrawing it incorrectly through the needle may be best avoided by careful attention to technique.
- The risk of postexpansion pulmonary edema is diminished by avoiding removal of very large quantities (e.g., more than 1000 mL) of pleural fluid and by using very low negative evacuation pressures.
- Transient hypoxia during thoracentesis may be avoided by the routine administration of oxygen and by continuous pulse oximetry.

Asthma is characterized by increased airway responsiveness to various stimuli. It is manifested by bronchoconstriction, widespread bronchial wall edema, and thick, tenacious secretions.¹ The characteristic that differentiates asthma from other airway diseases is its reversibility: Acute exacerbations of asthma are interspersed with symptom-free intervals.

Asthma affects about 5% of adults in the United States. About half of all cases are diagnosed before the patient reaches age 10, and another one-third are detected before age 40. The male–female ratio of this disease is 2:1 in childhood but equalizes during early adulthood.

The natural course of asthma has not been investigated thoroughly, but studies suggest that 50% to 80% of patients have a good prognosis, especially those with mild disease or disease that develops in childhood. Nevertheless, asthma has a high morbidity rate. The average asthmatic has 15 days of restricted activity each year and spends 5.8 days in bed. In the United States, over 4000 deaths per year are attributable to asthma.

Asthma is a heterogeneous disease. Clinically, it can be separated into two groups: allergic or extrinsic asthma, and nonallergic or intrinsic asthma. Many patients have components of both types. *Extrinsic asthma* accounts for less than 10% of patients and tends to develop early in life. It is associated with a well-defined sensitivity to inhaled allergens, a family history of allergic diseases, increased serum levels of immunoglobulin E (IgE), positive immediate skin tests, and blood eosinophilia. It may be seasonal (trees, grasses, spores) or perennial (animals, gardens, house dust). A good response to bronchodilator therapy is usually observed.

Intrinsic asthma is the more common type. An inciting allergen cannot be identified, a family history of allergies is less common, IgE levels may be normal or low, and skin tests are negative. Intrinsic asthma is perennial, tends to be more severe than extrinsic asthma, and has a limited response to bronchodilator therapy.

All asthmatics have hyperresponsive airways that narrow when exposed to various stimuli: allergic, infectious, pharmacologic, environmental, occupational, exercise-related, and emotional.

Allergic asthma occurs when inhaled allergens bind to IgE molecules bound to mast cells in the lining of the tracheobronchial tree. During the early response, various mediators are released, causing increased vascular permeability, mucosal edema, and bronchial smooth muscle contraction. A second wave of reaction, the late response, is seen hours to days later and involves the accumulation of inflammatory cells in the bronchial mucosa, thus perpetuating the reaction.

Although several theories attempt to explain the pathophysiologic changes that occur in nonallergic asthma, none adequately explains all clinically observed phenomena. Current hypotheses include the following:

- The cholinergic reflex theory, which suggests that asthmatics have increased parasympathetic reactivity
- The beta-adrenergic blockade theory, which proposes that asthmatics have defective adrenergic receptors, thus permitting unopposed intrinsic parasympathetic activity
- The alpha-adrenergic hyperresponsiveness theory
- The heat flux theory, which states that airway cooling is the primary stimulus for bronchoconstriction¹⁶

Research suggests that even patients without atopy have the same pathophysiology as atopic patients.²⁰

Respiratory infections, particularly viral infections, commonly precipitate bronchospasm. Viruses cause mucosal inflammation and lower the firing threshold of the subendothelial vagal receptors, resulting in enhanced airway reactivity. This hyperactivity may last up to 8 weeks, even in nonasthmatic persons.

Pharmacologic agents also may induce acute asthma. The agents most frequently implicated are aspirin and nonsteroidal antiinflammatory compounds, coloring agents, and beta-adrenergic antagonists.

Up to 10% of adult asthmatics suffer from the triad of aspirin-induced bronchospasm, nasal polyps, and eosinophilia. Ingestion of aspirin, nonsteroidal antiinflammatory compounds, and tartrazine (FDC yellow dye no. 5) and other dyes may induce severe asthma in these patients, possibly by diverting arachidonic acid metabolism toward the lipoxygenase pathway and causing the production of leukotrienes, which are potent bronchoconstrictors.

Sulfating agents are used widely as food preservatives and antioxidants in pharmaceutical products. Exacerbation of asthma has been reported after food ingestions and after the use of sulfite-containing drugs, including some inhalation bronchodilators.

A large variety of occupational dusts and fumes may provoke acute airway obstruction. Patients with occupational asthma classically give a cyclic history. They are symptom-free during weekends, vacations, and on arrival at work. As the workday progresses, wheezing develops. A history of similar symptoms in fellow employees may be noted. Three mechanisms are involved in occupational asthma: immunologic reactions (e.g., animal handlers), direct liberation of bronchoconstrictors (e.g., cotton workers), and direct irritant effects (e.g., meat wrappers).

Exercise also may stimulate an asthma attack. Exercise-induced bronchospasm is usually noted within 5 to 20 minutes after the completion of exercise and is related to thermal changes in the respiratory tree. Exercising in a cold, dry environment causes a more marked response than exercising in a warm, humid environment.

Endocrine factors have been recognized as yet another cause of airway hyperresponsiveness. Normal variations in progesterone and estradiol levels are believed to modulate airway reactivity.

Psychological factors also influence asthma exacerbations, probably through modification of vagal efferent activity. The extent to which psychological factors participate in the induction and continuation of an asthma attack is unknown but probably varies from patient to patient and from episode to episode.¹²

Regardless of the underlying precipitant, airway narrowing, bronchial wall edema, bronchial smooth muscle contraction, and mucosal plugging ensue. These changes result in increased airway resistance, decreased forced expiratory volumes and flow rates, lung hyperinflation, increased work of breathing, and ventilation–perfusion mismatch.

CLINICAL PRESENTATION

Asthma attacks frequently occur at night. The classic triad of symptoms is cough, dyspnea, and wheezing. Chest tightness and nonproductive cough may precede dyspnea and wheezing. As airway obstruction worsens, the expiratory phase becomes prolonged. Asthmatic patients coming to the emergency department are frequently anxious, tachypneic, tachycardic, and mildly hypertensive. Lung hyperinflation, accessory respiratory muscle use, muscle retraction, and pulsus paradoxus may be noted.

Patients may attempt to sit upright or lean forward in an effort to ease the work of breathing. These signs may be absent despite severe airway obstruction, however. ⁴ A silent chest indicates insufficient air movement or extensive mucous plugging and is an ominous sign. Cyanosis may appear only immediately before respiratory arrest and should not be relied on as an indication of the severity of the attack. The termination of an exacerbation is often marked by a cough productive of thick mucus plugs and bronchial casts (Curschmann spirals).

A subset of asthmatic patients experiences the sudden onset of severe symptoms. These individuals tend to respond rapidly to treatment but appear to be at significant risk for a fatal outcome.

Occasionally, an asthmatic patient may complain of intermittent dyspnea or cough on exertion. Patients with cough-equivalent asthma tend to have normal breath sounds on examination, even during an exacerbation, but reversible bronchospasm may be demonstrated on pulmonary function testing.

Complications of asthma include pneumothorax, pneumomediastinum, and subcutaneous emphysema. These may require insertion of a chest tube for evacuation. Mild atelectasis may occur as a result of bronchial mucous plugging, but rarely requires intervention other than conventional bronchodilator therapy. In addition, rib fractures and costochondral strain may occur as a result of excessive coughing. Cough syncope, a rare complication of asthma, is noted most frequently in moderately obese, middle-aged asthmatic men. Finally, dysrhythmias may occur as a result of hypoxia, especially in patients who have received oral adrenergic agents.⁸

DIFFERENTIAL DIAGNOSIS

Wheezing, coughing, and dyspnea are present in many conditions. Common problems include pneumonia, bronchitis, croup, bronchiolitis, chronic obstructive lung disease, congestive heart failure, pulmonary embolism, allergic reactions, and upper airway obstruction from edema or a foreign body. Less common problems include cystic fibrosis, hypersensitivity pneumonitis, carcinoid syndrome, and exposure to odors, dust, and gas. A careful history and physical examination should help differentiate asthma from these other conditions.

EMERGENCY DEPARTMENT EVALUATION

The ability to perform a thorough history and physical examination before initiating treatment is often limited by the patient's dyspnea. Aggressive therapy directed at relieving airway obstruction begins as soon as a diagnosis of asthma is established. Meanwhile, an attempt is made to obtain a history from family members or the patient. Important points to establish include the following:

- Duration and onset of the current attack
- Identification of precipitating causes
- Type and amount of medications used before arrival in the emergency department
- Response to prior therapy, including current or previous use of steroids
- Frequency of emergency department visits and hospitalizations
- Previous need for intubation or ventilation
- History of concurrent medications and allergies
- History of concurrent medical problems

Immediate attention is also directed to the patient's appearance, vital signs, chest examination, and heart examination. The presence of a pulsus paradoxus is noted.

Judging the state of a patient's ventilatory status and pulmonary function on clinical grounds alone can be misleading. The degree of tachycardia and tachypnea often do not correlate well with the degree of airway obstruction. Pulsus paradoxus may be absent in up to one-third of severe asthmatics. Furthermore, wheezing is absent if airflow is minimal.³ To complicate matters, all of the aforementioned clinical parameters can normalize with even minimal improvement in pulmonary function.^{3,17} Therefore, quantification of airway changes must be assessed using either the forced expiratory volume in 1 second (FEV₁) or the peak expiratory flow rate (PEFR). An initial FEV₁ of less than 1 L (less than 30% predicted) or a PEFR of less than 100 L/min (less than 20% predicted) indicates severe obstruction.²²

Hypoxemia is common during acute exacerbations.²⁰ Pulse oximetry may be useful in assessing and following oxygenation. A saturation of less than 91% generally correlates with severe hypoxemia. Arterial blood gas measurements (ABGs) need to be obtained only in patients experiencing severe or prolonged attacks. In general, hypercapnia, severe hypoxemia, or metabolic acidosis does not occur until the PEFR or FEV₁ is less than 25% of predicted values,²⁰ but young children and elderly patients commonly present exceptions to this rule. The degree of hypoxemia determined by the ABG generally reflects the extent of ventilation-perfusion mismatch. A normal or increased pCO₂ indicates severe airway obstruction and impending ventilatory failure.

Expectorated sputum may appear purulent because of the presence of eosinophils, but this finding may not reflect infection. A wet preparation of sputum may contain Charcot-Leyden crystals (eosinophilic granules), Curschmann spirals (mucus casts), and bacteria.

Chest radiographs may demonstrate hyperinflation and atelectasis but are usually nondiagnostic. A chest radiograph is necessary only if pneumonia, pneumothorax, or pneumomediastinum is suspected or if the patient fails to respond to aggressive bronchodilator therapy.¹¹

The electrocardiogram, although it occasionally reveals evidence of right ventricular strain, is generally not helpful, except to rule out concurrent cardiac problems. All older patients, especially those with cardiac disease, should be monitored during therapy.⁸

Blood tests, including a complete blood count, are unlikely to help guide the acute management of an asthma attack. A theophylline level, however, should be obtained to guide therapy if theophylline is used.

Asthma scores that incorporate subjective and objective criteria (pulse, respiratory rate, pulsus paradoxus, subjective dyspnea, accessory muscle use, wheezing, PEFR) should not be relied on for predicting emergency treatment or disposition.^{5,26}

EMERGENCY DEPARTMENT MANAGEMENT

Emergency department interventions are guided by pulmonary function tests (FEV₁, PEFR), vital signs, chest and heart examinations, and the patient's subjective assessment of dyspnea. The goal of emergency treatment is to ensure adequate oxygenation and to relieve airflow obstruction.

Unfortunately, no ideal therapy is available, and the use of multiple drug regimens is common. Supplemental humidified oxygen, inhaled beta-adrenergic agonists, oral or intravenous corticosteroids, and, to a lesser extent, inhaled anticholinergic agents are the mainstays of asthma treatment in the emergency department. The methylxanthines (e.g., theophylline) have only a minor role in emergency management; the cromones are reserved for maintenance therapy only. The role of leukotriene modifiers, ketamine, and halothane remains to be further defined. Guidelines for the diagnosis and management of acute exacerbations of asthma have been established by the National Asthma Education Program Expert Panel ([Fig. 146.1](#)).¹⁹

bronchoconstriction in the larger central airways. There may be an additive effect when beta-adrenergic agents and anticholinergic agents are used together, although this finding is not securely established.^{9,14e} Peak anticholinergic bronchodilation is achieved within 1 to 2 hours. Aerosolized atropine sulfate and glycopyrrolate, although effective, have fallen out of favor because of the high incidence of anticholinergic side effects (tachycardia, restlessness, irritability, dry mouth, thirst, and difficulty swallowing).

Methylxanthines

Theophylline and its salts have been used to treat acute bronchospasm for over 50 years. Studies suggest that the methylxanthines, when used alone or in combination with beta agonists during an acute episode, are associated with an increased incidence of side effects but do little to relieve bronchospasm. Methylxanthines have a narrow therapeutic-toxic window and are subject to many interactions with other drugs. Toxicity may result in life-threatening cardiac dysrhythmias or seizures.

Patients on chronic theophylline therapy who present with acute bronchospasm and a subtherapeutic theophylline level may benefit from oral theophylline or intravenous aminophylline, but methylxanthines otherwise should play no significant role in the acute treatment of airflow obstruction. There is controversy over the utility of aminophylline in patients requiring hospitalization.¹⁵

Other Agents

Magnesium sulfate, a physiologic regulator of intracellular calcium flux, is an effective bronchodilator. In addition to preventing histamine release from mast cells and opposing the action of acetylcholine, magnesium directly inhibits bronchial smooth muscle contraction. Both aerosolized magnesium (0.66 g in 10 mL of saline) and intravenous magnesium solutions (1.2 g over 20 minutes) have been used investigationaly to treat asthmatics who have failed maximal standard therapy, although neither form is currently approved for this indication in the United States. Bronchodilation is observed within 2 to 5 minutes after administration, but it disappears rapidly after treatment is discontinued; thus, additional bronchodilator therapy must accompany the use of magnesium. Side effects include hypotension, malaise, and a warm sensation. Cardiac rhythm, blood pressure, pulse, neurologic status, and renal function must be monitored closely.²⁶

Nedocromil and cromolyn inhibit the release of inflammatory cytokines from mast cells, but they have no role in acute management. Likewise, leukotriene inhibitors, although useful in long-term management, are not indicated for emergency department treatment.

Heliox, an 80:20 mixture of helium and oxygen, should be considered in patients with respiratory acidosis who fail conventional therapy. Helium is a low-density, biologically inert gas that lowers airway resistance and decreases respiratory work. Significant improvement may be noted within 10 to 20 minutes of initiating therapy.¹²

If the patient deteriorates or fails to improve despite intensive therapy, intubation and mechanical ventilation must be considered. Although there are no absolute criteria other than respiratory arrest and coma, the following patients should be considered for intubation and mechanical ventilation:

- Those with worsening pulmonary function tests despite vigorous bronchodilator therapy
- Those with decreasing pO_2 , increasing pCO_2 , or progressive respiratory acidosis
- Those with declining mental status or increasing fatigue.

Noninvasive respiratory therapies such as continuous positive airway pressure (CPAP) and biphasic positive airway pressure (BiPAP) have been shown to reduce the work of breathing and to improve oxygenation in some causes of respiratory failure. At this time, no clinical studies have been performed to evaluate these therapies in the treatment of acute asthma.

Expiratory airflow obstruction can result in air trapping and higher lung volumes in mechanically ventilated asthmatics. This condition may result in “auto-PEEP,” a continuously increased intrathoracic pressure that may decrease venous return and cause hypotension. Auto-PEEP may be avoided by using a rapid inspiratory flow rate, a reduced respiratory frequency, and a prolonged expiratory phase. This type of mechanical ventilation is commonly referred to as “permissive hypercapnia.” An acute deterioration can be treated by simply disconnecting the patient from the ventilator and allowing the lungs to deflate completely before reconnecting it.

The anesthetic agent halothane and the dissociative agent ketamine are potent bronchodilators. Both have a rapid onset of action and a rapid decay of effects. Although both are direct myocardial depressants, ketamine indirectly stimulates catecholamine release. Although the optimal dose for ketamine has not been established, a dose of up to 2 mg/kg has produced bronchodilation in critically ill asthmatics.¹⁶ Ketamine is contraindicated in patients with ischemic heart disease, severe hypertension, preeclampsia, or increased intracranial pressure; increased secretions are common, and hallucinations (“emergence reaction”) are not uncommon. Side effects of 1% halothane include cardiac dysrhythmias and increased intrapulmonary shunting. Close monitoring of heart rate, ABGs, and blood pressure is essential when using either agent.^{20,24}

Narcotics, sedatives, and tranquilizers should be avoided in acute asthma, because respiratory arrest may occur after their use. Mucolytics, expectorants, and hydration do not aid in the treatment of asthma. Antibiotics are advisable only when the sputum Gram stain or wet preparation show evidence of bacterial infection.

Asthma in Pregnancy

About 0.4% to 1.3% of pregnant women suffer from asthma. One-third improve during pregnancy, one-third remain unchanged, and one-third become worse. Asthma therapy during pregnancy is directed at providing adequate oxygenation for both mother and fetus. The management of pregnant asthmatics is essentially the same as for nonasthmatics. The use of subcutaneous or inhaled beta-adrenergic agents, theophylline, and corticosteroids appears to be safe during pregnancy.^{7,13}

DISPOSITION

Several asthma-scoring indices have been proposed to predict the need for hospitalization, but all have proven disappointing.^{5,22} The following patients should be considered for hospital admission:

- Those whose condition deteriorates in the emergency department
- Those who return for further therapy within several days after emergency department discharge
- Dyspneic patients with significant hypoxemia (pO_2 less than 60), hypercapnia, or acidosis
- Patients with a pretreatment FEV₁ less than 1.0 L (less than 30% predicted) or a PEF less than 100 L/min (less than 20% predicted), and a posttreatment FEV₁ less than 2.1 L (less than 60% predicted) or a PEF less than 300 L/min (less than 60% predicted)
- Patients who remain subjectively dyspneic after aggressive therapy
- Patients with continued abnormal vital signs after therapy
- Unreliable patients

Even patients who improve enough to be discharged from the emergency department have residual airway obstruction for up to several weeks after the acute episode subsides.¹⁹ Therefore, arrangements must be made for ongoing treatment and early follow-up. An 8- to 10-day course of oral corticosteroids (40 to 60 mg/d methylprednisolone and, in the practice of many clinicians, tapered) and a 10-day treatment regimen of a beta₂-adrenergic metered-dose inhaler (two puffs as needed, up to every 4 to 6 hours) should be prescribed. In addition, the role of chronic aerosolized steroids or cromolyn sulfate should be discussed with the patient. Instruction in the proper use of the inhaler is essential. Patients on chronic theophylline therapy should be continued on a long-acting preparation. If oral theophylline is used, the serum level must be monitored.

COMMON PITFALLS

- Failure to recognize that a silent chest or a normal pCO_2 is a sign of severe obstructive disease and may result in respiratory arrest.

- Withholding beta-agonist therapy in the emergency department because of beta-agonist use at home. This approach has no scientific basis and is extremely dangerous.
- Failure to use measurements of pulmonary function, in addition to clinical and subjective parameters of dyspnea, when judging the adequacy of bronchodilator therapy.
- Failure to give glucocorticoids to all but the mildest asthmatics, especially in those who fail to respond to one or two doses of beta agonists.

CHAPTER 147

Chronic Obstructive Pulmonary Disease

Erica E. Remer and David S. Howes

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Chronic obstructive pulmonary disease (COPD) comprises a spectrum of chronic respiratory diseases characterized by cough, sputum production, dyspnea, airflow limitation, and impaired gas exchange. The mortality rate is greater than 50% within 10 years of diagnosis.⁷ Affecting at least 15 million Americans, COPD is the fourth leading cause of death and costs more than \$15 billion dollars for treatment annually.^{6,7}

The term *COPD* includes conditions, other than asthma, that have the common feature of airflow obstruction. Chronic bronchitis is characterized clinically by a chronic productive cough that is due to excessive bronchial mucus production and airway inflammation. To be called *chronic bronchitis*, the cough must be present for 3 months a year in at least two successive years. *Pulmonary emphysema*, in contrast, is defined pathologically by an irreversible enlargement of the alveolar air spaces, with associated destruction of the alveolar wall and pulmonary capillary bed. Patients suffering from pure forms of each condition are the exception, and most patients exhibit characteristics of both.

The predominant risk factor for COPD is tobacco use.^{5,17} However, 5% to 10% of patients with COPD have never smoked, implicating other casual factors.³ Other risk factors include environmental pollution, passive smoke inhalation, occupational exposure, and repeated respiratory infections.^{5,17} There may also be genetic factors, the best defined being a α_1 -antitrypsin deficiency.¹⁷ Regardless of the inciting etiology, the ultimate outcome is irreversible airflow limitation.

The natural course of COPD is one of progressively worsening dyspnea, hypoxemia, and diminished exercise tolerance, with recurrent exacerbations. Many COPD patients have a component of reversible airway obstruction,⁷ but the fixed component seems to be the major determinant of outcome. In fact, the FEV₁ is the best prognostic indicator of disability and mortality.^{4,14,17} Chronic hypoxemia leads to progressive clinical deterioration due to cor pulmonale, which worsens already diminished lung function. Recurrent episodes of infection and respiratory failure ultimately result in death. Long-term ambulatory oxygen therapy is the only treatment that has been demonstrated to prolong life in patients with advanced COPD.^{4,6}

CLINICAL PRESENTATION

All patients with COPD exhibit airflow obstruction, but the pure forms of emphysema and chronic bronchitis have distinctive clinical features. Patients with emphysema tend to hyperventilate to compensate for the lungs' decreased ability to oxygenate the blood. These classic "pink puffers" work hard to establish a near-normal pO₂, and they appear barrel-chested, dyspneic, and tachypneic. They use pursed-lip breathing to create positive end-expiratory pressure in order to prevent early airway closure. Breath sounds are markedly diminished, with a prolonged expiratory phase.¹⁵

In contrast, patients with chronic bronchitis tolerate hypoxemia well and make no effort to hyperventilate. Chronic hypoxia induces a secondary polycythemia that, combined with the cyanosis of marked desaturation of hemoglobin, produces a plethoric appearance. These patients tolerate an elevated pCO₂ and have a less labored respiratory pattern. With the decreased work of breathing, the chronic bronchitic does not suffer from muscle wasting like the emphysematous patient. These features produce the picture of the "blue bloater." Lung examination reveals rhonchi, rales, and variable wheezing.¹⁵

Most patients presenting with an acute exacerbation of COPD do not fit either picture precisely. Patients typically complain of dyspnea and chest tightness and often note a change in the character of their sputum. Physical examination may reveal tachypnea and a variable degree of respiratory distress, as evidenced by accessory muscle use, retractions, and cyanosis. On auscultation, one may hear diminished breath sounds, a prolonged expiratory phase, wheezing, rales, or rhonchi. Signs of cor pulmonale should be sought: a centrally displaced point of maximal impulse, heart gallop, tricuspid murmur, peripheral edema, jugular venous distention or hepatojugular reflux, and hepatomegaly. This complication of long-standing hypoxemia is associated with substantial mortality.¹⁵

The causes of exacerbation include respiratory infection, noncompliance with (or underdosing of) medications, changes in weather, exposure to certain drugs (e.g., sedatives or beta-blockers), cardiac dysrhythmias, left ventricular dysfunction, and environmental exposure to pollens, fumes, allergens, or other irritants. Patients typically present with a gradual, but progressive, deterioration over hours to days.

Acute decompensation may be the result of a number of other conditions. Spontaneous pneumothorax in COPD carries a significantly higher complication and mortality rate than in patients with a more normal cardiorespiratory status. The chronic bronchitic patient is predisposed to embolic and thrombotic phenomena due to the hyperviscosity associated with polycythemia. Other disorders, such as congestive heart failure (CHF), pneumonia, acidosis, or renal or hepatic failure, may also overwhelm the COPD patient's limited reserves, resulting in respiratory failure.

DIFFERENTIAL DIAGNOSIS

COPD is a clinical diagnosis; it is usually made after extended observation of a patient at risk (most commonly due to cigarette smoking) who demonstrates progressive lung dysfunction. Because those at risk are likely to have sedentary lifestyles, they may present only when an acute event precipitates dyspnea at rest, unmasking previously undiagnosed lung disease.

Other conditions must also be considered in the patient who presents to the emergency department with wheezing, cough, dyspnea, or respiratory failure. Pneumonia or acute bronchitis may present with varying degrees of shortness of breath, cough, and bronchospasm with wheezing. Previously undiagnosed COPD may be discovered after the acute pneumonic process has resolved. Dyspnea and hypoxemia may also be seen in pulmonary embolism. An acute onset of respiratory symptoms and pleuritic chest pain, associated with risk factors such as recent surgery, malignancy, or immobility, or a swollen leg suggestive of deep venous thrombosis, strongly suggest consideration of this entity. It is often a challenge to diagnose or rule out left ventricular dysfunction in the face of COPD.²⁰ CHF may present with cough, dyspnea, and hypoxemia. Some patients exhibit wheezing, referred to as "cardiac asthma." Orthopnea, paroxysmal nocturnal dyspnea, and cardiomegaly are suggestive of CHF, but COPD patients with cor pulmonale may well demonstrate jugular venous distention. The chest radiograph may assist in distinguishing the two: Lack of cardiomegaly and pulmonary venous redistribution, and the presence of bullae and hyperinflation of the lungs suggests COPD. Many patients have histories of both conditions, and, if the clinical presentation and chest x-ray are not conclusive, it may be prudent to initiate therapy for both conditions.

EMERGENCY DEPARTMENT EVALUATION

If the patient's respiratory status allows a brief history to be taken, attention should be directed to the rapidity of onset and duration of symptoms, any precipitating factors, and the dosage and timing of medications. Information should be sought regarding the character of the sputum, the course of previous exacerbations, and any history of concomitant disease processes.

The physical examination focuses on the patient's mental status and the degree of respiratory distress. Hypercapnia and hypoxia can cause confusion, irritability, and somnolence. The cardiac and pulmonary examinations are vital, and repeated examinations are mandatory after therapeutic interventions in order to monitor the response to treatment.

Pulse oximetry is useful in monitoring the oxygen saturation and the effectiveness of oxygen supplementation. Arterial blood gas (ABG) analysis provides information

on the PaCO₂, reflecting the adequacy of ventilation. Baseline or prior blood gas results may be useful for comparison; in general, hypercapnia with acidemia suggests acute respiratory failure.

The chest radiograph is usually done portably at the bedside, unless the patient is stable and can tolerate being transported to the radiology suite for posteroanterior (PA) and lateral films. Its primary utility is not in demonstrating changes consistent with COPD, but in ruling out other disease processes, such as pneumothorax, atelectasis, infiltrate, lung mass, or CHF.

Measurements of airflow do not always yield accurate assessments of the severity of illness, but may be more useful in judging the response to therapy. The peak expiratory flow rate (PEFR) is the marker most commonly used in the emergency department setting, but, in contradistinction to the asthmatic's response, it does not typically demonstrate a marked change in COPD.

Laboratory studies are generally of limited value. A serum theophylline level should be obtained in patients who are taking the medication, as it has a narrow therapeutic window and myriad drug interactions.¹³ β-agonists may cause hypokalemia, although this is rarely clinically significant. A complete blood count may reveal anemia, which can compound the problem of hypoxemia, or a high white blood cell count, which may be a clue to pneumonia or another systemic infection. Other tests may be indicated if other disease processes are being investigated.

A twelve-lead electrocardiogram (ECG) may suggest right atrial enlargement, low voltage, or right ventricular hypertrophy or strain (cor pulmonale). Acute ischemic patterns must be appreciated to identify an acute coronary event that may be triggering or complicating the acute COPD attack. Continuous ECG monitoring may be useful in revealing dysrhythmias, which may be the cause or effect of the acute exacerbation.

EMERGENCY DEPARTMENT MANAGEMENT

The effective management of the acutely decompensated COPD patient depends on rapid estimation of the severity of illness, aggressive therapy, frequent reevaluation, and recognition of treatable entities that may have precipitated or complicated the patient's course. As with any critically ill patient, the patient should be placed on a cardiac monitor and have intravenous access established. It is difficult to determine whether dysrhythmias, such as atrial fibrillation and ventricular dysrhythmias, reflect coexisting heart disease or are caused by the COPD exacerbation and hypoxemia. Current evidence suggests that most patients exhibiting ventricular dysrhythmias have underlying left ventricular diastolic dysfunction.⁸

Treatment with oxygen is critical because hypoxemia is the major immediate threat to life. The goal is to maintain a PO₂ greater than 60 mm Hg, corresponding to an oxygen saturation of approximately 90%. A controlled oxygen delivery system is preferable; a Venturi mask system can deliver a precise oxygen concentration ranging from 24% to 50%. If the patient cannot tolerate a mask, low-flow oxygen (2 to 4 L/min) by nasal cannula may be utilized. Adjustments in oxygen delivery should be guided by continuous pulse oximetry and ABG determinations as needed. Although there is a concern of eliminating the hypoxic drive in chronic CO₂ retainers by administering oxygen, the percentage of patients at risk is small and the danger of hypoxemia far outweighs the potential hazard from hypercarbia.

Sympathomimetics, specifically β₂ agonists, are the agents of choice for acute COPD exacerbations, with maximal effectiveness noted in patients who have a reversible bronchospastic component.^{5,7,10,19} Undesirable side effects include tremor, agitation, insomnia, headache, cardiac tachyarrhythmias, and hypokalemia.¹⁹ Although bronchodilatation is equivalent when delivered by a metered-dose inhaler (MDI) coupled with a spacer device or by nebulizer aerosolization, the latter delivery method is generally used in the emergency department because dyspneic patients may have difficulty effectively performing the MDI procedure.^{10,17} Although there are many β₂ agonists available, albuterol, 2.5 mg, is the most widely used agent. It is used either in repeated treatments every 20 to 60 minutes or by continuous nebulization in severe cases.

Although anticholinergics are considered by some investigators to be the bronchodilators of choice in the management of chronic disease,^{3,11} their slower onset of action makes them a second-line treatment in the acute setting.^{10,20} Ipratropium bromide, a congener of atropine, which has little systemic absorption when inhaled, minimizing undesirable anticholinergic effects,¹⁰ has been shown to have an additive effect when combined with a β₂ agonist.^{2,7,10} Anticholinergics are considered by some investigators to be the bronchodilators of choice in the management of chronic disease.^{3,11}

Corticosteroids are considered useful in acute exacerbations of COPD,^{5,17,20} but are not reliably beneficial when used long-term. Thus, patients who do not respond to steroids when stable may still benefit from them during acute attacks.^{5,17} Because steroid use may suppress the adrenal-pituitary axis, patients with current or recent use may require steroids for the stress of any acute illness. High-dose parenteral methylprednisolone or oral prednisone appear to be equally effective. Inhaled steroids are not currently used in the acute setting.

Prior to the widespread availability of oral or inhaled, β₂ agonists, methylxanthines, most commonly theophylline preparations, were used as monotherapy for COPD. Symptomatic improvement of dyspnea and exercise tolerance is presumed to be at least partially due to mild bronchodilatation and positive inotropic effects on the diaphragm.¹³ However, theophylline has a narrow therapeutic window and is associated with frequent adverse effects. Nausea, vomiting, cardiac dysrhythmias, and seizures can be seen even at therapeutic levels. Although current recommendations do not support instituting methylxanthine therapy in acute exacerbations, if a patient is maintained on theophylline, one might continue intravenous therapy as guided by drug levels. The therapeutic range is 10 to 20 mg, and a 1-mg/kg bolus of aminophylline can be expected to raise the serum level by approximately 2 mg/dL.

Other medications may be utilized in the management of acute COPD. Magnesium sulfate has modest bronchodilatory effects, and may be given a trial as adjunctive therapy to patients with severe exacerbations who have normal renal function.^{18,20} There is no compelling evidence that mucolytics such as acetylcysteine are efficacious.⁵ Inhibitors of neutrophilic inflammation, proteinases, and prostaglandins are currently under investigation, but there are, as yet, no data suggesting their utility in COPD.^{1,3}

Although it is not typically addressed in the emergency department, cessation of tobacco use may well be the most important therapeutic intervention for COPD.^{4,6,17} Bupropion and nicotine replacement therapy may be very useful in assisting patients to stop smoking.³ COPD patients in the emergency department are also candidates to receive polyvalent pneumococcal and influenza vaccines in order to decrease the risk of future exacerbations.¹

It is estimated that only half of acute COPD exacerbations are due to bacterial infection, with the predominant species being *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Streptococcus pneumoniae*.¹⁶ If dyspnea is associated with a change in the volume or purulence of sputum, or if a new infiltrate is noted on chest x-ray, antibiotics should be instituted.^{1,6,10} A Gram stain of the sputum may aid in the selection of an antimicrobial, and adjustments may be needed according to geographic location and local resistance patterns. For less severe cases, oral therapy with tetracycline or doxycycline, a second- or third-generation cephalosporin, trimethoprim-sulfamethoxazole, or a β-lactam-β-lactamase inhibitor combination, with or without a macrolide, is appropriate.^{1,6} In hospitalized patients with pneumonia or toxicity, parenteral therapy should be instituted with a second- or third-generation cephalosporin, or a β-lactam-β-lactamase inhibitor, possibly in conjunction with a macrolide.⁶ Several of the newer fluoroquinolones, such as sparfloxacin and levofloxacin, may also see an expanded role in the treatment of acute COPD.¹⁶

In patients who do not respond to acute interventions and begin to show signs of respiratory failure, such as deterioration of mental status, worsening hypoxemia (PaO₂ less than 50 mm Hg), or worsening respiratory acidosis (pH less than 7.3), assisted ventilation is indicated.^{10,20} BiPAP or CPAP may prevent the need for invasive airway management, and may result in fewer complications and shorter hospital stays.^{12,20} However, in patients who are not candidates for these modalities, or in whom noninvasive ventilation has failed, endotracheal intubation and mechanical ventilation is the treatment of choice.

DISPOSITION

Most patients presenting with an acute exacerbation of COPD require admission to the hospital. However, if the patient responds to therapy and the vital signs and pulmonary function tests approach baseline, discharge may be considered if good follow-up is assured. The bronchodilator regimen should be maximized, and steroids should be continued for a short course. Antibiotics should be prescribed for exacerbations of chronic bronchitis. It should be recognized that approximately

15% of COPD patients who are discharged from the emergency department require readmission.²⁰

Accepted criteria for hospitalization of patients with COPD include poor response to outpatient therapy, severe limitation of function, inability to eat or sleep due to dyspnea, presence of significant comorbid conditions, worsening respiratory failure, new or progressive cor pulmonale, and the need for invasive procedures, especially those requiring analgesics or sedatives.^{4,20} Guidelines for admission to the intensive care unit are not as well defined. Treatment in an intensive care unit is indicated when the close observation, monitoring, and therapeutic interventions (including assisted ventilation) required by these patients cannot be provided elsewhere.

If transfer to another institution is required, it must be done carefully, because transfer is often associated with an interruption in treatment and increased patient fatigue. The transport team must be capable of managing the airway if decompensation occurs.

COMMON PITFALLS

- The COPD patient should not be expected to have as rapidly reversible disease as the asthmatic patient. Look for a slower course of improvement, and have a lower threshold for admission.
- Precipitating or complicating conditions may be overlooked when treating only the exacerbation of COPD. Thorough evaluation is mandatory.
- Oxygen should never be withheld due to concern about respiratory depression. If inadequate ventilation occurs, ventilatory support should be provided.
- It is easy to underestimate the severity of illness in patients with chronic dysfunction. Utilize radiography, pulse oximetry, ABG analyses, and pulmonary function tests liberally. Respect the patient's estimation of severity of illness.

CHAPTER 148

Lung Cancer

Marc Borenstein

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Lung cancer is the leading cause of cancer-related death in both men and women in the United States. The marked rise in the incidence of lung cancer closely parallels the increase in cigarette smoking by men during World War I and, subsequently, by women in the 1950s and 1960s. Occupational carcinogens for lung cancer have also been identified; they include asbestos, metal fumes, hydrocarbons, and radiation. Radon exposure in homes is an environmental risk factor for lung cancer in many regions of the United States. Cigarette smoking and occupational or environmental risk factors act synergistically to increase the risk of developing lung cancer markedly.^{2,6}

Lung cancer is divided into four main histologic types: large-cell carcinoma, adenocarcinoma, squamous cell (epidermoid) carcinoma, and small-cell (formerly called oat-cell) carcinoma. Although cigarette smoking has been implicated in all four types, the strongest association is with squamous cell and small-cell carcinomas.

Lung cancer is staged using an internationally accepted T (tumor), N (node), M (metastases) system. Five basic stages are recognized ^{5,8}:

Stage 0: carcinoma *in situ*
Stage I: no lymph node involvement
Stage II: spread to immediately adjacent nodes
Stage III: large tumor or localized nodal spread
Stage IV: any distant metastasis

Patients are carefully staged on the basis of physical examination, laboratory findings, radiographs, and results of scans and biopsy to determine whether the tumor is localized. Operative therapy is determined based on the patient's ability to tolerate the stress of surgery and the diminished pulmonary function that results from a surgical lobectomy or pneumonectomy. Operative candidates are then evaluated as to whether the tumor is resectable or unresectable. Often, resectability can be determined with thoracic computed tomography, but, for many patients, a surgical procedure is required to establish it.

CLINICAL PRESENTATION

Clinical presentations of lung cancer in the emergency department are highly varied and depend on the histologic type as well as the extent of the cancer. Patients may present with symptoms related to local extension, distant spread of the tumor, paraneoplastic effects, or the complications of treatment.

The diagnosis of lung cancer should be considered in patients with persistent cough or hoarseness, recurrent bronchitis, unresolving or recurrent pneumonia, and hemoptysis.¹ A background of smoking or environmental exposure should greatly raise the physician's concern. The risk of developing lung cancer increases disproportionately with the duration and amount of smoking. A symptomatic patient with a history of previously treated lung cancer should be evaluated carefully for tumor recurrence or the development of a second primary tumor.

Local tumor extension can produce superior vena caval obstruction (SVC syndrome) or tracheal or esophageal compression. Symptoms such as cough, dyspnea, hoarseness, chest pain, and thoracic pain are frequently encountered. Tumor in the lung apex (superior sulcus) can be associated with a brachial plexopathy, Horner syndrome, and pain in the shoulder (Pancoast syndrome). Jaundice usually results from extrinsic nodal compression of the biliary tree.

The symptoms of metastatic disease are protean.^{1,3} Central nervous system metastases may present as altered mental status, headache, or seizures. Bony pain may result from osseous metastases or pathologic fractures and typically precedes the development of clinically apparent neurologic deficits for weeks to months in patients with underlying spinal cord compression. Dyspnea may result from tumor infiltration, superimposed pneumonia, or complications of treatment. The patient may seek medical evaluation for a "lump" that has not gone away. Hepatic metastases usually present with right upper quadrant abdominal pain, anorexia, or nausea.

Paraneoplastic syndromes are frequent and are usually seen in association with small-cell carcinoma. Some of the more commonly encountered ones include the syndrome of inappropriate secretion of antidiuretic hormone, ectopic production of adrenocorticotropic hormone, and the Eaton-Lambert syndrome. Hypercalcemia is associated only with squamous cell carcinoma and can be used as a marker that reflects the persistence or regression of tumor. Migratory thrombophlebitis, nonbacterial thrombotic endocarditis, and disseminated intravascular coagulation (DIC) have all been described in association with lung cancer. ⁷

Complications of treatment include nausea, vomiting, electrolyte abnormalities, neutropenia, fever, and sepsis. A dilated cardiomyopathy with congestive heart failure may occur secondary to anthracycline toxicity. Acute radiation pneumonitis may manifest as cough, dyspnea, and fever.

The specific histologic types of lung cancer are characteristically associated with a number of distinct clinical manifestations. Squamous cell (bronchogenic) carcinoma and small-cell carcinoma both occur centrally, leading to complications from compression of mediastinal structures such as the recurrent laryngeal nerve (hoarseness, voice changes) and the trachea (respiratory distress). Pancoast syndrome is most often associated with squamous cell carcinoma. SVC syndrome is typically caused by small-cell carcinoma. Adenocarcinoma and large-cell carcinoma tend to occur as peripheral tumors and do not usually produce local obstruction.

In contrast to other histologic types, small-cell lung cancer is highly responsive to chemotherapy, in part because of its characteristically rapid cell division. Small-cell carcinoma is likely to metastasize early, however, and a thorough workup is necessary to ensure accurate staging of this cancer. Bone marrow biopsy is positive in approximately 50% of patients with small-cell lung carcinoma, making this test an essential part of the initial staging workup.

DIFFERENTIAL DIAGNOSIS

All patients suspected of having cancer should have the diagnosis proven by biopsy. This principle also applies to a suspected first recurrence of cancer after curative surgery, radiation therapy, or chemotherapy. Although biopsy and tissue diagnosis are not germane to the immediate evaluation of the cancer patient in the emergency department, it is essential to understand this concept and to recognize its importance when arranging for appropriate follow-up for the emergency department patient suspected of having lung cancer.

The differential diagnosis of the most frequent emergency department presentations includes the following:

Cough: bronchitis, pneumonia, obstruction
Dyspnea: chronic obstructive pulmonary disease, congestive heart failure, pneumonia, pleural effusion
Chest pain: pleurisy, pneumonia, myocardial infarction, pneumothorax, pulmonary embolism
Thoracic pain: musculoskeletal, degenerative joint disease
Lymphadenopathy: inflammatory, infectious

If a pulmonary nodule is discovered on a chest radiograph, the differential diagnosis should include tuberculosis, fungal infection, and vascular abnormality. ⁴

EMERGENCY DEPARTMENT EVALUATION

Although the range of potential presentations in lung cancer is broad, general guidelines can be used effectively in emergency management.

In the patient without a prior diagnosis of lung cancer, the emergency physician should ask about risk factors. A chest radiograph is the most useful test in most cases. It should be obtained in patients at risk: smokers, miners who present with persistent cough, and patients complaining of progressive hoarseness, voice changes, unresolved "bronchitis," recurrent pneumonias, or nontraumatic persistent chest pain.

In the patient with an established diagnosis of lung cancer (either in remission or under active treatment), the emergency physician must rule out serious complications, such as spinal cord compression, SVC syndrome, central nervous system metastasis, osseous metastasis, cytopenias, infection, and metabolic abnormalities. Complaints of cough, dyspnea, chest pain, bone pain, back pain, fever, headache, and changes in mental status must be regarded seriously. Laboratory testing should generally include a complete blood cell count; platelet count; determination of electrolytes, blood urea nitrogen, creatinine, and glucose; and chest radiograph. Skeletal radiographs, urinalysis, oximetry, arterial blood gases, and computed tomography may be indicated as well, depending on the specific clinical setting.

A common diagnostic error in the setting of known lung cancer is the failure to obtain adequate historical information regarding the type of lung cancer, the specific treatments received, and the dates of treatment. In some cases, the patient may not mention a history of lung cancer and may not have an understanding of the risks associated with microscopic residual disease. The patient may think that therapy was curative and fail to realize that there is a small but real risk of recurrence that requires ongoing surveillance.

EMERGENCY DEPARTMENT MANAGEMENT

The patient with lung cancer may present with life-threatening oncologic emergencies. These include airway compromise, respiratory insufficiency, fever with neutropenia, SVC compression, cardiac tamponade, seizures, hypercalcemia, hyponatremia, DIC, massive hemoptysis, altered mental status, pulmonary embolism, and overdose (accidental and intentional). Specific management principles are outlined in detail elsewhere in this text. The emergency physician must distinguish between those situations in which resuscitative measures are appropriate and those in which supportive and symptomatic care is indicated in lieu of endotracheal intubation, cardiopulmonary resuscitation, and ventilatory support. The patient may have a living will, an advance directive, or a do not resuscitate (DNR) order in place. The specific legal guidelines in this arena vary from state to state. Close communication with the patient's family and personal physician, if available, can be helpful. Seek it whenever possible.

DISPOSITION

Patients with cancer are frequently treated with complex regimens involving oncology, radiation therapy, surgery, and medical subspecialties. Care is usually coordinated by an oncologist, with close involvement of the patient's personal physician. After emergency assessment and stabilization, oncologic consultation is often invaluable to the emergency physician in determining further management and ultimate disposition. In some cases, the patient may be receiving investigational chemotherapy, and early consultation can provide important information regarding adverse reactions not readily available in general textbooks.

Patients with lung cancer who present with serious, life- or limb-threatening complications require urgent evaluation, treatment, and admission. Such complications include fever with neutropenia, pneumonia, sepsis, respiratory insufficiency (typically secondary to decompensated chronic obstructed pulmonary disease, irradiation, or chemotherapy), suspected spinal cord compression, and symptomatic SVC compression. They also include symptomatic or severe hyponatremia, symptomatic hypercalcemia, airway compromise, moderate hemoptysis, altered mental status, stroke, raised intracranial pressure, neurologic impairment (often secondary to paraneoplastic syndromes), coma, overdose (accidental or intentional), coagulopathy, and DIC.

Most patients who present *de novo* with symptoms suggestive of an underlying lung cancer can be evaluated and discharged from the emergency department with an emphasis on timely follow-up. Similarly, patients who have a history of previously treated lung cancer can often be managed on an outpatient basis, provided their presentation does not fall into one of the previously mentioned categories.

In general, few patients with lung cancer require transfer to another facility unless the hospital cannot provide a level of care consistent with the patient's needs. Alternatively, some patients may request transfer to another hospital where they have been receiving ongoing cancer care, particularly if they are receiving investigational treatment.

COMMON PITFALLS

- Failure to obtain a chest radiograph in the patient at risk for lung cancer or its recurrence
- Failure to recognize the high incidence of complications in the lung cancer patient population
- Failure to recognize the urgency and importance of back pain in the patient with lung cancer as potentially caused by spinal cord compression
- Failure to take a history thoroughly detailing the type, stage, and treatment of lung cancer
- Failure to obtain and thoroughly review medical records
- Failure to obtain oncology consultation for treatment planning

CHAPTER 149

Spontaneous Pneumothorax and Pneumomediastinum

Susan M. Dunmire

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Spontaneous pneumothorax and pneumomediastinum are not infrequently encountered in emergency medicine. These entities should be considered in any individual who presents with the acute onset of shortness of breath, chest pain, or subcutaneous emphysema.

Pneumothorax is defined as the presence of gas within the pleural space. A pneumothorax occurring in the absence of penetrating or blunt injury to the chest wall is termed a *spontaneous pneumothorax*. This can be classified either as primary (idiopathic), in which there is no underlying pulmonary disease, or as secondary to any of a wide variety of causes. With large accumulations of air in the pleural space, a *tension pneumothorax* may develop, which leads to hypotension due to impaired venous return.

Although most authorities agree that a primary spontaneous pneumothorax is the result of rupture of small subpleural cysts or blebs, the etiology of these structural abnormalities (congenital vs. acquired) is still controversial. Spontaneous pneumothorax recurs in up to 50% of patients within 2 years. The recurrence is much more likely to be on the same side as the initial pneumothorax.

Another less common but interesting entity is *catamenial pneumothorax*. It is a spontaneous pneumothorax occurring in young girls at the time of menstruation. Although its etiology is multifactorial, in some patients it is due to small implants of endometrial tissue in the pleural lining. ^{3,5,11}

Spontaneous *pneumomediastinum* is the result of alveolar rupture, with dissection of air along the bronchus and into the mediastinum. Although it is usually a benign entity, serious causes, such as esophageal rupture, must be ruled out. The cause of pneumomediastinum often cannot be identified. It can occur in patients with a history of vigorous vomiting or in those who use repetitive and prolonged Valsalva maneuvers to enhance the effects of inhaled, pipe-smoked cocaine. ¹⁰

CLINICAL PRESENTATION

Primary (idiopathic) spontaneous pneumothorax commonly occurs in young adults (male-to-female ratio, 5:1) between the ages of 20 and 40. ⁸ Affected individuals tend to be tall and thin and frequently have a history of cigarette smoking. ² There is also a strong association with Marfan syndrome. ⁹

Patients with spontaneous pneumothorax typically present with the sudden onset of constant ipsilateral chest or shoulder pain that may or may not increase with inspiration. The majority of patients complain of dyspnea, although the severity of that symptom depends on the size of the pneumothorax. Most patients have the onset of symptoms at rest or during sleep. Rarely, spontaneous pneumothorax can present as a tension pneumothorax with severe cardiopulmonary compromise.

Symptoms in adults with spontaneous pneumomediastinum include retrosternal chest pain and, less frequently, subcutaneous emphysema due to tracking of air into the chest wall, neck, face, abdominal wall, and scrotum. If enough air accumulates in the mediastinum, the pleura can rupture, resulting in an associated pneumothorax. Spontaneous pneumomediastinum in infants is a much more serious entity and can cause cardiopulmonary compromise by compression of the hilum. ¹³

DIFFERENTIAL DIAGNOSIS

Pulmonary embolism, exacerbation of chronic obstructive pulmonary disease (COPD) or asthma, pneumonia, and myocardial ischemia should all be in the differential diagnosis of a patient with shortness of breath and chest pain. Often, the entity of spontaneous pneumothorax is not considered until the chest radiograph is obtained.

Spontaneous pneumomediastinum usually presents as substernal chest pain. The differential diagnosis includes myocardial ischemia, gastroesophageal reflux, pulmonary embolism, and pneumonia.

Once the diagnosis of pneumothorax has been made, the physician is obligated to search for the underlying cause. In the case of spontaneous pneumothorax, it is important to reevaluate the history and physical examination to ensure that there is no sign of blunt or penetrating trauma. An elderly person may have forgotten a recent fall, resulting in rib fractures and an underlying pneumothorax. A puncture site in the neck or supraclavicular area can easily be missed in an unsuspected drug abuser who has penetrated the pleural space. In patients with spontaneous pneumomediastinum, it is also essential that esophageal rupture be ruled out.

One of the most common causes of secondary pneumothorax is COPD with rupture of bullae through the visceral pleura. The presentation can be misleading, in that patients may report only a worsening of chronic dyspnea. The unsuspected pneumothorax is often found on chest radiography during the evaluation of a COPD exacerbation. Because these patients already have compromised pulmonary function, the pneumothorax is usually treated aggressively and the patient monitored closely.

Pneumocystis carinii pneumonia has become an increasingly common cause of secondary pneumothorax as the population of patients with acquired immunodeficiency disease rises. A subgroup of patients with *Pneumocystis* pneumonia have an accelerated inflammatory response, with spontaneous rupture of necrotic lung tissue, resulting in pneumothorax. ¹

Other less common causes of secondary pneumothorax include malignancy, asthma (sometimes presenting as sudden severe respiratory compromise), pulmonary infarction, histiocytosis X, and Hamman-Rich syndrome (acute interstitial pulmonary fibrosis). Because, as previously noted, patients with significant underlying lung pathology may have respiratory decompensation with a relatively small pneumothorax, they require aggressive therapy and close monitoring.

EMERGENCY DEPARTMENT EVALUATION

Physical examination is often not very helpful in making the diagnosis of spontaneous pneumothorax. Patients often exhibit mild resting tachycardia and tachypnea. Depending on the extent of the pneumothorax, breath sounds may be diminished unilaterally. The presence of hypotension, tachycardia (more than 140 beats per minute), or tracheal deviation should immediately alert the emergency physician to the possibility of a tension pneumothorax requiring emergent decompression.

The diagnosis of pneumothorax is usually made by chest radiography, which reveals a peripheral lucent area containing no lung markings. Films taken in maximal expiration with the patient in an upright position optimize visualization of small pneumothoraces. The size of a pneumothorax may be roughly gauged from the plain chest film, but such estimates are notoriously unreliable. Algorithms that yield more accurate estimates of size are available but are relatively complicated to apply. ⁷

Patients with a significant (greater than 25%) pneumothorax have an increase in the alveolar-arterial oxygen gradient, although an arterial blood gas is rarely necessary. ⁶ The electrocardiogram is not helpful for diagnosis. Nonspecific changes, including T-wave inversion in the precordial leads, decreased amplitude of the R wave, and left axis deviation, are often noted.

The diagnosis of a spontaneous pneumomediastinum is often overlooked and requires a thorough examination and a high index of suspicion. On physical examination, auscultation of the heart may reveal a crunching sound during systole (Hamman sign). ⁴ Rarely, subcutaneous air may be present. On chest radiography,

a very thin lucent stripe can be seen outlining the heart and mediastinum. A lateral neck radiograph may reveal subcutaneous air. The electrocardiogram is useful only in helping to rule out ischemia in the patient presenting with substernal chest pain.

EMERGENCY DEPARTMENT MANAGEMENT

Most patients with primary spontaneous pneumothorax do not have significant cardiopulmonary compromise. Any hemodynamic instability should suggest the presence of tension pneumothorax requiring immediate needle decompression, followed by tube thoracostomy.

Invasive treatment of a spontaneous pneumothorax can be accomplished by several methods. Many simple pneumothoraces (greater than 25% or symptomatic) can be treated by placement of a pigtail catheter. Using the Seldinger technique, a pigtail catheter can be inserted at the anterior axillary line between the fourth and fifth ribs (nipple line). Care should be taken when the wire is introduced into the pleural space, and the clinician must be certain that all of the side holes of the catheter are within the pleural space. The pigtail catheter is then attached to suction. These patients should be admitted for observation overnight.

A pneumothorax that occurs in the setting of chest wall trauma should be treated with a tube thoracostomy to drain a possible coexisting hemothorax. These patients also require admission to the hospital and close monitoring.

The major controversy in the management of spontaneous pneumothorax arises when there is less than 25% collapse, and revolves around whether to allow the air to reabsorb spontaneously or to actively remove the air. It is estimated that pleural air is spontaneously reabsorbed at a rate of 1.0% to 1.5% of the volume of the hemithorax per day. Therefore, a small pneumothorax (less than 15%) would be expected to be reabsorbed within 10 to 15 days. A conservative approach would be to allow spontaneous reabsorption in asymptomatic young patients with a primary spontaneous pneumothorax of 15% or less. Some less conservative practitioners would increase this threshold for more active treatment to 25%. Those with three or more recurrences of a spontaneous pneumothorax are usually considered candidates for thoroscopic surgery.

Management of pneumomediastinum is conservative. It is essential, however, to exclude potentially catastrophic causes such as Boerhaave syndrome (esophageal rupture), which has a high mortality. A contrast-medium–enhanced esophagram is usually recommended in all patients with spontaneous pneumomediastinum,¹² although many clinicians choose to observe patients who are minimally symptomatic, appear well, and have developed pneumomediastinum after straining or vigorous Valsalva maneuvers.

DISPOSITION

Appropriate disposition of patients with spontaneous pneumothorax depends on the size of the pneumothorax, the therapeutic approach chosen, the reliability of the patient, and the availability of outpatient follow-up.

Patients with a small primary spontaneous pneumothorax, for which the physician has opted for conservative management (i.e., observation and spontaneous reabsorption), should have a follow-up radiograph within 24 hours to make sure the pneumothorax has not enlarged. If it has not, a follow-up radiograph should be performed in 7 to 10 days. Patients should be instructed to return for any increase in shortness of breath or chest pain or the development of fever.

Patients who have undergone placement of a pigtail catheter or a tube thoracostomy must be admitted to the hospital. The catheter or thoracostomy tube is connected to continuous suction. These patients do not require monitoring and do not require admission to an intensive care unit unless there is significant underlying pulmonary or cardiac disease.

Patients with spontaneous pneumomediastinum and a negative contrast-medium–enhanced esophagram may be discharged as long as they are highly reliable and have close outpatient follow-up arranged. Antibiotics are unnecessary if the esophagram is normal.

COMMON PITFALLS

- Spontaneous pneumothorax and spontaneous pneumomediastinum are diagnoses of exclusion. It is essential to consider other causes, including trauma, underlying pulmonary disease, infection, and malignancy.
- Management of spontaneous pneumothorax by observation alone can save hospitalization and health-care costs only if employed in the appropriate circumstances and only if the patient is compliant and receives appropriate discharge instructions.

CHAPTER 150

Pulmonary Embolism

Susan M. Dunmire

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Identifying and diagnosing the patient with pulmonary embolism (PE) remains one of the greatest challenges facing the emergency physician. Approximately 10% of patients with PE die within the first hour. Of the remaining patients, only about one-third are correctly diagnosed. The mortality of undiagnosed PE is estimated to be 30%.

The patient who has suffered a PE often presents with nonspecific signs and symptoms that may mimic a long list of both benign and life-threatening illnesses. The absence of a definitive noninvasive diagnostic test and the consequences of a missed diagnosis make evaluation a formidable challenge. Consequently, the emergency physician must always consider PE in any patient presenting with chest pain, shortness of breath, syncope, or unexplained hypoxemia or tachycardia. Once the possibility of a PE enters the differential diagnosis, it is the responsibility of the emergency physician to pursue the diagnosis until it can be adequately confirmed or ruled out. In the past several years, diagnostic tests have been added to aid in diagnosing PE and newer treatment modalities are now available.

CLINICAL PRESENTATION

PE occurs when a substance (usually thrombus, air, fat, or amniotic fluid) lodges in the pulmonary vasculature, resulting in an obstruction of blood flow to that particular portion of the lung. Virchow's triad of hypercoagulability, venostasis, and intimal damage to the blood vessel wall remains the basis for all risk factors for pulmonary thromboembolism (Table 150.1). However, it is important that the clinician recognize that 10% to 15% of patients with PE have no demonstrable risk factors at the time of presentation. The single most important risk factor is a history of deep venous thrombosis (DVT) or PE, which increases the incidence of PE 15- to 30-fold.³ Another important risk factor is hypercoagulability. A family history of DVT or PE at a young age may be suggestive of an inherited disorder of coagulation or thrombolysis. All three trimesters of pregnancy place the mother at increased risk for PE due to hypercoagulability, but it is often forgotten that this risk extends for a 3-month period postpartum. Central venous catheters in all locations are another important source of thromboemboli. One study of femoral catheters found a 25% incidence of lower extremity thrombus after the catheter was removed. While the presence of a risk factor may elevate the clinician's level of suspicion of a PE, it is important to reiterate that the absence of risk factors should not lower this level of suspicion.

Hypercoagulable state
Pregnancy or recently postpartum
Estrogen therapy
Protein C or S deficiency
Malignancy
Antithrombin III deficiency
Prolonged immobilization
Recent surgery
History of PE or DVT
Trauma (pelvis and lower extremities)
Burns
Obesity
Congestive heart failure
Central venous catheters
Intravenous drug abuse
Systemic lupus
Ulcerative colitis

TABLE 150.1. Risk Factors for Pulmonary Embolism

The presenting signs and symptoms of PE depend on the size of the thrombus load and the extent of preexisting cardiopulmonary disease. Healthy patients are often asymptomatic, whereas a patient with significant cardiopulmonary disease may not tolerate a relatively small embolus and may experience syncope or cardiac arrest.

Stein and Henry²⁴ have noted that patients with angiographically documented PE tend to have one of three basic clinical presentations. The first group has massive PE and presents with circulatory collapse. The second group has small emboli and resultant pulmonary infarction. These patients complain of pleuritic chest pain and hemoptysis and frequently have a higher PaO₂ than the other groups. The third group presents with unexplained dyspnea. These patients experience larger emboli, resulting in a higher incidence of hypoxemia and electrocardiogram (ECG) changes, and are more likely to have a positive ventilation-perfusion (V/Q) scan.²⁴

Among patients with angiographically proven PE, the most common symptoms are dyspnea (81%), pleuritic chest pain (73%), and cough (60%). Chest wall tenderness reproducing the patient's chest pain is not uncommon in PE and should not mislead the clinician into concluding that the pain is musculoskeletal in origin.⁴ Syncope is a common presentation of PE in the elderly.⁷

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of PE is extensive. The chest pain associated with PE can vary from the more typical pleuritic pain to reproducible pain with palpation of the chest wall to a substernal heaviness mimicking myocardial infarction. The ECG and cardiac isoenzymes may help to differentiate a myocardial infarction from a PE, but not in all cases. Electrocardiographic changes associated with PE include tachycardia and, less commonly, right heart strain (right axis deviation and/or the classic S1Q3T3 pattern).

Pneumonia is the most common "misdiagnosis" in autopsy-proven PE. Fever is present in more than 40% of patients with PE and, in some cases, may be quite high (39°C to 40°C). Common abnormalities found on chest x-ray include atelectasis, pleural effusions, and infiltrates.

The clinician should be particularly careful in making a diagnosis of "pleurisy" or "musculoskeletal chest pain." To diagnose musculoskeletal chest pain, a specific injury must be identified, and the pain should not only be reproducible with both palpation and motion, but also be attributable to a particular muscle group. Pleurisy is a diagnosis of exclusion once PE has been ruled out. A sudden onset of pleuritic chest pain should be worrisome to the clinician and mandate further investigation.

EMERGENCY DEPARTMENT EVALUATION

Evaluation of the patient with suspected PE begins with a careful history and investigation of potential risk factors. Initial clinical testing should include an ECG and a chest x-ray. An ECG can help to eliminate other diagnostic possibilities, such as myocardial infarction and pericarditis. A chest x-ray can rule out pneumothorax or pneumomediastinum, but PE is often associated with many nonspecific findings. The chest x-ray is also necessary for interpretation of a V/Q scan.

The value of an arterial blood gas in the workup of suspected PE is debatable. Although hypoxemia is present in the majority of patients with PE, a normal PaO₂ does not exclude the diagnosis. A retrospective study of patients with proven PE found that 29% of patients under 40 years of age (but only 3% of patients over 40) had a PaO₂ of greater than 80 mm Hg.¹² Nor does a normal A-a gradient rule out the diagnosis of PE. One study found that 35% of patients with a documented PE had a

normal PaO₂ and a normal A-a gradient.¹⁴

There has been great interest in the use of D-dimer levels in the evaluation of suspected PE. Plasma D-dimers are degradation products of cross-linked fibrin, and levels are elevated in diseases with thrombus formation. Several rapid quantitative D-dimer tests have become available, and some have been reported to be as accurate as the more time-consuming and expensive standard ELISA.^{6,17} An elevated D-dimer level is a nonspecific finding. The potential utility of a normal D-dimer level (less than 500 ng/mL) lies, however, in its negative predictive value.^{5,18} That is, a normal D-dimer level in a patient with a low clinical suspicion of PE may make further testing for PE (e.g., V/Q scan) unnecessary.

V/Q scanning remains the initial diagnostic test for PE in most medical centers. The perfusion scan is performed by injecting an infusion of radioisotope-labeled microaggregates of albumin. Normally, there is an even distribution of blood flow throughout the lungs. The ventilation scan is performed by having the patient inhale a radioactive gas or aerosol. PE initially causes a perfusion defect with minimal changes in ventilation (V/Q mismatch). As splinting and air-space collapse occur, ventilation also decreases in the affected area.

V/Q scans are generally read as normal, low probability, intermediate probability, or high probability. The PIOPED (Prospective Investigation of Pulmonary Embolism Diagnosis) study delineated the importance of combining the clinician's level of clinical suspicion for PE with the result of the V/Q scan ([Table 150.2](#)).²⁶ Only 2% of patients with a normal V/Q scan and a low clinical suspicion of PE were found to have PE on pulmonary angiography, whereas 96% of patients with a high-probability V/Q scan and a high clinical suspicion had PE.²⁵ A more recent study of 536 patients with a low clinical suspicion of PE and a low-probability V/Q scan revealed no deaths attributed to PE at 6-month follow-up.¹⁹

Clinical Suspicion	V/Q Results			
	High	Interm.	Low	Normal or Near-Normal
High	96%	66%	40%	NA
Intermediate	88%	38%	16%	6%
Low	50%	16%	4%	2%
All patients	87%	30%	14%	4%

NA, not applicable.
Adapted from The PIOPED Investigators. Value of the ventilation-perfusion scan in acute pulmonary embolism: results of the prospective investigation of pulmonary embolism diagnosis (PIOPED). *JAMA* 1992;267:1273-1278.

TABLE 150.2. Probability of Pulmonary Embolism Based on Clinical Suspicion and Results of Ventilation-Perfusion Scan

However, the difficulty with the V/Q scan lies in the fact that a substantial proportion of patients have low-probability or intermediate-probability V/Q scans. In the PIOPED study, these patients had an overall incidence of angiographically documented PE of 14% and 30%, respectively. Among those with a low-probability scan, the incidence of PE was 4% to 40%, depending on the estimated clinical likelihood of PE; the corresponding figures for patients with an intermediate-probability scan were 16% to 66%. Thus, in individuals with these “indeterminate” V/Q results, other diagnostic modalities are required to either establish or exclude the diagnosis. Duplex Doppler ultrasound of the lower extremities may be helpful at this point if it is positive. However, if the ultrasound is negative, the clinician must proceed with pulmonary angiography.

Pulmonary angiography remains the “gold standard” diagnostic test for PE against which all other tests are measured. The disadvantages of this test are its invasive nature and administration of iodinated contrast. The morbidity rate for pulmonary angiography is approximately 4% and consists of contrast allergy, cardiac arrhythmias, and cardiac perforation. The mortality rate is approximately 0.3% and is largely limited to patients with pulmonary hypertension.¹⁶

The diagnostic approach to suspected PE can thus be summarized as follows: If the clinician has a low clinical suspicion for PE and the V/Q scan is read as either normal or low probability, PE can be effectively ruled out. Similarly, if there is an intermediate or high clinical suspicion for PE and the V/Q scan is read as high probability, the likelihood of PE is generally high enough to initiate treatment. For other combinations of clinical likelihood and V/Q scan results, further testing is indicated. The role of D-dimer testing and other newer diagnostic modalities in this scheme remains to be investigated.

Helical computed tomography (CT) scanning has shown considerable promise as a diagnostic tool for suspected PE. It is noninvasive and is reported to have a sensitivity and specificity for the diagnosis of PE that approaches that of V/Q scanning.^{11,21} However, the sensitivity of helical CT in detecting subsegmental emboli is significantly worse.¹⁵ The clinical significance of these small emboli is not known. Other limitations of helical CT include variability of its reported sensitivity and specificity (depending on the level of expertise of the radiologist), a requirement for iodinated contrast, and the necessity for the patient to breath-hold for 20 seconds. Helical CT is particularly valuable in ruling out other disease processes that can mimic PE, such as pneumonia and thoracic aortic dissection. Some centers use the V/Q scan as the diagnostic tool of choice in the young patient with a normal chest x-ray, but prefer helical CT in the older patient or in the patient with an abnormal chest x-ray.

Transesophageal echocardiography (TEE) is useful in the diagnosis of massive PE. It has the advantage of being able to be performed at the bedside in a hemodynamically unstable patient. Findings on TEE that are suggestive of massive PE include right ventricular dysfunction, right ventricular dilatation, and, possibly, visualization of the thrombus.^{22,25}

EMERGENCY DEPARTMENT MANAGEMENT

Heparin remains the cornerstone of therapy for PE. Prompt anticoagulation with heparin has been shown to reduce mortality from PE to less than 10%.^{1,2} In patients with a moderate-to-high clinical suspicion of PE and no contraindication to anticoagulation, heparin should be initiated while awaiting diagnostic studies. Weight-based dosing of heparin has been shown to be optimal.²⁰

Heparin loading dose: 80 U/kg
Heparin maintenance dose: 18 U/kg/h

Low-molecular-weight heparin has been shown in several studies to be as effective as heparin in the treatment of DVT and PE.^{13,23} Its advantages over heparin include the possibility of home therapy and reduced hospitalization costs. Currently, enoxaparin (Lovenox) is the only low-molecular-weight heparin preparation approved by the Food and Drug Administration. It is approved for treatment of DVT with or without PE, but it is not yet approved for therapy of PE alone. The recommended dosage is 1 mg/kg subcutaneously every 12 hours.

Thrombolytic therapy should be initiated in any hemodynamically unstable patient with PE. In a patient with clinically suspected PE who is too unstable to undergo V/Q scanning or helical CT, bedside echocardiography is an ideal diagnostic tool. If it is unavailable, the clinician must weigh the potential risk of thrombolysis against that of progressive cardiopulmonary compromise from a massive pulmonary embolus. While heparin can prevent further clot formation, it is ineffective in dissolving already existing clot and therefore will not provide hemodynamic improvement in cases of massive PE. Streptokinase, urokinase, and recombinant tissue plasminogen activator (r-TPA) are all approved for the treatment of massive PE, but r-TPA is recommended because it produces a faster improvement in hemodynamic parameters than do the other two (usually within 2 hours).^{8,10} The usual dosage of r-TPA is 100 mg over 2 hours, but studies have investigated a rapid “bolus” protocol aimed at improving hemodynamic parameters as rapidly as possible.⁹

DISPOSITION

Any patient with an intermediate- or high-probability V/Q scan or a positive helical CT scan should be anticoagulated and admitted to the hospital. Warfarin therapy

should be initiated as soon as possible, and patients can be discharged to home once the INR is in the therapeutic range. Patients who qualify for low-molecular-weight heparin therapy may be given the first dose of low-molecular-weight heparin and warfarin in the emergency department and discharged to home. These patients require instruction for self-administration of the low-molecular-weight heparin and careful follow-up.

Patients who are hemodynamically unstable and require thrombolytic therapy may require transfer to a tertiary level facility for intensive care monitoring. It is important to initiate thrombolytic therapy in the hemodynamically unstable patient prior to transfer.

COMMON PITFALLS

- Failing to consider PE in any patient presenting with unexplained tachycardia, tachypnea, and/or hypoxemia. The clinical presentation of PE is quite variable and often nonspecific.
- Dismissing chest wall tenderness as musculoskeletal in origin when there are other clinical findings that suggest PE. PE can present with chest wall tenderness.
- Failing to recognize that PE commonly presents atypically in the elderly (often with syncope).
- Dismissing the possibility of PE because the patient has no identifiable risk factors. Assuming that a normal PaO₂ and A-a gradient rule out PE.
- Failing to initiate heparin therapy before diagnostic testing when there is a clinical suspicion of PE and no contraindication to anticoagulation.
- Failing to initiate thrombolytic therapy as early as possible in the hemodynamically unstable patient when there is a strong clinical suspicion of PE. Bedside echocardiography is the fastest and easiest diagnostic test for massive PE.

CHAPTER 151 *Hemoptysis*

Steven J. Parrillo

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Few complaints bring a patient to medical attention as readily as the coughing up of blood. Hemoptysis is a common symptom in adults, but it is quite uncommon in children. Etiologies and presentations are diverse. Adding to the diagnostic challenge is the fact that many cases of presumed hemoptysis are actually due to ear, nose, and throat (ENT) or gastrointestinal bleeding, so-called pseudohemoptysis. Although typically indicative of primary pulmonary pathology, hemoptysis can also result from numerous systemic illnesses. The severity of bleeding often does not correlate with the gravity of the underlying disease. As a matter of fact, the majority of major bleeding occurs in patients with bronchiectasis and bleeding diatheses, while minor bleeding is usually the case with cancer and bronchitis.

Many pathophysiologic mechanisms account for the bleeding. Primary bleeding sources include bronchial and nonbronchial arteries. The direct cause of bleeding varies greatly, depending on underlying etiology. [Table 151.1](#) lists the cause or causes of bleeding for several common problems. Several mechanisms may be responsible for bleeding in any given patient. Exsanguination is rarely the ultimate cause of death in hemoptysis. Rather, blood fills alveoli, impairing gas exchange. Death is secondary to hypoxemia.

Malignancies: invade vessels, or the tumor itself may become necrotic
Inflammatory and infectious problems: vascular engorgement of the tracheobronchial mucosa
Bronchiectasis: associated with abnormal vascular anastomoses between bronchial and pulmonary arteries
Lung abscesses: bronchial ulceration and necrosis
Mycetomas of cavitary TB: rupture and cause life-threatening hemorrhage
Left ventricular failure or mitral stenosis: increased intravascular pressure with capillary and venous rupture
Pulmonary embolism: infarction of lung parenchyma
Goodpasture syndrome: breakdown of the alveolocapillary basement membrane
Aortic aneurysm: erosion into adjacent vascular structures
Coagulopathy: exacerbation of an underlying reason for bleeding
Cocaine: intense vasoconstriction with cell injury

TABLE 151.1. Mechanisms of Bleeding in Hemoptysis

CLINICAL PRESENTATION

The overall picture of hemoptysis has changed in recent years. The most common causes are infections, malignancy, bronchiectasis, bronchitis, and cardiovascular disorders.^{5,8,17} Although tuberculosis (TB) was once a leading infectious cause, it is now much less common than pneumonia and bronchitis, except in areas of high TB prevalence, such as New York City.^{8,12} Only time will tell if the new multidrug-resistant strains will bring about a resurgence of TB.

In children, cystic fibrosis, congenital heart disease, and trauma head the list of causes of hemoptysis, not vascular abnormalities and neoplasms, as was once believed.^{5,6} Cystic fibrosis may be associated with recurrent, severe bleeding in both children and young adults. A case presentation reported significant hemoptysis in two children with bronchiolitis obliterans organizing pneumonia.¹³

The prevalence of immunocompromised patients has prompted study of common causes in that population. Although many of the data come from hospitalized patients, it appears that the vast majority of cases are infectious, mostly due to bacterial pneumonias. Even in that group, TB is not a common cause of respiratory tract bleeding.¹⁵

With the advent of thrombolytic therapy, researchers have sought to determine whether hemoptysis is a common problem. It appears that it is not.⁴

Goodpasture syndrome may present with hematuria and hemoptysis, as may vasculitis. Occult malignancy should always be considered in a cigarette smoker, even with a normal physical examination and chest radiograph.^{9,11}

[Table 151.2](#) lists the common causes of hemoptysis by category.

INFLAMMATORY
Bacterial pneumonia
Chlamydia pneumoniae
Coccidioidomycosis
Cryptococcosis
Histoplasmosis
Mycobacterium tuberculosis
Pneumocystis carinii pneumonia
Rocky Mountain spotted fever
Syphilis
Wegener granulomatosis
NEOPLASIA
Adenocarcinoma
Squamous cell carcinoma
Small cell carcinoma
HAEMATOLOGIC
Disseminated intravascular coagulation
Leukemia
Myelodysplastic syndrome
RENAL
Goodpasture syndrome
Wegener granulomatosis
OTHER
Chronic bronchitis
Cocaine
Coronary artery disease
Emphysema
Heart failure
Idiopathic
Mitral stenosis
Systemic sclerosis
Vasculitis

TABLE 151.2. Common Causes of Hemoptysis

DIFFERENTIAL DIAGNOSIS

Hemoptysis must be confirmed before the broad differential diagnosis can be considered. An appropriate, focused history and physical examination should eliminate gastrointestinal and otolaryngologic sources. Gastrointestinal bleeding can usually be identified by its dark red color, the presence of clots and food particles, and an acid pH. True hemoptysis is typically bright red, frothy, and normal to alkaline in pH. Mouth, throat, and nasopharyngeal sources of bleeding can usually be visualized, sometimes with direct, indirect, or fiberoptic laryngoscopy.

EMERGENCY DEPARTMENT EVALUATION

Whenever bleeding is an issue, hemodynamic stabilization takes precedence over efforts to make a definitive diagnosis. For that reason, the first question that needs to be answered concerns the rate and quantity of bleeding.

“Massive” hemoptysis is usually defined as bleeding of 600 mL within 24 to 48 hours, or at a rate of 100 mL/h or more. Differentiating massive from “submassive” or minor bleeding carries both diagnostic and prognostic implications, but may not be easy to do in the emergency department (ED). Mortality for the massive bleeding group is high (12% to 50%).⁸ Causes of mortality include asphyxiation (due to airway obstruction with blood) and exsanguination. Most series list TB and bronchiectasis as the most common causes of massive hemoptysis in adults. Other diseases associated with massive bleeding include lung abscess, malignancy, and aspergilloma. In children, massive bleeding is a predictor of mortality in congenital heart disease.⁵

Next, baseline cardiopulmonary status and overall physical condition must be determined. History, physical, and laboratory studies can help evaluate the patient's ability to respond to the physiologic stress of hemoptysis and the therapy it necessitates. To the patient with limited cardiopulmonary reserve or significant underlying disease, almost any amount of bleeding may prove detrimental. Indeed, a more useful definition of *massive hemoptysis* may be bleeding into the tracheobronchial tree at a rate that poses a threat to life.¹⁴

Finally, efforts to determine the cause should begin. “Baseline” ED evaluation includes history, physical examination, and chest radiograph. Depending on the clinical scenario, many clinicians would also do a complete blood count, urinalysis, arterial blood gas analysis, coagulation studies, electrocardiogram, and sputum evaluation (Gram stain, AFB, cultures). Definitive diagnosis may require a ventilation–perfusion scan, high-resolution¹² or standard computed tomography scans, bronchoscopy, bronchography, sputum cytology, pulmonary function testing, angiography, or specialized sputum studies. Most of those tests will not be done in the ED. Aggressive management must occur at the same time as evaluation. Some diagnostic modalities, most notably bronchial artery embolization, are both diagnostic and therapeutic.^{3,7}

It is worth noting that up to 22% of cases will have no identifiable etiology, even after exhaustive study.¹⁷ Those patients might then be classified as having idiopathic or cryptogenic hemoptysis. It is presumed that subtle airway or parenchymal disease is responsible for bleeding.

EMERGENCY DEPARTMENT MANAGEMENT

The primary goals of therapy are prevention of asphyxia and exsanguination, termination of bleeding, and treatment of the underlying cause.

Airway control and adequate oxygenation are the first priorities. Endotracheal intubation, which may be technically challenging, is the procedure of choice. Large tubes facilitate suctioning. Bag-valve-mask ventilation may be problematic in the patient who is briskly bleeding, because it may spread blood further through the tracheobronchial tree. Separate intubation of left and right main-stem bronchi may be achieved by someone skilled in the use of either the Carlens or Robertshaw tube. Intubation over a fiberoptic laryngoscope may allow selective intubation of one bronchus but requires skills that most emergency physicians have not learned. Empiric intubation of a main-stem bronchus will probably be necessary in that uncommon patient with severe hemorrhage.

In cases involving significant hemoptysis, the patient is placed in the Trendelenburg position, with the suspected bleeding source dependent. This position may protect the uninvolved lung from filling with blood and, in so doing, maximize gas exchange.

Isotonic fluids and blood products should be infused, as indicated, through large-bore intravenous lines, recognizing that some authors question the wisdom of initiating infusion before bleeding has been controlled. All patients with significant hemoptysis should be placed on a cardiac monitor. Some will require continuous hemodynamic monitoring.

Although most causes of bleeding require definitive therapy beyond the scope of emergency medical practice, there are times when treatment should begin in the ED. Examples include some coagulopathies and some infectious etiologies.

Pulmonary, ENT, and surgical consultants will soon attempt to localize the bleeding site, especially if surgery is being considered. Techniques including bronchoscopy and angiography may be both diagnostic and therapeutic.¹⁴ Consultants may employ topical vasoconstrictors and catheter tamponade to control bleeding. Intravenous pitressin therapy and bronchial artery embolization have been used successfully in patients with cystic fibrosis.^{2,7} Selective embolization carries the risk of systemic embolization. Although success rates of 80% are frequently cited, spontaneous recanalization may occur and may cause more bleeding. Flexible endoscopy may be done at bedside. Rigid endoscopy is usually performed in the operating room (OR).

Hemoptysis may be best controlled by dealing with the source of the problem: mitral valve surgery for stenosis or nephrectomy plus steroids in Goodpasture syndrome. Bleeding associated with cystic fibrosis may respond to intravenous pitressin therapy.²

There are times when surgery is the only way to control bleeding. The patient and the operating surgeon will benefit from accurate localization, identification of cause, and preoperative stabilization.¹⁰

DISPOSITION

Patients with significant bleeding should be admitted to an intensive care unit setting, preferably on the service of the surgeon who will go to the operating room. As in all situations of potentially exsanguinating hemorrhage, the OR must be readily available. Transfer to an appropriate facility must be arranged when definitive care is not available at the presenting institution. Stabilization must address airway control and hemodynamic needs. Given the difficulties of trying to establish an airway in a bleeding patient, consideration should be given to prophylactic intubation before transfer. At the very least, personnel effecting the transfer must be competent in emergency airway management.

Patients in the “submassive” group require an individualized approach. Many can be referred to an appropriate physician after the initial ED evaluation and institution of therapy when appropriate. It would be prudent to suggest to discharged patients that bronchoscopy may be an important part of the diagnostic process, especially in males, smokers, patients over 40, those with a localized abnormality on chest radiograph, and those in whom bleeding has lasted more than 7 days.¹⁶ Hemoptysis is a frightening symptom requiring patient reassurance.

Follow-up instructions must be specific. They should include the name of the physician and the time frame required. Patients must be reliable and hemodynamically stable. A conversation between the emergency physician and the primary care physician or consultant would be wise.

Patients at high risk for deterioration—those with limited pulmonary reserves or respiratory compromise—should be hospitalized. Those with mycetomas or cavitary TB are also at high risk.¹ Patients with significant underlying disease should be admitted. Immunocompromised patients may need to be admitted if the cause of bleeding is infectious. The possible public health risk of blood-borne diseases may also be a factor in the disposition decision.

COMMON PITFALLS

- Hemoptysis must be recognized and differentiated from nasopharyngeal or gastrointestinal bleeding.
- The bleeding rate must be estimated as accurately as possible. Dismissing a few ounces of hemoptysis as trivial during a brief evaluation is a potentially lethal error.
- Each patient's cardiopulmonary reserve and overall clinical status must be evaluated. Even a small amount of hemoptysis may have potentially devastating consequences for a patient with significant underlying disease.
- The patient must be closely monitored. Clinical deterioration may respond to such simple measures as repositioning the patient or performing endotracheal intubation, thereby preventing the further spread of blood through the lungs.
- In situations requiring transfer to a higher level of care, patient stability may require attention not only to hemodynamic status, but also to the airway. Prophylactic intubation should be considered.
- Radiographic lesions may be subtle. The emergency physician must obtain the radiologist's final report on all patients with hemoptysis and relay that report to

the patient or consulting physician.

CHAPTER 152

Sarcoidosis

Steven J. Parrillo and Christopher C. Ros

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Sarcoidosis is a multisystem, chronic granulomatous disease with diverse manifestations and a variable clinical course. It is characterized by a heightened cellular immune response at sites of disease activity; the lungs are the primary target organ and are involved in most cases.⁸ A number of etiologies have been postulated, including exposure to infectious agents (especially *Mycobacterium tuberculosis*), noninfectious environmental agents (especially beryllium), and autoantigens.⁸ Curiously, as of 1995 only nine human immunodeficiency virus (HIV)-infected patients had been reported to have coexistent sarcoidosis.^{4,6}

In the United States, the prevalence of sarcoidosis is about five per 100,000 in the White population and about 40 per 100,000 in the Black population. Among Black patients, women usually outnumber men 2 to 1. Although the peak incidence is in the middle years of life (20 to 40 years of age), the disease has been reported in children and the elderly. Sarcoid has also been identified in twins (monozygotic more commonly than dizygotic) and in husband-wife pairs.³ The vast majority of cases resolve spontaneously, with or without treatment. Indicators of a favorable prognosis include acute manifestations of inflammation, such as erythema nodosum, polyarthritides, fever, and bilateral lymphadenopathy. Poor prognostic indicators include Black race, lupus pernio, and chronic bone, lung, or nasopharyngeal involvement.⁷

CLINICAL PRESENTATION

In the United States, approximately 20% of sarcoidosis patients are asymptomatic, the diagnosis being suspected only because hilar adenopathy is seen on a chest film (Table 152.1). This group may need only to be referred to confirm the diagnosis. For the emergency physician, however, the more important issue is when to suspect and treat active disease.

Characteristic	Incidence (%)
Age	
<40	75
>40	25
May occur in the elderly	
Gender	
Male	66
Female	46
Race	
Black	90
Caucasian	10
Asymptomatic	10-20
Acute/subacute (fever, fatigue, malaise, anorexia, weight loss, respiratory symptoms)	20-40
Insidious (respiratory complaints without constitutional symptoms)	40-70

TABLE 152.1. Characteristics at Clinical Presentation³

In 20% to 40% of cases, acute or subacute sarcoidosis develops over a period of several weeks. The symptoms are usually mild and may include fever, malaise, anorexia, and weight loss. Most patients develop a more indolent form that develops over months. Most have vague respiratory complaints. Unfortunately, it is this group that is more likely to develop chronic disease with significant organ damage.

As a multisystem disease, sarcoidosis can present with symptoms referable to a variety of organ systems. The lungs, however, are almost always almost involved, and the clinical presentation is often dominated by the presence of interstitial lung disease. These patients are dyspneic, especially on exertion, and have a dry cough. Physical examination may reveal nothing more than dry rales, but wheezing suggestive of reactive airway disease may be heard. Ninety percent have an abnormal chest radiograph.

The radiographic findings of sarcoid are characteristic, with bilateral mediastinal lymphadenopathy being the classic, as well as the most common, finding (Fig. 152.1).

Figure 152.1. Typical type I radiograph. (Courtesy of K. Murray and M.D. Dalinka, Department of Radiology, Hospital of the University of Pennsylvania, Philadelphia.)

Radiographic evaluation is helpful to define pulmonary involvement, rather than stage the disease. There are three or four types of involvement shown on chest films (Table 152.2). Type I radiographs show bilateral hilar adenopathy without parenchymal changes. Type II films demonstrate bilateral hilar adenopathy plus diffuse parenchymal changes, but no fibrosis. In type III, there are diffuse parenchymal changes but no adenopathy. Some authors add a IV, showing fibrotic changes, whereas others subdivide III.

Stage	% of Patients	Prognosis (Likelihood of Resolution) (%)
0	5-10	-
I	50	60
II	25-30	46
III	15	12

TABLE 152.2. Radiographic Stage and Prognosis in Sarcoidosis

Radiographic typing has some limited prognostic significance, in that type I changes usually resolve, while changes in the other types are chronic. It is important to recognize that these are not stages of the disease, but represent different manifestations.³

Although myocardial sarcoidosis is found in 25% of autopsied cases, in only about 10% has there been an abnormal electrocardiogram (without clinical symptoms). Conduction disturbances, including complete heart block, are the most common cardiac presentations and may be the cause of death. Life-threatening ventricular dysrhythmias are also seen. As many as 25% of those with cardiac dysfunction die of congestive heart failure.⁹

Both hypercalciuria (30%) and hypercalcemia (10%) are common and may lead to nephrocalcinosis and nephrolithiasis. Glomerular disease and renal arteritis may occur, and hypertension is common. Primary renal infiltration with sarcoid granulomas is rare.³

Hypercalcemia may arise from increased intestinal calcium absorption due to overproduction of 1,25-dihydroxyvitamin D₃ by activated macrophages. Corticosteroids can control hypercalcemia by inhibiting the action of this hormone, but severe hypercalcemia in sarcoidosis is unusual. Hypercalcemia needs to be corrected, and treatment begins with conservative measures, such as decreasing oral calcium intake before corticosteroids are considered.¹¹

Approximately 25% of patients have eye involvement, most commonly anterior uveitis. Uveitis may develop rapidly and may become chronic. Other lesions include posterior uveitis, conjunctivitis, cataracts, and retinal hemorrhages.

Superficial lymphadenopathy is a frequent finding. Only 20% to 40% of patients have hepatomegaly or abnormalities of liver function. Portal hypertension is rare. Splenomegaly is seen in only 10%. Clinical disease is uncommon.

Skin lesions occur in about one-fourth of patients. Specific lesions include lupus pernio (Fig. 152.2), plaques, and symmetric maculopapular eruptions. The most common lesion is erythema nodosum, a hypersensitivity reaction most commonly seen in women of childbearing age but not specific to sarcoidosis.⁹

Figure 152.2. Lupus pernio. (Courtesy of Gerald S. Lazarus, MD, Department of Dermatology, Hospital of the University of Pennsylvania, Philadelphia.)

Joint involvement is very common in sarcoidosis, with 25% to 50% of patients suffering from arthralgias or true arthritis, mostly in larger joints. Both can be migratory and are usually transient. The arthritis associated with erythema nodosum can be incapacitating and may require corticosteroid therapy. Chronic arthritis is associated with chronic persistent disease and is most frequently seen in Black patients with skin involvement.³

Nasal and laryngeal involvement occurs infrequently but may cause severe airway compromise.

Only 5% of patients have neural involvement, with multiple cranial neuropathy (e.g., peripheral seventh nerve palsy) being most frequent. Aseptic meningitis and peripheral neuropathy occur occasionally. Seizures are infrequent. Neurologic symptoms usually improve with corticosteroid therapy.⁷

Two other syndromes have been described. Lofgren syndrome includes erythema nodosum and radiographic findings of bilateral hilar adenopathy, and may also be associated with arthritis of small and medium joints. Patients with the Heerfordt-Waldenstrom syndrome have fever, anterior uveitis, facial nerve palsy, and parotid enlargement.³

It is worth noting that sarcoidosis usually improves during pregnancy.³

DIFFERENTIAL DIAGNOSIS

If there were to be a “classic” presentation of sarcoidosis, it would be of a young adult suffering from a combination of fever, dyspnea, blurred vision, and erythema nodosum, with a chest radiograph showing bilateral hilar adenopathy. Most cases, of course, are not that typical. Virtually all of the diseases to be considered in the differential diagnosis have the propensity to occur in almost any anatomic location. Sarcoidosis is most likely to be confused with tuberculosis (or other mycobacterial infections), lymphoma, and some fungal disorders (e.g., coccidioidomycosis). Other diseases to be considered include leprosy, berylliosis, and hypersensitivity pneumonitis.

HIV infection must also be considered in patients suspected of having sarcoidosis. Patients with HIV commonly have several of the features found in sarcoid, including chest radiograph abnormalities, lymphocytopenia, and a positive gallium-67 chest scan.⁶

A definitive diagnosis of sarcoidosis cannot be made with certainty on initial clinical presentation in an emergency setting, although the clinical suspicion may be high. The patient who already carries the diagnosis of sarcoidosis, however, may present with a complication of the disease or a concurrent, perhaps unrelated, illness and should be evaluated accordingly.

EMERGENCY DEPARTMENT EVALUATION

The initial history should be directed to ascertain the duration and severity of the patient's symptoms, a previous diagnosis of sarcoidosis, and any previous need for

corticosteroid therapy.

The major complications of systemic sarcoidosis include upper airway obstruction from laryngeal involvement; cardiac dysrhythmias and conduction disturbances (especially heart block); congestive heart failure; advanced pulmonary fibrosis with cor pulmonale, superimposed tuberculosis, or bacterial infection; sudden loss of vision from ocular complications; incapacitating arthritis or arthralgias; space-occupying lesions of the brain and hydrocephalus; and hypercalcemia with its attendant cardiac, neurologic, and renal sequelae. Severe thrombocytopenia may occur. Abrupt corticosteroid withdrawal may cause the signs and symptoms of adrenal insufficiency.^{2,9,10 and 11}

Physical examination should focus first on the airway and cardiopulmonary systems, but attention should be given to all organ systems that potentially may be involved, as well as to the possibility of relative adrenal insufficiency secondary to rapid withdrawal of corticosteroid therapy.

Ocular, neurologic, skin, or joint complaints dictate the need for more specialized testing or examination. Funduscopic examination is essential in patients with altered mental status or abnormal neurologic findings.

Diagnostic studies in the emergency department should be directed toward detecting the potential problems associated with sarcoidosis. All patients should have a 12-lead electrocardiogram. Consideration should be given to ordering Holter monitoring for discharged patients. Chest radiography, pulse oximetry, and arterial blood gas analysis may be indicated in those who have respiratory complaints. Renal function studies, electrolytes, and calcium and platelet counts should be routine.

Strict criteria must be satisfied to make the diagnosis of sarcoidosis. The emergency physician must establish compatible clinical presentations or radiographic findings, or both; histologic evidence of noncaseating granuloma; and negative special stains and cultures for other entities (e.g., acid-fast bacilli or fungi on sputum or tissue biopsy specimens). A diagnosis based on only one of these features may be misleading.⁵

Outpatient evaluation often includes serum and cerebrospinal fluid (CSF) studies, isotopic imaging studies, biopsy, and bronchoalveolar lavage. Advances in gallium scanning have improved diagnostic accuracy, but this test is not diagnostic of sarcoidosis.¹² The Kveim-Siltzbach skin test is also helpful, but requires a biopsy at 6 weeks. Most patients will eventually have a 24-hour urinary calcium determination.³ Serum and CSF angiotensin converting enzyme levels are elevated in up to 50% of patients. Bronchoalveolar lavage reveals cells consistent with the diagnosis in the majority of those with pulmonary sarcoid.¹⁰

EMERGENCY DEPARTMENT MANAGEMENT

Incapacitating disease interfering with normal life activities merits serious consideration for corticosteroid therapy. Conversely, relatively asymptomatic disease warrants an optimistic outlook and conservative management without corticosteroids. Causes of symptoms or signs other than progression of sarcoidosis must be excluded to avoid inappropriate management. Systemic corticosteroids (e.g., prednisone 40 mg/d) remain the safest and best form of treatment.

Strong indications for steroid treatment include significant pulmonary parenchymal disease, hepatic disease, hypercalcemia, myocardial disease, incapacitating arthritis, severe thrombocytopenia, posterior ocular disease, neurologic disease, laryngeal involvement, or any other vital organ impairment. Weaker indications are persistent constitutional symptoms and abnormal results of liver function tests.¹³ Local corticosteroids are used for anterior ocular and skin disease.^{2,3,7,9,11}

Patients with cardiac conduction abnormalities due to granulomatous infiltration are usually refractory to conventional pharmacotherapy and often need to be admitted to the hospital to determine the most appropriate pharmacologic or electrical therapy. Cardiac transplantation has been performed successfully in younger patients with severe heart failure. Ventricular aneurysm resection may be required to eliminate refractory dysrhythmias.^{7,9} Lung transplantation has been performed for end-stage pulmonary disease.⁷

Hypercalcemia, if severe or symptomatic, may be treated in the normal fashion while high-dose corticosteroid therapy is initiated. Milder elevations of serum calcium levels may be treated with corticosteroids alone, with frequent monitoring.¹

Although corticosteroids remain the mainstay of treatment, a number of other agents have also been used. They include methotrexate, azathioprine, cyclophosphamide, chlorambucil, cyclosporine, nonsteroidal antiinflammatories, chloroquine, and hydroxychloroquine.

Sarcoidosis clears spontaneously in half of all patients.³

DISPOSITION

The emergency physician may require the advice and assistance of a variety of specialty consultants in diagnosing and managing the patient with suspected sarcoidosis. Pulmonary, ophthalmologic, dermatologic, and neurologic consultation may be necessary before any definitive therapy is undertaken.

Patients for whom hospitalization should be considered are those with cardiac or neurologic disease, hypercalcemia, severe thrombocytopenia, or any degree of airway compromise. Hospital admission should be considered strongly for diagnostic purposes at initial presentation.

Because frequent and long-term care is usually required, the family physician, internist, or pulmonary specialist is most commonly called on to provide primary outpatient therapy for sarcoidosis.

COMMON PITFALLS

- Sarcoidosis is frequently asymptomatic and should be included in the differential diagnosis of patients with eye findings, suggestive skin lesions, hypercalcemia, persistent cough, or unexplained fever and weight loss.
- The emergency physician should resist the temptation to announce a firm diagnosis or prognosis to the patient, yet it is essential that follow-up be arranged so that a definitive diagnosis can be made and appropriate treatment begun.
- Most cases of sarcoid resolve without treatment. Specialty consultation should be obtained before treating with systemic corticosteroids and when dealing with cardiac, neurologic, or ocular disease.
- Serum calcium level should be checked in all patients with suspected or previously diagnosed sarcoidosis.
- As a rule, hypercalcemia should not be treated on an outpatient basis.
- Patients with sarcoid should have an electrocardiogram, and most should have Holter monitoring.
- The presence of wheezing may incorrectly suggest reactive airway diseases. Corticosteroids may not be indicated in this setting.

Patients with esophageal disease generally present to the emergency department in one of four ways: (1) with odynophagia, (2) with heartburn or chest pain, (3) with dysphagia, or (4) with gastrointestinal (GI) bleeding. There is often a great deal of overlap in these symptoms, however. For example, disorders causing mucosal destruction may result not only in odynophagia, but also in dysphagia, whereas certain motor disorders may cause both dysphagia and chest pain. Esophageal disease that causes bleeding is usually due to varices (see [Chapter 154](#)). Esophageal perforation is discussed in [Chapter 106](#).

ODYNOPHAGIA

CLINICAL PRESENTATION

Odynophagia refers to pain on swallowing and implies mucosal disease of the oropharynx or esophagus. Inflammation of adjacent structures may produce symptoms indistinguishable from mucosal inflammation. The pain may be described as a retrosternal ache, a burning sensation, or a stabbing pain with radiation to the back. Esophagitis typically presents as odynophagia, with or without dysphagia. Other common complaints include atypical chest pain, a sensation of feeling each bolus of food as it passes down, heartburn, or, occasionally, anorexia and weight loss. The most important immediate consequences of esophagitis are local pain and impaired oral alimentation. Rarely, the initial manifestation of esophageal disease is GI bleeding.

Infectious esophagitis should always be a consideration in immunocompromised individuals. In esophageal candidiasis, odynophagia is usually relatively mild. If symptoms are so severe that the patient consciously limits oral intake, ulcerative esophagitis of some other etiology is likely. Oropharyngeal candidiasis is noted in many patients with candidal esophagitis, but it is not a very good predictor of its presence, except in patients with the acquired immunodeficiency syndrome (AIDS).

Herpetic esophagitis is the most common viral infection affecting the esophagus, and presents with odynophagia that is typically abrupt in onset. It is also suspected when symptoms of dysphagia or odynophagia do not improve with typical antifungal medications in immunocompromised patients.⁶ Immunocompetent patients often give a history of an upper respiratory tract infection before the onset of swallowing problems, and most have skin or oral lesions of herpes simplex virus (HSV) infection. In contrast, oropharyngeal and perioral lesions are frequently absent in immunosuppressed patients.

Cytomegalovirus (CMV) esophagitis presents in a similar fashion, with odynophagia, dysphagia, and variable degrees of substernal chest pain, but nausea and vomiting seem to be more common in CMV esophagitis.

Complications of candidal or viral esophagitis are uncommon; they include hemorrhage, perforation, esophageal narrowing with stricture formation, and dissemination of infection.

The true incidence of *medication-induced* esophageal injury is unknown, because many cases are not reported in the literature and many more go unrecognized. Tablets and capsules can adhere to the esophageal wall and dissolve locally in spite of normal esophageal function. Although patients with structural abnormalities and motility disorders are more likely to develop medication-induced esophagitis, most patients have normal esophageal motility.

Patients with pill esophagitis typically report retrosternal pain, odynophagia, and dysphagia that are temporally related to ingestion of medication. A significant proportion give a history of taking the medication with little or no water. Symptoms generally improve within a couple of days, provided the medication is discontinued, but complete resolution may take several weeks, and there are no sequelae. Pill esophagitis affects the proximal esophagus, usually at the level of the aortic arch or left atrium, in contrast to reflux esophagitis, which affects the distal esophagus. The most common complication is stricture formation.

Odynophagia is usually not a prominent component of *reflux esophagitis*, which is discussed elsewhere in this chapter.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of odynophagia includes diffuse infectious causes and localized trauma or inflammation.

Candidal esophagitis is increasing in incidence, probably because of aggressive immunosuppressive therapy in patients with cancer and the emergence of AIDS. HSV esophagitis is much less common, and CMV is recognized as an important cause of infectious esophagitis in patients with AIDS as well as in bone marrow transplant patients.

Pill-induced esophagitis may be confused with other causes of esophagitis if the patient does not relate the ingestion of medication with symptoms. As with other causes of esophageal pain, cardiac disease must be excluded. The age and sex of patients with drug-induced esophagitis reflects the population group most likely to receive commonly prescribed drugs. Doxycycline (the most frequent offender in the United States) and tetracycline are more commonly prescribed in younger patients for *Chlamydia* and respiratory infections. Potassium chloride and quinidine tablets, which also cause a large number of cases of pill-induced esophagitis, are more frequently used in elderly patients. Ferrous sulfate, aspirin, and nonsteroidal antiinflammatory agents are used by patients of all ages.

Odynophagia localized to the posterior pharynx may be due to a pharyngitis or abscess. Epiglottitis is another potential concern. The patient should also be asked about the possibility of ingestion of foreign bodies or food impaction.

EMERGENCY DEPARTMENT EVALUATION

The initial history should focus first on the duration and severity of the symptoms and on the patient's ability to maintain normal oral intake. The patient should be asked about a history of diagnosed human immunodeficiency virus (HIV) infection, risk factors for HIV, or other conditions associated with an immunosuppressed state. Patients should be further questioned about a possible association of symptoms with pill ingestion or possible foreign bodies, as well as any symptoms suggestive of esophageal reflux.

Esophageal candidiasis is common in patients with AIDS and immunosuppressed individuals, but severe odynophagia that results in diminished oral intake or dehydration is uncommon in patients with candidal esophagitis alone. More than one potential pathogen may be identified in severely symptomatic patients.

The physical examination should concentrate initially on the patient's state of hydration. Blood pressure, pulse, and orthostatic changes should be noted, as well as skin turgor and the condition of the mucous membranes.

The oropharynx should be examined for oral candidal or herpetic lesions, and signs of cancer or AIDS or other possible opportunistic infections should be sought. A soft-tissue lateral neck radiograph should be obtained if a retropharyngeal or prevertebral abscess or epiglottitis is a consideration. If hydration is adequate and the patient does not otherwise appear ill, evaluation may continue on an outpatient basis.

Two options are available for further evaluation of odynophagia: barium swallow and esophagoscopy. The advantages of the barium swallow are its lower cost, lesser degree of invasiveness, and decreased risk to health-care workers and other patients. However, findings on barium swallow are often nonspecific, making endoscopy necessary. Air-contrast barium studies also provide more sensitivity, but patients with severe odynophagia are often unable to perform these tests. Endoscopy allows one to obtain tissue samples for cytology or culture and is thus usually more useful in making a specific diagnosis. Other parts of the upper GI tract can be examined at the same time, increasing diagnostic ability without adding much to the cost, duration, or risk of the procedure.

Serologic tests for CMV and HSV, although commercially available, play little role in the diagnosis of acute esophageal disease.

EMERGENCY DEPARTMENT MANAGEMENT

A number of antifungal agents have been used to treat oral and esophageal candidiasis in patients with AIDS. Ketoconazole or one of its congeners is the drug of choice. Clinical experience with local therapy, such as nystatin and clotrimazole lozenges, suggests some efficacy against oropharyngeal candidiasis, but these are generally considered inadequate for esophageal candidiasis. Symptoms may clear and oropharyngeal candidiasis may be eradicated, even in the presence of persistent endoscopically visible esophageal disease. High doses of ketoconazole may be required in patients with AIDS. The usual starting dose is 200 mg twice daily, increased to 200 mg three times a day if needed. Fluconazole is more expensive but has more reliable oral absorption, a longer half-life, and less toxicity, and it is better tolerated. Fluconazole is also associated with a higher cure rate than other antifungal agents, such as itraconazole.¹ The combination of itraconazole and flucytosine may be an effective alternative if fluconazole cannot be used.² Patients who are granulocytopenic or who are otherwise at high risk for disseminated candidiasis are candidates for intravenous amphotericin B, as are those who are not at high risk but cannot take oral medications.

Foscarnet and ganciclovir appear to be similarly effective and safe in the treatment of AIDS-related CMV esophagitis. Consequently, the choice of the anti-CMV agent should be tailored to the individual patient according to side-effect profiles.¹³ HSV esophagitis may be self-limited in the immunocompetent host, but therapy with oral or intravenous acyclovir should be instituted in immunocompromised patients.

In patients presenting with mild esophageal symptoms that do not limit oral intake, an empiric trial of antifungal therapy with ketoconazole or fluconazole is reasonable regardless of the presence or absence of oral candidiasis. If symptoms improve after 7 to 10 days of treatment, a presumptive diagnosis of esophageal candidiasis may be made and the patient is continued on chronic suppressive therapy. If symptoms have not responded to a short course of empiric therapy, the patient should proceed to endoscopy to investigate the possibility of other causes.

If *medication-induced esophagitis* is recognized early and is treated appropriately, it is generally reversible. The offending medication should be discontinued or changed to liquid form when possible. Because swallowing and salivation occur less during sleep, patients should be instructed not to take medications immediately before bedtime. Other commonsense caveats apply: Small tablets are swallowed more quickly than larger ones, oval pills better than round ones, and coated pills faster than uncoated pills. Patients should also be instructed to take medications with plenty of water and to avoid lying down shortly after ingesting their pills. Symptomatic resolution and endoscopic healing of pill esophagitis is usually evident in 3 days to 6 weeks.¹⁶

DISPOSITION

Immunocompetent patients with mild symptoms may be treated as outpatients. Referral and follow-up are appropriate for these patients, as well as for those who do not respond to initial therapy.

Patients who are experiencing severe difficulty with swallowing and are unable to maintain hydration require hospital admission. Patients at risk for disseminated infection should be admitted for intravenous therapy.

Patients with pill esophagitis should be referred to their primary care physician to ensure that timely resolution of symptoms occurs.

COMMON PITFALLS

- Pain on swallowing is not always due to pharyngitis. Severe and potentially life-threatening conditions, including epiglottitis and retropharyngeal and prevertebral space abscesses, should be excluded. A careful history should be taken to ascertain the likelihood of an immunosuppressed state and a susceptibility to infectious esophagitis.
- Foreign bodies and food impaction are not uncommon, especially in the elderly and the alcoholic, whose oropharyngeal tactile sense is blunted. Pill esophagitis is likewise a probably underappreciated condition.

ESOPHAGEAL CHEST PAIN

CLINICAL PRESENTATION

The two most common esophageal disorders in patients presenting with angina-like chest pain are gastroesophageal reflux and esophageal motility disorders.

Symptomatic gastroesophageal reflux disease (GERD) is common. It is estimated that 10% of the general population has daily heartburn and that at least one-third of the population experiences heartburn once a month. Acid reflux can be detected in the distal esophagus for up to 75 minutes a day in healthy individuals, and many patients who suffer complications of acid reflux never experience heartburn or reflux.¹⁵ It has been widely held that nocturnal reflux is the most important factor in the pathogenesis of reflux disease. Twenty-four-hour esophageal pH has shown, however, that, in the majority of patients (those who have mild erosive esophagitis or no endoscopic abnormality), most reflux occurs in the daytime postprandial periods, and especially in the early evening, with relatively little reflux during the night. More severe esophagitis, which is due to greater acid exposure, is, however, associated with an increase in nocturnal reflux.

There has also been much debate about the relationship between the presence of hiatal hernia and GERD. Hiatal hernias seen on routine chest radiography do not correlate well with clinical reflux disease. However, approximately 80% of patients with hiatal hernia have an abnormal reflux frequency (as measured with 24-hour pH monitoring), compared with only about 40% of those without hernias.

The primary determinant of GERD is the structural and functional integrity of the lower esophageal sphincter (LES). The most important factor contributing to GERD is

transient relaxation of the esophagogastric junction.^{6,19} The incidence of GERD rises dramatically after age 40. Factors that influence the degree of reflux injury include the volume and pH of the gastric refluxate, the efficiency of gastroesophageal clearance, and the resistance and restorative repair capabilities of the esophageal epithelium. Patients with severe complications of GERD generally have an incompetent LES.¹⁵ Esophagitis results from excessive reflux of gastric juice rather than excessive gastric secretion.⁹

Patients typically suffer from GERD for years before seeking medical help. The predominant complaint is that of pyrosis, or "heartburn," which is due to mucosal irritation caused by refluxed gastric contents. The discomfort is usually described as a burning pain felt behind the sternum, often seeming to ascend from the epigastrium toward the throat, where a bitter taste may be sensed, and sometimes radiating to the back. There may be radiation of the discomfort to the neck or left arm. The intensity is variable, ranging from a dull ache to severe pain; the duration of discomfort may be minutes or hours. Symptoms may occur spontaneously and are rarely precipitated by swallowing, although they may also seem to be brought on by exercise, bending, or lying down. A large meal, as well as certain foods, such as chocolate, peppermint, alcohol, onions, and fat, increase esophageal acid exposure, while cola, beer, and milk increase gastric acid secretion. Orange juice, tomato juice, and coffee have a direct irritative effect on the esophagus.¹⁹ Heartburn often disappears quickly on drinking liquids or antacids.

Interestingly, only 30% to 40% of patients who complain of heartburn have demonstrable mucosal injury of the esophagus, and, conversely, reflux disease can occur without heartburn.

Strictures, manifested clinically by dysphagia, are the most common complication of reflux esophagitis. They appear to be caused by a combination of deep esophageal mural inflammation, fibrosis, spasm, and edema.

Motility disorders comprise the second group of esophageal disorders presenting predominantly as chest pain. *Achalasia*, a disorder characterized by the absence of peristalsis throughout the esophagus and, usually, deficient LES relaxation during swallowing, is associated with chest pain in about one-half of patients with the condition. The pain is rarely severe and may vary in quality. Chest pressure may be due to esophageal dilation from delayed emptying of food; heartburn or odynophagia may be due to stasis esophagitis and bacterial overgrowth or to esophageal pill retention. Reflux esophagitis is distinctly unusual, because LES pressure is high. Achalasia is eventually diagnosed in up to 10% of patients with noncardiac chest pain.

The primary neurologic defect responsible for achalasia remains unknown. The most consistent pathologic finding is a decrease of ganglion cells in the myenteric plexus at the LES. The disorder may occur at any age, but its exact incidence and prevalence are unknown. The disease typically follows an indolent course; at the time of presentation, symptoms have usually been present for an average of about 7 years. Longitudinal population studies of patients with achalasia suggest the disease does not affect life expectancy.

Diffuse esophageal spasm is characterized by simultaneous contractions in the body of the esophagus occurring with at least 30% of swallows. The contractions are frequently repetitive, spontaneous, of prolonged duration, or of high amplitude. Patients present with dysphagia or intermittent chest pain. The chest pain is not necessarily related to eating, although it may be triggered by the ingestion of very hot or very cold liquids. The diagnosis of diffuse esophageal spasm requires that both clinical and manometric criteria be fulfilled, because asymptomatic individuals can display similar manometric features. No organic lesion is demonstrable radiographically, endoscopically, or histologically.

In *nutcracker esophagus*, motility is ordered and peristaltic, but the waves are of longer duration and higher amplitude than normal.

DIFFERENTIAL DIAGNOSIS

A cardiac etiology must always be excluded when a patient presents with burning substernal chest pain. Chest pain of esophageal origin may be impossible to distinguish from angina by history alone. One must remember that the administration of an antacid or "GI cocktail" is a therapeutic intervention and not a diagnostic procedure. It has been well documented that cardiac chest pain can respond to these preparations, for reasons that are open to speculation.

Even among patients with a history that is classic for cardiac ischemia, a significant percentage (approaching 30% in some studies) undergoing cardiac catheterization have normal or clinically nonsignificant occlusions.^{3,6} Unfortunately, there are no characteristic features of chest pain that are pathognomonic of esophageal disorders, including response to antacids, nitroglycerin, or calcium channel blockers. Even pain that is associated with dysphagia and is unrelated to exertion may be ischemic in origin.

EMERGENCY DEPARTMENT EVALUATION

If a cardiac cause can be excluded and the patient gives a history of heartburn without dysphagia, weight loss, or GI bleeding, no laboratory or imaging studies are needed in the emergency department.

Further evaluation is needed if heartburn persists after treatment or if it recurs when treatment is stopped. Heartburn refractory to treatment, or heartburn accompanied by dysphagia, odynophagia or GI bleeding, requires endoscopy to exclude other causes.⁹ However, endoscopy shows no evidence of ulcerations in most patients who seek treatment for uncomplicated reflux symptoms.¹⁵ The most useful tests for diagnosing reflux disease are barium swallow, endoscopy, and 24-hour gastric pH monitoring, all of which are performed on an outpatient basis.

Evaluation of esophageal motility disorders usually employs esophageal manometry and is also carried out on an outpatient basis (see subsequent chapter section, "Dysphagia").

EMERGENCY DEPARTMENT MANAGEMENT

Mild symptomatic esophagitis can usually be managed empirically with lifestyle and dietary modifications, antacids, and nonprescription H₂-antagonists.^{9,12}

Lifestyle modifications alone are rarely sufficient to relieve symptoms of mild GERD, but they can be an adjunct to pharmacologic management.⁴ Patients are often advised to raise the head of the bed approximately 6 in. or to elevate their shoulders with a wedge. The effects of these maneuvers on esophageal acid exposure are modest and appear to be greater when the patient has severe disease. This is consistent with pH monitoring studies that show that, in the majority of patients, most acid exposure occurs during the daytime. The nonpharmacologic measures most likely to benefit the patient are a reduction in fat intake, elimination of tobacco use, and elevation of the head of the bed.¹⁵

Antacids provide rapid relief and are useful in controlling daytime symptoms, but they are inadequate for patients with moderate-to-severe symptoms, who require around-the-clock therapy. For mild reflux esophagitis, H₂-antagonists, prokinetic agents, or sucralfate may be used initially. Superior healing rates of erosive esophagitis have been noted with H₂-blockers. However, because H₂-antagonists at higher doses than those used in peptic ulcer disease are needed for more severe esophagitis, proton pump inhibitors (PPIs) are usually a more cost-effective alternative. In general, they result in faster healing rates and greater symptom relief than H₂-antagonists.^{7,16,19} The dose of omeprazole is 20 mg/d, and the dose of lansoprazole is 30 mg/d.^{4,7} Therapy is usually continued for 6 to 8 weeks. All patients who do not respond to a 4-week trial of PPIs for typical GERD symptoms should be considered for endoscopy to establish a diagnosis.^{10,19}

Sucralfate, which inhibits pepsin, as well as absorbs and inactivates bile salts, has been shown to be superior to placebo and comparable to antacids and H₂ blockers. Cisapride increases LES tone, accelerates gastric emptying, and has similar efficacy to H₂-antagonists in the treatment of mild esophagitis.^{9,19} Metoclopramide increases LES pressure and accelerates gastric emptying in retention states. Its effectiveness is not clear-cut, and it has a relatively high side-effect profile; it is not recommended as first-line therapy.

The treatment of esophageal motility disorders is discussed in the next section.

DISPOSITION

If the diagnosis of GI chest pain is not in doubt, the patient can be discharged and referred to the primary care physician. For resistant symptoms or suspected complications of reflux esophagitis, the patient may be referred to a gastroenterologist for endoscopy or 24-hour pH monitoring.

COMMON PITFALL

Chest pain due to coronary artery disease may be misdiagnosed as GI in origin, especially when substernal burning or atypical chest pain appears to be relieved by antacids or a “GI cocktail.”

DYSPHAGIA

CLINICAL PRESENTATION

Dysphagia refers to difficulty or impairment in swallowing. Difficulty in moving a food bolus from the mouth to the upper part of the esophagus is termed *oropharyngeal dysphagia*, whereas a problem with the passage of food or liquid down the esophagus to the stomach is referred to as *esophageal dysphagia*. Whenever the esophagus does not empty in a coordinated, sequential manner, dysphagia may be accompanied by odynophagia, heartburn, GI chest pain, or nausea and vomiting. Globus hystericus is the constant sensation of a lump in the throat, associated with the need to swallow with no identifiable cause. In contrast to true dysphagia, there is no difficulty when swallowing is actually performed.²⁰

Dysphagia is often the principal presenting symptom of esophageal motility disorders, which usually present during middle age and are more common in women.¹⁶ These include primary esophageal disorders, such as achalasia, diffuse esophageal spasm, and nutcracker esophagus, as well as esophageal dysfunction secondary to other conditions, most notably scleroderma. Although patients with these disorders frequently experience dysphagia, not all patients with abnormal motility have symptoms.

Achalasia, discussed previously and characterized by deficient peristalsis and failure of the LES to relax on swallowing, is the best studied disorder of esophageal motility. Dysphagia to both liquids and solids is present in nearly all patients with achalasia, but is usually intermittent at first and typically worsens with time. The site of obstruction is often correctly located by the patient in the xiphoid area. Patients with achalasia learn maneuvers to assist esophageal emptying, such as throwing the shoulders back, extending the neck, or performing a Valsalva maneuver.¹⁶

Food eventually empties into the stomach as gravity aids in its passage through the nonrelaxing sphincter, but stagnant undigested food may also be regurgitated. This occurs most commonly at night because of the recumbent position; vomitus may be noted on the pillow on awakening in the morning. Not surprisingly, aspiration is a complication of achalasia and may present as cough, pneumonia, or lung abscess. Weight loss is also a feature of the motility disorders and is due not only to the physical difficulty of swallowing, but also to decreased oral intake because of fear of dysphagia and chest pain.

Nutcracker esophagus and diffuse esophageal spasm, also discussed previously, are also characterized by dysphagia and intermittent chest pain but are much less well studied than achalasia.

Obstructive dysphagia may be due to *benign* structural lesions of the esophagus, including esophageal webs and rings and intramural hematomas and dissections.¹⁸ Webs are squamous mucosal protuberances that are either congenital or acquired, usually single, and located in the proximal 2 to 4 cm of the esophagus. Rings could easily be called distal esophageal webs; however, these terms are entrenched in the literature. The typical ring lies within the LES at the squamocolumnar junction. Like a web, it is a mucosal lesion. Its cause is unknown, but a hiatal hernia is usually present. Rings more than 20 mm in diameter are rarely symptomatic; those less than 13 mm in diameter almost always cause dysphagia.^{16,20} Rings are probably congenital, but the elasticity of the ring decreases with age, explaining why symptoms rarely occur before age 40.⁸

Intramural hematomas and dissections are rare submucosal lesions of the esophagus. Esophageal hematomas and dissections present in much the same manner as esophageal perforations. Nonbloody emesis followed acutely by chest pain, often radiating to the back, dominates the clinical picture of both. Patients with perforations, however, appear more toxic, and their condition deteriorates rapidly. Esophageal carcinoma is a very important cause of dysphagia and is important to recognize early in its course, because the prognosis is dismal by the time a patient presents with progressive dysphagia. Squamous cell carcinoma accounts for 98% of malignant lesions of the esophagus; adenocarcinoma arising from Barrett's esophagus comprises the remainder. Squamous cell tumors are equally distributed among the upper, middle, and lower thirds of the esophagus. Heavy alcohol intake and smoking significantly increase the likelihood of squamous cell carcinoma of the esophagus, while adenocarcinoma tends to occur in patients with a long history of GERD.²⁰

The symptoms of esophageal carcinoma are usually insidious in onset. Initially, substernal discomfort and slight alterations in eating habits may go unrecognized. Patients may complain of substernal burning that mimics reflux esophagitis. Carcinoma should be suspected if reflux esophagitis is refractory to therapy or if symptoms change. In addition to dysphagia, anorexia and weight loss are other common manifestations. As the esophageal lumen progressively narrows, clearance of liquids and, eventually, even secretions becomes difficult, leading to recurrent aspiration pneumonia. As with other esophageal disorders, physical examination is unrevealing except for signs of malnutrition. Laboratory evaluation may reveal anemia secondary to blood loss from the tumor.

DIFFERENTIAL DIAGNOSIS

Oropharyngeal dysphagia should first be distinguished from esophageal dysphagia. Patients with *oropharyngeal dysphagia* describe difficulty in passing food from the mouth to the esophagus. Associated manifestations may include drooling, nasal regurgitation, inability to initiate swallowing, coughing during swallowing, aspiration pneumonia, and dysarthria or nasal speech. There may be weight loss due to fear of eating.¹¹

In 80% of cases, the underlying cause is neuromuscular, including central, peripheral, and motor end-plate disorders. Central neuromuscular causes include cerebrovascular accidents or tumors (usually in the region of the brainstem), Parkinson disease, multiple sclerosis, and amyotrophic lateral sclerosis.

If the history suggests *esophageal dysphagia*, the distinction must be made between motor disorders and obstructive lesions. The two are easily confused, because both present as esophageal dysphagia. The history is often helpful, because chest pain is a more significant and more frequent complaint in patients with motility disorders. The dysphagia associated with achalasia tends to occur with solids and liquids from the outset, whereas progressive, obstructive lesions present as difficulty swallowing solids, which then progresses to difficulty swallowing solids, liquids, and secretions.

EMERGENCY DEPARTMENT EVALUATION

The evaluation of dysphagia should begin, as always, with attention to the airway, breathing, and circulation and particularly to hydration status. A basic history and physical examination should be performed. Just as when evaluating patients with symptoms suggestive of reflux, a cardiac cause of chest pain should first be considered before implicating the esophagus. If, after initial questioning, esophageal dysphagia is suspected, a chest radiograph should be obtained once the patient's condition has been stabilized. Radiographic hints that achalasia may be present include a widened mediastinum (caused by a dilated esophagus), the presence of an air–fluid level in the posterior mediastinum (caused by the dilated, fluid-filled esophagus), and the absence of a gastric air bubble (because swallowed air cannot get into the stomach). A chest radiograph may also reveal an extrinsic mass causing compression of the esophagus.

The remainder of the diagnostic evaluation can generally take place on a nonemergent outpatient basis. Double-contrast barium esophagography provides excellent visualization of structural lesions and should be the initial test performed in patients with esophageal dysphagia or odynophagia.¹⁷ An upper GI series is not a suitable substitute for a barium esophagram, because this study focuses on the stomach.^{16,20}

Patients with suspected motility disorders are better studied with dynamic techniques or cinefluorography. In achalasia, these reveal a paucity of peristaltic movements and a dilated, fluid-filled esophagus tapering to a characteristic “bird's beak” narrowing at the LES. Patients with diffuse esophageal spasm demonstrate

diffuse, powerful contractions, appearing as “curling,” that obliterate normal peristaltic contractions. ¹⁰

Esophageal manometry is the gold standard for diagnosing motility disorders. However, it will provide a diagnosis in only 25% of patients and is normal in half of those patients referred for dysphagia. Provocative testing during manometry, using edrophonium, esophageal balloon distention, or acid perfusion, may further clarify the diagnosis. ²⁰

Obstructive lesions can be further evaluated by barium swallow under fluoroscopy, which can usually be performed as an outpatient. Esophageal rings, webs, and carcinoma may be seen; occasionally, some findings, such as proximal dilation with rapid tapering at the LES, may mimic achalasia. More typical findings of mass lesions are asymmetric stenosis, distinct mucosal irregularities, strictures, and masses. If any suspicious abnormality is seen after the barium study, the patient should undergo upper GI endoscopy for biopsy and cytologic brushings.

Endoscopy is indicated in all patients suffering from food impaction, whether the food bolus is eventually passed or not, because this may be the first sign of an obstructive lesion.

EMERGENCY DEPARTMENT MANAGEMENT

In patients in whom normal alimentary intake has been prevented, attention should initially focus on hydration and nutritional status.

Pharmacologic options for managing painful motility disorders are directed principally at reducing smooth muscle spasm or decreasing LES pressure. Treatment of diffuse esophageal spasm is aimed at decreasing the amplitude of esophageal contractions by the use of nitrates and calcium channel blockers. Patients who fail medical therapy can be treated with myotomy or dilations. ^{11,21,27} Treatments for achalasia include sublingual isosorbide dinitrate and calcium channel blockers with meals or on a prn basis for pain and dysphagia. Other medications, such as anticholinergics, psychotropics, and analgesics, may also be tried. ^{3,5,6,16} Botulinum toxin administered by endoscopic injection may give relief of dysphagia for up to 1 year. ^{6,14,16} Pneumatic dilation is a final therapeutic avenue.

Although some squamous cell carcinomas are responsive to chemotherapy, most esophageal cancers are incurable. Esophageal dilation is an integral part of most palliative treatment programs. A small amount of bleeding is commonly seen after dilation, but massive bleeding is unusual. The major risk of esophageal dilation is perforation, which occurs at a rate of one in every 400 to 1000 dilations. Management of esophageal perforation depends on the degree of spillage, the time to diagnosis, and the patient's fitness for surgery. In the past, surgical treatment was considered the only management option, but there has been some experience with a conservative approach using antibiotics and parenteral alimentation, always in conjunction with a thoracic surgery consultation. The surgeon's opinion should be sought early on.

DISPOSITION

Patients with dysphagia whose hydration and nutritional status are adequate may be discharged home and should be referred to their primary care physician or gastroenterologist for further evaluation and treatment. If coronary artery disease cannot be ruled out, the patient should be admitted to a monitored bed; a cardiac evaluation must be undertaken before a GI workup is launched.

COMMON PITFALLS

- Failure to consider cardiac ischemia in patients who describe chronic, intermittent, nonspecific chest discomfort
- Failure to evaluate and refer patients with mild dysphagia, in whom a potentially treatable obstructive lesion may be the cause
- Attribution of persistent symptoms of dysphagia to “globus hystericus” or anxiety without referring the patient for further testing

CHAPTER 154

Upper Gastrointestinal Bleeding

Edward A. Panacek

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Over 2% of all hospital admissions in the United States, and over 5% of admissions from emergency departments, are related to acute gastrointestinal bleeding. In the vast majority of these patients, the bleeding source is in the upper gastrointestinal tract.⁶ Although bleeding stops spontaneously in up to 80% of patients, approximately 10% of those admitted require intervention to control their hemorrhage. Despite advances in diagnostic and therapeutic care, the overall mortality of admitted patients is 8% to 10% and has remained relatively unchanged for the past 40 years.^{6,7,10} For this reason, gastrointestinal bleeding should always be considered potentially life-threatening until proven otherwise.

The source of gastrointestinal bleeding is generally divided into three anatomic regions. *Upper gastrointestinal bleeding* (UGIB) is defined as occurring proximal to the ligament of Treitz. This anatomic site is important, in that bleeding distal to the ligament of Treitz rarely regurgitates back into the duodenum or stomach. Exceptions are seen in patients with bowel obstruction or massive bleeding, such as in aortoenteric fistula. *Middle gastrointestinal tract bleeding* is from the ligament of Treitz to the ileocecal valve (i.e., the jejunum and the ileum). *Lower gastrointestinal tract bleeding* is that which occurs in the colon or rectum.

The most common causes of UGIB are listed in [Table 154.1](#); up to 30% of patients may have multiple causes or numerous anatomic sites involved. UGIB can occur in people of any age but is most common in adults older than 40, and it is more common in males than in females (2:1 ratio). Elderly patients have less ability to compensate for acute hemorrhage, and the majority of deaths occurs in elderly patients.^{3,7}

MOST COMMON (90%)	
Peptic ulcer (duodenal two-thirds, gastric one-third)	40%
Erosive gastritis	25%
Varices (esophageal and gastric)	20%
Mallory-Weiss tear	5%
UNCOMMON (10%)	
Epistaxis, hemoptysis	
Aortoenteric fistula	
Boerhaave syndrome	
Carcinoma	
Vascular anomalies	
Caustic ingestion	
Anastomotic ulcer	

TABLE 154.1. Causes of Upper Gastrointestinal Tract Bleeding

CLINICAL PRESENTATION

Most patients with acute UGIB have obvious related signs or symptoms, but there are also more subtle presentations. Thus, these patients can present primarily with severe tachycardia, angina, acute myocardial infarction, hypotension, syncope, weakness, confusion, or even full cardiac arrest.

The classic presentation, however, is with hematemesis. Another common presentation is with abdominal pain or cramps, usually with a change in bowel habits. The character of the pain varies depending on the underlying disorder, but it is most often described as “burning” or “sharp” and is located in the epigastrium. Although it is often assumed that hematochezia (the passage of obviously bloody stools) is a result of lower gastrointestinal hemorrhage, UGIB is still a common cause. Maroon, burgundy, currant-jelly, and melanotic stools differ from each other in that they contain varying amounts of metabolized hemoglobin. Stool appearance alone generally does not help to localize the site of hemorrhage and is more dependent on the volume and timing of the bleeding. One exception to this rule is that the black, tarry stool of melena requires substantial digestion of the blood during its passage through the gastrointestinal tract, and therefore almost always represents a bleeding source proximal to the right colon.

When severe, UGIB can result in varying degrees of hemodynamic compromise. An acute blood loss of 10% of normal volume can usually be compensated through contraction of the venous compartment, with minimal physiologic change. Greater degrees of blood loss (10% to 20%) initiate reflex sympathetic mechanisms, resulting in peripheral vasoconstriction, tachycardia, widened pulse pressure, and orthostatic hypotension. Such patients often complain of thirst, apprehension, weakness, or light-headedness. When blood loss exceeds 20%, reflex mechanisms can no longer fully compensate; hypotension develops and organ perfusion is impaired. This can result in oliguria, mental confusion or coma, metabolic acidosis, and dyspnea.

DIFFERENTIAL DIAGNOSIS

The exact anatomic site or cause for bleeding in the upper gastrointestinal tract cannot always be determined in the emergency department, but the differential diagnosis can usually be narrowed to the most likely causes. In fact, 90% of UGIBs are the result of only four causes (see [Table 154.1](#)).

The single most common cause is *peptic ulcer disease* involving the duodenum or stomach. The usual history is that of persistent burning, sharp, or aching pain in the epigastrium that develops 1 to 2 hours after eating. However, bleeding peptic ulcers are sometimes painless, and melena can be the sole presentation. Predisposing factors for peptic ulcers include cigarette smoking, ingestion of alcohol, and hereditary factors. It is now also felt that many ulcers are related to infections with *Helicobacter pylori*.¹⁷

Erosive gastritis is also a common cause of UGIB. The resultant bleeding can range from minimal to massive. The clinical presentation is often indistinguishable from that of peptic ulcer, and suspicion of the diagnosis is generally based on the clinical setting and history. The most common predisposing factor is the use of nonsteroidal antiinflammatory drugs. Other risk factors include use of alcohol, prolonged corticosteroid use, and major trauma, burns, or head injury.

Patients with bleeding esophageal or gastric *varices* can be among the most difficult to manage. Because varices result from portal hypertension, this diagnosis should be suspected in patients with a history of cirrhosis or other stigmata of severe hepatic dysfunction. Bleeding can be sudden and massive. Complicating the evaluation, however, is the fact that up to 50% of episodes of UGIB in patients with known varices are not due to the varices (they are usually due to gastritis or peptic ulcer disease). Patients with variceal hemorrhage have a very poor prognosis, with a mortality rate of 70% within 1 year of the first bleeding episode. They account for one-third of all deaths from UGIB.

Mallory-Weiss tears are longitudinal lacerations or ruptures of the gastroesophageal junction, usually caused by recurrent forceful vomiting or retching. They are uncommon in children. The history of sudden hematemesis of bright red blood after retching is characteristic, but it is present in only half of patients. Risk factors include alcohol, hiatal hernia, and underlying esophagitis. The amount of bleeding can range from mild to massive, but, in the absence of complicating medical conditions, the course is usually benign.

A number of other less common conditions account for the remaining 10% of episodes of UGIB (see [Table 154.1](#)). *Aortoenteric fistula* typically carries a high mortality, with patients generally presenting with extremely massive bleeding resulting from erosion of an aortic aneurysm or a synthetic aortic graft into the distal duodenum. There is usually no time for diagnostic studies, and the patient must be moved rapidly to the operating room. Some patients experience a “herald” bleed of smaller volume within a week before the massive hemorrhage, but this is not usual.

Massive *epistaxis* and, occasionally, *hemoptysis* can sometimes be misinterpreted as UGIB when patients cannot provide a clear history.

EMERGENCY DEPARTMENT EVALUATION

Stabilization takes precedence over comprehensive evaluation in patients with potential UGIB. Patients who are hemodynamically or otherwise unstable must undergo rapid resuscitation and initial treatment concurrent with a brief, focused history and examination.

The history and physical examination often help to localize the bleeding source and indicate the severity of hemorrhage, but they have their limitations. Patients can be misled by food products or medications that look very much like blood. Only 10 mL of blood can turn all of the water in a toilet bowl red. Estimates regarding the amount of blood lost are notoriously inaccurate, whether reported by patients or prehospital personnel.

The history should focus on the following areas:

Onset of bleeding (specifically, was the onset before or after vomiting?)

Amount of blood loss

Relevant medical history (e.g., prior bleeding episodes, history of hepatic disease, aortic graft repair or known aneurysm, alcohol use, use of nonsteroidal antiinflammatory agents)

Associated symptoms (e.g., abdominal pain, peritoneal symptoms, change in bowel habits)

Complicating symptoms (e.g., chest pain, dyspnea, light-headedness, or syncope)

The goals of the initial physical examination are to assess the patient's hemodynamic status, estimate the severity of bleeding, search for clues to the bleeding source, and identify evidence of other organ complications. A supine systolic blood pressure of less than 100 mm Hg or an orthostatic pulse increase of more than 20 to 30 beats per minute suggests an acute blood loss of at least 1 L in an adult. However, changes in vital signs are less specific at the extremes of age, and, conversely, some patients can tolerate substantial volume losses with minimal changes in the vital signs. Findings of flat neck veins; cold, mottled extremities; altered mental status; or diaphoresis can contribute to the clinical assessment, but they are too subjective to be relied on primarily. Occasionally, blood in the gastrointestinal tract can induce nausea, with an increase in vagal tone resulting in a paradoxical bradycardia despite profound hypovolemia.

Underlying hepatic disease can be suggested by spider angiomas, gynecomastia, jaundice, or palmar erythema. Portal hypertension is suggested by ascites, splenomegaly, or a caput medusae. Purpuric lesions or petechiae suggest an underlying coagulopathy. Findings consistent with arthritis suggest an underlying rheumatic disorder for which the patient may be on nonsteroidal antiinflammatory agents.

The nose and oropharynx should be examined for potential bleeding sources, particularly in atypical or confusing cases. The abdominal examination focuses on areas of tenderness, or evidence of ascites, but should also determine whether peritoneal signs are present. Iron and bismuth can make the stools appear melanic, so the stool should be formally tested to confirm the presence of blood. Of note, stools can test positive for occult blood for 2 weeks after a single episode of bleeding. False-positive results have been associated with iron preparations, ingestion of red meats, and bromide preparations. False-negative results can be caused by magnesium-containing antacids, ascorbic acid, and activated charcoal, as well as a number of other medications and food substances. As such, test results should be interpreted with skepticism if they conflict with the clinical picture.

A nasogastric tube should be placed in all patients in whom gastrointestinal bleeding is suspected, regardless of the presumed source or degree. There is no evidence that passage of a nasogastric tube in a patient with esophageal varices results in variceal trauma or increases bleeding. Even if the patient has obvious hematemesis, a tube should be placed to assess ongoing bleeding and to decrease the risk of aspiration. Flecks of red blood that accompany initial gastric intubation can be ignored. Testing of nonbloody aspirates for occult blood is of little clinical use. If blood is found, the nasogastric tube should be capable of fully evacuating the stomach; a large evacuator tube is necessary when large amounts of blood or clots are present. Lavage should be carried out, ideally with the patient in the left lateral decubitus position, until the gastric contents become clear, but large volumes of tap water lavage should be avoided, as they can induce hyponatremia. Either normal saline or tap water can be used for the lavage. Iced fluids should be avoided because they may interfere with normal coagulation function and can also induce hypothermia. There is no advantage to the addition of vasoconstrictors or antacids to the lavage fluid. A negative nasogastric tube aspirate does not exclude UGIB, because it does not reliably sample material past the pylorus. The nasogastric tube aspirate may be negative in up to 25% of patients with a bleeding duodenal ulcer, although this percentage is lower if the aspirate contains bile.

Initial laboratory evaluations should include a complete blood cell count; determination of electrolyte, blood urea nitrogen, and creatinine levels; and tests of coagulation. An elevated blood urea nitrogen value is frequently seen in the setting of an UGIB or small intestinal hemorrhage, particularly when there is hypovolemia or some degree of renal insufficiency. A chest radiograph is indicated in patients in whom aspiration is clinically suspected. Abdominal films are indicated in the subset of patients in whom there is concern about perforation, obstruction, or abdominal aortic aneurysm. Barium contrast studies have limited indications in the emergency setting and can interfere with subsequent endoscopy and angiographic studies.

EMERGENCY DEPARTMENT MANAGEMENT

Patients transported by emergency medical services should have a large-bore (14- to 18-gauge) intravenous catheter placed and normal saline infused at a rate dependent on the patient's stability. They should also be placed on a cardiac monitor. Low-flow oxygen supplementation is suggested, especially for elderly or symptomatic patients. Transport should not be delayed.

Once the patient reaches the emergency department, acute resuscitative interventions and stabilization assume the highest priority. The overall approach to the emergency department management of UGIB is outlined in [Table 154.2](#). In practice, the first three steps are usually executed simultaneously. Definitive localization of the bleeding site and identification of the cause are not always possible, nor necessary, in the emergency department setting.

-
1. Assess the patient's overall clinical status and hemodynamic stability.
 2. Resuscitate and replete intravascular volume.
 3. Localize the general anatomic location of bleeding (i.e., upper, middle, or lower).
 4. In ongoing bleeding, determine the cause or source.
 5. If bleeding is persistent, initiate interventions.
 6. Make decisions concerning patient disposition and the use of consultants.
-

TABLE 154.2. Emergency Department Management of Upper Gastrointestinal Bleeding

If not already initiated by prehospital personnel, patients with any degree of compromise should be immediately placed on a cardiac monitor and be given supplemental oxygen. Intravenous access should be established with one or two large-bore (14- to 18-gauge) catheters, depending on the severity of the patient's

condition and the presence of active bleeding. Initial laboratory studies should be sent at the same time, including a sample for type and crossmatch for at least 4 U of blood. One or 2 L of crystalloid is infused initially, or until the patient is stable. The hematocrit is rechecked after each 2 L of intravenous fluid or every 2 to 4 hours. If the clinical condition has not substantially improved after 2 L of fluid, and there is clinical evidence of ongoing hemorrhage or severe anemia, blood product transfusions should be considered. Of note, the hemoglobin and hematocrit values are difficult to interpret in the setting of acute bleeding, because compensatory hemodilution may not fully occur for 6 to 12 hours. Therefore, a normal blood cell count does not rule out an acute massive hemorrhage. Even when an upper source is obvious, a nasogastric tube must be inserted to assess for ongoing mild bleeding.

When active bleeding continues, or the patient's condition otherwise remains unstable, other diagnostic options must be considered. These include acute endoscopy, radionuclide imaging, and arteriography. Of these, endoscopy is the most valuable and the most available. In many situations, these studies would best be performed not in the emergency department but on the inpatient service. In other situations, the emergency department is the most appropriate setting for further study, particularly when the patient's condition remains unstable.

Emergent endoscopy is indicated in any patient with active bleeding that does not clear with lavage, or in patients who present with hemodynamic instability in the setting of liver disease (portal hypertension).¹³ Urgent endoscopy may also be indicated when an aortoenteric fistula is suspected, although the patient's clinical condition in such cases usually does not allow time for endoscopy. In preparation for endoscopy, the patient's stomach must be fully evacuated to allow for optimal visualization. This is best performed with a large gastric lavage tube.

Emergent endoscopy provides potential therapeutic options for treatment of persistent UGIB. Cauterization of actively bleeding ulcers or "visible vessels" with a bipolar heater probe or laser can significantly reduce further bleeding, the need for surgery, and subsequent mortality. Injection sclerosis of visible vessels is also an option.⁵ However, except in patients with variceal bleeding or other persistent hemorrhage, emergency endoscopy has not been shown to provide any advantage in reducing mortality, morbidity, or transfusion requirement. In stable patients, endoscopy can be safely delayed for 1 to 2 days.⁴

The administration of histamine-2 (H₂) antagonists and similar medications has been shown to prevent bleeding from stress ulcers in high-risk patients in the intensive care unit (ICU) and to speed the healing of peptic ulcers. However, none of these agents has been proven to be of benefit in controlling the bleeding in the acute setting.¹⁵ Only omeprazole (40 mg intravenously q12h) has been shown to be beneficial for patients with recent UGIB, but not active bleeding.⁸ Nonetheless, unless there is a specific contraindication, it is recommended to initiate therapy with an H₂ antagonist by giving an initial bolus dose in the emergency department (e.g., cimetidine 300 mg, or ranitidine 50 mg intravenously). If early endoscopy is indicated, antacids and sucralfate should be withheld to avoid interfering with endoscopic visualization.

The therapeutic approach to patients with acute hemorrhage from esophageal varices is substantially different from that employed with other types of UGIB. The presence of hepatic disease, portal hypertension, or even prior variceal hemorrhage does not reliably predict a variceal source for the bleeding. As noted previously, in up to 50% of such patients, bleeding is due to peptic ulcer disease or gastritis. For this reason, emergent endoscopy is necessary both diagnostically and therapeutically in these patients.⁴ In the acute setting, emergent endoscopic therapy is often used in combination with pharmacologic agents, and the rate of initial control of bleeding is 90% to 95%.⁴

Endoscopic therapy is divided into two types: endoscopic variceal sclerotherapy and band ligation. With the first, sclerosing agents are injected into the esophageal vessels, causing thrombosis and eventual necrosis. Up to 30% of patients can have complications, including ulcerations and fibrosis.¹³ Band ligation involves endoscopic placement of a rubber band around the varix, inducing obstruction and eventual tissue necrosis that obliterates the varix. This has recently become the therapy of choice, due to lower complication rates, for acute variceal hemorrhage at most centers.¹⁶ However, the technique is more difficult technically, and active bleeding can preclude adequate visualization.

Another therapeutic option for variceal hemorrhage is intravenous vasopressin, a potent nonselective vasoconstrictor, which can be used in conjunction with endoscopic therapy or as the sole therapy when sclerotherapy is unsuccessful or unavailable. The dosage is 0.2 to 0.4 U/min by constant infusion. Vasopressin must be used with caution in patients with coronary artery or other vascular disease; a reduction in dosage or the concurrent use of nitroglycerin decreases the risk of adverse effects such as myocardial or extremity ischemia.⁴ Studies have shown that somatostatin and its analogues are as effective as vasopressin, with fewer side effects.² Although somatostatin remains investigational, a long-acting analogue, octreotide, is available; the dosage is 25 to 50 µg/h intravenously.⁴

When sclerotherapy and vasoconstrictor therapy have been unsuccessful, balloon tamponade is the next therapeutic option. The Sengstaken-Blakemore tube (with three lumens) and the Minnesota tube (with four lumens) are among a number that are available. They are less successful than sclerotherapy but can control bleeding acutely in up to 80% of cases.⁴ However, the use of these tubes is associated with a number of major complications, including esophageal necrosis and rupture, pulmonary aspiration, and airway compromise. The tubes come with an explicit list of instructions that should be reviewed in detail before their use, and they are best placed by an experienced practitioner.

Although the vast majority of patients with UGIB never require surgery, early surgical consultation is advisable for any patient who has been hemodynamically unstable or who requires early blood transfusions. Most of the indications for surgical intervention are defined by the patient's clinical course during the initial 24 hours of hospitalization. However, for patients who present with hypotension or shock and massive uncontrollable hemorrhage that is not from varices, immediate surgery should be considered. For variceal bleeding, acute endoscopic therapies and balloon tamponade should be considered before turning to surgical intervention.⁴

DISPOSITION

Historically, all patients with UGIB were admitted to the hospital, but it is now accepted that there is a subset of patients who can safely be discharged from the emergency department with close follow-up.^{3,12,14,15} Of patients requiring hospitalization, about half meet high-risk criteria for rebleeding or other complications that necessitate admission to a monitored ICU or telemetry bed.^{7,9}

Though each study has used different thresholds or predictive factors, the general criteria for outpatient management are listed in [Table 154.3](#). Some investigators recommend an age cut-off of 60 years, but the majority use an age of 75.^{1,9} Candidates for outpatient management must have reliable access to close outpatient follow-up and a demonstrated history of compliance with medical instructions, and they must have remained stable during 4 to 6 hours of emergency department observation.

Age younger than 75 years
No unstable comorbid illness
No evidence of portal hypertension or ascites on examination
Normal coagulation function
Systolic blood pressure > 100 mm Hg and no orthostatic changes within 1 hour of presentation to emergency department
Nasogastric aspirate free of fresh blood after initial lavage
Hemoglobin at least 10 g/dL
Patient compliant with reliable access to close follow-up

TABLE 154.3. Criteria for Outpatient Management of Acute UGIB

The specific criteria for admission to an ICU are listed in [Table 154.4](#). Patients should be admitted to an ICU or monitored bed if their condition is unstable in the emergency department, if bleeding persists, or if they are at high risk for rebleeding or associated complications. Patients with UGIB who do not meet criteria for

discharge or for admission to the ICU are appropriately admitted to a nonmonitored ward bed.

Unstable vital signs in the emergency department
Persistent bleeding that does not clear with lavage
Advanced age (older than 75 years)
Presence of coagulopathy
Portal hypertension or ascites
Severe anemia (e.g., hematocrit <20%)
Large drop in hematocrit (>8%)
Unstable comorbid disease (e.g., unstable coronary artery disease, chronic obstructive pulmonary disease, renal insufficiency, peripheral vascular disease, cerebrovascular disease)
Endoscopic findings of a "visible vessel" or an "overlying clot" or a variceal source
Use of vasopressin drip or esophageal tamponade balloon

TABLE 154.4. Intensive Care Unit Admission Guidelines for Patients with UGIB

A number of recent studies have shown that early endoscopy performed in the emergency department can identify a subset of up to 25% to 50% of patients who would otherwise be admitted, but who can safely be managed as outpatients. It is argued that this aggressive approach can provide overall cost savings. [11,12,15](#)

Those who are discharged with outpatient follow-up should be placed on H₂ blockers (e.g., cimetidine 300 mg four times a day or 800 mg two times a day) and prescribed liquid antacids as needed. The advantages of a bland diet are controversial, but known gastric stimulants such as alcohol, tobacco, and caffeine are best avoided. Frequent small meals may also be beneficial. Follow-up should be arranged within 3 to 7 days, with instructions to return earlier for recurrence of bleeding, worsening of pain, or any orthostatic symptoms. [17](#)

Emergency consultation with a gastroenterologist or endoscopist is indicated for patients who remain clinically unstable despite resuscitative efforts and for those whose bleeding persists after initial gastric lavage. This is particularly true if the patient may have a variceal bleeding source. Patients who remain unstable or have persistent bleeding also require early surgical intervention and early surgical consultation. [3,17](#)

Patients who require ICU admission or emergency consultation should be considered for transfer to a referral hospital if either general surgery or endoscopy consultants are not available. Because UGIB patients often have encephalopathy and recurrent vomiting, transport personnel must be skilled in airway management and resuscitation. The patient must have multiple large-caliber intravenous lines in place, and crossmatched blood should be sent with the patient, if available.

COMMON PITFALLS

- Because a number of foods, medications, or other substances can be mistaken for blood in the gastrointestinal tract, the presence of blood in the gastrointestinal tract should be confirmed by testing.
- Despite new developments in diagnosis and therapy, the mortality rate in acute UGIB remains at 8% to 10%. Therefore, all such patients should be considered to have a potentially life-threatening medical problem until proven otherwise.
- Although it is uncommon, patients may exsanguinate into the gastrointestinal tract, with no acute external evidence of blood.
- Accurate assessment of hemodynamic status is critically important. Some patients can lose up to 20% to 30% of their blood volume and still maintain a normal blood pressure in a supine position.
- The nasogastric aspirate may be falsely negative in up to 25% of patients with acute UGIB. These are usually patients with a duodenal bleeding source.
- Among patients with acute UGIB and a known history of variceal hemorrhage, only about half have recurrent bleeding from varices.
- Using specific criteria, a subset of patients with UGIB can be safely managed as outpatients.
- Aortoenteric fistula typically presents as sudden massive hematemesis. This entity is notoriously difficult to diagnose preoperatively, and diagnostic studies are often not helpful or are unavailable. Emergent surgical intervention is the only treatment.

[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Peptic ulcer disease (PUD) eventually affects one of every ten Americans. The prevalence of PUD in the population, between 1.7% and 2.9%, implies that there are 4 to 8 million active cases at any given time.⁹ Despite these disconcerting numbers, there has been a significant decline in the total number of cases since the 1960s. Interestingly, the disease is becoming less common in developed countries and more common in developing nations.¹¹

Duodenal ulcer is more common than gastric ulcer (5:1), and men are afflicted more commonly than women (1.8:1). The incidence is increased in patients with renal failure and transplants, alcoholic cirrhosis, and chronic obstructive pulmonary disease (COPD). The stereotypes of young or middle-aged affluent men developing duodenal ulcers and the elderly or poor developing gastric ulcers are grossly inaccurate. Among the elderly, gastric or duodenal ulceration is an increasing problem. Although mortality rates for PUD have generally declined over the past 30 years, they remain amazingly high for the elderly—50 to 100 times greater at age 75 than at age 35.^{11,20}

MECHANISMS OF FORMATION

The mechanisms of peptic ulcer formation in the stomach and in the duodenum are not thought to be the same, but they do share some elements. There appears to be an imbalance between the production of acid and the ability of the mucosa to prevent itself from being damaged ([Table 155.1](#)). Acid secretion has been considered the key to ulcer formation, and indeed, ulcers will not form without it. Furthermore, reduction of acid secretion or acid neutralization promotes ulcer healing.

Endogenous Aggressive Factors	Endogenous Defensive Factors
Acid	Mucosal barrier
Pepsin	Mucus
Bile	Bicarbonate
Lysolecithin	Cell renewal
	Mucosal blood flow
	Prostaglandins

From Elias S. Medical principles for treatment of peptic ulcer. Scand J Gastroenterol 1987;117:28-32.

TABLE 155.1. Factors Acting On or in Gastric Mucosa

Because duodenal and gastric ulcers develop in patients who are not acid hypersecretors, acid production is not the sole factor involved; weakened defensive factors also play a role in ulcerogenesis. Healthy gastric or duodenal mucosa is an impressive barrier to the diffusion of hydrogen ions and can maintain a gradient of 3 million to 1 between lumen and blood. It also secretes bicarbonate and mucus, which form a buffering gel over the mucosa. Mucosal gel thickness is increased by the E prostaglandins and diminished by aspirin and nonsteroidal antiinflammatory drugs (NSAIDs). Maintenance of normal blood flow to the mucosa is an essential component of resistance to injury.

When ulceration does occur, pain results from direct chemical irritation by hydrochloric acid and disordered motor activity of the stomach and duodenum.

Research has focused on the small microaerophilic gram-negative spiral bacterium *Helicobacter pylori*, which is strongly linked to the formation of duodenal ulcers. This agent increases antral gastrin production, causes chronic gastric metaplasia and duodenitis, and decreases mucosal integrity. The most compelling evidence for the role of *H. pylori* in peptic ulcer disease is that the 1-year relapse rate for duodenal ulcers is less than 15% following eradication therapy but 70% to 80% after H₂-receptor antagonist therapy alone. Its eradication from the gastrointestinal (GI) tract on first presentation has been routinely advocated; this strategy has been associated with accelerated ulcer healing, a reduced rate of ulcer recurrence, and cure of the disease.

Regimens in current use include “standard triple therapy” with bismuth subsalicylate, metronidazole, and tetracycline for 2 weeks, combined with an H₂-receptor antagonist for 4 weeks. “Dual therapy” combines a proton pump inhibitor such as omeprazole 40 mg/d plus clarithromycin 500 mg t.i.d. for 2 weeks. Other current Food and Drug Administration (FDA)– approved regimens for the eradication of *H. pylori* include combinations of one or two antibiotics with either ranitidine, a bismuth salt, or a proton pump inhibitor ([Table 155.2](#)).^{3,4,7,10,12,13,14,15,16} and ^{17,19,21} Eradication of *H. pylori* does not affect symptoms of nonulcerative gastritis or symptoms of dyspepsia.

Therapy	Regimen (dosage × no. of days)	Eradication Rate (%)
Bismuth-based triple therapy with H ₂ -receptor antagonist		
Bismuth subsalicylate	2 tabs q.i.d. × 14	
Metronidazole	250 mg q.i.d. × 14	
Tetracycline	500 mg q.i.d. × 14	
Ranitidine (or equivalent)	150 mg b.i.d. × 28 (or equivalent)	77-82
H ₂ -receptor antagonist-based therapy		
Ranitidine bismuth citrate	400 mg b.i.d. × 28	
Clarithromycin	500 mg t.i.d. × 14	75-84
Proton pump inhibitor-based dual therapy		
Clarithromycin	500 mg t.i.d. × 14	
Omeprazole	40 mg q.d. × 14 (or 20 mg q.d. × 14)	64-74
Esomeprazole	30 mg q.d. × 14	
Amoxicillin	1 g b.i.d. × 14	66-77
Proton pump inhibitor-based triple therapy		
Esomeprazole	30 mg b.i.d. × 14	
Amoxicillin	1 g b.i.d. × 14	
Clarithromycin	500 mg b.i.d. × 14	86-92

TABLE 155.2. Current FDA-Approved Therapeutic Regimens for *Helicobacter pylori* Infection

In some patients with duodenal ulcer, there is an increase in the number of acid-producing gastric parietal cells and a direct relation between acid hypersecretion and the severity of ulcer disease. However, 50% of ulcer patients have normal acid secretion and show no relation between the severity of illness and the level of acid secretion. Other explanations of duodenal ulcer formation involve the delivery of a large, unbuffered acid load to the duodenum with subsequent mucosal damage, as occurs, for example, in the Zollinger-Ellison syndrome, in which serum gastrin levels are astronomic and normal feedback inhibition does not occur. More than 90% of

duodenal ulcers occur within 3 cm of the junction of the pyloric and duodenal mucosa, and most are small (less than 1 cm).

Gastric ulcers are larger and more extensive, and the majority are found on the lesser curvature of the stomach at the junction of the body and antral mucosa. Formation is probably related to an abnormality of the gastric mucosal barrier. Although their role in ulcer formation is yet to be proved, human bile, aspirin, and ethanol increase the permeability of the gastric mucosa to hydrogen ions. Pyloric dysfunction, bile reflux, and gastritis have been proposed to lead to gastric ulceration by weakening the normal mucosal defense mechanisms. Many factors may predispose to the development of ulcers (Table 155.3). Of these factors, cigarette smoking plays a major role both in ulcer formation and in recurrence through several mechanisms (Table 155.4). Of the other predisposing factors, aspirin and NSAIDs cause anatomic and physiologic alterations of the gastric mucosa, but there is still no conclusive evidence that they actually produce ulceration. Despite popular opinion, alcohol and caffeine ingestion have not been conclusively linked to ulcer disease. Diet also is not clearly related to PUD, and, at present, the only reasonable dietary recommendation for ulcer patients is to avoid foods that produce symptoms.⁹

DEFINITELY RELATED
Family history
Associated disease (COPD, cirrhosis, chronic renal failure)
Male gender
Advanced age
Smoking
POSSIBLY RELATED
Use of certain drugs (e.g., ASA, NSAIDs)
Psychological profile
NOT RELATED
Diet (caffeine, spicy or fatty foods)
Alcohol

TABLE 155.4. Effects of Smoking on Peptic Ulcer Disease

COMPLICATIONS

PUD continues to produce major complications despite the introduction of several apparently effective pharmacologic agents. However, the type of surgical procedure performed for complications of PUD has changed since the introduction of H₂ blockers. Fewer elective procedures are performed in the relatively fit, younger population, and more emergent operations are performed on older and sicker patients who are less able to tolerate surgery.¹⁸

Perforation continues to occur in peptic ulcer patients despite the availability of reasonably effective medical treatment.¹⁸ Perforation is heralded by a dramatic change in the pain pattern. Either severe pain and a surgical abdomen develop rapidly secondary to release of air and secretions into the peritoneal cavity, or a constant, deeper pain increases gradually with the slower development of surgical signs as a result of posterior penetration or a partially occluded perforation. Whether presenting suddenly or gradually, perforation is a surgical emergency requiring rapid diagnosis, resuscitation, and operation.

Hemorrhage from peptic ulcers is usually self-limited but is occasionally massive and life-threatening; it accounts for 20% to 30% of patients who require surgery for PUD.⁹ It is a common complication of PUD, with presentations ranging from melena alone to frank hypovolemic shock. Upper GI bleeding should be anticipated in any ulcer patient.

Gastric outlet obstruction, the result of scarring from repeated episodes of ulceration and fibrous healing, is usually associated with duodenal ulcer. It may also be caused by edema from an active ulcer. Fluid and gas accumulate in the stomach, causing fullness or distress that is often relieved by vomiting. Massive distention of the stomach can occur; volume depletion and electrolyte disturbances may be dramatic. In the emergency department, fluid resuscitation should be performed and the stomach should be decompressed by means of a nasogastric tube, but surgery may be necessary for definitive treatment. Gastric outlet obstruction may be the indication for as many as 30% of ulcer operations.⁶

Nonhealing, the failure of a gastric ulcer to improve with medical treatment, is suggestive of malignancy.

CLINICAL PRESENTATION

Peptic ulcer is a chronic but not necessarily life-long disease, frequently running a course of 10 to 15 years and marked by periods of acute exacerbation and remission. Pain may develop without obvious cause and persist for several days or weeks, but rarely longer. Because these episodes sometimes resolve with over-the-counter preparations, many patients do not seek medical assistance. Most ulcer patients experience a benign course, except for occasional symptomatic periods, but 10% to 20% develop some complication of the disease.

Most patients present to the emergency department for relief from a constant burning, gnawing, or aching pain. The pain of PUD is primarily epigastric, but it can be localized anywhere in the upper abdomen. With perforation of a posterior duodenal ulcer, pain often begins in the epigastrium and moves to the back. If pneumoperitoneum develops, pain may be referred to the shoulder as well.

The description and location of the pain is not as important in diagnosis as is its timing and any exacerbating and ameliorating factors. Gastric ulcer usually produces pain immediately after eating, when acid production increases in response to food. The pain of duodenal ulcer is most common between or just before meals and at night, when the upper GI tract is empty. Ingestion of food or antacids may bring rapid relief. Pain at 2 or 3 a.m. is classic for duodenal ulcer, probably because acid production is high and unbuffered by food. Acid production is at its lowest later in the morning, and pain is rarely present at this time. The classic history of a repetitive pain–food–relief sequence remains one of the better clinical diagnostic clues to PUD.

Asymptomatic peptic ulcer is not uncommon; an estimated 20% to 25% of all ulcers may be silent.⁸ In fact, nearly a third of patients with ulcer perforation and a fifth of those with upper GI hemorrhage have no previous symptoms of ulcer disease.

Uncomplicated PUD does not produce remarkable physical findings. Epigastric tenderness may be noted, but guarding and rebound are not present. Bowel sounds are most often normal, and there is no organomegaly. Rectal examination may show guaiac-positive stool if there has been unrecognized bleeding. The purpose of the physical examination is to exclude complications and other diseases, rather than to confirm the presence of peptic ulcer. Thus, examination of the heart and lungs

is indicated to help rule out cardiac or pulmonary disease masquerading as an abdominal process.

Guarding, rebound, and a tense abdomen signal perforation of an ulcer. There may be slight improvement immediately following perforation, but, within hours, shock ensues. Patients with perforation usually lie perfectly still, because the slightest movement produces intense peritoneal pain. In the elderly, findings may be minimal or absent, tending to delay the diagnosis in the group least able to tolerate delay.

Hemorrhage from PUD may cause surprisingly few physical findings on examination. A history of melanic stools should be sought, and orthostatic vital signs may help uncover clinically important but nonobvious bleeding. Frequently, significant bleeding presents with hematemesis; a nasogastric tube can be inserted to determine whether blood or "coffee grounds" are present in the stomach.

Gastric outlet obstruction usually produces some degree of bloating and a tympanitic epigastrium or succussion splash secondary to a distended stomach.

DIFFERENTIAL DIAGNOSIS

Myocardial infarction and angina are perhaps the most important diagnoses to consider in the differential diagnosis. They may present atypically as midepigastic pain, with complaints of nausea, bloating, and burning surprisingly similar to those of PUD, but without the typical periodicity and ameliorating factors. Moreover, many ulcer patients also have coronary artery disease. A careful history and electrocardiographic (ECG) examination can usually differentiate heart disease, however.

Gastritis usually produces a constant feeling of bloating and may not be relieved by antacids. Gastroenteritis produces colicky or crampy abdominal pain associated with diarrhea and vomiting. Biliary tract disease causes upper abdominal pain (classically after ingestion of fatty foods), but typically there is no history of early-morning pain or improvement with antacids. Esophagitis as a complication of hiatal hernia may be associated with intense pain immediately or shortly after swallowing. The constant, boring pain of pancreatitis frequently radiates to the back and is associated with elevated serum amylase levels.

A host of other conditions can produce pain in the upper abdomen, but, for the most part, these conditions are readily ruled out by history and physical examination.

EMERGENCY DEPARTMENT EVALUATION

A careful history and physical examination remain the most important methods for evaluating uncomplicated peptic ulcer. However, because other diseases may also present with epigastric distress, and because some complications of PUD may not be immediately apparent, additional diagnostic interventions are recommended.

For any patient in the age group at risk for coronary artery disease, an ECG should be performed and cardiac monitoring used, at least initially. A nasogastric tube should be passed if bleeding or obstruction is suspected, but routine use is probably unnecessary. Chemical tests for the presence of occult gastric blood are available, but their value is questionable because clinically insignificant iatrogenic bleeding often accompanies nasogastric tube insertion.

The chest x-ray is a useful adjunct for detecting free air from perforation and for ruling out thoracic disease. The patient is placed in an upright sitting position for 10 to 15 minutes before the x-ray to allow time for any free air to rise to the diaphragm; insufflating 100 to 200 mL of air through the nasogastric tube may enhance the chances of detecting free air radiographically. Unfortunately, pneumoperitoneum is seen on x-ray in less than 50% of patients with perforation, and the absence of this finding is often associated with delayed diagnosis and significantly increased mortality.

Abdominal x-rays can also be useful but are not routinely necessary. If the chest x-ray does not show free air, but suspicion of perforation is still high, an upright abdominal or left lateral decubitus view can be ordered. Contrast studies are also not a routine part of emergency department evaluation, but they are sometimes performed (using water-soluble contrast material) in an effort to identify suspected perforation. Likewise, endoscopy in the emergency department for uncomplicated PUD is not warranted.

A complete blood count is justified in most emergency department patients who complain of abdominal pain. Low red cell and hematocrit values may reveal significant recent blood loss, and the red cell indices can suggest that anemia is from chronic blood loss. The white cell count is usually normal in uncomplicated PUD, but it may help to differentiate upper abdominal pain of other causes. The white count rises with perforation. Serum amylase or lipase determinations are helpful if pancreatitis is a possibility, but they are not of much value for uncomplicated PUD.

Electrolytes, blood urea nitrogen, serum creatinine, and type and screen are useful for critically ill patients and those who are bleeding, vomiting, or "third-spacing" fluids. Liver function tests, including alkaline phosphatase and bilirubin levels, may be useful when a hepatobiliary process remains in the differential diagnosis. Hypochloremic hypokalemic metabolic alkalosis may be noted with intractable vomiting or gastric outlet obstruction.

Relief with antacids is a strong part of the classic peptic ulcer history and can be a helpful indicator, but it is not diagnostic of PUD. As many as one-fourth of ulcer patients may have concomitant coronary artery disease; thus, it is often difficult to ascribe symptoms or relief of symptoms to one or the other.¹⁸ The indiscriminate use of "GI cocktails" consisting of various combinations of antacids, anticholinergics, barbiturates, and viscous lidocaine, particularly as a diagnostic maneuver, should be discouraged.

EMERGENCY DEPARTMENT MANAGEMENT

Most patients with PUD have normal vital signs, are in minimal distress, and do not require any major intervention. These patients may be given antacids to help relieve pain. Because salicylates and other NSAIDs are associated with the development of peptic ulcer, these agents should be discontinued if in use.

With the recognition that *H. pylori* therapy plays a central role in the pathogenesis of peptic ulcer, the objective of therapy is now eradication and cure. Thus, patients with documented peptic ulcer disease by upper GI contrast radiography or endoscopy should be treated for *H. pylori*. This should be done with appropriate consultation to guide the decision on the most effective antibiotic regimen. Detection of *H. pylori* can be confirmed on histologic mucosal biopsies, by culture, serologically by ELISA, and urea breath test.² Serology is now widely used for routine detection and to monitor treatment. Caution should be used for those patients who display signs and symptoms of gastric hypersecretory state, recent antibiotic therapy, and recent use of NSAIDs. If there is nothing to suggest that complications have occurred, specific diagnostic testing for *H. pylori* may be unnecessary, and treatment for eradication may begin as discussed.^{3,4,7,10,12,13,14,15,16 and 17,19,21}

Traditional agents for peptic ulcer disease are used in an adjunctive role and for symptomatic relief of peptic ulcer. Additionally, these agents neutralize or reduce acid secretion, accelerate the rate of ulcer healing, and prevent recurrence and complications.

H₂-receptor antagonists competitively inhibit the action of histamine on H₂ receptors located in gastric parietal cells and dramatically reduce basal acid secretion as well as secretion in response to feeding, gastrin, hypoglycemia, and vagal stimulation. They are generally safe and effective. Currently, four H₂ antagonists are available in the United States: 800 mg of cimetidine is equivalent to 300 mg of ranitidine, 40 mg of famotidine, or 300 mg of nizatidine. A single bedtime dose of 800 mg of cimetidine (or equivalent doses of the other three H₂ blockers) appears to be roughly as effective as several doses given throughout the day. When used primarily for exacerbations of PUD, low-dose maintenance therapy with H₂-receptor antagonists may also be safe and effective.

Sucralfate is an aluminum salt of sucrose that forms a polymer in the acid environment of the stomach. This polymer adheres selectively to the ulcer crater, forming a physiologic dressing for the damaged mucosa and protecting it from acid; other mechanisms may be at work as well. Sucralfate appears to heal ulcers as effectively as H₂ blockers. It is nonabsorbable and has a very low incidence of side effects. The usual initial dose is 1 g four times a day or 2 g twice a day.

Anticholinergics have been used for PUD for many years and are available in a number of formulations. They decrease acid production, but they also produce dry mouth, urinary retention, and other anticholinergic side effects.

Other agents now available have been found to be at least as efficacious as the H₂ blockers. These include the prostaglandin congeners, such as misoprostol, which

increase the cytoprotective properties of the gastric mucosa, and proton pump inhibitors, such as omeprazole, which effectively reduce gastric acid secretion. [15](#)

Patients with complications of PUD require more intensive management, including intravenous infusion of crystalloid or blood, supplemental oxygen, cardiac monitoring, and more specific endoscopic or surgical intervention.

Transfusion is indicated for bleeding patients who fail to stabilize after receiving 2 L of crystalloid, have known coronary artery disease, or are experiencing angina. Trends in hemoglobin and hematocrit values are more useful than a single value; any significant decrease should be considered an indication for transfusion.

DISPOSITION

Patients who are obviously critically ill, have unstable vital signs, or are suffering from a complication of PUD require prompt consultation with a specialist. Other patients may need admission for pain control, gastric decompression, or fluid resuscitation, and do not necessarily require monitoring. Cases of apparently uncomplicated PUD may be referred to a family physician or internist. Initiation of PUD therapy in the emergency department does not obviate the need for outpatient referral, to identify patients who do not respond and may be candidates for endoscopy.

Ulcer patients who require admission may need to be transferred to another institution for endoscopy, critical care services, or surgery. Potentially unstable patients should be transported by an advanced life-support unit.

COMMON PITFALLS

- Failure to consider other life-threatening etiologies for epigastric pain, especially myocardial infarction or abdominal aortic aneurysm
- Failure to recognize sudden changes in symptomatology that herald the onset of a serious complication
- Failure to place a nasogastric tube when indicated
- Failure to refer the patient to an appropriate specialist for evaluation of response to therapy and the need for further diagnostic workup

CHAPTER 156

Gastrointestinal Foreign Bodies

Valerie C. Norton

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Gastrointestinal (GI) foreign bodies present a diverse set of challenges to the emergency physician. Presentations range from the obvious to the occult, from the mundane to the bizarre, and from the benign to the life-threatening. Management options are accordingly diverse as well, ranging from watchful waiting to emergent endoscopy or surgery.

Physicians must be familiar with the signs and symptoms of ingested foreign bodies, especially in patients such as small children or psychiatric patients who have no obvious history of ingestion. They must have a good understanding of various removal techniques for foreign bodies in the esophagus or rectum. They must also know which situations require emergent intervention and whom to consult when intervention is necessary.

About 80% of cases involve ingestion of foreign bodies by a child (see [Chapter 271](#)). Children tend to ingest coins, toys, and other small objects left within their reach. Adult patients at highest risk include psychiatric patients, prisoners, those with impaired mental status or intoxication, those with underlying esophageal abnormalities (e.g., strictures), and denture wearers, who have reduced sensation of the palate.¹⁶ Adults most commonly have trouble with boluses of meat and animal bones, though psychiatric patients and prisoners may intentionally ingest unusual objects, such as razor blades or open safety pins.

Ingested foreign bodies frequently become lodged in the esophagus, often requiring urgent removal. Much more rarely, objects fail to pass the pylorus or the ileocecal valve. Over 80% of ingested foreign bodies that pass into the stomach will traverse the rest of the gut uneventfully.¹⁵ Objects that are less likely to pass spontaneously are those longer than 6 cm; sharp objects, such as pins and toothpicks; and blunt objects wider than 2.5 cm.¹

Of primary concern are objects lodged in the esophagus, because these are at highest risk for complications such as mucosal erosions, perforation, or airway compromise. Objects typically lodge at the level of the cricopharyngeus muscle, the level of the aortic arch, or the lower esophageal sphincter. High esophageal impactions are most common in children; adults most often have obstructions at the lower esophageal sphincter.¹⁵ Foreign bodies with toxic contents, such as button batteries and packages of cocaine, represent special cases (discussed in [Chapter 333](#) and [Chapter 326](#), respectively). A button battery lodged in the esophagus is a true emergency requiring immediate endoscopic removal.

Rectal foreign bodies are usually the result of sexual misadventure or assault, though occasionally a patient will present with an ingested foreign body, such as an animal bone, that has passed through the entire gut only to become lodged in the rectum.^{2,17} Men are at least 28 times more likely than women to present with rectal foreign bodies.¹⁵ Objects inserted into the rectum include vibrators, vegetables, broomsticks, drugs or other contraband, and even live animals, such as gerbils. Many objects are not visible on x-ray, though most are low-lying and palpable on rectal examination. Mucosal lacerations and rectal perforations are fairly common, especially in assault victims, and may result in life-threatening sepsis.

CLINICAL PRESENTATION

Healthy adults with ingested foreign bodies often give a clear history of the inciting incident and may report a foreign-body sensation if the object is lodged in the upper esophagus, where somatic nerve endings are present. If a meat bolus or other object is impacted in the lower esophagus, they usually complain of more visceral-type chest pain, odynophagia, and difficulty handling secretions. Objects that have passed into the stomach or beyond frequently cause no symptoms, unless obstruction or perforation has ensued.

Small children and adults with impaired mentation may not give a clear history of foreign-body ingestion. Clinicians may have to rely on symptoms of obstruction, such as drooling if the object is in the esophagus, or vomiting and distension if it is impacted below the stomach. Patients may also present with GI bleeding or signs and symptoms of peritonitis due to perforation. Small children often display indirect symptoms such as gagging and choking, refusal to eat, irritability, or respiratory distress if the object is compressing the trachea or causing aspiration of saliva.

Patients with rectal foreign bodies usually state clearly that something is in the rectum, though they may be very vague as to how it got there. These patients or their partners have often made multiple prior attempts to remove the object.¹⁵ Occasional patients may be unaware of the object if intoxicated at the time of insertion, or may be too embarrassed to admit to it, complaining instead of rectal pain or bleeding. Patients with extraperitoneal rectal perforation may present with sepsis, while those with intraperitoneal perforation present with peritonitis.

DIFFERENTIAL DIAGNOSIS

In the absence of a history of ingestion or insertion of a foreign body, the differential diagnosis is difficult. It should include all processes that can obstruct, irritate, erode, or perforate the GI tract. Other organ systems may initially be the focus of concern, because esophageal pain can mimic cardiac angina, and children with esophageal obstruction may present with stridor or other respiratory symptoms that may be mistaken for croup or asthma.

Subacute and chronic presentations do not rule out foreign bodies. A wealth of literature has reported objects dwelling in the stomach or intestines for years before causing symptoms. Esophageal foreign bodies have been impacted for a month or more in some children, without serious sequelae.^{4,7,9} Clinicians should also be aware that even when there is a clear-cut history of foreign-body ingestion or insertion, other unsuspected pathologies may be present, such as a second foreign body, a mucosal laceration, or underlying esophageal disease.^{1,2,14}

EMERGENCY DEPARTMENT EVALUATION

Initial assessment should aim at immediate detection and treatment of those with frank airway compromise, sepsis, or perforation. In more stable patients, the physical examination may find signs of esophageal obstruction, such as drooling or gagging; signs of lower intestinal obstruction; or evidence of GI bleeding. In the majority of patients with upper GI foreign bodies, the physical examination is unrevealing. By contrast, rectal foreign bodies are usually palpable on rectal examination. Some authors advise against a digital rectal examination prior to obtaining radiographs, because examiners may injure themselves if an unexpectedly sharp object is present.¹⁵

Imaging studies are often very helpful, though a negative study does not rule out a radiolucent foreign body. For suspected esophageal foreign bodies, both anteroposterior and lateral radiographs of the neck and chest are recommended to avoid missing a second foreign body located behind the first or one lower in the esophagus. Both views also help to rule out a tracheobronchial foreign body.^{14,15} Flat objects in the esophagus, such as coins, typically appear “en face” on anteroposterior views and “on end” on lateral views, because the easily compressible esophagus typically lies somewhat flattened between the trachea and the spine. Tracheal coins, by contrast, typically appear “on end” on anteroposterior views, because the more rigid tracheal rings have their widest diameter in the sagittal plane.¹⁵

Some authors have advocated the use of a hand-held metal detector in lieu of plain films to evaluate the presence and location of metallic foreign bodies.¹² Accuracy appears to be good for coins, but not for smaller metal objects, making this modality of questionable utility unless one is certain that the object is a coin.¹¹ In addition, the number of patients studied so far has been too small to know whether metal detectors can make the crucial distinction between the lower esophagus and the

stomach when localizing a coin.

Objects below the esophagus may be evaluated with standard plain films or contrast radiography if necessary. In most cases, the primary reasons to obtain radiographs are to determine (1) whether an ingested object has passed beyond the esophagus and (2) whether the object has any physical characteristics that will make passage or extraction more difficult, such as a sharp edge.

EMERGENCY DEPARTMENT MANAGEMENT

Patients with signs of airway compromise require definitive airway management and emergent endoscopic consultation to remove the foreign body. Those with signs of hollow viscus perforation, massive bleeding, or sepsis require immediate resuscitation, intravenous antibiotics, and emergent surgical consultation.

The management of stable patients depends on the type, location, and duration of impaction of the foreign body. Management guidelines are summarized in [Fig. 156.1](#). In the esophagus, sharp objects and button batteries require immediate endoscopic removal. Blunt esophageal foreign bodies are typically objects in the midesophagus to upper esophagus, objects at the lower esophageal sphincter, or food boluses. Objects in the upper half of the esophagus are unlikely to pass spontaneously, mandating intervention. The standard of care at most large institutions is prompt endoscopic removal. [1,15,16](#) If endoscopy is not readily available, it may be postponed briefly if the patient is able to handle secretions. Most experts recommend removal within 12 to 24 hours. [1,5,16](#)

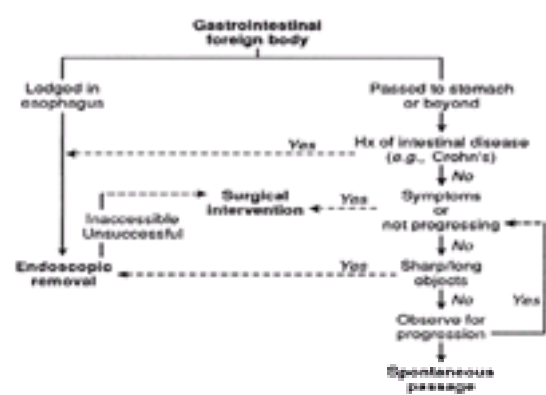

Figure 156.1. Management of gastrointestinal foreign bodies.

Objects lodged at the lower esophageal sphincter are often managed with a trial of watchful waiting with or without measures to relax the sphincter, because many of these objects will pass spontaneously. Glucagon may be given to help relax the lower esophageal sphincter in a dose of 1.0 to 2.0 mg intravenously, though its use is controversial and may cause vomiting. [15,16](#) This dose may be repeated once in 20 to 30 minutes if unsuccessful. If passage has not resulted in 12 to 24 hours, most authors recommend endoscopic removal. [1,4,16](#)

The management of esophageal food boluses depends on the degree of symptoms experienced by the patient as well as the composition of the bolus. Boluses causing high-grade obstruction and inability to handle secretions require emergent endoscopic removal. [1,16](#) Most authors also recommend prompt endoscopic removal of boluses that are seen radiographically to contain sharp bones, because these are more likely to cause esophageal perforation. Other boluses may be managed by watchful waiting with or without glucagon, with removal in less than 24 hours if passage does not occur. [1,16](#) The use of gas-producing liquids such as carbonated beverages to aid in break-up and passage of the bolus has been reported [8](#) but remains controversial. Proteolytic enzymes are contraindicated, as they can cause severe damage to the esophageal mucosa.

Although endoscopic removal of esophageal foreign bodies is standard at many institutions, the choice of technique is controversial in some areas because of cost concerns. A number of authors have advocated the alternative, less costly techniques of fluoroscopic Foley catheter extraction and esophageal bougienage (advancement of the foreign body with an esophageal dilator). [3,5,6](#) and [7,9,13](#) In experienced hands and in selected patients, these techniques have success and complication rates comparable to those of endoscopy. These alternative techniques should be limited to patients with a blunt foreign-body (usually a coin) impaction of less than 24 hours' duration, no history of esophageal disease, and no signs of respiratory distress or airway compromise. [3,6,9](#)

Patients with radiographic signs of esophageal edema or underlying esophageal disease are not ideal candidates and will have lower success rates. [7,13](#) Advanced airway management should be immediately available at all times. The procedure should be terminated if resistance is met or multiple attempts are needed, as serious complications have occurred in these settings. [3,13](#)

Cost is becoming less of an issue as flexible endoscopy under conscious sedation in the emergency department increasingly replaces rigid endoscopy under general anesthesia in the operating room, [16](#) resulting in lower charges and shorter recovery times. In many institutions, flexible endoscopy may now be comparable to catheter extraction or bougienage in terms of cost and convenience.

Objects in the stomach and small intestine are much less problematic than those in the esophagus, because the vast majority will pass spontaneously. The exceptions are sharp objects, which may cause perforation in up to 35% of patients; they should be removed endoscopically if still in the stomach or duodenum. [1,15](#) Some authors also recommend endoscopic removal of objects more than 6 cm long or 2.5 cm wide that are found in the stomach or duodenum, as these are less likely to pass. [1,16](#) Small, blunt objects can be followed clinically, with repeat x-rays weekly if passage in the stool is not noted. A high-fiber diet may aid passage of the foreign body. Blunt objects should be given 3 to 4 weeks to pass out of the stomach before resorting to endoscopic removal. [1,16](#) Objects may be given 2 to 3 weeks to traverse the rest of the gut. The development of symptoms or the failure of the object to progress mandates surgical consultation.

Rectal foreign bodies frequently require surgical consultation to bring about removal, although various authors report being able to remove 20% to 60% of objects in the emergency department. [2,17](#) Removal in the emergency department is dependent on the ability to achieve adequate relaxation of the anal sphincter and adequate purchase on the foreign body. Many patients with long histories of rectal stimulation have lax anal tone and may require only lidocaine gel, with or without conscious sedation, to relax the sphincter. Other patients may require infiltrative local anesthesia, and some may only achieve adequate relaxation with spinal or general anesthesia in the operating room.

Soft, low-lying objects with an edge can often be grasped and removed manually or with forceps. Some objects create suction on the rectal mucosa with downward traction, which can be overcome by passing a Foley catheter beyond the object and insufflating air into the rectum. [10,15](#) Sigmoidoscopy after removal is mandatory to look for complications such as abscesses or mucosal lacerations, as these are very common. [2,15,17](#) Hard, smooth-edged, or high-lying objects usually cannot be removed manually and require surgical consultation for removal by flexible sigmoidoscopy in the operating room or endoscopy suite. [17](#) Laparotomy is a last resort for foreign bodies in which sigmoidoscopy is unsuccessful.

DISPOSITION

Asymptomatic patients with uncomplicated, blunt foreign bodies in the stomach or small intestine can be discharged from the emergency department with observation of the stools and radiographic follow-up at appropriate intervals to ensure progress of the object through the gut. All others require consultation with an endoscopist or a surgeon, depending on the type and location of the foreign body and the presence of any complications. Following the uncomplicated removal of a foreign body in the emergency department, asymptomatic patients who have fully recovered from any sedation can be sent home with close follow-up by their primary care provider or an appropriate consultant. Patients who remain symptomatic or who develop complications after a procedure require admission.

COMMON PITFALLS

- Failure to consider an esophageal foreign body in patients without a foreign-body history but with suggestive symptoms, such as gagging, drooling, wheezing, or refusal to eat
- Failure to obtain immediate endoscopy for patients with high-grade esophageal obstruction, sharp esophageal foreign bodies, or button batteries in the esophagus
- Inappropriate use of Foley catheter or other removal techniques in patients with sharp or irregularly shaped esophageal foreign bodies, prolonged impactions, signs of respiratory compromise, or when initial attempts meet resistance—all of these may lead to serious complications.
- Inappropriate, repeated attempts to remove hard, smooth, or high-lying rectal foreign bodies in the emergency department. This may lead to further mucosal damage or even rectal perforation.
- Failure to obtain sigmoidoscopy after removal of rectal foreign bodies to rule out mucosal lacerations

Because amylase is found in a variety of extrapancreatic locations (including the salivary glands, the small intestine, and the female genital tract), reliance on the amylase level alone may be misleading.

Necrotizing acute pancreatitis is a systemic disease. In- trvascular volume loss due to massive edema and exudation of fluid into the peritoneal cavity, due to systemic effects of released vasoactive substances, or due to pancreatic hemorrhage may lead to frank hypovolemic shock.³ Two classic signs of retroperitoneal hemorrhage are the Cullen sign (periumbilical ecchymosis) and the Grey Turner sign (flank ecchymosis), but these are uncommon. In fact, the term *hemorrhagic pancreatitis* has been abandoned because hemorrhage is not usually a major component of acute pancreatitis.² In some cases, the clinical picture is dominated by manifestations of remote organ system dysfunction or by the systemic effects of pancreatic abscess.

The hallmarks of *chronic pancreatitis* include abdominal pain, weight loss, steatorrhea, exocrine and endocrine dysfunction, and pancreatic calcification.

Patients with chronic pancreatitis often present to the emergency department with recurrent attacks of abdominal pain, although, in some patients, pain is overshadowed by weight loss and the effects of pancreatic endocrine or exocrine dysfunction (i.e., diabetes mellitus or malabsorption and steatorrhea).

More than 90% of the gland must be destroyed before exocrine insufficiency results in clinically significant malabsorption of protein, fat, and fat-soluble vitamins. Pancreatic endocrine dysfunction, with deficient insulin and glucagon secretion, may result in diabetes mellitus that is occasionally “brittle” and associated with frequent episodes of hypoglycemia.

Pancreatic cancer, which is most often ductal in origin, can simulate the pain and glandular damage seen in patients with chronic pancreatitis. More than 90% of patients have pain, jaundice, or weight loss at the time of diagnosis. Clinical pancreatitis and diabetes mellitus are noted in up to 14% and 33% of patients, respectively.

DIFFERENTIAL DIAGNOSIS

The most common conditions confused with acute pancreatitis are acute cholecystitis and peptic ulcer disease, but essentially any intraabdominal emergency may be mimicked. The pain of cholecystitis is located more often in the right upper quadrant, tends to be more gradual in onset, and is not always constant. Ultrasound examination and radionuclide scanning are useful in establishing the diagnosis of biliary tract disease. An elevation of the alkaline phosphatase level in the absence of a comparable elevation in serum transaminase levels is also suggestive. Although simple acute cholecystitis may be complicated by acute pancreatitis, the serum amylase value may be elevated in both conditions. Gallstones should be excluded early in all patients with acute pancreatitis, because their presence is associated with increased morbidity and mortality.⁵

Alcoholic gastritis is commonly present in association with alcohol-induced pancreatitis, and distinguishing between the two entities clinically is often difficult or impossible. Tenderness and peritoneal signs are more likely to represent pancreatitis, but a posterior penetrating ulcer may produce features of both illnesses. Other serious disorders may be responsible for significant abdominal pain in association with elevated serum am- ylase levels, and failure to recognize this fact may lead to a dangerous misdiagnosis. These disorders include intestinal obstruction, ruptured ectopic pregnancy, mesenteric infarction, dissecting aortic aneurysm, peritonitis, acute appendicitis, and diabetic ketoacidosis. The differential diagnosis of upper abdominal pain must also include myocardial infarction, pneumonia, and renal colic.

The diagnosis of chronic relapsing pancreatitis is primarily a clinical one. Diagnosing pancreatic cancer against a background of chronic pancreatitis may be difficult, however. Chronic pancreatitis can produce all of the symptoms of pancreatic cancer and can cause focal or diffuse enlargement of the gland as well.

Calcific deposits are fairly specific for chronic pancreatitis, however, while jaundice is much more common with carcinoma of the head of the pancreas. Endoscopic retrograde cholangiopancreatography (ERCP) is often useful in identifying pancreatic cancer, although an identical picture can be seen in both entities⁷; ERCP also allows the collection of pancreatic secretions for cytologic examination.⁷

EMERGENCY DEPARTMENT EVALUATION

The challenge of the emergency department evaluation of unsuspected pancreatitis is to make the diagnosis and to exclude other causes of abdominal distress, yet to keep in mind the fact that other serious illness may occur in combination with pancreatitis. Once the diagnosis is made, one must assess the severity of the pancreatitis to make an appropriate disposition.

The diagnosis of pancreatitis is based primarily on the history and physical examination and is *supported* by laboratory studies, most notably the serum amylase level. The “gold standard” of diagnosis is direct inspection or pathologic examination of the pancreas; all other diagnostic modalities are indirect tests. Thus, it is often stated that pancreatitis should remain a “working diagnosis” that one should feel free to modify in the face of a changing clinical picture.

Because the serum amylase value is a reasonably sensitive test, the diagnosis should be questioned if the level is normal. Nevertheless, a normal amylase value was found in about one-third of patients with clinical pancreatitis in one series, and there is no correlation between the severity of pancreatitis and the degree of amylase elevation.¹⁵ There are several possible reasons for this. Renal clearance of amylase is rapid, and the serum amylase level in pancreatitis may remain elevated for only up to 72 hours; thus, in a patient who presents a few days after the onset of symptoms, the level may be only minimally elevated or normal.¹⁵ Moreover, in some individuals who have had many episodes of acute pancreatitis, extensive scarring may result in a “burned out” pancreas that releases little amylase. One other cause for spuriously low serum amylase measurements is severe hypertriglyceridemia, in which there may be a circulating amylase inhibitor; this laboratory artifact may be corrected for by measuring the serum amylase activity on serial dilutions of plasma.

Despite the reasonably good sensitivity of the serum amylase test, it is nonspecific, at least when the conventional upper limit of normal is employed.²² (Interestingly, elevated serum total amylase in patients with clinical pancreatitis was noted in one series to be due to the salivary isoenzyme in 26% of individuals.²³) Using a higher cut-off level greatly increases the specificity of the total amylase determination, while sensitivity appears to be maintained.²¹ The urinary amylase–creatinine clearance, although recommended as a more specific test for acute pancreatitis, particularly to distinguish it from biliary tract disease, appears to offer no advantage.¹⁵

Because of its availability and high specificity (99%), the serum lipase level is the confirmatory test that is most widely used when the diagnosis of pancreatitis is in doubt.²¹ Because the pancreas is the only major source of lipase, an increased level (and particularly a level more than three times the upper limit of normal) is very specific for acute pancreatic inflammation. Other confirmatory tests, such as measurements of amylase isoenzymes (pancreatic and salivary), trypsinogen, serum elastase, and phospholipase A₂, have been investigated, but they are less widely available for use in emergency department patients.^{15,21,24} A number of these tests not only are more specific (about 85%) than the total amylase (at least using its conventional upper limit of normal), but also are reported to remain abnormal for significantly longer (7 to 14 days) than the total serum amylase level.^{11,21}

Plain radiographs of the chest and abdomen should be obtained primarily to rule out other entities, such as pneumoperitoneum, small bowel obstruction, and aortic aneurysm.¹⁵ The abdominal radiograph in acute pancreatitis may show regional or localized ileus (“sentinel loop”), gallstones, widening of the duodenal sweep, blurring of the left renal outline and psoas margin, elevation of one or both hemidiaphragms, or pleural or pericardial effusion.⁸ These radiographic findings are caused initially by motility disturbances in the surrounding bowel and later by pancreatic edema and peripancreatic fluid collection. The finding of pancreatic calcifications is an indication that previous episodes of acute pancreatitis have occurred, and it is essentially diagnostic of chronic pancreatitis.

Other diagnostic imaging studies are sometimes extremely helpful. Ultrasonography can identify pancreatic edema as well as such complications as pancreatic pseudocyst or abscess. It is also useful in identifying the presence of gallstones or dilatation of the biliary tree, findings that have obvious diagnostic and therapeutic implications.¹⁹ A practice guideline for acute pancreatitis recommends that an abdominal ultrasound should be part of the evaluation of the initial episode of acute pancreatitis and should be performed during the initial 24 to 48 hours of hospitalization.² Its most important use among patients with additional episodes of pancreatitis is to determine whether the cause is gallstones. Ultrasound visualization is difficult, however, if the pancreas is surrounded by large amounts of adipose tissue or if there are overlying distended loops of bowel.

In recent years, dynamic, contrast-enhanced computed tomography (CECT) has become the imaging gold standard for evaluating the presence and extent of

pancreatic necrosis and other local anatomic sequelae of acute pancreatitis, such as pseudocyst, abscess, or fistula. As such, it has become a routine part of the diagnostic workup of most patients. CECT assessment of disease severity is based on semiquantitative estimation of pancreatic and peripancreatic inflammation, presence and degree of necrosis, and associated abnormalities, such as pleural effusion or ascites. ⁶

[Table 157.3](#) lists the CT severity index developed by Balthazar and Ranson. ¹ The practice guideline for acute pancreatitis by the American College of Gastroenterology recommends that CECT be performed among patients that are clinically demonstrated to have severe pancreatitis. Magnetic resonance imaging has not been shown to be superior to CT. ^{15,20}

CT Grade	Grade Score	Definition
A	0	Normal pancreas
B	1	Focal or diffuse pancreatic enlargement
C	2	Nonspecific pancreatic abnormality + haziness/strandy densities in peripancreatic fat
D	3	Single, ill-defined fluid collections
E	4	Multiple, ill-defined fluid collections or pancreatic or peripancreatic gas

Gland Necrosis (%)	Necrosis Score	Definition
None	0	Uniform pancreatic enhancement
<30	2	Nonenhancement of regional or gland equivalent in size to the pancreatic head
30-50	4	Nonenhancement of 30%-50% of the gland
>50	6	Nonenhancement of over 50% of the gland

Severity index = Necrosis score + Grade score.
 Mild pancreatitis = severity index of 1-3.
 Moderate pancreatitis = severity index of 4-6.
 Severe pancreatitis = severity index of 7-10.

Adapted from Balthazar EJ, Freeny PJ, van Sonnenberg J. Imaging and intervention in acute pancreatitis. Radiology 1984;191:297.

TABLE 157.3. Balthazar CECT Scoring System

ERCP should be considered for patients in whom the cause of pancreatitis remains unclear after initial evaluation. ERCP may be helpful in elucidating the cause of pancreatitis in up to half of such individuals, ²² revealing small pancreatic tumors, pancreatic ductal stricture, gallstones, pancreas divisum, choledochocoele, or sphincter of Oddi dysfunction.

After establishing the diagnosis of acute pancreatitis, the second priority is to determine its severity. Five percent to 10% of patients develop serious complications or die of the disease. Severe cases are indicated by the presence of organ failure (including shock, pulmonary insufficiency, and renal failure) and/or local complications (especially pancreatic necrosis). ^{2,4}

An increased risk of major complications has been associated with a number of clinical features, the so-called Ranson criteria or their modifications ([Table 157.4](#)). ^{2,18} Among them are age greater than 55; leukocytosis (reflecting the degree of inflammatory response); elevated serum lactate dehydrogenase and aspartate aminotransferase levels (suggesting hepatic and other tissue injury or necrosis); marked hyperglycemia (reflecting possible pancreatic endocrine dysfunction); hypocalcemia (from the formation of soaps by necrotic pancreatic tissue or other poorly defined mechanisms); rising blood urea nitrogen levels (secondary to third-space fluid losses or renal impairment); a falling hematocrit (reflecting both initial hemoconcentration and hemorrhagic necrosis); arterial hypoxemia (due to pleural effusion or adult respiratory distress syndrome from systemic effects of severe pancreatic damage); and the development of metabolic acidosis or marked fluid retention.

ON ADMISSION
Age >55 yr
WBC >16,000/mm ³
Blood glucose >200 mg/dL
Lactate dehydrogenase >350 IU/L
Aspartate transaminase >250 IU/L

WITHIN 48 HOURS
BUN >5 mg/dL
FaO ₂ <60 mmHg
Serum calcium <8 mg/dL
Hematocrit fall >10%
Base deficit >4 mEq/L
Fluid sequestration >6 L

Mortality is based on number of prognostic signs: 0-2, 1%; 3-4, 15%; 5-6, 40%; >6, 100%.
 Adapted from Ranson JHC. Etiologic and prognostic factors in human acute pancreatitis: a review. Am J Gastroenterol 1982;77:663.

TABLE 157.4. Ranson Criteria for Predicting the Severity of Acute Pancreatitis

The APACHE-II score is based on 12 physiologic variables, the patient's age, and any history of severe organ system insufficiency or immunocompromised state. Studies indicate that measurement of the APACHE-II score on the day of admission has high sensitivity and specificity in distinguishing mild from severe pancreatitis, and is superior to other grading systems for this purpose. ² An advantage of the APACHE-II system is that it can be done at presentation and can be followed daily, whereas other systems (including Ranson's signs) rely, to a degree, on data points collected at 48 hours. When the APACHE-II score is less than 8 during the first 24 to 48 hours, the patient usually survives. One study found the APACHE-II score to be superior to CT grading in the initial evaluation of the severity of acute pancreatitis. ⁶ The practice guideline for acute pancreatitis recommends that a formalized severity index be generated for each patient ([Table 157.5](#)). The APACHE-II score and/or Ranson's criteria score should be generated on the day of admission to help identify patients with severe pancreatitis. ^{2,3}

EARLY PROGNOSTIC SIGNS
Ranson's signs ≥3
APACHE-II score ≥8

ORGAN FAILURE
Shock: systolic blood pressure <90 mm Hg
Pulmonary insufficiency: FaO ₂
Renal failure, creatinine >2 mg/dL
Gastrointestinal bleeding >500 mL/24 h

LOCAL COMPLICATIONS
Necrosis
Abscess
Pseudocyst

Adapted from Banks PA. Practice guidelines in acute pancreatitis. Am J Gastroenterol 1997;92:137.

TABLE 157.5. Prognostic Factors for Severe Pancreatitis

Emergency department evaluation of chronic pancreatic disease should focus on both functional and structural components. Clinical examination should seek evidence of endocrine and exocrine manifestations such as hyperglycemia or hypoglycemia, hyperlipidemia, steatorrhea, and nutritional deficiencies.

Structural abnormalities in chronic pancreatitis or cancer can be identified by imaging or endoscopy. Plain abdominal radiographs show diffuse calcification of the pancreas in about 20% of cases of chronic pancreatitis. Ultrasonography, CT, and ERCP can all be used to diagnose ductal abnormalities, pancreatic tumors, pseudocyst, abscess, or phlegmon.

EMERGENCY DEPARTMENT MANAGEMENT

Ninety percent of all cases of acute pancreatitis may be treated with supportive measures only. The aim of medical therapy is generally held to be “to place the pancreas at rest.” Although it is commonly recommended that oral intake should be withheld, it appears that the oral intake of clear liquids is not harmful, at least in mild to moderately severe cases. Intravenous fluids should be administered as needed, and electrolyte abnormalities such as hypokalemia, hypocalcemia, and hypomagnesemia corrected. In patients with moderate-to-severe pain, meperidine has traditionally been the analgesic of choice because it is thought to cause less spasm of the ampulla of Vater than morphine.¹¹ Antiemetics such as prochlorperazine or hydroxyzine may be given to control vomiting. Nasogastric suction, long thought to be a necessary component of management, has not been shown to offer any additional benefit in mild-to-moderate pancreatitis if ileus is not present.¹⁷ Likewise, anticholinergics are no longer believed to be of value. Although it was speculated that H₂ blockers might serve to decrease the severity or the duration of episodes of acute pancreatitis by decreasing the acid stimulus to pancreatic secretion, several studies have shown them to have no benefit.¹⁷

About 5% of cases of acute pancreatitis result in serious complications or death (see [Table 157.2](#)). These patients commonly require large amounts of fluid replacement (and sometimes colloid) because of retroperitoneal sequestration of pancreatic exudate and remote systemic effects of released vasoactive substances. A central venous or Swan-Ganz catheter and an indwelling urinary catheter may be needed to monitor intravascular volume status and to guide fluid replacement. In patients with ileus or intractable vomiting, a nasogastric tube should be inserted. Surgical consultation is indicated for patients with clinically severe pancreatitis or evidence of large peripancreatic fluid collections, abscess, or pancreatic necrosis on CT. Antibiotic administration should be reserved for those patients with evidence of established infection.

In patients with chronic pancreatitis or pancreatic cancer, the overall goals of therapy are symptom relief and prevention or correction of local and systemic complications. Pancreatic enzyme supplementation and balanced nutritional intake are the basics of therapy for pancreatic exocrine insufficiency.⁹ Provision of adequate amounts of supplemental oral pancreatic enzymes (pancreatin or pancrelipase) can lead to relief of pain, presumably by a process of negative feedback inhibition.⁹ Diabetes mellitus as a consequence of endocrine insufficiency requires obsessive attention to insulin administration and diet to avoid ketoacidosis and other complications.

Control of chronic abdominal pain is also of prime importance. Impaired absorption of orally administered medications because of pancreatic disease may necessitate the use of parenteral analgesics. Surgery may be necessary for the treatment of regional complications of chronic pancreatitis (e.g., drainage of a pseudocyst, decompression of the biliary tree, or alleviation of duodenal obstruction).¹⁶

DISPOSITION

Patients with mild pancreatitis, in whom the likelihood of biliary tract disease is believed to be low, may be managed on an outpatient basis if they are able to tolerate clear liquids in the emergency department and have no evidence of systemic complications. For these individuals, a clear-liquid diet and oral analgesics should be prescribed, and close follow-up should be arranged. Patients with alcohol-associated pancreatitis should be encouraged to stop drinking.

All other patients must be admitted to the hospital. If severe or necrotizing acute pancreatitis is suspected, admission to an intensive care unit is mandatory for critical care monitoring of cardiac, pulmonary, and renal function. In the patient with unremitting fulminant or infected pancreatitis, a surgeon should be consulted for possible laparotomy to debride the necrotic pancreas and to ensure that there is no other cause amenable to surgical treatment. Prompt surgery is indicated when there are signs of sepsis or pancreatic abscess.⁸ For patients who do not respond to initial supportive measures, peritoneal lavage has been recommended to help remove the toxic pancreatic exudate from the abdominal cavity. Individuals with gallstone-induced pancreatitis may benefit from early endoscopic papillotomy.

For patients with chronic pancreatitis or pancreatic cancer, indications for hospital admission include uncontrollable pain, severe nutritional deficiencies, or complications requiring surgery. Any adjustments in the regimen for analgesia or pancreatic enzyme supplementation should be carried out in consultation with the patient's primary care physician.

COMMON PITFALLS

- No clinical or laboratory finding is pathognomonic of pancreatitis. The serum amylase value is not a specific test, nor is an elevated serum amylase value a *sine qua non* for making the diagnosis. Because many disorders can cause abdominal pain and an elevated serum amylase concentration, these entities must be actively excluded before the diagnosis of pancreatitis can be definitively made. In addition, acute pancreatitis and another serious intraabdominal disorder may be present simultaneously.
- Another potential pitfall in the evaluation of the patient with acute pancreatitis is underestimating the severity of an attack. Measurements of APACHE-II and/or Ranson's criteria should be made to estimate severity. The criteria in [Table 157.4](#) and [Table 157.5](#) are helpful in providing objective guidelines by which the clinician can identify patients with a high likelihood of clinical deterioration.
- Pancreatic cancer can mimic the pain and glandular damage encountered in cases of chronic pancreatitis.

Viruses are responsible for the majority of cases of acute hepatitis. The primary hepatotropic viruses include hepatitis A virus (HAV); hepatitis B virus (HBV); hepatitis C virus (HCV); hepatitis D virus (HDV, also called the delta agent); hepatitis E virus (HEV); and the non-A through E hepatitis viruses. In addition, Epstein-Barr virus (EBV), cytomegalovirus (CMV), and other viruses are known to cause hepatitis as part of a systemic infection, as are a variety of bacteria, rickettsiae, and protozoal organisms ([Table 158.1](#)). A similar histopathologic picture can result from a variety of toxic and anoxic processes.

TABLE 158.1. Infectious Agents Known to Cause Hepatitis

CLINICAL PRESENTATION

The clinical manifestations of hepatitis, regardless of cause, are protean and vary from individual to individual with respect to severity of symptoms, duration of illness, and outcome. The ultimate course of the illness is thought to depend on the nature of the etiologic agent, the extent of preexisting or underlying liver disease, and, with infectious causes, the interaction between host factors and the pathogen.

In its classic presentation, viral hepatitis has a highly characteristic clinical picture that is easily recognizable in its various stages. After a variable incubation period, a “prodromal phase” of illness occurs, with symptoms such as anorexia, low-grade fever, malaise, and lassitude. Often characterized as “flu-like” symptoms, they are nonspecific constitutional complaints typical of a variety of viral illnesses. Gastrointestinal symptoms may predominate, particularly in the adult patient, and abdominal discomfort representing hepatic, and occasionally splenic, enlargement may be reported. Within days to weeks after the onset of symptoms, the patient who enters the “icteric phase” of the illness first notes discoloration of the urine, representing the early rise of direct-reacting bilirubin and the spillage of bilirubin pigment into the urine. Subsequently, light (clay-colored) stools develop, scleral icterus may be noted, and clinical jaundice may become evident both to the patient and to the clinician as the serum bilirubin level exceeds 3 to 4 mg/dL. At this point, particularly in hepatitis A, symptoms may begin to resolve, heralding the convalescent phase of the illness.

Physical findings are highly variable in that the examination may be completely normal or may reveal frank jaundice and evidence of hepatic dysfunction. Liver enlargement and tenderness are common, and splenomegaly and lymphadenopathy may be present in 15% to 20% of cases.

Hampered frequently by unfamiliarity with the patient; by misleading, confusing, vague, or nonspecific historical details; and by multiple etiologic possibilities, the emergency physician may not recognize hepatitis when it does not present as the classic textbook picture. This may occur, for example, when surreptitious toxin ingestion is involved or when the patient is reluctant to reveal specific risk factors for viral hepatitis.

If the patient is frankly jaundiced, hepatitis is usually readily considered. Recognition of the more subtle findings of scleral discoloration, sublingual yellowing, or evidence of excoriations, which may be evident only on careful head-to-toe examination, also may lead to the discovery of hepatic disease.

When frank jaundice is absent, however—the rule rather than the exception in viral hepatitis—a higher index of suspicion is necessary. When present, constitutional symptoms alone are not at all specific for hepatitis but nonetheless are usually a sensitive marker for active hepatic disease and may provoke initial preliminary laboratory screening.

Extrahepatic manifestations are particularly prevalent in hepatitis B and are generally considered to be due to formation of immune complexes, with deposition in various extrahepatic sites. They include urticaria and morbilliform rashes, arthralgias and frank arthritis, hematuria and proteinuria, and, less commonly, vasculitis of the mixed cryoglobulinemia or polyarteritis nodosa types.¹¹ Other extrahepatic manifestations are not believed to be immunologically mediated. Pancreatitis, pneumonitis, and myocarditis are thought to be due to direct viral involvement.

Occasionally, a patient presents with advanced hepatic failure and no history of previous hepatitis. This may occur in the context of progressive chronic hepatitis, a toxic insult, or acute-on-chronic hepatitis. Unexplained encephalopathy (which may be as subtle as a personality change), coagulopathy, hypoglycemia, or respiratory alkalosis should prompt consideration of a hepatic disorder and a diligent search for confirmatory evidence.

DIFFERENTIAL DIAGNOSIS

Viral Hepatitis

Acute viral hepatitis is characterized by four stages: the incubation period, the preicteric phase, the icteric phase, and convalescence. During the incubation period, there are no clinical manifestations of disease, but viral replication is occurring, and serologic and chemical markers of this activity and the host response to it can be measured. Clinical manifestations appear only if and when enough hepatocytes are invaded.

The etiologic agent causing hepatitis cannot be determined from the clinical presentation; all of the hepatotropic viruses are capable of producing a similar clinical

picture. Therefore, in evaluating the patient with presumed viral hepatitis and attempting to determine the cause, it is imperative to understand the significance of the serologic markers associated with the various types.

Hepatitis A

HAV is spread primarily by the fecal–oral route, although the virus can be found in the blood as well as in the liver, bile, and stool during the later part of the incubation period. The 2-week period before the onset of jaundice is the time of greatest infectivity; viremia, fecal shedding in the stool, and infectivity diminish markedly by the time the icteric phase begins (Fig. 158.1). Source outbreaks are the result of fecal contamination of water supplies (e.g., with poor sanitation or during disasters), or when food becomes contaminated. The disease may also be spread by oral–anal contact.

Figure 158.1. Serologic course of viral hepatitis A. Children usually have only mild symptoms with no jaundice. Adults more often develop jaundice. (Adapted from Hoofnagle JH. Serologic diagnosis of acute and chronic hepatitis. In: Hepatology Update/Portal Hypertension: Viral Hepatitis [postgraduate course of the American Association for the Study of Liver Diseases]. *Hosp Med* 1988;6:26.)

The incubation period is short: 2 to 7 weeks. The “preicteric” phase of hepatitis A, usually lasting 4 to 14 days, presents nonspecifically with weakness, malaise, anorexia, nausea, and vomiting. There may be pain in the right upper quadrant and a characteristic loss of taste for cigarettes. Rash, urticaria, and joint pain occur infrequently, but the diagnosis of acute hepatitis should be considered in patients with these complaints. The term *preicteric* is presumptive, because not all patients go on to have clinically evident jaundice. Children with hepatitis A typically present with gastroenteritis and commonly do not develop jaundice.

The presence of dark urine frequently heralds the onset of the icteric phase and is often what prompts the patient to seek medical attention. Most of the other symptoms, with the exception of malaise, resolve shortly after the appearance of jaundice, which may persist for up to a month. Jaundice appears in the minority of patients infected with HAV.

The convalescent period is variable; weakness and malaise may last for months. This tends to be true less often with hepatitis A than with the other viral hepatitises, but such an observation is of little use in making the initial diagnosis. The onset of hepatitis A is usually more abrupt and less insidious than of the other types of viral hepatitis, but this observation is not useful in the individual case.

Figure 158.1 depicts the usual serologic and biochemical course of hepatitis A. The alanine aminotransferase (ALT, formerly serum glutamic pyruvic transaminase [SGPT]) level begins to rise late in the incubation phase, just before the onset of symptoms. Fecal shedding has peaked before this time and is abating. During the symptomatic period, about 4 to 5 weeks after exposure, immunoglobulin-M (IgM) antibodies to HAV (anti-HAV IgM) begin to rise. Because this antibody usually becomes undetectable after 4 to 5 months, its presence implies recent infection; HAV itself is not measured. Antibodies of the IgG variety (anti-HAV IgG) rise a little later and remain detectable for life. The presence of such antibodies in the serum of at least 50% of adults reflects the high incidence of asymptomatic or unrecognized disease early in life, and is responsible for the effectiveness of pooled serum in preventing disease in exposed individuals.

Hepatitis B

HBV is spread by the parenteral route, including exposure to blood or certain blood products, contaminated needles and syringes (both in drug abusers and accidentally in health-care workers), infected excretions or saliva, sexual contact, and perinatal contact. Its prevalence is high among homosexual men, intravenous drug abusers, dialysis patients, and patients and staff of institutions for the mentally retarded, and in certain endemic regions of the world.

Hepatitis B has an incubation period of 45 to 160 days. During this phase, the virus is actively replicating and is present not only in the hepatocyte, but also in virtually all body fluids, including blood, saliva, semen, and vaginal secretions. The implications of this fact are important: Patients can transmit disease during this incubation period, biochemical and serologic markers can be measured before disease becomes clinically apparent, and appropriate immunoprophylactic measures given after exposure, but before the onset of symptoms, may prevent or ameliorate the disease.

Acute hepatitis B usually follows a course similar to that of hepatitis A. Infrequently, a serum sickness–like illness occurs with the onset of symptoms. Jaundice is more likely to occur in hepatitis B than in hepatitis A, but still occurs in a minority of cases. Eighty percent to 85% of cases resolve completely, leaving the patient immune to hepatitis B. One percent to 3% of cases evolve into fulminant hepatitis, with a mortality rate of 90%; the remaining 5% to 10% of cases become chronic.

The serologic and biochemical course of acute hepatitis B is depicted in Fig. 158.2. The first marker to appear in the serum is the hepatitis B surface antigen (HBsAg), indicating infection with hepatitis B. Next, DNA polymerase, HBV DNA, and the hepatitis B e antigen (HBeAg) appear in the serum. These reflect active HBV replication and infectivity and appear well before the onset of biochemical damage to the liver. Of this group, only HBeAg can be measured easily; the presence of antibody to the HBeAg (anti-HBe) suggests low infectivity. In patients who become symptomatic, the ALT level rises and, in some, jaundice appears. Most patients seen at this time will still be HBsAg-positive.

Figure 158.2. Serologic course of acute hepatitis B. This is more likely to cause jaundice than type A or non-A/non-B types. (Adapted from Hoofnagle JH. Serologic diagnosis of acute and chronic hepatitis. In: Hepatitis Update/Portal Hypertension: Viral Hepatitis [postgraduate course of the American Association for the Study of Liver Diseases]. *Hosp Med* 1988;6:33.)

It is important to understand the significance of the next immunologic event—the appearance of antibody to the hepatitis B core antigen (anti-HBc), first of the IgM class and then IgG. This rise precedes the rise in antibodies to the surface antigen (anti-HBs). (In Fig. 158.2, note the gap between the box labeled *HBsAg* and the

line labeled *anti-HBs*.) Therefore, in some patients recently infected with HBV who are seen during this gap or, “window,” the sole specific marker of recent infection with HBV is the presence of anti-HBc IgM.

Anti-HBsAg is a neutralizing antibody; therefore, its rise correlates with abatement of symptoms and the return of ALT to normal levels and signifies immunity to HBV. Thereafter, the patient will test positive only for Anti-HBs, Anti-HBc IgG, and Anti-HBe.

The *carrier state* occurs when HBsAg remains positive for 6 months or more in the absence of clinical or laboratory features of acute infection. Some carriers represent a source of infection (those with circulating HBV particles and HBeAg). The carriage rate in the United States is only 0.1% to 0.5%, although, in some parts of the world, it is 5% to 20%.

Chronic persistent hepatitis (CPH) and *chronic active hepatitis* (CAH) are two distinct forms of chronic liver disease that may be due to hepatitis B or a variety of other causes. Although each has reasonably distinct clinical presentations and biochemical profiles, the diagnosis can be made on histologic grounds only. In CPH, there is chronic inflammatory infiltration but minimal fibrosis, and the lobular architecture is preserved. In CAH, there is a far more aggressive histologic picture, with piecemeal necrosis and intralobular fibrous septa. Symptomatology and biochemical abnormalities tend to be less severe with CPH, and the long-term prognosis is generally good. Biochemical abnormalities and clinical manifestations, both hepatic and extrahepatic, commonly are more severe in CAH, and the long-term prognosis tends to be poor, with progression to cirrhosis and end-stage liver disease. Treatment with immunosuppressive agents such as prednisone and azathioprine may be beneficial in the patient with CAH unrelated to hepatitis B. The role of the emergency physician is to identify those individuals who would benefit from workup and evaluation of these entities, as well as to appreciate the long-term clinical implications and the potential complications in patients with these forms of chronic liver disease.

[Figure 158.3](#) depicts the serologic course of chronic HBV disease. Note that the HBsAg remains positive, antibodies (anti-HBs) are lacking, and the patient remains susceptible to further liver damage or to superinfection with hepatitis D.

Figure 158.3. Serologic course of chronic HBV disease. (Adapted from Hoofnagle JH. Serologic diagnosis of acute and chronic hepatitis. In: Hepatitis Update/Portal Hypertension: Viral Hepatitis [postgraduate course of the American Association for the Study of Liver Diseases]. *Hosp Med* 1988;6:33.)

Hepatitis C

After the introduction of donor screening for HBV infection, posttransfusion hepatitis continued to be a significant problem. This led to the conclusion that most posttransfusion hepatitis was caused by another blood-borne pathogen, which was designated non-A, non-B (NANB) hepatitis. After the discovery of HCV in 1989 and the routine screening of the blood supply in the United States since 1990, it became clear that 80% to 90% of parenterally transmitted NANB hepatitis was caused by HCV.

HCV is an RNA virus of the Flaviviridae family. Extensive genetic heterogeneity of this virus may explain variations in clinical course, difficulties in vaccine development, and variations in response to therapy.¹ It may also explain why the virus so frequently escapes immunosurveillance, leading to chronic infection.

The incidence of newly acquired HCV infection has fallen dramatically since 1989 due to the effectiveness of blood donor screening.¹ Currently, the risk of transfusion-related hepatitis C is in the range of one in 100,000 U transfused. Aside from blood transfusion, other parenteral sources of HCV infection include intravenous drug use, noninjection illegal drug use (sharing instruments for intranasal cocaine use), hemodialysis, organ transplantation, and occupational exposure. Low levels of transmission occur in sexual and household contacts and perinatally, (i.e., vertical transmission). There is no evidence that breast feeding transmits HCV from mother to baby. Sporadic cases also occur.

Hepatitis C viral RNA can be detected in blood within 1 to 3 weeks of exposure. Anti-HCV can be detected in 50% to 70% of patients at the onset of symptoms and in approximately 90% of patients 3 months after onset of infection. However, the majority of infected patients are asymptomatic and anicteric.

The symptoms of HCV—malaise, weakness, and anorexia—are similar to those seen with other types of hepatitis; however, compared with hepatitis B, the acute disease is usually milder, the peak ALT level lower, and the patient less likely to be icteric. Serum transaminase levels fluctuate and may even normalize during the course of both acute and chronic disease and may not indicate resolution of disease. Acute HCV infection rarely causes fulminant disease.

Chronic disease, with persistent although sometimes intermittent viremia, occurs in 85% of infected patients.¹⁰ Most patients with chronic disease are clinically well, with a small minority (20% or fewer) experiencing mild intermittent fatigue and malaise.

Unfortunately, approximately 20% of patients with chronic human immunodeficiency virus (HIV) infection experience a slow, insidious course that results in cirrhosis. Concomitant alcohol use may hasten such an eventuality. Currently, hepatitis C is the leading reason for liver transplantation in the United States. Chronic hepatitis C infection also leads to an incidence of hepatocellular carcinoma of 1% to 5% after 20 years. In the presence of cirrhosis, the rate of acquiring hepatocellular carcinoma rises to 1% to 4% per year.

A commercially available enzyme immunoassay (EIA) is routinely used to detect antibodies to regions of the HCV genome. The test detects anti-HCV in approximately 90% of infected patients. Antibody is detectable 5 to 6 weeks after the onset of clinical hepatitis in 80% of patients, but seroconversion may take as long as 32 weeks in some individuals. The limitations of anti-HCV screening are that (1) anti-HCV is not detected in 10% of infected persons; (2) assays do not distinguish among acute, chronic, and past infection (i.e., positive titers do not reflect either infectivity or immunity); (3) there is a prolonged interval between onset of illness and seroconversion in some cases; and (4) positive tests are frequently false-positive in populations with a low prevalence of infection.

The more specific recombinant immunoblot assay (RIBA) may be used to screen out false-positive results. Future development of a test for IgM would help in determining the time of onset of disease. Polymerase chain reaction (PCR)—band assays have been developed to detect the RNA virus directly, but these are mainly of research interest.

It appears that passive immunization with immune serum globulin derived from patients with previous HCV infection is unlikely to prevent disease, and no active vaccine is presently on the horizon. Patients with chronic hepatitis C have been treated with α -interferon, but, unfortunately, only 25% show long-term improvement as measured by a reduction in clinical and virologic markers. Ribavirin may prove to be useful adjunctive therapy. It is not known whether combination treatment with α -interferon can prevent the development of cirrhosis and hepatocellular carcinoma.

Hepatitis D

Hepatitis D, or delta hepatitis, is caused by a defective virus, the replication of which is dependent on the presence of HBsAg synthesis. The virus consists of the

delta-antigen-bearing core encapsulated by an HBsAg coat.

It should not be surprising that a virus that requires HBV for its replication follows a similar transmission pattern. The clinical course of HDV infection depends on whether it is acquired at the same time as HBV (coinfection) or whether HDV infects a patient with chronic HBV infection (superinfection).

In coinfection, the fate of HDV parallels that of HBV. Because most cases of acute HBV are subsequently cleared, HDV, which requires the presence of HBV for replication, is also cleared. The clinical course of HDV is similar to that described for hepatitis B, although it is often more severe.

Because patients with HDV superinfection, by definition, have not been able to mount an immunologic response sufficient to clear their HBV infection, in these individuals, HDV replication may go unchecked, resulting in fulminant hepatitis in a large proportion. Rarely, acute delta superinfection results in clearance of HBV in a chronically infected patient, a phenomenon attributed to nonspecific stimulation of the immune system by a new antigen. This apparently occurs in only about 3% of patients.¹¹ It is important to remember that immunity to hepatitis B renders one immune to hepatitis D infection.

Bearing in mind the serologic courses of acute and chronic HBV infection, it is simple to predict the serologic courses of HDV coinfection and superinfection. [Table 158.2](#) lists the serologic features of HBV/HDV coinfection and HBV/HDV superinfection. The antidelata IgM rises within 5 weeks of HDV infection and then persists in low titer, whereas the antidelata IgG continues to rise as long as HBV infection persists. Thus, IgG antibody to delta does not indicate immunity, but it is consistent with ongoing infection if associated with the presence of HBsAg.³

HBV/HDV Coinfection		HBV/HDV Superinfection	
HBsAg + ¹ anti-HBcIgM+	Implies recent HBV infection	Anti-HBc IgM - Anti-HBc IgG +	Implies chronic HBV infection
Anti-delta IgM+	Implies recent HDV infection	Anti-delta IgM +	Implies recent HDV infection

¹Unless in window period.

TABLE 158.2. Serologic Factors in HBV/HDV Coinfection and HBV/HDV Superinfection

Hepatitis E

Hepatitis E, formerly called enterically transmitted non-A, non-B hepatitis (ET-NANB), is responsible for more than 50% of acute viral hepatitis occurring in some developing countries.⁵ It is generally of little concern in the United States, although “imported” cases have occurred in patients who have traveled to endemic areas, such as India, Nepal, Pakistan, and parts of the former Soviet Union and Mexico.

As its former name suggests, hepatitis E is enterically spread. The incubation period is 2 to 9 weeks (average, 6 weeks), with an icteric phase that lasts 3 to 6 weeks. Nausea, vomiting, and diarrhea, which are frequent, usually resolve with the onset of jaundice. Fulminant disease occurs in 5% of cases, with a predilection for pregnant women. A carrier state has not been demonstrated.

A fluorescent antibody-blocking assay to detect hepatitis E infection is available experimentally through the Centers for Disease Control and Prevention. Patients who receive pooled immune globulin in the United States before travel to endemic areas are unlikely to be protected against hepatitis E because anti-HEV antibodies are not present in the American population. Travelers to endemic areas should be advised as to enteric precautions, whether they are immunized or not.

Non-A through E Hepatitis

There remains a small population of patients exposed to blood or blood products and of other individuals with clinical hepatitis in whom all serologic studies on both the donor and the recipient patients are negative. Acute or chronic hepatitis in which both nonviral causes and infection with any of the five hepatitis viruses have been excluded is described as non-A through E hepatitis.² With the discovery of new viruses and the development of new serologic tests, these patients will undoubtedly be further differentiated.

Other Viruses

The discovery of two new viruses has raised questions concerning their role in the etiology of viral hepatitis.

One of these, independently discovered and named hepatitis G virus (HGV) and hepatitis GB virus C (HGBV-C), is an RNA virus of the Flaviviridae type. It appears to be blood-borne and has been found in as many as 10% of patients with non-A through E hepatitis. Its role has been questioned, and its definition as a true hepatotropic cause of acute or chronic hepatitis is yet to be determined.⁶

Similarly, hepatitis F virus has been isolated from the stool of a patient with hepatitis and transmitted to primates. As with hepatitis G, the role of this virus as a significant cause of non-A through E hepatitis is unclear.

Infectious, Nonviral Causes

Although uncommon, hepatitis can accompany a wide variety of bacterial, rickettsial, and protozoal diseases. Included in this list are legionellosis, salmonellosis, tularemia, leptospirosis, brucellosis, plague, syphilis, gram-negative sepsis, gram-positive toxic shock syndromes, Q fever, mycoplasma disease, tuberculosis, toxoplasmosis, ehrlichiosis, and malaria (see [Table 158.1](#)).

Autoimmune Hepatitis

Autoimmune hepatitis is a chronic inflammatory liver disorder of uncertain etiology. A standardized definition and diagnostic criteria have been developed.⁷ The diagnosis relies heavily on the exclusion of viral etiologies, lack of exposure to alcohol and other hepatotoxic agents, and hypergammaglobulinemia with gamma globulin levels greater than 1.5 times the upper limits of normal.

Clinically, the presentation may be extremely variable and difficult to differentiate from viral hepatitis. Two types have been described based on the presence of circulating autoantibodies. Type I (classic) autoimmune hepatitis has been associated with antinuclear and anti-smooth muscle antibodies, and type II has been characterized by the presence of autoantibodies against liver-kidney microsome type I (anti-L K M-1). Both types are more prevalent in young females, and appropriate diagnosis is crucial, as they may be treated with prednisone and immunosuppressive therapy.

Toxic and Metabolic Causes

Liver injury from toxic or metabolic causes may result from direct hepatocellular toxicity or from idiosyncratic injury due to a hypersensitivity-type reaction.⁸ Toxic exposures also may manifest as cholestasis, in which elevations of alkaline phosphatase and bilirubin levels predominate.

Pharmacologic and chemical agents produce a diverse spectrum of hepatic insults, including both acute and chronic liver disease ([Table 158.3](#)). Although any evidence of hepatic dysfunction should prompt a diligent search for both intentional and inadvertent exposure to any of a number of chemical agents, several agents deserve specific mention because of the inherent likelihood of hepatocellular injury, because of their widespread use, or because of their particular relevance to the practice of emergency medicine.

Clinical/Morphologic Presentation	Examples
Hepatitis (acute)	<ul style="list-style-type: none"> o-Arthylidopa Isoniazid Phenytoin Chlorothalidol Nonsteroidal antiinflammatory agents
Cholestasis	<ul style="list-style-type: none"> Isoniazid Anabolic steroids Flutamide Oral contraceptive agents Erythromycin estolate Methimazole Chlorpropamide Chlorpromazine
Hepatic necrosis	<ul style="list-style-type: none"> Carbon tetrachloride Amanita phalloides mushrooms Acetaminophen Yellow phosphorus
Hepatitis (chronic)	<ul style="list-style-type: none"> o-Arthylidopa Arsenic Isoniazid Halothane

TABLE 158.3. Drug-Induced Hepatitis

Acetaminophen is among the more common agents encountered in the acute setting that are likely to be responsible for what may be striking liver enzyme elevations. Toxicity is dose dependent, but several factors have been shown to contribute in a synergistic way to toxicity even at relatively low doses. These include concomitant alcohol ingestion, chronic phenobarbital use, or chronic exposure to moderately large doses of acetaminophen.

Hepatitis due to *isoniazid* clinically resembles acute viral hepatitis and may occur in as many as 20% of patients taking the drug, with the risk and severity of injury increasing with the age of the patient. Clinical toxicity generally occurs in the first few months of therapy, but transaminase elevations greater than two to three times normal at any time must be considered potentially serious, because progression to fulminant hepatitis may occur.

Lovastatin, a cholesterol-lowering agent, is generally well tolerated but has been associated with severe hepatocellular injury. Moreover, there is concern that concomitant use of nicotinic acid (also widely used for the treatment of hypercholesterolemia) may promote additional toxicity.

While overt hepatotoxicity to *phenytoin* is unusual, use of the drug is particularly common, and prevention of serious toxicity requires an awareness of the nature and mechanisms of injury. Hepatic injury is believed to be caused by toxic metabolites; current evidence has implicated a heritable metabolic defect that may predispose to a viral hepatitis–like hypersensitivity reaction within weeks of starting therapy at usual therapeutic doses. Like the other toxic exposures, early detection and interruption of therapy can result in complete resolution and the avoidance of serious hepatic injury.

Troglitazone (Rezulin) is a newer oral agent used in the treatment of patients with type 2 diabetes mellitus. The U.S. Food and Drug Administration has received numerous postmarketing reports of hepatotoxicity, with some patients experiencing fatal hepatic failure.⁹ The basis for this idiosyncratic reaction is unknown and therefore unpredictable. It is now recommended that ALT levels be monitored during therapy and that any patients with ALT levels more than three times the upper limit of normal discontinue the drug immediately. The drug is no longer being distributed in some European countries.

Flutamide is an antiandrogen drug used in the treatment of metastatic prostate cancer. Well-documented cases of serious hepatotoxicity have been reported. Although the toxicity appeared to be reversible, several patients have died with massive hepatic necrosis, emphasizing the need for prompt consideration and diagnosis.

Hepatitis has been reported to be associated with the use of several of the *nonsteroidal antiinflammatory drugs* (NSAIDs). Because of the frequency with which NSAIDs are used, emergency physicians should be aware of their potential for causing hepatic toxicity. Sulindac has received special attention because it has been well established as a cause of hepatitis, including fatal hepatic necrosis.

Well described as causes of fulminant hepatic failure, *halothane* and *methoxyflurane* are unusual causes of hepatitis. Patients may present with fevers and jaundice 1 to 2 weeks postoperatively. Specific risk factors may include obesity, multiple exposures to halothane over a brief period, and previous untoward reactions to halothane. Although no specific therapy is indicated, the emergency physician may be in the position of evaluating the postoperative patient who returns to the emergency department after discharge from the hospital. Recognition of this entity may avoid a fruitless search for other causes and, more importantly, will prevent reexposure.

Another cause of elevated transaminase levels (transaminitis) that should be considered in the differential diagnosis is *hepatobiliary disease*. Elevated ALT and aspartate transferase (AST, formerly serum glutamic oxaloacetic transaminase [SGOT]) levels should not lead one on a fruitless search for infection or toxic causes of hepatitis when the chemistry patterns suggest hepatobiliary obstruction (i.e., elevated serum bilirubin, alkaline phosphatase, and g-glutamyl transpeptidase levels [GGTP]).

EMERGENCY DEPARTMENT EVALUATION

Evaluation of suspected hepatitis may be divided into several steps. The first step is to make the diagnosis, which, in light of the previous discussion, may not be entirely straightforward. Clearly, a reasonable index of suspicion is necessary in most cases, and the physician must consider the relative likelihood of illness in each particular patient compared with the risk of excessive testing in the many patients with nonspecific symptomatology.

If the likelihood of hepatitis is present but low, as in a patient followed serially for development of hepatocellular disease after a needlestick, a reasonable approach is initially to order a serum AST level as a preliminary screen. The AST is a cytoplasmic enzyme that is released with hepatocellular injury. Although nonspecific, this is a sensitive screen, and a normal AST value virtually excludes hepatocellular disease.

In the patient in whom hepatic disease is believed to be more likely or who has an abnormal AST on the preliminary screen, more extensive laboratory testing is necessary. This should consist of indices of necrosis (AST and ALT) as well as indices of cholestasis (alkaline phosphatase, total bilirubin, or GGTP). Although they lack diagnostic specificity, certain patterns may be helpful in limiting the differential diagnosis and directing further evaluation. For instance, a transaminase elevation of greater than ten times normal strongly suggests acute viral or toxic injury and essentially excludes chronic hepatitis. Elevation of alkaline phosphatase and bilirubin values suggests intrahepatic or extrahepatic obstruction. Transaminase elevations of two to three times normal, with the AST higher than the ALT, suggest alcoholic injury.

In the second step of the workup, after the diagnosis of liver disease has been made, specific tests of hepatic synthetic function are necessary. Tests of serum protein, albumin, and glucose levels should be ordered routinely and can be used in conjunction with the serum bilirubin level to assess the extent of hepatocellular dysfunction. If central nervous system involvement is suspected, or if unexplained lethargy, psychiatric symptoms, or other indicators of encephalopathy are present, an arterial ammonia level may be obtained that can serve as a useful baseline for further serial evaluations.

At the third step, other evaluations are performed to define more specifically the cause of the illness. If hepatocellular necrosis is the dominant picture, detailed serologic studies (anti-HAV IgM, HBsAg, anti-HBs, anti-HBc, anti-HCV, and Monospot test) are warranted, as well as a diligent historical search for foreign travel to hepatitis E–endemic regions and drug or toxic exposures. If cholestasis is the dominant picture, ultrasound examination should be performed to exclude mechanical obstruction. If none is found, a search for drug or toxic exposures is warranted.

EMERGENCY DEPARTMENT MANAGEMENT

Patients with acute viral hepatitis may present to the emergency department because of signs and symptoms typical of a viral syndrome that may include prostration, nausea, vomiting, and dehydration. Treatment for these patients is symptomatic and is usually limited to intravenous fluids, acetaminophen, and antiemetics. Metoclopramide (Reglan) is the antiemetic agent of choice, because phenothiazines can impair hepatic excretory function and may produce cholestasis.

Patients who present without symptoms or present because they have noticed jaundice require no specific therapy.

For patients with diagnosed viral hepatitis, there is no specific therapy indicated beyond routine supportive care and symptomatic treatment. If the prothrombin time is prolonged, the patient should receive intravenous vitamin K. Immune globulin is of no use in the patient who has already contracted hepatitis. Corticosteroids are probably harmful rather than beneficial.

Patients who present because they have been exposed, or think they have been exposed, to hepatitis present a different management problem. (For needlestick patients, see [Chapter 198](#).) Immunoprophylaxis is highly effective if given under the proper circumstances. Because this treatment should be guided in part by serologic studies, it is often not initiated in the emergency department.

If results of serologic testing are not available, or not available in a timely fashion, therapy must be empiric and, as such, must be based on probabilities. The discussion that follows and the material in [Table 158.4](#) should help guide immunoprophylactic therapy.

Type	Persons at Risk	Immunoprophylaxis
A	Household and sexual contacts* Staff and attendees of daycare centers Staff and residents of custodial institutions	Immune globulin, 0.02 mL/kg i.m.
B	Sexual contacts Percutaneous or transmucosal exposure	Hepatitis B immune globulin, 0.06 mL/kg i.m. Begin active immunization (Hepavax or Recombivax)
C	Intravenous drug abusers, intranasal cocaine abusers, homosexuals, multiple sexual partners, perinatal exposure, household contacts	None
D	Same as B	Protection against hepatitis B
E	Travelers to endemic areas	None or serum pooled from U.S. donors
Non-A through E	Percutaneous exposure to blood or certain products of patients with no serologic evidence of HAV, HBV, or HCV	None

*Residents of dormitories and barracks are frequently considered in this group.

TABLE 158.4. Immunoprophylaxis of Viral Hepatitis

Patients considered to be at risk for contracting hepatitis A include household and sexual contacts of persons with hepatitis A; staff and attendees at daycare centers; and staff and residents in close contact at custodial care institutions. Immune globulin, which is derived from pooled human serum but treated so as not to be capable of transmitting HIV infection or other diseases, is given as a single intramuscular dose of 0.02 mL/kg as soon as possible within the first 2 weeks after exposure. Casual contacts need not be treated; such patients need little more than education and reassurance.

Postexposure prophylaxis for hepatitis B is indicated for sexual contacts of persons with hepatitis B, or after percutaneous or transmucosal exposure to HBsAg-positive blood. Treatment is with hepatitis B immune globulin, 0.06 mL/kg intramuscularly; active immunization is begun at the same time. This recommendation assumes that serologic data are available on the index patient with hepatitis and that the immune status of the exposed patient is known. If the data are not available but can be obtained within 5 to 7 days, it is reasonable to wait. If not, one must make a decision based on lifestyles and risk factors; the history obviously should include information regarding sexual contacts and intravenous drug use.

Immunoprophylaxis has not proven useful in patients who have been exposed to hepatitis C or in those suspected of being exposed to non-A through E hepatitis.

DISPOSITION

Most patients with hepatitis do not require hospital admission, because there is nothing that can be done for them in the hospital that cannot be done at home. Hospitalization is recommended under the following circumstances: persistent nausea and vomiting that is unresponsive to treatment; dehydration or electrolyte imbalance that cannot be corrected in the emergency department during a reasonable length of stay; or signs of hepatic deterioration, as evidenced by changes in sensorium or prolongation of the prothrombin time (50% activity is commonly used as a criterion). Obviously, patients with signs or symptoms suggesting a fulminant course require admission. The absolute levels of serum transaminase values should not be a criterion for admission.

Patients with acute viral hepatitis who are discharged should be prescribed antiemetic agents and instructed to ensure adequate caloric intake. It is best to allow patients to eat small meals of foods of their choice rather than insist they follow some of the high-calorie or high-protein dietary regimens that have been proposed. Prolonged bed rest, once a staple of care, has been shown to be of no value and has its own risks.⁵ Most patients will limit their physical activities as needed. Alcohol consumption should be avoided during the acute illness. After complete recovery, alcohol consumption has not been shown to be any more harmful than for the general population.⁴ Estrogen-based oral contraceptives may be continued during hepatitis.

Patients with acute hepatitis should be seen by an internist or gastroenterologist for follow-up within a few days; it is sensible to wait for the results of serologic tests before this visit. Patients with any prolongation of the prothrombin time are often admitted to the hospital, but those who are not should probably be seen the next day. Instructions should include an admonition to return if food and fluids cannot be kept down or if there is any change in sensorium.

Finally, it is the duty of the emergency physician in many locales to notify public health authorities of cases of acute hepatitis.

COMMON PITFALLS

Diagnostic Errors

- Missed toxic ingestion or exposure, with possible continued or recurrent exposure
- Failure to recognize hepatitis B or hepatitis C by performing serologic tests during “window periods” between infection and seroconversion
- Missed hepatobiliary disease, with failure to diagnose surgically correctable lesions
- Diagnosis of viral or alcoholic hepatitis as hepatobiliary disease, with operative intervention in a patient with excessive anesthetic risks
- Failure to recognize atypical presentations as secondary phenomena of liver disease and not primary events (e.g., coagulopathy, altered mental status, psychiatric abnormalities, hypoglycemia)

Evaluation Errors

- Failure to recognize the distinction between liver tests and liver function (e.g., patients with cirrhosis may have nearly normal enzyme levels; patients with “sky high” transaminase levels may have reasonably intact synthetic capability)
- Failure to distinguish between acute and chronic disease in patients who are anti-HCV positive
- Inappropriate admission of patients with uncomplicated hepatitis and markedly elevated ALT or AST levels without evaluation of synthetic factors or clinical status, or inappropriate discharge of patients with early evidence of synthetic failure
- Excessive emergency department evaluation because of inappropriate use of strategies and preliminary laboratory results

Inappropriate Follow-Up

- Failure to follow up contacts for recommended prophylaxis
- Inappropriate restrictions: Patients with hepatitis need not be excluded from school or work simply because of the diagnosis of hepatitis; education regarding precautions is indicated.

Failure to Consider the Pharmacokinetic Role of the Liver

- Administration of hepatotoxic drugs for symptomatic treatment in patients with hepatic injury (e.g., phenothiazines for nausea or NSAIDs for pain)
- Administration of hepatically cleared drugs, with resultant decrease in clearance and unexpectedly high serum levels or duration of action

CHAPTER 159

Hepatic Failure and Cirrhosis

David M. Cline and E. Jackson Allison, Jr.

[Clinical Presentation](#)
[Complications of Hepatic Failure and Cirrhosis](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Acute hepatic failure differs clinically, prognostically, and therapeutically from an exacerbation of chronic liver failure, but the priorities for the management of both entities are similar. Despite significant recent advances in the management of hepatic encephalopathy, the exact mechanism for the widespread neural inhibition seen in this condition continues to elude investigators. Ammonia, a substance liberated from the intestinal flora and known to accumulate in hepatic failure, is a key factor in the development of hepatic encephalopathy.¹¹ However, ammonia accumulation causes an excitable state rather than neural inhibition, and the severity of hepatic coma does not correlate well with blood ammonia levels.² Although several other theories have been proposed, no single mechanism has explained all the features of this disorder.

Viral hepatitis has traditionally been regarded as the most common cause of fulminant hepatic failure (FHF) worldwide.¹⁸ An analysis of six studies found acetaminophen overdose to be the single most common cause of acute hepatic failure in industrialized countries.⁹ In 23% of cases, the cause could not be determined. Acute and chronic ingestion of the antituberculous drugs isoniazid and rifampin and Reye syndrome are other important causes of FHF. Less common causes include fatty degeneration of pregnancy, heat stroke, *Amanita phalloides* mushroom poisoning, cancer metastatic to the liver,¹⁷ and the illicit drug ecstasy.⁵

Hepatic cirrhosis most commonly is caused by alcoholism; chronic active hepatitis is the second most common cause. Typically, there is progressive destruction of the normal sinusoidal architecture over several years, with resulting fibrosis. Progressive hepatocellular dysfunction results in impaired glycogen storage, coagulopathy, and loss of detoxifying capability. Continued fibrosis shunts blood away from the hepatic artery directly into the portal vein, resulting in secondary portal hypertension and esophageal varices.

CLINICAL PRESENTATION

The presentation of FHF is, to some degree, dependent on the specific etiologic agent, but the majority of patients have altered mentation, coagulopathy with clinical bleeding, jaundice (especially in children), motor dysfunction, and fetor hepaticus, a sweetish, musty, or pungent odor on the breath.

The manifestations of hepatic encephalopathy in both FHF and cirrhosis are similar, but the onset is generally slower with cirrhosis. FHF may present with rapid deterioration of mental status, with progression over several hours from slowed response times to frank coma. Patients with cirrhosis commonly present with euphoria, depression, or muscular incoordination, or may demonstrate more obvious mental status changes. Symptoms such as malaise, lethargy, fluid retention, loss of libido, and pruritus are common, and typical physical findings include hepatomegaly, spider nevi, ascites, and jaundice. Asterixis, a flapping tremor best seen with the patient's arms outstretched and wrists hyperextended, is a classic symptom that is not present in all cases. The factors most commonly precipitating hepatic encephalopathy in cirrhotics are gastrointestinal bleeding, use of tranquilizing drugs or alcohol, overuse of diuretics, and infection.

Complications of Hepatic Failure and Cirrhosis

Cerebral edema is a universal feature of acute hepatic failure and the most common cause of death in untreated cases. Early warning signs include systemic hypertension and increased muscle tone, which progresses to decerebrate posturing and eventual respiratory arrest if left untreated.³ Hypoglycemia, thought to be secondary to inefficient degradation of insulin, impaired glycogen storage, or reduced hepatic metabolic capacity, may be profound and recurrent. More than 50% of patients demonstrate clinical evidence of coagulopathy, usually in the form of gastrointestinal, nasopharyngeal, or bronchial tree bleeding. Hypotension secondary to decreased systemic vascular resistance may occur in the absence of hemorrhage. Patients typically are tachypneic, with a respiratory alkalosis. Artificially increasing the pCO₂ toward normal leads to deterioration. Hypoxia and noncardiogenic pulmonary edema are common. Prerenal azotemia, acute tubular necrosis, or renal failure of unknown cause may occur. Hypokalemia and hypocalcemia are common.

Spontaneous bacterial peritonitis, pneumonia, urinary tract infection, bacteremia, or other bacterial infection complicates the hospital course of 80% of patients in FHF, and these infections account for 25% of deaths.¹⁶ Febrile cirrhotics with abdominal pain and tenderness should be considered to have spontaneous bacterial peritonitis until proven otherwise.

Because of portal hypertension and secondary esophageal varices, death from gastrointestinal bleeding is more common with cirrhosis than with FHF. In the later stages of cirrhosis, ascites may become markedly symptomatic and limit ventilation and atrial filling.¹² The hepatorenal syndrome, or functional renal failure, occurs in advanced cirrhosis and is usually fatal despite treatment.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of jaundice includes hemolysis, obstructive jaundice, viral hepatitis, hepatotoxic ingestions, septicemia, and numerous minor causes. The association of mental status changes with jaundice should alert the emergency physician to the possibility of hepatic encephalopathy. In the patient without chronic liver disease, the differential diagnosis of hepatic encephalopathy includes viral hepatitis, fatty degeneration of pregnancy, Reye syndrome, and hepatotoxic ingestions such as acetaminophen, isoniazid, rifampin, *A. phalloides* mushrooms, carbon tetrachloride, or ecstasy. Historical information, such as pre-illness activity, previous suicidal behavior, and the presence of fever or malaise, may help to differentiate among potential causes. There are few clinical features that help to differentiate hepatic encephalopathy from other causes of acute mental status change, with the exception of fetor hepaticus. Unfortunately, fetor hepaticus is commonly mistaken for simple halitosis. The coexistence of jaundice and altered mental status should always alert the clinician to the possibility of hepatic failure.

Patients with hepatic cirrhosis may have chronic jaundice and may sustain acute mental status changes for reasons other than hepatic encephalopathy. Because alcoholic patients are at greater risk for accidents as well as for bleeding, subdural hematoma must be ruled out in cirrhotics with an altered sensorium. Patients with renal failure from other causes may present with features suggestive of severe liver disease—an altered sensorium, fluid retention, and coagulopathy. Alcoholics may develop pancreatitis or alcoholic hepatitis, with severe dehydration and associated mental status changes that may mimic hepatic encephalopathy.

EMERGENCY DEPARTMENT EVALUATION

The validity of information from the patient should be questioned, and additional information should be sought from prehospital personnel, family, the patient's private physician, and previous medical records. The conjunctiva and skin should be examined for the presence of jaundice. The respiratory system should be carefully assessed for the possibility of aspiration or pulmonary edema in advanced cases. Although an enlarged liver is common in alcoholic liver disease, the liver is usually small in FHF or advanced cirrhosis. A rectal examination is necessary to check for evidence of gastrointestinal bleeding. A careful neurologic examination should be done with attention to subtle changes in mental status, using serial sevens or formal psychometric testing. Asterixis, alterations in motor tone, or abnormal posturing should be noted.

The diagnosis of hepatic encephalopathy is largely clinical; no single laboratory test can confirm the diagnosis with certainty. Hypoxemia and hypoglycemia should be ruled out. A serum ammonia level should be measured, but patients may be encephalopathic before an elevation in the serum ammonia is observed.³ A complete blood count, serum electrolyte determination, and coagulation studies should be performed to determine proper treatment. Serum aminotransferases, bilirubin, serologic tests, and serum amino acid levels may aid in diagnosis but do not alter management acutely. An electrocardiogram is advisable, especially in patients with

preexisting heart disease.

EMERGENCY DEPARTMENT MANAGEMENT

The treatment of hepatic encephalopathy in patients with acute hepatic failure requires a more aggressive approach than in those with an exacerbation of chronic liver disease. Hepatic encephalopathy in acute hepatic failure develops rapidly and is almost always complicated by cerebral edema, with possible central herniation of the brain.¹³

Immediate attention should be given to securing a patent airway and initiating artificial ventilation if the patient is comatose or lacks an active gag reflex. Supplemental oxygen should be given, even in the absence of pulmonary edema. Fluid resuscitation should be aggressive in hypotensive or bleeding patients and should be undertaken despite the possibility of pulmonary edema. Pulmonary capillary wedge pressure measurements may be needed to guide therapy in patients who do not respond to boluses of less than 1 L of normal saline. Persistent hypotension signals the need for vasopressors. Dopamine (2 to 20 µg/kg/min) is recommended for initial treatment, but nor-epinephrine (0.5 to 30 µg/min) may be required.³ Dopamine is useful in attempting to preserve urine flow and renal function.

Patients should be placed on a cardiac monitor and quickly assessed for cardiac manifestations of electrolyte imbalance. Patients with altered mental status or a blood glucose level below 100 mg/100 dL should receive 50% dextrose and thiamine intravenously, followed by an infusion of 10% or 20% dextrose solution.³ Patients who demonstrate clinical signs of significant, increased intracranial pressure, such as abnormal posturing or unreactive pupils, should receive mannitol 0.5 g/kg intravenously over 10 minutes.¹³ Arterial pCO₂ should be maintained at about 25 mm Hg. Ventilated patients often require sedation; fentanyl (2 µg/kg) and atracurium (0.4 mg/kg) are recommended to prevent surges in intracranial pressure related to agitation.¹³ Consideration should be given to monitoring intracranial pressure with an extradural monitor, which, however, carries some risk and may be problematic if clinical bleeding is present.⁸

Fresh-frozen plasma (2 to 4 U) should be given when the prothrombin time is more than 1.5 times normal and there is evidence of active bleeding.⁹ Platelet infusions (2 to 4 U) are recommended when thrombocytopenia is severe or there is active bleeding unresponsive to correction of clotting factor abnormalities. Administration of cimetidine or ranitidine can reduce the incidence of gastrointestinal bleeding.¹⁰

Proven or suspected infection should be treated promptly, using cultures to modify empiric therapy. The responsible organisms are usually gram-negative; cefotaxime (1 to 2 g i.v.) or a similar broad-spectrum cephalosporin is recommended.¹⁸ Aspiration pneumonia also should be considered in these patients, and if suspected, should be treated with pulmonary toilet, ventilatory support as needed, and broad-spectrum antibiotics. Urinary tract infection requires treatment with intravenous antibiotics providing good gram-negative coverage. A large prospective trial showed that prophylactic antibiotics (cefuroxime 1.0 g i.v.) significantly reduced the incidence of infection in FHF.¹⁵

Lactulose, which increases intestinal motility and lowers colonic pH, accelerates recovery from hepatic coma, but its exact mechanism of action is not known. Oral lactulose can be given as a syrup, 50 cc every 1 to 2 hours until results are obtained, or can be given as an enema, 300 cc in a liter of saline.⁴ Oral neomycin, 2 to 4 g/d, also has been shown to be effective, but should be withheld if an aminoglycoside is being considered for treatment of a coexisting infection. Metronidazole, 800 mg/d, is an alternative.¹⁵ Acetylcysteine improves survival from acetaminophen overdose, even late in its course,⁷ and may have benefits in the treatment of FHF from other causes.⁶

The management of gastrointestinal bleeding in patients with cirrhosis is much more difficult than in those with FHF. After initial resuscitation with necessary fluid and blood components, endoscopic sclerotherapy appears to be the best method to manage acute variceal bleeding. Patients ultimately may require a portacaval shunt to prevent rebleeding.

There has been promising work in the area of artificial liver support.^{14,20} Decisions concerning liver support measures are best made by a gastroenterology consultant. In many cases of severe acute hepatic failure, transplantation is the only means of increasing the chance of survival.¹

When patients with hepatic cirrhosis present to the emergency department with non-life-threatening conditions, care must be taken to avoid interventions (e.g., medications) that may cause clinical deterioration. Sedatives may trigger clinical hepatic encephalopathy. Nonsteroidal antiinflammatory drugs may induce renal failure in cirrhotic patients. Even acetaminophen may be harmful in cirrhotic patients. For the management of symptomatic ascites in cirrhotic patients, paracentesis has fewer side effects than diuretics and a comparable rate of fluid reaccumulation. Cirrhotics with recurrent variceal hemorrhage are now being routinely treated with a transjugular intrahepatic portosystemic shunt, which has an associated 25% incidence of chronic hepatic encephalopathy.¹⁹ In some cases, the only means of correcting the encephalopathy is to reverse the shunt by transhepatic embolization.

DISPOSITION

Because patients with chronic liver disease commonly respond poorly to intermittent illness or other stress, indications for their admission to the hospital are generally less stringent than for other patients. For example, because cirrhotics have a limited ability to fight off infection, admission for intravenous antibiotic treatment should be considered for most infections.

Patients with advanced hepatic encephalopathy require admission to an intensive care setting, and immediate consultation with a gastroenterologist or a hepatologist is indicated. For severe cases, consideration should be given to transporting the patient to a facility capable of liver transplantation, provided intensive care transport is available.

COMMON PITFALLS

- Failing to consider a hepatotoxic drug as the cause of the patient's symptoms. Patients who have ingested a hepatotoxic drug may be unwilling to give an adequate history and may present early in the course of their illness, before there is obvious clinical evidence of hepatic failure. Teenagers ingesting acetaminophen are a common example.
- The diagnosis of hepatic encephalopathy cannot be ruled out on the basis of a serum ammonia level.
- Hypoglycemia should be treated empirically in patients with altered mental status. One bolus of 50% dextrose may not be adequate therapy because of depleted glycogen stores; maintenance infusions of D₁₀ or D₂₀ should be administered.
- It is essential that the emergency physician attempt to identify causes of coma other than hepatic encephalopathy in patients with cirrhosis. In particular, subdural hematoma, drug overdose, and meningitis should be ruled out.

[Chapter References](#)

Since the first human orthotopic liver transplant (OLT) in 1963, progressive improvements in surgical technique, immunosuppressive regimens, and medical care of these patients now result in 5-year survival rates approaching 80%.^{3,5,14} Currently, over 100 centers perform more than 4,000 OLT operations each year in the United States. With improved survival rates and more centers performing liver transplantation, the number of OLT recipients presenting to the emergency department (ED) with complications continues to rise.

TRANSPLANT ANATOMY

The donor graft is prepared for implantation by undergoing a cholecystectomy.⁶ The OLT recipient undergoes a bilateral subcostal incision, which is extended cephalad in the midline, creating a characteristic “Mercedes Benz” incision pattern. The recipient may be placed on femoral to axillary venovenous bypass, permitting clamping of the recipient portal vein and inferior vena cava (IVC). After vascular clamping, a hepatectomy is performed and the donor graft is inserted. Hepatic artery, portal vein, and both suprahepatic and infrahepatic IVC anastomoses are performed. Vascular clamps are released and reperfusion of the graft occurs. Immediate intraoperative production of bile by the newly transplanted liver is an excellent indicator of graft function.

Biliary reconstruction most commonly consists in an end-to-end reanastomosis (choledochocholedochostomy) with or without T-tube placement. T-tube placement affords direct monitoring of bile production, as well as access for evaluation of the biliary system by T-tube cholangiography. Despite these advantages, T-tube use has recently declined due to a high rate of postoperative complications. A Roux-en-Y loop with a choledochojejunostomy is an alternative form of biliary reconstruction. While choledochocholedochostomy is the preferred technique for biliary reconstruction in most adults, children and adults requiring repeat transplantation or having intrinsic biliary system disease undergo choledochojejunostomies. Pneumobilia is a normal result of choledochojejunostomy.

TYPICAL POSTTRANSPLANT COURSE

Following surgery, OLT recipients spend several days in an intensive care unit, during which time their liver function indices are closely monitored. The patient continues on an aggressive immunosuppressive regimen, begun intraoperatively, designed to minimize immune-mediated graft rejection. A two-drug regimen consisting of tacrolimus and prednisone is increasingly replacing the previously common triple-drug regimen of cyclosporine, azathioprine, and prednisone.

Early postoperative complications of transplantation include bleeding and primary graft failure. Systemic coagulopathy, thrombocytopenia, and portal hypertension–induced abdominal venous collaterals render OLT candidates susceptible to bleeding complications. Postoperative bleeding is usually the result of dehiscence of a vascular anastomosis; patients present with intraperitoneal hemorrhage before discharge from the hospital. Emergency physicians are much more likely to encounter OLT patients with upper gastrointestinal tract bleeding from peptic ulcer disease.¹⁶ Upper and lower gastrointestinal tract bleeding in OLT patients is managed in the standard fashion.

Graft failure is a multifactorial process. Graft harvest technique, ischemia time, and reperfusion injury all influence graft viability. Early bile production, restoration of normal clotting function, and the absence of lactic acidosis are signs of good graft function. Profound hypoglycemia, progressive coagulopathy, metabolic acidosis, progressive encephalopathy, and hemodynamic instability clinically characterize graft failure.

In the absence of graft dysfunction, the OLT recipient is transferred to a ward bed and remains an inpatient for 1 to 2 weeks. Close outpatient care at the transplant center continues for an additional 1 to 2 months, during which time patients undergo careful adjustments of their immunosuppressive regimens. Patients are then followed on a monthly basis for the remainder of the first year after transplantation. The follow-up interval after 1 year is decided on a case-by-case basis.

CLINICAL PRESENTATION

OLT patients present to the ED with a wide variety of illnesses. Emergency physicians encounter vascular and biliary complications, rejection, infectious and metabolic complications, and medication-related adverse effects in OLT patients.^{17,10,15,16}

Vascular Complications

Vascular complications include hepatic artery thrombosis (HAT), portal vein thrombosis (PVT), and hepatic artery rupture.⁴ Together they account for about 10% of graft failure in adults and 30% of graft failure in children. The vascular supply to the donor common bile duct is dependent on the newly reconstructed hepatic artery. The graft, in contrast to the native liver, has no collateral arterial blood supply, and any disruption to hepatic artery blood flow inevitably leads to bile duct necrosis, with resultant bile duct leaks, graft dysfunction, abscess formation, and sepsis.

Although both HAT and PVT tend to occur within the first month and most often within the first week following transplantation, either may occur later, usually in association with episodes of acute rejection. The incidence of HAT varies from 4% to 25%, and it accounts for about 75% of post-OLT vascular complications. Patients with HAT or PVT typically have clinical (jaundice, dark urine, clay-colored stools) and laboratory (elevated transaminase and bilirubin levels) evidence of graft dysfunction, varying degrees of right upper quadrant abdominal pain, and fever. HAT is rare, and patients with it typically present acutely ill, in hypovolemic shock.

Biliary Complications

The incidence of biliary complications, including bile leaks and obstructions to bile flow, is 17% to 28%.^{8,17} Patients typically complain of abdominal pain, jaundice, or fever, and evidence of cholangitis or peritonitis may be present. Unfortunately, some patients with biliary complications present with isolated fever or elevated liver enzymes without jaundice or abdominal pain. The abdomen may even be soft and nontender. Emergency physicians should strongly consider the possibility of a biliary complication whenever faced with an OLT patient presenting with any combination of abdominal complaints, fever, or evidence of graft dysfunction.

Immune-Mediated Disease

Immune-mediated disease in organ transplant recipients consists of hyperacute, acute, and chronic forms of rejection, as well as graft-versus-host disease. Acute and chronic rejection are the most clinically relevant immune-mediated diseases in OLT patients, because the liver is relatively resistant to hyperacute rejection and graft-versus-host disease.¹⁶ Acute and chronic rejection are classified on the basis of time of occurrence and histology. Between 60% and 80% of patients in some

published series have at least one episode of acute rejection. Chronic allograft rejection develops in approximately 5% to 9% of OLT recipients and may cause graft failure.

Acute rejection commonly manifests as malaise, generalized weakness, progressive jaundice, right upper quadrant pain, and, often, fever. Occasionally, acute rejection may be clinically asymptomatic, with elevation of liver enzymes the only clue to the diagnosis. A pattern of early alkaline phosphatase and bilirubin elevation, followed shortly by a rise in aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels, is typical of acute rejection. Although suggestive, this pattern is not specific for acute rejection, and may occur with cholestasis, cholangitis, drug toxicity, and other states of hepatic dysfunction.

The clinical presentation of chronic rejection is similar to that of an acute rejection. Patients may report low-grade fever, fatigue, progressive jaundice, right upper quadrant pain, clay-colored stools, and dark urine. Patients with chronic rejection usually experience a more gradual clinical deterioration compared with patients suffering acute rejection. Laboratory findings of chronic rejection are persistently elevated transaminase levels, increasing cholestasis, and declining hepatic synthetic function.

Infectious Complications

Infection continues to be a major source of morbidity and mortality in OLT patients.^{2,12} Up to 67% of recipients have at least one serious infection following OLT. Approximately 50% to 60% of these infections are bacterial, 15% are fungal, 5% to 15% are viral, and less than 10% are caused by *Pneumocystis carini* or *Toxoplasma* species. Most infections occur during times of peak immunosuppression. Specifically, OLT recipients are at high risk for serious infections in the first several months following transplantation.

Patients maintained on high levels of immunosuppressive medications following acute rejection episodes, patients with indwelling central lines, and patients with biliary complications (e.g., biliary strictures) also remain at high risk for serious infections irrespective of duration posttransplantation. Emergency physicians should bear in mind that OLT recipients are immunocompromised and may present to the ED appearing well and complaining only of isolated fever, only to deteriorate rapidly during their subsequent hospital course.

Metabolic Complications and Medication-Related Adverse Effects

The immunosuppressive regimens that make graft survival possible are a frequent source of adverse effects. In addition to promoting infection, immunosuppressive medications may result in metabolic, renal, neurologic, hematologic, dermatologic, and bone disorders. Drug–drug interactions may precipitate these events, and the potential for adverse drug interactions should always be considered ([Table 160.1](#)).

MEDICATIONS THAT LOWER CYCLOSPORINE (NEORAL, SANDIMMUNE) AND TACROLIMUS (PROGRAF) LEVELS	
Nafcillin	
Phenobarbital	
Carbamazepine	
Phenytoin	
Rifampin	
Valproic acid	
MEDICATIONS THAT ELEVATE CYCLOSPORINE (NEORAL, SANDIMMUNE) AND TACROLIMUS (PROGRAF) LEVELS	
Cimetidine	Clarithromycin
Diltiazem	Erythromycin
Fluconazole	Inosipim
Triclorazole	Ketoconazole
Methylprednisolone	Metoclopramide
Venipamil	

Avoid nonsteroidal antiinflammatory drugs, as they may further compromise renal function in patients taking either tacrolimus or cyclosporine. Oral contraceptives are contraindicated, due to the increased risk of a thrombotic event (e.g., hepatic artery thrombosis). No live virus vaccinations should be administered to OLT recipients or any of their close household contacts.

TABLE 160.1. Significant Drug Interactions

The corticosteroids OLT patients receive result in all of the typical complications of chronic steroid excess, including adrenal suppression, cushingoid appearance, and osteoporosis. Osteoporosis-related fractures, especially vertebral body compression fractures, are a common problem in OLT patients because of preexisting hepatic osteodystrophies coupled with the osteopenic effects of corticosteroids.⁹

Dose-dependent cyclosporine or tacrolimus nephrotoxicity is common. Initial presentation may be occult, with azotemia and a rise in creatinine occurring with minimal symptoms. Corticosteroids, cyclosporine, and tacrolimus all induce insulin resistance, and OLT recipients may develop diabetes mellitus with hyperglycemic symptoms. Additionally, the immunosuppressive regimens OLT patients require have been associated with a variety of neurologic (tremors, headaches, altered mental status, seizures) and gastrointestinal symptoms (nausea, vomiting, and diarrhea).^{19,20}

Late Complications

Late complications are defined as those that occur more than 1 year after transplantation. The most common causes of late deaths are chronic rejection and new malignancies.¹ Major nonfatal late complications include biliary stricture, renal impairment, and infection.¹³

DIFFERENTIAL DIAGNOSIS

The differential diagnoses for some of the more common presenting complaints are provided in [Table 160.2](#). The frequently nonspecific presentations of the major complications usually preclude making a specific diagnosis on clinical findings alone.^{10,11} In addition, multiple diagnoses are common, owing to the interrelationship between many of the complications (e.g., HAT causing bile duct necrosis, leading to bile leakage and abscess formation).

TABLE 160.2. Final Diagnoses for Common Presenting Complaints^a

EMERGENCY DEPARTMENT EVALUATION

ED evaluation of OLT patient begins with a thorough history and physical examination. Important historic factors include etiology of liver failure, date of transplant, history of postoperative complications, recent diagnostic studies, and current medications. A review of systems should determine the presence of fever, nausea, vomiting, abdominal pain, jaundice, acholic stools, and dark urine. Emergency physicians should bear in mind that serious OLT complications may present with

deceptively nonspecific symptoms and normal initial physical examinations.

Because the presentations of many important complications of OLT are nonspecific, patients presenting to the ED generally require extensive laboratory testing. Laboratory tests should include a complete blood count and platelet count to screen for overimmunosuppression related to medications. Electrolytes and serum creatinine concentrations are useful to detect the nephrotoxic effects of either tacrolimus or cyclosporine. Total bilirubin, AST, ALT, alkaline phosphatase, and prothrombin time levels are used to evaluate graft function. Patients presenting with a fever should have blood and urine cultures and a urinalysis ([Table 160.3](#)).

Infection Disease	Time of Presentation after OLT	Diagnostic Evaluation	Treatment*
Bacterial infections	Peak in months 1-2; progression declines in incidence after 12 mo, unless patient is still taking high-dose immunosuppressive regimen, including live vaccines	Blood, urine, and sputum cultures;† Culture of all remaining sites and biopsies to find if T3 tube still present	Empiric broad-spectrum antibiotic coverage pending culture results (e.g., vancomycin 1 g i.v. q12h and ampicillin/sulbactam 3 g i.v. q6h)
Fungal infections	Peak in months 1-2; rare after 2 mo, unless patient is still taking high-dose immunosuppressive regimen	Blood, urine, and sputum cultures	Amphotericin B or itraconazole†
Viral infections	Most common in month 2 after OLT, rare after 2 mo; cytomegalovirus is most common infection	Blood, urine, and sputum cultures;†	Ganciclovir or foscarnet
Protozoal infections	Rare, but occasionally occur months 1-4; P. carinii pneumonia is the most common pathogen	Chest radiograph and sputum cultures; nasal swabs; bronchoalveolar lavage; diagnosis is not usually made in ED	Trimethoprim-sulfamethoxazole 20 mg/kg i.v. divided q.d. for 14-21 days

*Medication changes must be adjusted based on patient's renal function.
†Obtain sputum cultures and chest radiograph when clinically appropriate (e.g., patient with fever and cough). Consider nasal cultures and Chlamydia titers for diagnosis of infectious aetiology.
‡Fungal and bacterial therapy are not routinely indicated in the ED. They are usually reserved for the OLT patient's hospital course when fungal sites have been documented or the patient's condition fails to improve with empirical therapy.
§Cytomegalovirus of clinically significant disease without further diagnostic testing, such as polymerase chain reaction, serologic studies, or in situ hybridization, is performed later in the patient's hospital course and is not an immediate priority during the ED visit.

TABLE 160.3. Time of Occurrence and Management of Infections in OLT Recipients

When suspicion of vascular complications arises, several diagnostic modalities may be useful. Duplex ultrasonography and spiral computed tomography (spiral CT) are noninvasive modalities that have a reported sensitivity of more than 90% for detecting vascular complications. Angiography is helpful in equivocal cases. Emergency physicians should have a low threshold for using ultrasonography or spiral CT to evaluate OLT patients for vascular complications in the presence of abdominal complaints or laboratory evidence of graft dysfunction.

Although ultrasound or CT imaging may suggest biliary complications, definitive diagnosis is made by visualization of the biliary tract with T-tube cholangiography, endoscopic retrograde cholangiopancreatography, percutaneous transhepatic cholangiography, or operative exploration.

Rejection is definitively diagnosed by liver biopsy. The histologic triad of portal tract inflammation and mononuclear cell involvement of portal vein branches and small bile ducts is diagnostic for acute rejection. Liver biopsy in chronic rejection reveals destruction and loss of interlobular bile ducts, mononuclear portal inflammation, arteriopathy, centrilobular cholestasis, and varying degrees of hepatocellular damage.

EMERGENCY DEPARTMENT MANAGEMENT

A majority of OLT patients with vascular complications require surgical intervention for definitive therapy, and management of their cases should be done in concert with the liver transplant team.

Patients diagnosed with bile leaks require parenteral antibiotics, percutaneous drainage of any abscess, and, occasionally, surgical intervention for refractory cases. Bile leaks occurring earlier in the post-OLT period tend to be more severe and are often unresponsive to conventional therapy, probably because the higher initial level of immunosuppression renders patients incapable of eradicating infection. Infections tend to be polymicrobial and include the typical biliary tract bacterial pathogens (*Enterobacter*, *Enterococcus*, *Bacteroides*, and *Clostridium* species). Broad-spectrum gram-positive, gram-negative (including *Pseudomonas aeruginosa*), and anaerobic coverage is recommended pending culture results. Many patients diagnosed with biliary strictures may be nonoperatively managed with stents or balloon dilation of their strictures.

Treatment of acute rejection involves the administration of high-dose intravenous methylprednisolone. Therapy is rarely initiated in the ED, because the definitive diagnosis of rejection is usually made later in the patient's hospital course by liver biopsy. Corticosteroids are effective in reversing 65% to 80% of acute rejection episodes. Patients who do not respond to glucocorticosteroids are treated with regimens using muromonab-CD3 (Orthoclone OKT3), with an 85% salvage rate. Chronic rejection does not respond to immunosuppressive regimens as uniformly as do acute rejection episodes. OLT recipients in whom chronic rejection is suspected should be referred to a liver transplant center for evaluation, because many patients with chronic rejection will suffer eventual graft failure and require retransplantation.

Emergency physicians should remember that rapid deterioration might occur in clinically stable OLT patients with acute infections, particularly during times of peak immunosuppression. High-risk OLT patients presenting with fever, including recipients within 6 months of transplant, should receive empiric broad-spectrum antibiotic therapy pending definitive culture results. Antibiotic coverage should include gram-positive organisms, gram-negative organisms (including *P. aeruginosa*), and anaerobic organisms. Specific therapy against fungal, viral, and protozoal pathogens is rarely instituted in the ED.

DISPOSITION

Serious illness is common in OLT patients presenting to the ED. Not surprisingly, OLT recipients typically undergo extensive diagnostic evaluations and are frequently hospitalized. Much of the diagnostic testing these patients require is time-consuming and beyond the scope of everyday emergency medicine practice. Appropriate ED goals are assessing the severity and possible causes of an acute illness, stabilization, and transfer of care to the primary liver transplant team. Emergency physicians should involve the liver transplant team early in the decision-making process to help coordinate the timing and location of the evaluation, especially if transfer to a tertiary care center is necessary.

New-onset graft failure mandates admission. The causes of graft failure are diverse, and their evaluation is best performed in the inpatient setting.

In general, febrile OLT patients that are less than 1 year posttransplantation and are without an obvious source of infection are admitted. Febrile patients that are more than 1 year posttransplantation but are still maintained at a high level of immunosuppression (e.g., chronic rejection patients) should also be hospitalized. Well-appearing, febrile patients that are more than 1 year posttransplantation, with an uncomplicated post-OLT course, and whose immunosuppressives have been tapered, may be managed on an individual basis. Because maintaining a desired level of immunosuppression is vital in preventing rejection episodes, admission is mandatory if compliance with the immunosuppressive regimen is in doubt (e.g., because of intractable vomiting).

COMMON PITFALLS

- Failure to appreciate the complex and fragile nature of OLT patients
- Failure to coordinate the ED evaluation of OLT recipients with their liver transplant team
- Forgetting that OLT recipients are immunocompromised hosts and failing to manage fever aggressively, especially in the early post-OLT period
- Using the leukocyte count as a marker for severity of infection. Over 50% of OLT patients with serious bacterial infections have a normal leukocyte count.
- Assuming that a soft and nontender abdominal examination excludes hepatobiliary complications
- Forgetting that OLT patients are predisposed to adverse effects of medications because of the complexity of their drug regimens. One must ensure that medications prescribed to OLT patients in the ED do not have adverse interactions with the medications the patient is already taking.

CHAPTER 161

Nonsurgical Causes of Abdominal Pain

Darrell C. Sandel and Sheldon Jacobson

[Familial Mediterranean Fever](#)
[Porphyria](#)
[Abdominal Vasculitis](#)
[Angioedema](#)
[Intestinal Pseudoobstruction](#)
[Sickle Cell Disease](#)
[Chronic Lead Intoxication](#)
[Addison Disease](#)
[Narcotic Withdrawal](#)
[Psychogenic Abdominal Pain](#)
[Abdominal Pain in Acquired Immunodeficiency Syndrome](#)
[Chapter References](#)

Abdominal pain is the presenting symptom in 4% to 8% of adult emergency department (ED) visits.^{3,17} Appropriately, much of the emergency physician's effort is focused on ruling out surgically correctible disease. Of patients with abdominal pain not due to obstetric or gynecologic problems, approximately 8% to 10% have obvious surgical disease. Of the remaining, most have self-limited abdominal pain, and some have an undiagnosed surgical or inflammatory disorder. These and other less common entities are listed in [Table 161.1](#). In general, undertake evaluation for one of these disorders only if there has been recurrent or persistent pain lasting for a period of days and if a preliminary workup, including abdominal computed tomography (CT) imaging, has been negative. Additional factors that should be considered include the patient's age, ethnicity, and family history, or a known history of one of the diseases in question.

Acute intermittent porphyria
 Heavy-metal poisoning
 Abdominal tuberculosis (Dietl crisis)
 Abdominal epilepsy
 Abdominal migraine
 Black widow spider bite
 Vasculitis
 Abdominal angina
 Intestinal pseudoobstruction
 Sickle cell crisis
 Right-sided colonic diverticulitis
 Meckel's diverticulitis
 Familial Mediterranean fever
 Massive intravascular hemolysis
 Narcotic withdrawal
 Factitious or drug-seeking behavior
 Psychogenic abdominal pain
 Addisonian crisis
 C1 esterase inhibitor deficiency
 Spastic colon
 Irritable bowel syndrome
 Inflammatory bowel disease

TABLE 161.1. Nonsurgical Causes of Abdominal Pain

FAMILIAL MEDITERRANEAN FEVER

Familial Mediterranean fever (FMF) is a disease that is most common in non-Ashkenazi Jews, Turks, Armenians, and Middle Eastern Arabs, but generally not in other Mediterranean populations.^{13,18} It is characterized by bouts of abdominal pain with signs of peritonitis. Fever and pleuritis are very common, and arthritis and migratory skin lesions can also occur. It can mimic an acute abdomen and be accompanied by an elevated white cell count with a left shift and a high erythrocyte sedimentation rate. Episodes of the disease generally last 24 to 72 hours. The diagnosis is usually made by the second decade of life, and very rarely after the age of 40. A family history cannot always be obtained, as the transmission is autosomal recessive. Diagnosis is clinical, although work on genetic markers may someday make a laboratory diagnosis possible.¹³

FMF can be treated with oral colchicine 0.6 mg q1h for three doses, and then 0.6 mg q2h for an additional dose. Intravenous colchicine is not recommended unless the patient is unable to tolerate oral medications. Long-term prophylactic treatment with colchicine reduces the rate of recurrence and also helps prevent amyloidosis, the long-term complication of FMF. Opiates can be used to treat the pain. Patients should be admitted for observation, and surgical consultation obtained. A diagnosis of FMF should never be definitively made in the ED.

Patients with suspected FMF should be admitted and observed, given the possibility of misdiagnosis.

PORPHYRIA

The porphyrias affect the biosynthesis of heme and result in the accumulation of excessive porphyrins and their precursors. They are inherited enzyme disorders, almost always autosomal dominant with poor penetrance. They are characterized by abdominal pain with or without manifestations of autonomic dysfunction or neuropsychiatric symptoms. Other presenting conditions in patients with porphyria include demyelinating syndromes, SIADH, hypertensive crisis, and acute psychosis. There are many variants, depending on the particular enzyme deficiency and the heme precursor accumulated. The most common porphyria that causes abdominal pain is acute intermittent porphyria.^{7,19}

The diagnosis is difficult, given the low prevalence. The pain of porphyria is usually out of proportion to physical signs, and fever is usually absent. A family history is helpful but not always present. Although not totally sensitive or specific, a Watson-Schwartz urine test should be ordered to look for porphobilinogen.^{7,19} The urine dipstick for urobilinogen yields a strong false-positive result. The diagnosis is made by a finding of elevated 24-hour levels of urine and stool porphyrins.

Management is largely supportive. Intravenous glucose infusion may abort attacks. Intravenous hematin also may be helpful, although studies have not been large enough to prove its efficacy.¹¹ Many drugs can precipitate attacks; potentially harmful drugs are listed in [Table 161.2](#).¹⁷

Barbiturates	Succinimides
Sulfonamide antibiotics	Carbamazepine
Meprobamate	Valproic acid
Clutethimide	Pyrazolones
Methyprylon	Griseofulvin
Ethchlorvynol	Ergots
Phenytoin	Danazol
Mephentermine	Alcohol
Chlorpropamide	Estrogens and progestins

From Cecil Textbook of Medicine, 19th ed, Chap. 191. Philadelphia: WB Saunders, 1992.

TABLE 161.2. Potentially Toxic Drugs in the Treatment of the Acute Porphyrias

ABDOMINAL VASCULITIS

Abdominal vasculitis occurs in several disease processes, but polyarteritis nodosa, systemic lupus erythematosus, and Henoch-Schönlein purpura are probably the most common. The spectrum of presentation varies from acute severe ischemia to mild pain, malabsorption, and abdominal angina.

Patients with abdominal vasculitis may have peripheral manifestations of vasculitis as well. The abdominal pain may be epigastric or periumbilical, reflecting ischemia of the fore-gut or midgut, respectively. Fever is prominent in some cases. The key issue in these conditions is considering the diagnosis and then obtaining appropriate tests, such as angiography. Abdominal vasculitis should always be considered in patients with abdominal pain who also have a history of rheumatologic disease.

ANGIOEDEMA

Hereditary angioneurotic edema is transmitted as an autosomal dominant trait. Symptomatic patients have low levels of C1' esterase inhibitor (type 1), or they have a dysfunctional inhibitor (type 2); either condition allows activation of the complement system.¹ Initial symptoms usually arise in adolescence but can have their onset in later life.

Classically, patients with angioedema do not have urticaria. Angioneurotic edema of the skin involves the deeper portions of the dermis and the subcutaneous layers, as well, and does not cause pruritus, whereas urticaria results from edema in the superficial layers of the skin and is pruritic.

Attacks of hereditary angioneurotic edema may begin with abdominal pain due to angioedema of the bowel wall. The pain is often colicky and is associated with nausea and vomiting, but there are scant physical findings in the abdomen. Fever is usually absent, and white blood cell counts are normal. During an attack, serum levels of C2 and C4 are low. Between attacks, the diagnosis can be established by assaying for the presence of the C1' esterase inhibitor.

Use of angiotensin converting enzyme inhibitors (ACE inhibitors) has also been associated with angioedema.¹⁰ There have been case reports of individuals presenting with small bowel angioedema thought to be secondary to ACE inhibitors.⁴ Strong consideration should be given to withholding ACE inhibitors in patients with persistent, unexplained abdominal pain.

Attacks are self-limited but generally last 24 to 72 hours. Because the upper airway can be involved acutely, a major clinical concern is sudden upper airway obstruction requiring epinephrine administration, intubation, or cricothyrotomy.

C1' esterase inhibitor concentrate has been successful in small randomized trials in patients with known functional C1' esterase inhibitor deficiency and angioedema. It may be used in cases of facial, laryngeal, or severe abdominal angioedema,^{14,21} but it is not indicated for minor subcutaneous attacks.⁵ It should not be used in patients with ACE inhibitor-associated angioedema.

Anabolic steroids, which increase production of the inhibitor, are effective in reducing the frequency of attacks, but they are not used acutely. Management is otherwise supportive. Admission is usually advisable because of the risk of upper airway involvement.

INTESTINAL PSEUDOObSTRUCTION

Intestinal pseudoobstructions are a group of diseases that present as bouts of recurrent abdominal distention, obstipation, and, on occasion, colicky abdominal pain. The presentation can be identical to that of small bowel mechanical obstruction. Pseudoobstruction can be caused by a primary disorder of the myenteric plexus or the smooth muscle itself, or may be secondary to a host of systemic diseases (Table 161.3). The diagnosis is made by ruling out other causes of abdominal pain and motility disorders, including adult Hirschsprung disease and mechanical obstruction. The differential diagnosis also includes toxic megacolon, typhlitis, and idiopathic colonic dilation of the elderly (Ogilvie syndrome). Definitive diagnosis requires manometric and electrophysiologic testing, as well as biopsy.

TABLE 161.3. Causes of Secondary Intestinal Pseudoobstruction

SICKLE CELL DISEASE

It is not uncommon to see patients with sickle cell disease and vasoocclusive painful crisis in many emergency practices. These patients can present with pain almost anywhere in the body, including the abdomen. What is not commonly appreciated is that a few patients with homozygous sickle cell disease have their first painful crisis in their late teens or early 20s, frequently presenting with cryptogenic abdominal pain. Patients with established sickle cell disease can also pose a diagnostic challenge because their abdominal pain can be caused by a vasoocclusive event involving any of the abdominal viscera or the abdominal wall.

In addition, almost all patients with sickle cell disease have gallstones; acute cholecystitis, common duct obstruction, and ascending cholangitis are ever-present dangers in these immunocompromised patients. Abdominal pain also can develop for reasons unrelated to sickle cell disease, but the primary process may be misdiagnosed as crisis pain.

The laboratory evaluation of sickle cell patients with abdominal pain is often misleading. Many vasoocclusive crises are not associated with fever, and the white blood cell count is typically chronically elevated in these patients, commonly with a left shift. In addition, many sickle cell disease patients are icteric because of chronic hemolysis. Many have intrinsic liver disease as well, but liver function test abnormalities are not helpful unless there is a significant deviation from baseline values. For patients presenting with right upper quadrant pain, diagnosis can be assisted by the use of abdominal ultrasonography, nuclear scans of the biliary system, or abdominal CT scanning.

CHRONIC LEAD INTOXICATION

Chronic lead intoxication can present as a painful abdominal crisis (lead colic). Abdominal pain can be slowly progressive or subacute in onset. There is abdominal tenderness with voluntary guarding, but true peritoneal findings are rare. Patients commonly complain of fatigue, weakness, musculoskeletal pains, irritability, and constipation. Hemolytic anemia is usually evident, and the red blood cells show basophilic stippling. An occasional patient may have the triad of lead nephropathy, "saturnine" gout, and hypertension. The diagnosis is made by determining blood lead and erythrocyte protoporphyrin levels. Chelation therapy is often successful in relieving manifestations outside the central nervous system.

ADDISON DISEASE

Addison disease can present as a dramatic acute syndrome with vasomotor collapse, altered mental status, and characteristic electrolyte abnormalities. A subacute-to-chronic form of the disease, however, can present with recurrent abdominal pain, often associated with nausea and vomiting and usually with a negative abdominal examination.

The most common cause of primary adrenal insufficiency is idiopathic or autoimmune destruction of the gland. Patients with the acquired immunodeficiency syndrome (AIDS) have a high incidence of adrenal gland involvement from a number of mechanisms. Other presenting complaints include salt craving, anorexia, weight loss, and generalized weakness. Characteristic physical findings include orthostatic hypotension, freckling and hyperpigmentation of the skin, and surgical scars. Classic laboratory findings include hyperkalemia, hyponatremia, mild azotemia, mild metabolic acidosis, and hypoglycemia.

If the diagnosis of Addison disease is suspected, a serum cortisol level should be ordered and, if the patient's condition permits, a 1-hour ACTH stimulation test (see [Chapter 172](#)). Treatment should begin immediately with administration of intravenous corticosteroids (hydrocortisone 60 mg q6h, or dexamethasone if awaiting an ACTH stimulation test), glucose, and saline.

NARCOTIC WITHDRAWAL

Narcotic withdrawal frequently produces crampy abdominal pain, often associated with nausea, vomiting, and diarrhea. Diagnosis of this syndrome is frequently difficult unless the patient admits to narcotic addiction. Other signs and symptoms of narcotic withdrawal (e.g., mydriasis, rhinorrhea, piloerection) may be present, but these features are rarely prominent.

Patients often ask specifically for an analgesic medication or name a specific narcotic agent they have successfully used for their problem in the past. If narcotic withdrawal is suspected, confrontation in the ED is not helpful. These patients should be referred to a primary care physician and should have early psychiatric evaluation. The use of methadone detoxification or clonidine to relieve the patient's symptoms must be considered on an individual basis.

PSYCHOGENIC ABDOMINAL PAIN

Psychogenic abdominal pain involves a diverse group of psychiatric disturbances, including somatoform disorders, eating disorders, conversion reactions, depression, and hypochondriacal neurosis. Abdominal pain can also occur as a somatic delusion or as an hallucinatory phenomenon, but it generally is found in association with bizarre symptoms and evidence of underlying thought disorder. Women represent a disproportionately large percentage of patients with psychogenic abdominal pain in several studies. As noted previously, early psychiatric consultation is important, but it must be kept in mind that psychogenic abdominal pain must always remain, to some degree, a diagnosis of exclusion.

ABDOMINAL PAIN IN ACQUIRED IMMUNODEFICIENCY SYNDROME

The diagnosis of abdominal pain in patients with human immunodeficiency virus (HIV) infection and AIDS is challenging. There are no large ED-centered studies looking at this problem, but a number of studies have reviewed the outcome for specific disease entities, and data exist from large case series of patients admitted to subspecialty services.^{1,20} Although the exact prevalence is not known, a number of entities are fairly common.

The differential diagnosis of abdominal pain in AIDS is summarized in [Table 161.4](#). HIV-positive patients without AIDS probably have disease incidences similar to those of HIV-negative patients. As the disease progresses, however, the differential diagnosis expands and reliance on typical cues and laboratory tests becomes problematic.

Sclerosing cholangitis
Calculous cholecystitis
Acalculous cholecystitis
Pancreatitis
CMV enterocolitis
C. difficile colitis
Mycobacterium avium-intracellulare enteritis
Lymphoma
Renal stone disease (with ddi)
Appendicitis
Cryptosporidial infection
Gastrointestinal Kaposi's sarcoma
Intussusception (rare)

TABLE 161.4. Differential Diagnosis of Abdominal Pain in Acquired Immunodeficiency Syndrome

For instance, one large case series of appendicitis in HIV-positive patients with and without AIDS showed leukocytosis and fever to be absent in more than 50% of patients.⁹ As AIDS progresses, the differential diagnosis becomes skewed toward uncommon diseases. For example, in patients with right upper quadrant pain, the incidence of sclerosing cholangitis increases dramatically, and acalculous cholecystitis can be seen. Cytomegalovirus (CMV) colitis tends to be associated with diffuse pain and with diarrhea, often bloody. This symptom is of special concern, as it is associated with perforation and poor survival. Cryptosporidial disease can cause abdominal pain but is associated with profuse, unrelenting diarrhea.

Pancreatitis is another vexing problem in AIDS. It is associated with the use of drugs, including pentamidine, indinavir (ddi), and, uncommonly, trimethoprim-sulfamethoxazole. CMV, herpes simplex virus, *Mycobacterium avium* complex, and *Cryptococcus* have also been implicated. Treatment is supportive and includes withholding of offending agents.⁸ Asymptomatic hyperamylasemia has also been noted in AIDS patients.

Patients with HIV and/or AIDS have somewhat higher rates of operative complications, but this fact should not preclude surgical consultation where indicated. Studies have shown good results when patients with appendicitis or cholecystitis undergo operation.^{9,15} Small case series of laparoscopy have also been encouraging.²

CHAPTER 162

Inflammatory Bowel Disease

Howard A. Werman

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation and Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Inflammatory bowel disease (IBD) comprises two chronic intestinal disorders: ulcerative colitis and regional enteritis or Crohn disease. Both are characterized by recurrent episodes of gastrointestinal disturbances separated by periods of remission, and both are associated with a variety of systemic manifestations. The emergency physician must be familiar with IBD for two reasons. First, these two disorders must be considered in the differential diagnosis of patients with gastrointestinal complaints, particularly if they are recurrent. Second, patients with well-established diagnoses of IBD often present to the emergency department (ED) for management of acute exacerbations and complications of their disease.

The cause of both disorders remains unknown. Immunologic, infectious, genetic, dietary, and psychological factors have all been implicated.⁸ For both diseases, there is a bimodal distribution in the age at onset, with peaks at 15 to 25 years and at 55 to 60 years.⁷ Ten percent to 15% of patients with IBD have relatives who are also affected. The incidence of Crohn disease has been rising over the past 20 years; the incidence of ulcerative colitis, which had been stable, has also risen in the past few years.

Ulcerative colitis tends to remain localized to the colon; in the majority of patients, the disease is found in the rectum and left colon only. The entire colon is affected (pancolitis) in the most severe cases. Ulcerative colitis is usually limited to the intestinal mucosa and submucosa. Diffuse involvement producing a finely granular, friable mucosa explains the propensity for bloody diarrhea noted in these patients. Crohn disease can be found along the entire gastrointestinal tract. In 30% of cases, only the terminal ileum is involved; 20% of patients have colonic disease only. Both small and large bowels are affected in the remaining 50%. Disease of the mouth, esophagus, and stomach is found in less than 1% of patients. The lesions of Crohn disease tend to involve all of the bowel wall layers and extend into the mesentery. Deep ulcerations, which often penetrate the bowel wall, are common and account for the development of fissures, fistulas, and abscesses. About one-third of patients with Crohn disease will manifest perianal complications such as abscesses, fistulas, fissures, and skin tags.

CLINICAL PRESENTATION

The most common signs and symptoms in patients with Crohn disease are chronic diarrhea, abdominal pain, fever, anorexia, and weight loss. The presentation characterizes 75% to 80% of patients with this disease, but the symptoms are so nonspecific, there is typically a long delay (weeks to months) in establishing the diagnosis. The presentation of cases seen in the ED varies, depending on the site of involvement of Crohn disease. Patients with primary ileal disease present with right lower quadrant abdominal pain that is associated with fever, abdominal distention, vomiting, and either profuse watery diarrhea or decreased output of stool and gas. Severe cases of Crohn colitis are characterized by abdominal pain associated with fever and massive diarrhea. Less common causes of emergent presentations include severe epigastric pain similar to peptic ulcer disease, acute pancreatitis, and large aphthous ulcers of the mouth.

As in Crohn disease, the presentation of ulcerative colitis is quite variable. In fact, separation of these disorders on the basis of clinical findings alone can be very difficult. In mild cases, occasional constipation and rectal bleeding may be the only complaints. In the more severe forms, patients have more than six to eight bloody diarrheal stools per day, as well as crampy abdominal pain, tenesmus, fever, tachycardia, and anemia. Ulcerative colitis is more commonly associated with rectal bleeding, whereas abdominal pain, abdominal masses, and perianal lesions are more common in patients with Crohn disease.

A common reason for patients with well-established IBD to present to the ED is complications of their underlying disease.² The major intestinal complications of Crohn disease and ulcerative colitis include intraabdominal abscess formation, bowel perforation, massive hemorrhage, intestinal obstruction, dehydration, perianal complications (fissures, fistulas, and perirectal abscesses), and toxic megacolon. Complications such as massive hemorrhage and toxic megacolon are more commonly seen in ulcerative colitis, whereas abscesses, obstruction, and perianal complications are far more common in Crohn disease. In addition to recognizing these complications, the emergency physician must also be aware that medications taken by patients with IBD, particularly corticosteroids, may mask the findings typically associated with complications.

Toxic megacolon is perhaps the most dramatic complication seen in patients with IBD. This process is the result of a loss of muscular tone in the patient with advanced disease. Toxic megacolon should be suspected in patients with active colitis who report a decrease in stool output, particularly if they are on antidiarrheal agents or have undergone a recent colonoscopy. Affected patients appear toxic; the abdomen is distended, tender, and tympanic. Fever, tachycardia, and signs of volume depletion are noted. Other findings include leukocytosis, anemia, electrolyte disturbances, and an abdominal radiograph demonstrating a long, continuous dilated segment of bowel (greater than 6 cm in width). The mortality associated with this complication can be as high as 50% if perforation occurs.

Ten percent to 20% of patients with IBD have extraintestinal manifestations of their disease.⁵ Occasionally, these symptoms actually appear before gastrointestinal ones, particularly in children. The most common of these manifestations are erythema nodosum, pyoderma gangrenosum, nongranulomatous anterior uveitis, polyarthritis, ankylosing spondylitis, and hepatobiliary disease.¹ In Crohn disease with small bowel involvement, malabsorption syndromes and fluid and electrolyte disturbances can occur. Gallstones are found in up to 33% of patients with Crohn disease. Calcium oxalate nephrolithiasis is also common. Patients with IBD may also develop a hypercoagulable state, resulting in deep venous thrombosis, pulmonary embolus, and, occasionally, arterial occlusion. Patients with thromboembolic complications have a mortality rate of approximately 25%. Pneumaturia and recurrent urinary tract infection occasionally occur with Crohn disease, because of enterovesical fistula.

A long-term complication, particularly of patients with ulcerative colitis, is colon carcinoma. Patients with ulcerative colitis have ten to 30 times the risk of developing colon cancer when compared with the general population, and patients with Crohn disease have a threefold increase in risk. Symptoms of a new colon cancer may overlap considerably with those of IBD, often making diagnosis difficult.

DIFFERENTIAL DIAGNOSIS

The major challenge for the emergency physician is to differentiate IBD as a cause of diarrhea, vague abdominal pain, malaise, and low-grade fever from other treatable causes of these symptoms. Several other entities present with similar complaints. Acute infectious diarrheal illness due to *Shigella*, *Salmonella*, *Campylobacter jejuni*, cytomegalovirus, or *Yersinia* must be considered. Parasitic disease such as amebiasis can also masquerade as IBD. Stool cultures and examination of stool for ova and parasites are necessary to identify an infectious cause of the patient's symptoms. In addition, serologic tests can be used to rule out invasive amebiasis, but in up to 50% of cases of infectious diarrhea, no pathogen can be identified. When the symptoms primarily involve the rectum, anal intercourse-associated bowel syndrome should be considered. Symptoms of chronic diarrhea, low-grade fever, and cachexia are also consistent with human immunodeficiency virus infection.

Antibiotic-induced colitis attributable to the overgrowth of *Clostridium difficile* must also be considered. Ischemic colitis and diverticulitis, generally seen in older patients, and radiation colitis may present, with a clinical and pathologic pattern similar to that of IBD.

When abdominal pain is the major complaint, IBD must be distinguished from other causes of the acute abdomen, including appendicitis, cholecystitis, other causes of intestinal obstruction, abdominal aortic aneurysm, and mesenteric occlusive disease. These entities can often be distinguished from IBD on the basis of history and physical examination. Abdominal radiographs, a complete blood cell count, serum amylase and lipase determination, and urinalysis can also be helpful. The emergency physician should consider IBD as a cause of abdominal complaints only after these other potentially serious causes of abdominal pain have been excluded.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

In evaluating the patient with known IBD, the physician must first be concerned with identifying any significant complications of IBD, particularly gastrointestinal hemorrhage, intestinal obstruction, bowel perforation, and toxic megacolon. Particular attention should be given to patients on corticosteroids, whose symptoms may be masked by these drugs. Physical examination should be focused on the abdomen, evaluating for tenderness, rigidity, distention, rebound, and the presence of a mass.

The stool should be examined for the presence of blood. Other diagnostic aids include a complete blood cell count and abdominal radiographs. Patients with significant hemorrhage, obstruction, or perforation as a result of IBD are managed in the same manner as other patients with these conditions. Aggressive fluid management, gastrointestinal decompression, blood product administration as necessary, and surgical consultation are indicated. Antibiotic coverage of gram-negative and anaerobic bacteria is appropriate in cases of suspected perforation. In patients maintained on corticosteroids, stress doses of intravenous corticosteroids (hydrocortisone 300 mg/d) are also administered to prevent symptoms of adrenal insufficiency.

Patients with toxic megacolon are given a 24- to 48-hour trial of intensive medical therapy for the disease before surgical intervention is undertaken. Such therapy includes aggressive fluid and electrolyte replacement, gastrointestinal decompression, and antibiotic coverage for bowel pathogens (enteric bacilli and anaerobes). The use of corticosteroids is somewhat controversial in cases of toxic megacolon; stress doses are typically given in patients already maintained on corticosteroids.

Patients with an acute or subacute exacerbation of their IBD may present to the ED without any evidence of an emergent complication requiring surgical intervention. A careful history should ascertain the frequency of bowel movements, associated symptoms, severity of abdominal pain, and history of hospitalizations. The physical examination should assess signs of toxicity, dehydration, and metabolic imbalance and should include a careful abdominal examination. Laboratory evaluation should include a complete blood cell count and blood chemistry profile. If there is suspicion of liver involvement, liver function studies should be ordered. Abdominal radiographs are useful to detect clinically inapparent intestinal perforation, obstruction, or toxic megacolon. An abdominal computed tomography scan may be helpful in identifying intraabdominal abscesses, mesenteric inflammation, and fistulas.⁴

For patients who do not require hospital admission, arrangements should be made for follow-up with a gastroenterologist or internist. Continuing management, which usually includes dietary adjustment, bowel rest, antibiotics, and medications such as sulfasalazine and steroids, should be planned in discussion with the consulting physician. Typical outpatient medications include oral prednisone 40 to 60 mg/d, sulfasalazine 4 to 6 g/d, and antidiarrheal agents such as loperamide (Imodium) or diphenoxylate (Lomotil).

Patients admitted to the hospital usually require intravenous fluids, corticosteroids, and sulfasalazine. The exact medication regimen is best determined by the hospital consultant but typically includes methylprednisolone 60 mg/d intravenously, sulfasalazine 4 to 6 g/d, and, in some cases, hyperalimentation. Other agents, such as metronidazole, 6-mercaptopurine, cyclosporine, and corticosteroid enemas, may also be used.^{3,6} Because of the toxicity profile associated with sulfasalazine, 5-aminosalicylic derivative agents are now available for either oral or topical use.

DISPOSITION

Fortunately, most cases of IBD can be managed in an outpatient setting. Patients who should be considered for hospital admission include those with severe manifestations (more than six bowel movements daily, severe abdominal pain, grossly bloody stool); those with systemic toxicity (fever, tachycardia, weight loss, cachexia); those with dehydration or metabolic disturbances; those with acute complications (intestinal obstruction, bowel perforation, gastrointestinal hemorrhage, toxic megacolon); and those who are refractory to outpatient therapy. Surgical consultation is indicated in those patients with complications of the disease, including intestinal obstruction or hemorrhage, perforation, abscess or fistula formation, toxic megacolon, and perianal disease.

COMMON PITFALLS

- There is commonly a delay of several months from the onset of symptoms of IBD to the time the diagnosis is established. Thus, failure to suspect IBD and refer patients appropriately is not uncommon. Patients with previous episodes of similar symptoms, with a family history of IBD, with perirectal disease, or with any extraintestinal manifestations (rashes, back pain, arthritis, iritis) that might suggest the diagnosis should be referred to an appropriate specialist for endoscopic evaluation or barium examination.
- Severe abdominal pain, fever, tachycardia, and dehydration can be primary manifestations of IBD, yet these symptoms and signs are also associated with such complications as perforation, abscess formation, and peritonitis. Thus, the physician may fail to consider and recognize these serious complications. In addition, corticosteroids can mask abnormal findings in some patients, making the diagnosis of these serious complications even more difficult and problematic.

DIARRHEA

The patient with diarrhea presents emergency physicians with a problem that is not only physical, but also social and personal. *Diarrhea* is defined as the passage of a greater number of stools of decreased form than usual. The term *gastroenteritis* should be reserved for those diarrheal diseases in which the patient also exhibits nausea and vomiting; *dysentery* refers to diarrhea containing blood and pus.

Almost 100 million cases of gastroenteritis and acute diarrheal episodes occur annually in the United States; half of these cause restriction of activity for more than a full day. Physicians are consulted in 8.2 million cases, and 250,000 people require hospitalization.⁹ In the United States, mortality is rare and occurs mainly in the elderly and in young children.¹²

The most common causes of acute diarrhea, by far, are infectious agents. Less commonly implicated causes are drugs and toxins, chemotherapy, fecal impaction (overflow diarrhea), and psychosocial stress. Among infectious causes of diarrhea, viruses account for 50% to 70% of all cases, bacteria for 15% to 20%, and parasites for 10% to 15%. When patients present to the emergency department (ED) for evaluation, the complaint is either an acute onset of diarrhea or an acute exacerbation of chronic diarrhea. Diarrhea is especially problematic in particular settings: children in daycare settings, travelers to tropical and semitropical regions, homosexual males, immunocompromised individuals, people living in unhygienic environments, and those exposed to contaminated water or food.

Although an enormous number of stimuli may produce diarrhea, the four basic pathophysiologic mechanisms are alterations in mucosal morphology, alterations in ion secretion from the intestinal villi, alterations in intestinal motility, and osmotic diarrhea. The majority of diarrheal illnesses are noninflammatory, usually arising in the upper small bowel from the action of an enterotoxin or other process that specifically alters the absorptive function of the villus tip. Dysentery usually arises in the colon from an invasive process, with or without a cytotoxin.⁴ Along with stabilizing the patient hemodynamically, the goal of the emergency physician is to determine whether the patient's diarrhea is inflammatory, which usually signifies a more severe diarrheal illness, and whether specific therapy is warranted.

CLINICAL PRESENTATION

Diarrhea is both a symptom and a sign. As a symptom, diarrhea can be described as an increase in stool frequency, an increase in stool volume, and a decrease in stool consistency. Possible associated gastrointestinal symptoms are nausea, vomiting, abdominal discomfort, abdominal cramps, bloating, tenesmus (constant urge to defecate), rectal urgency, perianal discomfort, intestinal gas-related complaints, and incontinence. As a sign, diarrhea is defined objectively as an increase in watery stool excretion to an amount greater than 200 mL every 24 hours.⁴

Depending on the etiology, the diarrhea may be liquid or soft, nonbloody or bloody, mucoid, and voluminous or scant. Physical examination may reveal fever, tachycardia, abdominal tenderness, or dehydration. When fever and bloody stool are present, the patient usually has intestinal inflammation due to invasive bacteria. From the standpoint of functional impairment from the illness, diarrhea may be categorized as mild (no change in normal activities), moderate (forced change in activities), or severe (disability with confinement to bed).⁶

When evaluating complaints of diarrhea, the physician should first distinguish whether the diarrhea is truly diarrhea or nondiarrheal rectal discharge, rectal bleeding, or abnormally colored stools. When seeking care in the ED for diarrhea, many patients do so out of concern about other issues in addition to the diarrhea. Once the diagnosis of diarrhea is confirmed, the clinician must decide whether the patient is seriously ill; what diagnostic workup is necessary; whether an etiology can be identified; whether any specific treatment is necessary; and what the health implications are for the family and the community. The severity of illness is directly correlated with the patient's volume and electrolyte status and whether the diarrhea has an inflammatory origin.

DIFFERENTIAL DIAGNOSIS

Although there are hundreds of causes of acute diarrhea, most cases presenting to the emergency physician are infectious.

Viral Diarrhea

The most common cause of diarrhea in most EDs, virus-induced diarrhea is characterized by destruction of villus mucosa. Shortened villi decrease the intestinal surface area available for fluid absorption and alter ion secretion.²⁰ Norwalk virus and rotavirus are responsible for more than 50% of viral enteric infections.¹¹

Rotavirus is responsible for more diarrheal disease–associated morbidity than any other single agent, in developed as well as developing countries. Hallmarks of viral diarrhea are the absence of high fever and the occurrence of many nonbloody stools per day. Concomitant upper gastrointestinal distress with or without nausea is common, but severe abdominal pain is not characteristic. While improved hygiene has reduced bacterial diarrheal illness in the developed world, it has had less effect in preventing spread of viral gastroenteritis, in particular, rotavirus.¹¹

Bacterial Diarrhea

Compared with viral diarrhea, bacterial enteritis causes more severe alterations of the mucosal morphology by invasion of the mucosa and submucosa of the terminal ileum and colon, resulting in inflammation. Edema, bleeding, and leukocytic infiltration of the colonic wall typically occur, which results in the appearance of red blood cells and white blood cells in the stool. Common etiologies are *Salmonella*, *Shigella*, *Escherichia coli*, *Yersinia*, and *Campylobacter*. A characteristic feature is fever, which may be quite marked, especially in the pediatric patient.⁹ Passage of many stools per day, particularly when they are bloody and explosive in character, suggests bacterial enteritis. Special care must be taken when evaluating patients with suspected dysentery to eliminate the possibility that they may have a surgical cause (such as diverticulitis, appendicitis, or ischemic colitis) for their diarrhea, abdominal pain, or toxic appearance.

Food Poisoning

Although any toxin-produced gastrointestinal syndrome can be called *food poisoning*, this term is most commonly applied to gastroenteritis syndromes in which upper gastrointestinal symptoms predominate. Food poisoning occurs when infectious agents within the gut produce enterotoxin or when the enterotoxin is ingested from contaminated food. Depending on the type of organism that produces it, the enterotoxin can cause upper or lower gastrointestinal symptoms. The distinguishing feature of these conditions is not the characteristics of the diarrhea itself, but the typical clinical picture of nausea, vomiting, diarrhea, and a history of ingestion of a suspicious food. Concurrent illness in other persons exposed to the same food strongly suggests food poisoning.

Staphylococcal food poisoning is the most common form and typically occurs when food is contaminated by *Staphylococcus aureus* and then not cooked at a temperature sufficient to kill the bacteria. It is manifested by nausea, vomiting, abdominal cramps, and diarrhea 2 to 6 hours after eating food contaminated by the heat-stable, preformed enterotoxin. *Bacillus cereus* causes two distinct food-poisoning syndromes. In one, a heat-stable toxin produces primarily vomiting and abdominal cramping 2 hours after eating contaminated rice. The diarrheal syndrome results from ingestion of meat products contaminated with an enterotoxin produced by *B. cereus*. Scombroid fish poisoning is a food poisoning that causes a histamine-like reaction after ingestion of heat-stable toxins produced by bacterial action on dark-meat fish (tuna, mackerel, and related species). Ciguatera food poisoning results from the ingestion of a neurotoxin that accumulates in fish species that frequent coral reefs (e.g., red snapper, sea bass). Affected patients develop gastroenteritis and a potpourri of neurologic symptoms, such as paresthesias, dysesthesias, weakness, and even altered mental status.

E. coli 0157:H7

E. coli 0157:H7 is a common cause of bloody and nonbloody diarrhea and is estimated to cause more than 20,000 infections each year. The organism produces a Shiga-like toxin, which causes colonic vascular damage and allows inflammatory mediators to gain access to the circulation, at times initiating the hemolytic–uremic syndrome.⁵ Transmission can be either from ingestion of contaminated beef or water or from person to person. Symptoms and signs that distinguish *E. coli 0157:H7* from other bacterial enteric diseases are the absence of fever in the presence of other symptoms and signs of inflammatory colitis, such as abdominal pain and bloody stool.

Hemolytic–uremic syndrome occurs in 6% of affected patients, usually 6 days after onset of the diarrhea, and it is the most common cause of acute renal failure in children. Clinical features of hemolytic–uremic syndrome include hemolytic anemia, thrombocytopenia, and acute renal failure. Once an isolate has been identified, the local health department should be notified so that, if the infected child attends daycare, the facility can increase its surveillance for diarrheal illness.

Protozoan Diarrhea

Giardia lamblia is neither rare nor exotic. Travel history, sexual history, pregnancy, and drinking well water are important risk factors. When evaluating patients suffering from persistent nonspecific complaints of chronic diarrhea, such as bloating and excessive flatulence, it is important to consider *G. lamblia* as the cause. Giardiasis presents similarly to a functional bowel disorder. Typically, the diarrhea is noninflammatory and does not contain blood, pus, or eosinophils.

Entamoeba histolytica predominantly affects individuals of lower socioeconomic status who live in developing countries. *E. histolytica* is an enteric protozoan that exists in either cyst or trophozoite form and causes infection after ingestion of the cysts.¹⁴ Amebiasis causes an inflammatory colitis by invasion of the colonic epithelium by trophozoites that disrupt tissue planes. This occurs in 10% of asymptomatic carriers of the cysts. Hepatic infection results from the organism ascending the portal venous system; hepatic necrosis may result from obstruction of portal vessels. The diagnosis remains dependent on the morphologic identification of cysts in the affected patient's diarrhea.¹⁴

Traveler's Diarrhea

Traveler's diarrhea is a self-limited illness that usually resolves spontaneously within a few days, but it has the potential for wrecking a meticulously planned business trip or vacation. *Traveler's diarrhea* is usually defined as the passage of at least three unformed stools in a 24-hour period, together with nausea, vomiting, abdominal pain or cramps, fecal urgency or tenesmus, or the passage of bloody or mucoid stools, in a person who lives in an industrialized region and who has traveled to a developing semitropical or tropical country.¹⁸ Among the 35 million people who travel from industrialized countries to a developing country annually, traveler's diarrhea has an incidence rate of 20% to 50% per 2-week stay. Although different organisms predominate in different regions, the principal agents in most of the high-risk areas are, in decreasing order of frequency, enterotoxigenic *E. coli*, *Rotavirus*, *Salmonella*, and *Campylobacter*.¹⁸ The most common sources of traveler's diarrhea are contaminated food and water.

Antibiotic-Associated Diarrhea

Although some antibiotics are much more strongly associated with the development of a pseudomembranous colitis, virtually every antibiotic has been implicated. An overgrowth of *Clostridium difficile*, which occurs when native bowel flora are killed by antibiotics, is responsible for elaborating the enterotoxin. The enterotoxin induces a severe colitis with a pseudomembranous appearance that is bloody and positive for fecal leukocytes. The onset of the disease can be delayed considerably, even after the antibiotic has been stopped. In recently hospitalized patients in whom infectious diarrhea develops, *C. difficile* appears to be the pathogen most often encountered.¹⁶

Diarrhea in Acquired Immunodeficiency Syndrome

Diarrhea is a common and distressing symptom in acquired immunodeficiency syndrome (AIDS) patients, occurring in over 90% of individuals at some time during the course of their illness. AIDS patients are at risk for all the infectious causes of diarrhea in the immunocompetent population and are also at risk from other pathogens as well. A significant amount of morbidity and mortality of late AIDS is associated with gastrointestinal disease.¹⁵ Enteric protozoal infections are the most common causes of diarrhea in AIDS patients, followed by cytomegalovirus and *Mycobacterium avium-intracellulare*. Microsporidia, *Isoospora belli*, and *Cryptosporidium parvum*, the most common causes of protozoal diarrheal illness in AIDS patients, cause disruption of small intestinal villus architecture and severe malabsorption, maldigestion, and diarrhea.¹⁵ Cytomegalovirus-induced colitis produces diarrhea that can be persistent or intermittent, lower abdominal pain, fever, and weight loss.¹⁷ *M. avium-intracellulare* infects the small intestine and is characterized by diarrhea, abdominal pain, fever, nausea, weight loss, and malabsorption. The frequency of unexplained diarrhea in AIDS patients remains approximately 20%, even after extensive evaluations are performed. Many factors have been implicated in this idiopathic diarrhea, among them an alteration in intestinal villus architecture, undetectable infections, and human immunodeficiency virus (HIV)–induced cellular infection.¹⁷

Inflammatory Bowel Disease

Inflammatory bowel disease must be considered as an explanation for complaints of disordered bowel function in the patient with known disease, but first

presentations of Crohn disease and ulcerative colitis are rare causes of acute diarrhea in the ED. Typically, patients presenting with inflammatory bowel disease give a history of weight loss during the preceding weeks or months. Other clinical and laboratory expressions of an ongoing inflammatory process can often be found, such as fever, elevated erythrocyte sedimentation rate, and anemia. If no infectious process is identified for persistently bloody stool, endoscopy and contrast studies should be considered to determine whether inflammatory bowel disease is present.

EMERGENCY DEPARTMENT EVALUATION

Most cases of diarrhea are managed, without the need for medical attention, by the affected patient or by a family member. Medical evaluation should occur for a subset of patients with more severe illness. Assessment of the severity of illness, presence of dehydration, character of stool patterns, and presence of fever, vomiting, or dysentery help to focus the evaluation to determine the likely cause of the illness. A detailed history, including travel, sexual practices, or immunocompromised status, is crucial, because it often points to the etiology. On physical examination, special attention is given to abdominal examination, which is most notable for generalized tenderness and increased bowel sounds but no peritoneal signs. Specific indications for further medical evaluation of patients with diarrhea are dehydration, dysentery, significant abdominal pain, suspicion of a concurrent systemic illness, and disease in the very young, the elderly, and the immunocompromised.

Fecal leukocytes are found in some patients with diarrhea and are caused either by organisms or by any factor that provokes inflammation and ulceration of the intestinal wall. Normal feces should have few or no white blood cells. The fecal sample can be examined as a wet preparation under the high-dry lens or as a Wright stain or Gram stain under the oil lens. Some authorities consider hemocult-positive diarrhea in patients with acute enteric illness to be clinically equivalent to numerous fecal leukocytes.²² The most commonly identified bacterial pathogens in patients with fecal leukocytes include *Shigella*, *Salmonella*, *Campylobacter*, *Aeromonas*, *Yersinia*, *Vibrio parahaemolyticus*, and *C. difficile*. Fecal leukocytes can also be seen in other conditions, such as appendicitis and inflammatory bowel disease. This finding is important because it identifies an inflammatory process that merits treatment and follow-up. [Table 163.1](#) lists the infectious agents that produce fecal leukocytes.

Bacterial Agent	Stool Appearance	Systemic Illness	Rectal Bleeding	Colitis	Other Notes
<i>Shigella</i>	Discolored, bloody	Yes	Yes	Yes	Shigellosis
<i>Salmonella</i>	Discolored	Yes	Yes	Yes	Salmonellosis
<i>Campylobacter</i>	Discolored	Yes	Yes	Yes	Campylobacteriosis
<i>Aeromonas</i>	Discolored	Yes	Yes	Yes	Aeromonas infection
<i>Yersinia</i>	Discolored	Yes	Yes	Yes	Yersinia infection
<i>Vibrio parahaemolyticus</i>	Discolored	Yes	Yes	Yes	Vibriosis
<i>C. difficile</i>	Discolored, watery	Yes	Yes	Yes	Pseudomembranous colitis
<i>Escherichia coli</i>	Discolored	Yes	Yes	Yes	E. coli infection
<i>Staphylococcus aureus</i>	Discolored	Yes	Yes	Yes	Staphylococcal enterocolitis
<i>Streptococcus</i>	Discolored	Yes	Yes	Yes	Streptococcal enterocolitis
<i>Clostridium perfringens</i>	Discolored	Yes	Yes	Yes	Clostridial enterocolitis
<i>Clostridium botulinum</i>	Discolored	Yes	Yes	Yes	Botulism
<i>Clostridium parvum</i>	Discolored	Yes	Yes	Yes	Clostridial enterocolitis
<i>Shigella</i>	Discolored, bloody	Yes	Yes	Yes	Shigellosis
<i>Salmonella</i>	Discolored	Yes	Yes	Yes	Salmonellosis
<i>Campylobacter</i>	Discolored	Yes	Yes	Yes	Campylobacteriosis
<i>Aeromonas</i>	Discolored	Yes	Yes	Yes	Aeromonas infection
<i>Yersinia</i>	Discolored	Yes	Yes	Yes	Yersinia infection
<i>Vibrio parahaemolyticus</i>	Discolored	Yes	Yes	Yes	Vibriosis
<i>C. difficile</i>	Discolored, watery	Yes	Yes	Yes	Pseudomembranous colitis
<i>Escherichia coli</i>	Discolored	Yes	Yes	Yes	E. coli infection
<i>Staphylococcus aureus</i>	Discolored	Yes	Yes	Yes	Staphylococcal enterocolitis
<i>Streptococcus</i>	Discolored	Yes	Yes	Yes	Streptococcal enterocolitis
<i>Clostridium perfringens</i>	Discolored	Yes	Yes	Yes	Clostridial enterocolitis
<i>Clostridium botulinum</i>	Discolored	Yes	Yes	Yes	Botulism
<i>Clostridium parvum</i>	Discolored	Yes	Yes	Yes	Clostridial enterocolitis

TABLE 163.1. Infectious Agents that Produce Fecal Leukocytes

Relatively well-appearing patients presenting with signs and symptoms of bacterial enteritis can be treated empirically with antibiotics, and stool cultures need not be sent. In the patient with symptoms of hypovolemia, red or white cells in the stool, or an abnormal abdominal examination, selected investigation may be warranted. [Table 163.2](#) lists specific indications for sending diarrhea for culture and sensitivity. Clinicians should be wary of resistant infections because of the recent emergence of multidrug-resistant bacterial diarrheal illnesses.²¹ If the patient has been on antibiotics before the onset of diarrhea, *C. difficile* must be considered and stool should be sent for *C. difficile* toxin assay. The emergency physician should rarely send stool for ova and parasites. However, illnesses lasting longer than 14 days should prompt an examination for parasites, particularly in immunocompromised patients and in travelers who have returned from areas where untreated water is consumed. In immunocompromised patients, endoscopy and biopsy are indicated when the illness persists, routine stool cultures are unrevealing, and a course of empiric antibiotics has not led to resolution.¹⁴

Immunocompromised individuals
Travel history to 3 rd world
Homosexual activity
Failure to respond to empiric antibiotic therapy
Individuals with close contact to others where fecal-oral spread can occur (daycare workers, healthcare workers, food handlers)
"Toxic" appearance
Persistent diarrhea
Suspicion of antibiotic-resistant bacteria

TABLE 163.2. Indications for Stool Culture in Patients with Acute Diarrhea

EMERGENCY DEPARTMENT MANAGEMENT

The assessment and treatment of dehydration and the relief of symptoms remain the cornerstones of ED care.

Fluid and Electrolyte Resuscitation

The most important intervention is fluid and electrolyte repletion. For mildly dehydrated individuals, resuscitation with oral fluids having sodium concentrations in the range of 45 to 75 mEq/L is recommended (Pedialyte or Rehydralyte solutions).⁶ For moderately dehydrated individuals, the ideal formulation of oral fluids is Na 60 to 90 mEq/L, K 20 mEq/L, Cl 80 mEq/L, citrate 30 mEq/L, and glucose 20 g/L; the World Health Organization's oral rehydration therapy contains these substances. Sports drinks, diluted fruit juices, and flavored soft drinks augmented with saltine crackers, broths, and soups can meet fluid and salt needs in nearly all nondehydrated, otherwise healthy persons with acute diarrhea. A homemade version of oral rehydration solution is made by preparing two separate glasses that are consumed alternately. The first contains 8 oz of orange juice or other potassium-containing fruit juices, one-half teaspoon of honey, and 1 pinch of table salt; the second glass contains 8 oz of clear water plus one-fourth teaspoon of baking soda.⁶

Dietary Advice

During a bout of acute diarrhea, calories facilitate enterocyte renewal. Boiled starches (potatoes), cereals (rice, noodles) with salt, saltines, bananas, yogurt, broths, steamed vegetables, and fruits are ideal foods during episodes of diarrhea. Although clinical lactose intolerance is uncommon in cases of acute diarrhea, many authorities recommend avoidance of dairy products in the first few days of illness.

Antimotility Agents

Codeine, diphenoxylate with atropine (Lomotil), and loperamide (Imodium) reduce urgency, frequency of bowel movements, and stool volume in diarrheal illness. They work by slowing the intraluminal flow of liquid, facilitating intestinal absorption. Loperamide is generally the recommended agent when antimotility agents are

prescribed, due to its safety and efficacy; stool quantity has been reported to be reduced by approximately 80%.⁸ Loperamide is the recommended treatment for AIDS patients in the absence of inflammatory disease of the colon and when diarrhea persists in the face of empiric antimicrobial and antiparasitic therapy. Antimotility agents may be used in patients with infectious enteritis of mild-to-moderate severity, but their use may be hazardous in the setting of severe dysentery. These agents should be used with caution in children and should not be used in infants.

Bismuth Subsalicylate and Attapulgate

Bismuth subsalicylate is effective therapy for acute diarrhea, either bacterial or viral, reducing the number of stools passed by approximately 50%.⁷ The antidiarrheal effect is mediated by an antisecretory salicylate effect rather than by adsorption of toxin. It is also effective in relieving the vomiting associated with enteric viral infections. Additionally, it has antibacterial properties, which may explain its value in the prevention of traveler's diarrhea. The dose is 30 to 60 mL every 30 minutes for eight doses. An important caveat is to warn patients that this medication will turn their feces black. Attapulgate (Kaopectate), a claylike material, may make stools more formed by absorbing intracolonic water. It is very safe.

Antibiotics in Acute Diarrhea

Patients with signs and symptoms of acute dysentery and patients with traveler's diarrhea should be treated empirically with antibiotic therapy. A majority of patients with numerous fecal leukocytes respond favorably to antimicrobial therapy and can therefore be treated empirically. [Table 163.1](#) lists the antimicrobial therapy of choice for different pathogens. Patients with traveler's diarrhea are characteristically infected with bacterial pathogens, and their illness is shortened by antimicrobial therapy. Generally, a quinolone antibiotic is recommended as empiric therapy for 3 to 5 days, unless diarrheal culture results are available to tailor therapy.

After appropriate evaluation, AIDS patients with acute diarrhea can be started on empiric therapy with quinolone antibiotics for 10 days. As in infections outside the gut in immunocompromised patients, curative treatment requires prolonged therapy.

Patients with diarrhea lasting 2 to 4 weeks without systemic symptoms or dysentery may be treated empirically for *Giardia* with metronidazole, which is also effective against the small bowel bacterial overgrowth associated with persistent diarrhea. Metronidazole is also an effective agent of choice for *C. difficile* colitis and intestinal amebiasis.⁶

Special Advice to Travelers

Educating travelers about the prevention and treatment of diarrhea is important, because it is estimated that 25% to 40% of travelers in the developing world develop diarrhea.¹⁸ Travelers committed to preventing diarrhea should be advised to follow the old British colonial axiom, "Cook it, boil it, peel it—or forget it." Instructions should include methods of diarrhea prevention, use of prophylactic agents, and methods of replenishing fluid and electrolytes. Bismuth subsalicylate, quinolone antibiotics, and vibramycin are effective prophylactically and as self-administered treatment of traveler's diarrhea.

DISPOSITION

The emergency physician can manage almost all cases of diarrhea presenting to the ED. Patients with diarrhea who are significantly dehydrated and who remain unable to tolerate oral fluids should be considered for admission. Situations in which there is a possible pathologic process, such as inflammatory bowel disease or ischemic bowel, require medical or surgical consultation. Moderately ill patients who are sent home, patients with traveler's diarrhea, and AIDS patients should have follow-up arranged with their primary care providers.

COMMON PITFALLS

- Overdiagnosing viral gastroenteritis. There is a temptation to label all diarrheal illnesses of uncertain cause as viral. Particularly in older patients, the diagnosis of viral gastroenteritis is statistically less likely, and many serious causes of diarrhea are more likely. If there are white blood cells or red blood cells in the stool or if the abdominal examination is abnormal, diarrhea should not be attributed to a viral cause.
- Failing to examine the stool. There are few truly useful tests in emergency medicine; examination of the stool is one of them.
- Failing to watch for antibiotic-resistant bacterial enteric infections. The incidence of multidrug-resistant infections is on the rise.
- Many surgical problems, including small bowel obstruction, inflammatory bowel disease, mesenteric infarction, and cancer, can present with diarrhea. The emergency physician must be vigilant to distinguish between these diseases and infectious diarrhea.

PROCTITIS

Proctitis is formally defined as inflammation of the rectal mucosa. Alternatively, it can be defined as anorectal symptoms associated with sigmoidoscopic findings limited to the distal 15 cm of the rectum. Proctitis should be distinguished from *proctocolitis*, which has different infectious etiologies. *Acute proctitis* is a nonspecific term that refers to several specific disease conditions that include inflammatory bowel disease, infections, venereal disease, antibiotics, radiation, and chemotherapy.¹

The epidemiology of proctitis in ED patients varies with demographics. In urban areas with large populations of homosexual males, high rates of sexually transmitted infectious proctitis are seen; in facilities treating more elderly populations, proctitis is more frequently the sequela of other gastrointestinal disorders, exemplified by radiation proctitis or ulcerative proctitis.

CLINICAL PRESENTATION

Most patients have similar nonspecific symptoms of rectal discomfort, tenesmus (urge to defecate), and hematochezia. Other symptoms are pain with defecation, disordered bowel function (typically constipation), lower abdominal pain and pelvic pain, mucopurulent rectal discharge, and feelings of incomplete evacuation. Infectious and inflammatory conditions that involve the anal mucosa are typically very painful. Rectal mucosal erythema, friability, and a mucopurulent discharge are noted on physical examination. Patients with proctitis attempt frequent fecal evacuation that typically produces bloody mucus and little fecal matter.¹⁹ Symptoms of fever, weight loss, abdominal pain, nausea, and vomiting indicate that proctitis may be manifestation of a more generalized process.

DIFFERENTIAL DIAGNOSIS

Before diagnosing symptoms of rectal pain and discharge as proctitis, the clinician must first exclude other entities that can cause these symptoms, such as perirectal abscess, rectal polyps, and anal fissures. The causes of proctitis are divided into infectious causes, most typically venereal diseases, and noninfectious causes.

Infectious Proctitis

Both homosexual and heterosexual anal intercourse have the potential for transmitting enteric pathogens and venereal infections, especially when people have multiple sexual partners and fail to use condoms. The most common infectious cause, and by far the most common cause in sexually active homosexual men, is gonorrhea.¹³ In symptomatic gonococcal proctitis, the usual presenting complaint is rectal discharge, often noted as staining of the underwear. Additionally, scant bloody discharge and rectal pain may be noted spontaneously or with rectal intercourse. Gonococcal infection of the rectum occurs commonly in conjunction with gonococcal urethritis. Gonococcal infection of the female rectum is most commonly the result of anal intercourse, but may be caused by the spread of the organisms through vaginal secretions. Perhaps 10% to 20% of all patients with genital gonorrhea have positive rectal cultures for the organism.

Along with gonorrhea, chlamydia should be considered in patients with proctitis that appears to be sexually transmitted.¹³ Infections with lymphogranuloma venereum (LGV) types are more severe but much less frequent than those due to the other strains of chlamydia. Although some patients are asymptomatic, anorectal pain, tenesmus, left lower quadrant abdominal tenderness, constipation, and a bloody mucopurulent discharge can be noted. Chlamydial proctitis may have a subacute or even chronic presentation, with regional adenopathy and fibrosis and stricture of the rectum. Granulomatous rectal changes with LGV chlamydial strains resemble

Crohn disease, especially when perirectal abscesses and fistulas are present. ¹³

Proctitis due to herpes simplex virus (HSV) infection, either type 1 or 2, is a common cause of proctitis; however, HSV-2 infections are more severe and recur more frequently. The predominant complaints are severe anorectal pain, discharge, and change in bowel habits (constipation being more frequent than diarrhea). Systemic symptoms are fever, chills, and malaise. Vesicles, in clusters surrounded by an erythematous base, hemorrhage, vascular congestion, and pus may extend as high as 15 cm up the rectal mucosa. With severe HSV proctitis, urinary dysfunction, impotence, neuralgia, and paresthesias in the buttocks and thighs may occur secondary to viral infection of the sacral plexus. Persistent herpes proctitis is seen almost exclusively in AIDS patients.

Noninfectious Proctitis

Patients who have signs and symptoms of rectal disease and histories of anal erotic activity may manifest primarily noninfectious consequences of their sexual behavior. Foreign objects inserted into the anus may cause mucosal damage and allow penetration by normal colonic organisms, with secondary inflammation. Anal and lower rectal mucosal inflammation due to the trauma of sexual activity may be extremely difficult to differentiate from inflammatory changes secondary to infectious agents.

Allergic proctitis occurs when substances used as lubricants during anal intercourse sensitize through abraded anal skin or intact mucosa. When used as lubricants, soaps, shampoos, cooking oil, suntan preparations, or medicinal creams may be directly irritating and can reduce the protective effectiveness of condoms. Even lubricating jelly has been associated with allergic contact sensitivity due to the propylene glycol vehicle.

Ulcerative colitis is a chronic inflammatory bowel disorder of unknown origin that is characterized by inflammation of the bowel. The proximal extent of the colonic mucosal inflammation varies among individuals, but the rectum is almost always involved. With predominantly rectal involvement, constipation and tenesmus are typical complaints. Patients with ulcerative proctitis usually have milder manifestations of inflammatory bowel disease and typically do not have the systemic manifestations of the disease.

Radiation proctitis is caused by pelvic irradiation for gynecologic or prostate malignancies. Symptoms of anorectal pain and bloody discharge can be severe. Proctoscopic findings are erythematous and edematous mucosa in the acute phase and characteristic telangiectasias and ulcerations in the chronic phase. Large ulcerations can result in distal rectal strictures or rectovaginal fistulas. ²

EMERGENCY DEPARTMENT EVALUATION

An accurate diagnosis can be made by use of a careful history, anoscopy, culture, rectal biopsy, and stool analysis. ¹ A sexual history is important in the evaluation of anorectal complaints. The patient may not volunteer a sexual history because of embarrassment or fear of a hostile response from health-care personnel. Patients with a history of receptive anal sex are at risk for a variety of sexually transmitted infections, including HIV infection. ³ Also important to obtain is a history of previous treatment for sexually transmitted disease, because it may have been ineffective in eradicating unrecognized rectal infection. Anoscopy with appropriate cultures identifies most sexually transmissible intestinal infections and should be carried out in all those who practice receptive anal intercourse who present with symptoms suggestive of proctitis.

Although specimens can be obtained with a pledget blindly inserted 2 cm into the canal and rotated, swabbing under direct anosopic visualization raises the positive yield on Gram stains from 34% to 79%.³ Cultures for sexually transmitted disease should be obtained not only from the rectum, but also from the urethra and the cervix. Immunofluorescence stains and viral cultures for HSV should be carried out, even when no lesions are grossly visible. Whenever patients have proctitis secondary to sexually transmitted disease, they should also be tested for concomitant infections such as syphilis and AIDS.

EMERGENCY DEPARTMENT MANAGEMENT

The ED management of infectious proctitis is analogous to that of urethritis. When sexually transmitted disease is suspected based on patient history, empiric therapy for gonorrhea and chlamydia is recommended, because they commonly cause infectious proctitis and antibiotic therapy does not compromise subsequent evaluation. Third-generation cephalosporins and quinolones are the preferred treatment for gonococcal infections. Doxycycline or macrolide antibiotics should be prescribed to treat chlamydial infections. Occasionally, rectal LGV requires several courses of antibiotic therapy.

Systemic therapy of herpetic proctitis with acyclovir is indicated when the diagnosis is suspected. Oral acyclovir effectively reduces the duration of symptomatic lesions, rectal pain, discharge, and the period of viral shedding. In immunocompetent hosts, the dosage is 400 mg five times daily for 10 days. AIDS patients require intravenous acyclovir for longer courses of therapy. ³ Patients with symptoms or signs of severe herpes proctitis, such as severe pain or urinary retention, should be admitted for aggressive pain control and intravenous acyclovir.

Even when a new presentation of proctitis does not appear to be due to infection, it is wise to treat empirically for common infectious etiologies. Pseudoinfectious and allergic proctitis are best treated by removal of the agents causing the disease. Ulcerative proctitis is responsive to oral, parenteral, and rectal administration of corticosteroids. Treatment should also be aimed at treating the perianal discomfort, which can be severe. Sitz baths for 20 minutes three to four times daily are helpful.

DISPOSITION

Most patients with proctitis can be managed in the ED without consultation or admission. Consultation is advisable when there is a problem with the diagnosis of an unusual mucosal appearance, a question of perirectal infection, systemic symptoms or local signs suggesting malignancy, or a suspicion of inflammatory bowel disease. If outpatient therapy is elected, these patients require close follow-up. Worsening of symptoms or failure to improve on antibiotic therapy and Sitz baths within 48 hours necessitates admission and further endoscopic evaluation. All patients should be referred to an appropriate physician for follow-up endoscopy and evaluation of culture results.

COMMON PITFALLS

- Failure to elicit a sexual history
- Failure to question a sexual history once elicited; many patients do not at first admit to rectal intercourse.
- Failure to visualize the mucosa by anoscopy and to examine and culture any exudate
- Failure to consider sexually transmitted disease, which can occur in men, women, and children
- Failure to arrange for proper identification and treatment of contacts
- Failure to consider or identify other rectal lesions that mimic proctitis, such as anal fissure, anal fistula, and perirectal abscess

CHAPTER 164

Lower Gastrointestinal Bleeding

Daniel T. Schelble and David J. Peter

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The chief complaint of “rectal bleeding” includes symptoms ranging in severity from minor anorectal bleeding, to severe bleeding that has stopped, to massive persistent hemorrhage with shock. The evaluation, management, and disposition of each case are determined by the severity of the patient's symptoms. The bleeding stops spontaneously in about 80% of cases, with recurrent bleeding in about 25%.^{3,10,16} In one database report of patients undergoing colonoscopy for lower gastrointestinal bleeding, 66% were hospitalized, 35% required transfusion, and 15% required surgery.¹⁵

Lower gastrointestinal bleeding has a hospitalization incidence of 20 to 25 episodes per 100,000 population per year and a mortality of 4% to 10%.^{10,11,14} The incidence increases 200-fold from the third to ninth decade of life, and most episodes occur in the elderly.^{1,10} As a group, the elderly have decreased cardiovascular reserve in the face of hemorrhage, often have comorbid disease, and have decreased tolerance for major surgery.^{2,14} Lower gastrointestinal bleeding is a common problem in the emergency department that will increase in incidence with the aging of our population.

CLINICAL PRESENTATION

By definition, lower gastrointestinal bleeding occurs *distal* to the ligament of Treitz, including the small intestine, large intestine, rectum, and anus. It is generally intermittent and encompasses an extensive range of etiologies, severity of bleeding, and clinical significance. Large bleeds with rapid intestinal transport present with the bright red or maroon stools of hematochezia. With slower intestinal transport or less bleeding volume, the stools are darker or black and tarry (melena). Hematochezia is the chief complaint in up to 90% of patients with lower gastrointestinal bleeding. It is about six times more likely to be due to lower gastrointestinal bleeding than to upper gastrointestinal bleeding, while melena is about four times more likely to be due to an upper gastrointestinal source.¹⁵ Minor anorectal bleeding commonly presents with traces of blood on the stool, undergarments, or toilet tissue, or within the toilet bowl. Occult bleeding is that detected by screening or coincidental guaiac stool testing or during the evaluation of iron-deficiency anemia, without other apparent etiology.

The severity of the clinical presentation is directly related to the volume and rate of blood loss. Rapid and severe losses present with rectal bleeding and cardiovascular decompensation, which may be manifested by near-syncope, syncope, myocardial infarction, stroke, or shock (pallor, tachypnea, tachycardia, hypotension, confusion). Slower, prolonged losses may present with the symptoms of anemia (fatigue, weakness, dyspnea, heart failure) or asymptomatic melena.

The loss of as little as 60 mL of blood can produce a black or melanotic stool. Rectal bleeding with symptoms of hypovolemia (weakness, orthostatic dizziness, near-syncope) is associated with the relatively rapid loss of at least 1000 mL of blood and usually causes the patient to seek medical attention immediately. The sudden loss of 2000 mL of blood (40% of circulating volume) can be fatal, and about 10% of unattended adults who sustain such a loss will die. In a series of patients with lower gastrointestinal bleeding evaluated by colonoscopy, 19% presented with positive orthostatic changes or shock, and 35% required transfusion.¹⁵

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of lower gastrointestinal bleeding is broad ([Table 164.1](#)).

Diverticulosis
Angiodysplasia
Neoplasm, including polyps
Inflammatory bowel disease
Upper gastrointestinal bleeding
Anorectal disorders
Infectious
Postpolypectomy and iatrogenic
Less common sources (trauma, colonic varices in portal hypertension, mesenteric ischemia, aortoenteric fistula, endometriosis, radiation enteritis, coagulopathy)

TABLE 164.1. Sources of Lower Gastrointestinal Bleeding in Adults

Diverticulosis has historically been described as the most common cause of severe lower gastrointestinal bleeding in adults,^{2,18} but angiodysplasia has been identified as nearly as frequent or more frequent cause as diagnostic capabilities have improved.^{3,6} Diverticulosis should be considered in all patients older than age 40, and the prevalence increases in each succeeding decade of life. More than 50% of patients have diverticula by age 60.^{2,3}

Diverticular bleeding is often arterial, sudden, and severe, and is usually dark red or maroon; pain is usually absent or mild.³ Bleeding tends to occur in right colon diverticula, and accompanying symptoms of diverticulitis are uncommon. Bleeding stops spontaneously in 99% of patients who require transfusion of less than 4 U of blood, while most patients requiring 4 or more units usually continue to bleed.¹² The chance of recurrent diverticular hemorrhage is in the range of 20% to 40%, and surgery is required in up to 25% of cases.^{2,12,18}

Angiodysplasia (vascular ectasia) produces degenerative vascular abnormalities, primarily of the colon. Like diverticulosis, angiodysplasia can cause painless major hemorrhage with red or maroon stools, depending on location and volume of the bleeding. Bleeding due to angiodysplasia tends to be venous and more commonly recurrent than that due to diverticulosis. The prevalence increases with age, and up to 25% of all elderly patients are found to have angiodysplasia during colonoscopy. Rebleeding occurs in up to 85%. Therapeutic interventions such as colonoscopic coagulation, angiographic therapy, or surgery may be required.⁶

Neoplasms, whether benign or malignant, usually present with occult or mild chronic bleeding. Some authors state that neoplasms and polyps rarely or only occasionally cause severe lower gastrointestinal bleeding,^{3,6} while others report an incidence ranging from 6% to 33% in severe gastrointestinal bleeding.^{1,11,18} A change in stool or bowel habits, weight loss, obstructive symptoms, or detection of a mass on abdominal or digital rectal examination should alert one to the possibility of malignancy. Adenocarcinoma is a common cause of minor, intermittent bleeding.

Inflammatory bowel disease, including Crohn disease and ulcerative colitis, is usually associated with minor bleeding and diarrhea. Younger adults are most commonly affected. There is often a history of previous episodes, and the diagnosis is usually known by the patient. The incidence of massive bleeding is usually reported in the range of 3% to 9%.^{1,18} Rebleeding occurs in up to 35%. Urgent surgery is often recommended after life-threatening hemorrhage.

Upper gastrointestinal bleeding accounts for hematochezia in 10% to 15% of cases and must be included in the differential for apparent lower gastrointestinal

bleeding.¹⁵ It is usually accompanied by a history of peptic ulcer disease, gastritis, varices, epigastric pain, hematemesis or coffee-ground emesis, non-steroidal antiinflammatory drug use, or liver disease. It is important to place a nasogastric tube in all patients with suspected lower gastrointestinal bleeding and also to recognize that a negative nasogastric aspirate does not completely rule out an upper gastrointestinal source. Ten percent to 16% of patients with upper gastrointestinal bleeding will have a negative nasogastric aspirate.¹⁷ It should also be noted that *small intestinal bleeding* may account for 3% to 5% of lower gastrointestinal bleeding cases.¹⁸

Anorectal disorders (hemorrhoids, fissures, fistula, proctitis, prolapse, impaction) usually cause minor bleeding and accounted for about 28% of rectal bleeding patients seen in one general practice study.⁴ Up to 11% of patients, however, may have an anorectal source, accounting for "significant" bleeding. Hemorrhoids are the most common cause of rectal bleeding, especially in patients under the age of 50.⁸ Hemorrhoids may present with pain and swelling consistent with thrombosis or with painless minor bleeding. Fissures usually result from the passage of hard stool and are usually painful, again with only minor bleeding. Radiation proctitis, infectious proctitis, fecal impaction, and rectal prolapse are associated with mucosal bleeding and are usually minor. Nevertheless, the presence of anorectal disease does not rule out the possibility of a more significant proximal source.

Infectious diarrhea usually causes minor bleeding in the face of predominant diarrhea and other gastroenteritis-related symptoms (nausea, abdominal pain and cramping, fever). Bacterial dysentery is a common cause of bloody diarrhea and pain in some settings.

Other less common causes of gastrointestinal bleeding include trauma, colonic varices in portal hypertension, mesenteric ischemia, aortoenteric fistula, endometriosis, radiation enteritis, and coagulopathy.¹ Overall, these entities account for a small percentage of cases.

Postpolypectomy bleeding occurs in 0.1% to 0.4% of patients following endoscopic polypectomy.¹ This bleeding usually presents in the first 2 weeks following the procedure and can be significant.

No definite etiology is identified in about 10% of cases of acute lower gastrointestinal bleeding, despite current diagnostic techniques.³

EMERGENCY DEPARTMENT EVALUATION

The initial priority in the evaluation of lower gastrointestinal bleeding is to identify hypovolemia and institute treatment, if necessary. A finding of hypotension or tachycardia should alert the emergency physician to the significance of the hemorrhage in terms of blood loss and continued rate of bleeding. Frequent reevaluation, especially of vital signs, including orthostatics, is imperative.

Orthostatic testing has been variably defined in the literature. A decrease in systolic blood pressure of 10 mmHg or an increase in heart rate of 20, two minutes after postural change to standing, has been used in upper gastrointestinal bleeding studies and is associated with an increase in mortality from 8.7% to 13.6%.¹⁴ Positive orthostatic testing occurred in 30% of patients with "significant" lower gastrointestinal bleeding in one study.¹⁶ Although orthostatic testing is recommended for all patients with lower gastrointestinal bleeding who can tolerate standing for 2 minutes without experiencing syncope, significant bleeding can occur in spite of normal vital signs and negative orthostatic testing.

If these are signs of hypovolemia or shock, intravenous fluid resuscitation with a minimum of two large-bore catheters must be immediately initiated. The patient should be placed on a monitor, given oxygen, and moved into an area of the department where close monitoring is available. Immediate and ongoing resuscitation, with crystalloid fluids and blood products as indicated, is the most important emergency department intervention in these unstable patients.

Specimens should be drawn for baseline laboratory studies, including a complete blood count, coagulation profile, liver function tests, chemistry profile, and a type and screen (if stable) or type and crossmatch (if unstable) for 4 to 6 U of packed red blood cells. An electrocardiogram is recommended for all elderly patients, patients with severe anemia, and those with cardiopulmonary complaints.

Abdominal x-rays are not indicated. An upright chest radiograph or supine chest and lateral decubitus radiographs are helpful in assessing pulmonary status and ruling out free air. Laboratory testing is used to define the severity and ongoing activity of bleeding, as well as underlying comorbidities and cardiovascular reserve.

Serial hemoglobin determinations often confirm the accuracy of the initial clinical assessment and also give an indication of the severity and activity of bleeding. Although the initial hematocrit may be normal, a decrease after volume replacement suggests significant initial blood loss or continued significant bleeding. An elevated blood urea nitrogen-to-creatinine ratio suggests volume depletion and possibly a greater likelihood of upper gastrointestinal bleeding.¹⁴ Urine output, as measured by a Foley catheter, is a quick and useful indicator of the effectiveness of fluid replacement and may serve as an indirect indicator of the adequacy of fluid replacement. Saline or tapwater enemas have never been proven effective at diminishing or stopping lower gastrointestinal bleeding.

After the institution of resuscitative measures, the history should be obtained, with an emphasis on establishing the duration and intensity of bleeding, the nature and color of the stools, and the character of any pain. Patients often present with problems other than gastrointestinal bleeding (fatigue, dizziness, confusion, shortness of breath, chest pain, shock, cardiopulmonary arrest), and gastrointestinal bleeding should be considered in the differential diagnosis of these entities. A history of previous bleeding, gastrointestinal disorders (e.g., cirrhosis, peptic ulcer disease, inflammatory bowel disease), retching, tenesmus, weight loss, near-syncope or syncope, chest pain, shortness of breath, altered mental status, alcohol use, and medications may be helpful. Syncope has been noted in 10% of patients with significant lower gastrointestinal bleeding. Any medical history of unstable or potentially unstable comorbid disease should be elicited.⁷

Physical examination may reveal jaundice, abdominal wall varices ("caput medusae"), abdominal distention, or a palpable mass. Abdominal rigidity, guarding, rebound, or the absence of bowel sounds suggests peritonitis or perforation. Again, the examination should specifically try to identify unstable comorbid disease, such as congestive heart failure, angina, and stroke.

A digital rectal examination should be performed to detect masses or other rectal pathology and to obtain a stool specimen for direct observation and testing for occult blood (Hemoccult or Hematest). Aside from gastrointestinal bleeding, black stools can be caused by iron, charcoal, bismuth, food dyes, beets, Jello, Kool-Aid, and some antibiotic syrups. Testing for occult blood by either Hemoccult or Hematest method detects hemoglobin in stool. False-positive results can be produced by red meat, raw fruits and vegetables, some iron preparations, iodide, and bromide preparations. False-negative results can occur as a result of small hemorrhages in which the hemoglobin has lost its peroxidase activity in transit. Peroxidase activity loss is enhanced by magnesium-containing antacids and ascorbic acid.

A nasogastric tube should be placed in all patients with suspected significant lower gastrointestinal bleeding in which the rectal examination did not reveal an obvious source. The aspirate should be examined for red blood, "coffee-ground" material consistent with partially digested blood, and bile to help evaluate for an upper gastrointestinal source. As previously stated, a clear aspirate does not completely rule out upper gastrointestinal bleeding. Testing for occult blood in the gastric aspirate is unnecessary and often false-positive, due to blood from nasopharyngeal trauma during insertion. In any case, the gross appearance of the gastric aspirate provides the clinician with the needed information.

If active bleeding originates from the anorectum or lower sigmoid colon up to 25 cm from the anus, anoscopy and rigid proctosigmoidoscopy usually reveal the source. It is also helpful to document blood coming from proximal to the limits of the scope. Blood above the scope does not necessarily mean the source is more proximal, as blood may have refluxed back up the colon. A barium enema should not be used in the evaluation of lower gastrointestinal bleeding, because it may prevent the later use of colonoscopy or angiography.

EMERGENCY DEPARTMENT MANAGEMENT

Further management in the emergency department setting usually involves consultation with a variety of specialists while stabilization procedures and serial examinations are continued.

Colonoscopy has become the procedure of choice in acute lower gastrointestinal bleeding that has stopped. Its use in the setting of active bleeding is controversial. It offers the advantages of both diagnosis and endoscopic therapy. Urgent colonoscopy identifies the bleeding site in about 75% to 94% of cases,^{1,16} and endoscopic therapy is successful in up to 80% or 90% of cases.¹ Shock is the only absolute contraindication. If bleeding is massive and ongoing, colonoscopy is not possible; the

patient requires angiography.

Angiography is used for continuous, severe, or massive lower gastrointestinal bleeding, or when other modalities have failed to reveal a source. Diagnostic yields are in the range of 40% to 85%.^{3,9,18} Continuous bleeding rates as low as 0.5 mL/min can be detected.¹³ Therapeutic intervention with vasopressin infusion or arterial embolization with autologous clots, metal coils, or absorbable gelatin can be provided as well. Complications of angiography include hematomas, arterial embolization and dissection, renal failure, contrast reactions, and bowel ischemia and infarction. The complication rate is about 2% to 9%.

Radionuclide scanning with technetium-99m-labeled red blood cells or technetium-99m sulfur colloid is the least invasive but most controversial of the modalities available for the evaluation of lower gastrointestinal bleeding. The technique provides rough localization, distinguishing the right from left colonic bleeding sites, or proximal from more distal sources. Slow bleeding (rates as low as 0.1 mL/min) and intermittent bleeding can both be detected. Reported false-positive rates range from 0% to 48%, and prospective localization of the bleeding site for angiography or surgery is reported to be correct in 39% to 95% of cases.^{5,14} Radionuclide scanning may be used for screening before angiography, but its use is controversial. It is especially valuable for patients who cannot tolerate angiography or other procedures because of underlying medical problems. However, bleeding scans should not delay therapy in patients with massive bleeding.

Surgical consultation should be considered when there has been massive initial bleeding, when bleeding continues, when the source of bleeding has been detected and is amenable to surgery, or when perforation is identified or strongly suspected.

DISPOSITION

Admission is indicated for patients with any lower gastrointestinal bleeding (excluding minor bleeding), for patients with continued bleeding, for patients with significant associated or underlying comorbid disease or injury, and for those with poor social support or questionable reliability for follow-up. Patients with stable vital signs and no significant comorbidity can go to the floor. Admission to an intensive care unit can be guided by the BLEED classification tool.⁷ Any one positive criterion indicates the need for intensive care unit admission, including (1) ongoing bleeding, (2) low systolic blood pressure (less than 100), (3) elevated prothrombin time, (4) erratic mental status, and (5) presence of unstable comorbid disease. The majority of patients with minor lower gastrointestinal bleeding amenable to surgical or medical treatment, stable vital signs, good social support, and reliability for follow-up care can be sent home, but all cases of lower gastrointestinal bleeding require follow-up.

COMMON PITFALLS

- Failure to appreciate the significance and volume of lower gastrointestinal bleeding, leading to delays in therapy
- Failure to consider gastrointestinal bleeding as a precipitant for near-syncope or syncope, angina, dyspnea, fatigue, anemia, altered mental status, or shock. The rectal examination should be performed early in the evaluation of these presentations.
- Failure to place a nasogastric tube early in the evaluation of significant bleeding to help rule out an upper gastrointestinal source
- Failure to consider the possibility of coexisting serious causes of bleeding once a relatively benign, treatable source of bleeding has been established. Beware of the diagnosis of hemorrhoids in lower gastrointestinal bleeding.
- Failure to perform and record serial laboratory and clinical evaluations
- Failure to recognize that it may take several hours for the hematocrit to reflect the magnitude of blood loss
- Failure to consider other clinical entities (e.g., infarction, pulmonary embolism) when vital signs remain abnormal despite adequate volume replacement and when there is no further evidence of bleeding
- Failure to appreciate the possibility of perforation, especially when there has been previous instrumentation
- Reliance on the color of the stool as an indicator of the source or location of bleeding. The color of the stool is unreliable because of variability in degradation and transit time.

Severe acid–base abnormalities, although potentially life-threatening in themselves, also serve as important indicators of serious underlying conditions or disorders. Precise identification of the cause of an acid–base disturbance is rarely required for proper immediate treatment, but the abnormality often provides a critical clue for the identification of an underlying disturbance. A thorough understanding of the principles of acid–base pathophysiology permits the physician to expand the diagnostic considerations and makes it possible to proceed promptly with appropriate interventions.

BASIC PHYSIOLOGY

The hydrogen ion concentration or its negative logarithm (pH) is a fundamental measure of the character of all organic solutions. Because cellular enzyme systems function over a very narrow range of hydrogen ion concentrations, maintaining a stable internal milieu is important for normal function. Three homeostatic systems help to maintain pH close to baseline.

Soluble buffer systems effect an immediate response to changes in pH. In the extracellular space, these include the carbonic acid, phosphoric acid, hemoglobin, and plasma protein systems. These extracellular buffers account for one-third of the body's acute buffering capacity. Intracellular tissue proteins are responsible for the remaining two-thirds.

Through a *rapid* or *respiratory response*, changes in ventilation can promptly cause hydrogen ions to be excreted or retained by changing the concentration of components of the carbonic acid buffer system.

Renal mechanisms mediate a slower response to changes in the total body hydrogen ion load by causing net excretion or generation of hydrogen ions.

For the clinician, the carbonic acid system is the single most important buffer system, for two reasons. First, changes in respiratory rate permit the rapid excretion (or retention) of large quantities of hydrogen ions by changing the P_{CO_2} , which in turn affects the serum bicarbonate and pH. Because of the effect of ventilatory changes on its constituents, the carbonic acid buffer system is said to be open-ended.

Second, the carbonic acid system's components are easily measured. Although inferences concerning systemic acid–base balance can be made by analyzing any buffer system, ease of measurement makes the carbonic acid system the most attractive for clinical use. In fact, common clinical terminology relies exclusively on the carbonic acid system's components to define acid–base status.

PATHOPHYSIOLOGY

Pathologic processes can modify the body's acid–base equilibrium in two fundamental ways: Disease can either increase or decrease the body's soluble hydrogen ion activity (a metabolic disturbance), and disease can either increase or decrease ventilation (a respiratory disturbance).

The disruption of acid–base equilibrium by a single disease process is termed a *primary disturbance*. This disruption initiates a series of compensatory responses that tend to return the pH toward normal. The compensatory response rarely returns the pH to the normal range and never overshoots the normal range.

The body responds to a primary metabolic disturbance by adjusting the respiratory rate and, thus, the P_{CO_2} (*respiratory compensation*), and it responds to a primary respiratory disturbance by increasing or decreasing renal hydrogen ion excretion (*metabolic compensation*) ([Table 165.1](#)).

	Usual pH	Hydrogen Ion Concentration	Serum Bicarbonate (Measured as Total CO_2 Content)	P_{CO_2}
Metabolic acidosis	<7.38	Primary increase	Immediate decrease	Rapid compensatory decrease
Metabolic alkalosis	>7.42	Primary decrease	Immediate increase	Variable compensatory increase
Acute respiratory acidosis	<7.38	Secondary increase	Immediate and compensatory increase	Primary increase
Chronic respiratory acidosis	<7.38	Secondary increase	Slow larger compensatory increase	Primary increase
Acute respiratory alkalosis	>7.42	Secondary decrease	Immediate and compensatory decrease	Primary decrease
Chronic respiratory alkalosis	7.42–7.48	Secondary decrease	Slow larger compensatory decrease	Primary decrease

TABLE 165.1. Primary Disturbances and Compensatory Responses in Terms of Changes in Carbonic Acid Constituents

A disease process causing a single primary acid–base abnormality is termed a *simple acid–base disturbance*. When two or more primary acid–base abnormalities occur simultaneously, possibly as a result of more than one disease process, the abnormality is termed a *mixed acid–base disturbance*.

Although the degree and rapidity of compensatory responses to simple acid–base disturbances vary from patient to patient, empiric data have defined a range of what can be considered the expected compensatory response for each type of simple disturbance. [Table 165.2](#) lists the anticipated compensatory responses for the different types of primary simple acid–base disturbances.¹⁸ Patients with acid–base profiles falling outside the range for a simple acid–base disturbance with its anticipated compensation should be suspected of having a mixed disorder.

SIMPLE METABOLIC ACIDOSIS
Predicted decreased P_{CO_2} mm Hg = $1.2 \cdot \Delta[HCO_3^-]$ mEq/L
Predicted P_{CO_2} mm Hg = $1.5 \cdot [HCO_3^-]$ mEq/L + 8 ± 2
Anticipated P_{CO_2} approximates last two digits of arterial pH
SIMPLE METABOLIC ALKALOSIS
Predicted increased ΔP_{CO_2} mm Hg = $0.67 \cdot \Delta[HCO_3^-]$ mEq/L
SIMPLE ACUTE RESPIRATORY ACIDOSIS
Predicted decreased ΔpH units = $0.8 \cdot \Delta P_{CO_2}$ mm Hg
Predicted increased $\Delta[HCO_3^-]$ mEq/L = $1 \cdot \Delta P_{CO_2}$ mm Hg
SIMPLE CHRONIC RESPIRATORY ACIDOSIS
Predicted decreased ΔpH units = $0.3 \cdot \Delta P_{CO_2}$ mm Hg
Predicted increased $\Delta[HCO_3^-]$ mEq/L = $3.5 \cdot \Delta P_{CO_2}$ mm Hg
SIMPLE ACUTE RESPIRATORY ALKALOSIS
Predicted increased ΔpH units = $0.8 \cdot \Delta P_{CO_2}$ mm Hg
Predicted decreased $\Delta[HCO_3^-]$ mEq/L = $2 \cdot \Delta P_{CO_2}$ mm Hg
SIMPLE CHRONIC RESPIRATORY ALKALOSIS
Predicted increased ΔpH units = $0.17 \cdot \Delta P_{CO_2}$ mm Hg
Predicted decreased $\Delta[HCO_3^-]$ mEq/L = $5 \cdot \Delta P_{CO_2}$ mm Hg

TABLE 165.2. Formulas Describing Expected Compensatory Response to Primary Acid–Base Disturbances

Table 165.3 and Table 165.4 list the causes of the simple or mixed acid–base disturbances most common in the emergency department. The emergency physician must be able to recognize simple and mixed acid–base abnormalities to identify all the disease processes operative in a given patient, although their differentiation rarely is necessary for treatment of the hydrogen ion disturbance *per se*.

SIMPLE METABOLIC ACIDOSIS
Diabetic ketoacidosis
Starvation ketoacidosis
Alcoholism
Lactic acidosis
Uremia

Diarrhea/vomiting
Organic acidosis/forming
Metabolic acidosis with excessive bicarbonate administration

TABLE 165.4. Mixed Acid–Base Disturbances

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The physician often must begin the laboratory evaluation before completing the history and physical examination. Acid–base disturbances should be suspected in patients who appear critically ill, are experiencing extreme dyspnea, have an abnormal mental status, or complain of vomiting or diarrhea. Arterial blood gas and serum electrolyte determinations provide enough data for the initial metabolic assessment.

The physician should attempt to interpret acid–base abnormalities only after completing the initial evaluation and formulating a set of preliminary hypotheses about the most likely cause or causes. To identify acid–base abnormalities accurately, the physician should then ask three questions:

1. Does the patient have an acidemia or an alkalemia? *Acidemia* is defined as a pH less than 7.38, and *alkalemia* as a pH greater than 7.42. An *acidosis* is any process that causes acid to accumulate; an *alkalosis* is a process that causes hydrogen ion depletion. If the patient is acidemic, at least one of the processes present must be an acidosis.
2. Is the disturbance respiratory or metabolic? Look at the serum bicarbonate and arterial P_{CO_2} (Table 165.5).

	pH	P_{CO_2}	HCO_3^-
Metabolic acidosis	Decrease	Decrease	Decrease
Metabolic alkalosis	Increase	Increase	Increase
Respiratory acidosis	Decrease	Increase	Increase
Respiratory alkalosis	Increase	Decrease	Decrease

TABLE 165.5. Respiratory vs. Metabolic Acidosis/Alkalosis

3. Is the acid–base disturbance simple or mixed? When the appropriate formula (see Table 165.2) is applied, a significant deviation from the parameters expected for a simple disturbance indicates the presence of a mixed disorder.

Simple Metabolic Acidosis

This is the most common acid–base disturbance in hospitalized patients and is often present in emergency department patients.⁷ The diagnosis of the underlying cause is aided by considering the *anion gap*, defined as serum sodium – (chloride + CO_2 content).²⁶ The normal range for the anion gap has been reduced to 6 ± 3 mEq/L from its previously accepted range of 12 ± 4 mEq/L, because the normal range of the serum chloride is slightly higher with newer analytic methods.²⁴ This gap

represents anions that are present in the serum but not routinely measured.⁹ A normal anion gap in an acidotic patient indicates the presence of excess hydrochloric acid; an anion gap greater than 14 mEq/L may indicate an excess of organic acids.

[Table 165.3](#) classifies the causes of metabolic acidosis according to the presence or absence of an abnormal anion gap.⁸ The emergency physician is likely to evaluate many patients with an increased anion gap. When using the anion gap diagnostically, several factors must be kept in mind:

1. A moderate increase in the anion gap (12 to 20 mEq/L) is noted in many situations in which a metabolic acidosis is not present. These include dehydration, alkalosis, spurious laboratory values, and treatment with citrate, lactate, or certain antibiotics.
2. An anion gap greater than 25 mEq/L is seen only with lactic acidosis, ketoacidosis, and the toxin-associated acidoses.¹¹
3. Common sense indicates that in a pure, high anion gap metabolic acidosis, the degree to which the anion gap exceeds normal limits should be matched by an equal decrease in the serum bicarbonate level. This does not occur for several reasons. Nonbicarbonate intracellular buffers accept hydrogen ions, blunting the decrease in serum bicarbonate. The longer the duration of acidosis, the greater the contribution from intracellular buffers.²⁴ The unmeasured anions associated with different acidoses have different volumes of distribution. The greater the added anion's capacity to diffuse into cells, the lower the drop in the serum bicarbonate and the lower the anion gap. Also, acidemia itself decreases the anion gap by decreasing the negative charge on serum proteins that makes a major contribution to the normal anion gap.²⁴ Finally, variable clearance rates of the added anions can alter the anion gap. If an organic anion is rapidly cleared, the anion gap will be lower for any degree of acidosis.⁶

Several conditions tend to lower the anion gap. These include hypoalbuminemia (there is a decrease in the anion gap of about 3 mEq/L for every 1-g/L decrease in the serum albumin), hypercalcemia, lithium intoxication, paraproteinemia secondary to multiple myeloma, and hypertriglyceridemia, which can spuriously elevate the serum chloride determination.¹³ Organic acidoses in these patients may thus result in a smaller anion gap than otherwise predicted.²⁴

The serum potassium level must be closely monitored in patients with suspected metabolic acidosis.¹ The emergency physician should perform a rapid assessment of the serum potassium level (by seeking electrocardiographic evidence of hyperkalemia) in patients with suspected acidosis. In general, the serum potassium level increases as the patient becomes more acidemic. This increase may result from the interaction of the excess hydrogen ion with intracellular buffer systems.¹⁹ Animals made acidemic by the addition of mineral acids such as HCl experience a greater increase in serum potassium per unit decrease in pH than do those made acidemic by organic acids such as lactate.¹⁹ There is no reliable formula by which to estimate the expected change in serum potassium arising from a given change in pH.¹

Simple Metabolic Alkalosis

Metabolic alkalosis is a common condition that should be suspected in patients with very high values for the total serum CO₂ content. Most metabolic alkaloses are initiated by primary volume depletion, potassium depletion, or both. Patients with this disorder rarely present with a pH in the life-threatening range (greater than 7.60), but they may require vigorous fluid administration or potassium repletion.

The compensatory responses to metabolic alkalosis are weak. The ventilatory response (which would require hypoventilation to increase the P_{CO₂}) is limited by systemic defenses against hypoxia, and the kidney cannot alkalize the urine if the patient is hypokalemic or significantly volume-depleted.²¹ Metabolic alkalosis, therefore, tends to be self-perpetuating if untreated.¹⁸

Primary Respiratory Disturbances

Primary respiratory abnormalities are classified as acute or chronic according to their duration. Because the renal compensatory process becomes effective only with the passage of time (48 to 72 hours), patients with primary acute respiratory disturbances have a pH further from normal than patients with chronic disturbances. In chronic respiratory alkalosis, alone among the primary acid–base disturbances, compensation can be so effective that the pH may return to normal.²

The immediate treatment of a severe primary respiratory disturbance is mechanical intervention, such as increasing ventilation for respiratory acidosis or adding dead space to the upper airway for respiratory alkalosis. Longer-term treatment involves identifying and treating the underlying cause. The physician must avoid treatment that suddenly normalizes the P_{CO₂} in a patient with chronic respiratory disturbance. In these instances (when renal compensatory mechanisms have previously normalized the pH), rapid normalization of the respiratory parameters risks a dangerous overshooting of normal pH.

Patients with respiratory acidosis require the most emergent intervention, because the P_{CO₂} can rise quickly to cause both a life-threatening acidosis and serious encephalopathy (CO₂ narcosis).⁷ An arterial blood gas determination is mandatory for patients with abnormal mental status, especially if they manifest any clinical evidence of ventilatory dysfunction.

Acute respiratory alkalosis is common in emergency practice, particularly in the hypoxic or febrile patient. Although most cases of this acid–base abnormality do not require treatment, it should lead to a search for a specific underlying cause.

Mixed Acid–Base Disturbances

When a mixed disorder is present, the patient may be acidemic or alkalemic, or may have a normal pH. Any two primary acid–base disturbances (other than acute respiratory acidosis and acute respiratory alkalosis) can coexist. Knowing the patient's history permits the physician to make a more accurate assessment of the underlying processes.

Metabolic acidosis with respiratory acidosis or alkalosis is diagnosed when the P_{CO₂} deviates significantly from that predicted (see [Table 165.2](#)) in a simple metabolic acidosis. Combined metabolic acidosis and respiratory acidosis is seen in situations such as cardiac arrest or the postictal state, in which ventilation is inadequate for the degree of metabolic acidosis. Combined metabolic acidosis and respiratory alkalosis is commonly noted in salicylate poisoning, in which salicylate induces metabolic acidosis and also directly stimulates ventilation in excess of that induced by the acidosis.

One should be cautious in diagnosing mixed disturbances in patients with a rapidly changing clinical status, because the formulas for the expected response to simple metabolic acidosis were derived from P_{CO₂} levels in patients who had achieved a steady state. Thus, there is an increased chance of overdiagnosing a mixed disorder in many acutely ill patients.¹⁸

The combination of *metabolic acidosis and metabolic alkalosis* often manifests with a relatively normal pH and an anion gap elevation significantly exceeding the decrease in total CO₂ content.²⁰ A common setting for this mixed disturbance is the patient with alcoholic ketoacidosis who has been vomiting. If combined metabolic acidosis and metabolic alkalosis occurs in a patient with a normal anion gap acidosis, however, there is no anion gap elevation to serve as a marker for the disturbance.

An example would be a patient with severe diarrhea (metabolic acidosis caused by loss of sodium bicarbonate in the stool) associated with vomiting (metabolic alkalosis caused by loss of gastric hydrochloric acid). Unless this disturbance is suspected because of the clinical setting, the presence of two acid–base abnormalities may become evident only when one of the deficits is corrected. In the vomiting and diarrhea example, rapid volume correction with normal saline but without concomitant bicarbonate replacement might unmask the normal anion gap acidosis, with the serum bicarbonate decreasing as volume is restored.

CONTROVERSIES IN MANAGEMENT

Diabetic Ketoacidosis

Insulin administration, rehydration, and close monitoring (and replacement) of potassium are the mainstays of emergent therapy of diabetic ketoacidosis (DKA). Judicious administration of bicarbonate may be useful in patients with severe acidosis and cardiovascular compromise.¹⁷ Although bicarbonate has traditionally been recommended for patients with DKA whose pH is below 7.1, even patients with a pH between 6.9 and 7.1 do not benefit from receiving bicarbonate.¹⁴ Bicarbonate is

still recommended in patients with a pH below 6.9, however.¹⁶

Adverse effects of excessive bicarbonate administration in DKA include tissue hypoxia from bicarbonate's leftward shifting of the oxyhemoglobin dissociation curve; augmentation of hepatic ketogenesis; hypertonicity and sodium overload; hypokalemia; and late alkalemia, when bicarbonate is regenerated from keto acids.¹⁰ Some patients have reportedly deteriorated after aggressive bicarbonate treatment; this deterioration has been attributed to either a "paradoxical" central nervous system acidosis^{12,14} that occurs after vigorous bicarbonate administration (which does not cross the blood-brain barrier) or cerebral edema from activation of a membrane $\text{Na}^+ - \text{H}^+$ exchanger by the organic acidosis.²⁸

Lactic Acidosis

This common acidosis is defined as a pH below 7.35 and a serum lactate level greater than 6 mmol/L, but because serum lactate measurements are unavailable to most emergency physicians, the diagnosis is often made by excluding other causes of acidemia in patients with a compatible history and clinical picture.¹⁵ Most patients with lactic acidosis have some degree of tissue hypoxia leading to overproduction and underuse of tissue-generated lactate. The treatment of patients with lactic acidosis should center around improvement of tissue oxygenation and identification and treatment of its underlying cause.^{2,26,27} A bicarbonate infusion of 1 to 2 mEq/kg may be considered as a temporizing measure in the presence of severe acidemia.

Cardiac Arrest

A common emergency department setting in which the use of bicarbonate is considered is cardiac arrest. Classically, the arrest victim would be expected to manifest a combined metabolic and respiratory acidosis, although the actual acid-base status varies depending on the cause and duration of the cardiac arrest. Neither animal nor human data have demonstrated the effectiveness of bicarbonate in increasing survival after cardiac arrest, and there have been reports of severe hyperosmolality, alkalosis, hypernatremia, and even pediatric intracerebral hemorrhage from injudicious bicarbonate administration.^{3,4,22,23} The 1997 American Heart Association *Advanced Cardiac Life Support* guidelines⁵ unequivocally support the use of bicarbonate in cardiac arrest associated with hyperkalemia, in tricyclic or phenobarbital overdose, and in patients with preexisting bicarbonate-responsive metabolic acidosis. Bicarbonate therapy may also be considered during prolonged cardiopulmonary resuscitation in which the patient has been adequately ventilated but is not responding to standard resuscitative measures. When bicarbonate is used, the initial dose should be 1 mEq/kg, with subsequent doses and timing determined by the arterial pH.

Toxin-Induced Acidosis

Methanol and ethylene glycol are two low-molecular-weight alcohols that can produce severe metabolic acidosis when ingested. If treatment begins promptly, recovery can be excellent despite severe acidemia. Parenteral sodium bicarbonate is an effective interim treatment. In contrast with other high anion gap acidoses, the organic anions generated in these poisonings cannot be converted back to bicarbonate by the liver. The physician should administer 1 mEq/kg of bicarbonate if the pH is below 7.20 and gauge the quantity and frequency of further doses by the response. Additional treatment includes administration of ethanol or 4-methylpyrazole to delay the formation of toxic intermediates, and hemodialysis for removal of native toxin.

Use of Alternative Alkalinizing Agents

A number of alternatives to bicarbonate for the treatment of metabolic acidosis have been investigated. These include dichloroacetate (a stimulator of the enzyme pyruvate dehydrogenase), Carbicarb (a mixture of sodium bicarbonate and sodium carbonate that generates less carbon dioxide during the buffering process), and THAM, a commercially available solution of tromethamine that buffers both metabolic and respiratory acids. None of these bicarbonate alternatives is currently recommended for emergency department use.²

COMMON PITFALLS

- Emergency physicians must be proficient in differentiating simple from mixed acid-base disturbances. They should search for and aggressively treat any underlying causes of significant disturbances. The limitations of the standard formulas that assist in the categorization of acid-base disturbances must be understood.
- There is significant controversy about the indications for and appropriate doses of sodium bicarbonate in several common emergency conditions. Bicarbonate should be used in hyperkalemia, toxin-induced metabolic acidosis, or severe DKA, and can be used for alkalization after appropriate overdoses. In selected cases of suspected lactic acidosis, bicarbonate can be given cautiously and with close monitoring. Bicarbonate should be avoided in hypoxic lactic acidosis. In metabolic acidosis of unknown cause, bicarbonate should not be withheld if there is cardiovascular compromise and a pH below 7.0.

CHAPTER 166

Diabetic Ketoacidosis

Micheal D. Rush and Robert A. Schwab

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Diabetic ketoacidosis (DKA) is a syndrome of hyperglycemia, ketonemia, and acidosis resulting from absolute or relative insulin deficiency. It occurs most commonly in insulin-dependent diabetics, but it may also be seen in patients with non-insulin-dependent diabetes.²⁹ DKA is the presenting illness in approximately 15% to 26% of patients with newly diagnosed diabetes, particularly in those with type 1 diabetes.⁷

DKA is a common illness. According to 1990 Centers for Disease Control (CDC) surveillance data, DKA was a listed diagnosis on 104,000 hospital discharge summaries.⁵ Precipitating factors include noncompliance with medication, infection, myocardial infarction, alcohol use, pregnancy, trauma, and emotional stress.⁶ Inadequate diabetic education and training may be a significant contributing factor in patients with recurrent episodes of DKA. The overall mortality rate is about 5%; despite intensive research and advances in treatment, mortality rates have not declined significantly in the past 20 years.³ Death may result from metabolic derangements attributable to DKA itself or to complications of treatment. Most often, however, death in DKA is due to associated concurrent illness.^{3,15}

The pathophysiology of DKA involves physiologic derangements induced by insulin deficiency. Hyperglycemia occurs as a result of decreased peripheral use of glucose.

Catecholamines, cortisol, and growth hormone, released in response to the stress of precipitating illness, contribute to glucose overproduction.¹⁸ In the absence of adequate insulin, however, glucose is unavailable as a substrate for cellular energy production, and changes in hepatic metabolism occur to produce alternative energy sources. Triglyceride synthesis is inhibited in favor of lipolysis, which produces the ketoacids aceto- acetate (AcAc) and beta-hydroxybutyrate (BHBA). These ketoacids can be used as substrate by the brain and other tissues, but they cause ketonemia and metabolic acidosis.

The combination of hyperglycemia and ketoacidosis results in a hyperosmolar state leading to osmotic diuresis, volume depletion, and electrolyte losses, all of which contribute to the clinical picture of DKA.

CLINICAL PRESENTATION

The most common presenting signs and symptoms of DKA can be predicted on the basis of an understanding of the precipitating factors and pathophysiology of the disease. Early on, the clinical picture may be dominated by the underlying cause, such as symptoms of infection or pancreatitis. Most often, however, the metabolic derangements of DKA tend to obscure the precipitating factors.

Hyperglycemia leads to blurred vision, polyuria, polydipsia, and polyphagia; ketoacidosis causes nausea, vomiting, and the characteristic fruity odor of acetone on the breath. Respiratory compensation for the acidosis manifests initially as tachypnea, and results in Kussmaul breathing as acidosis becomes more severe. As the syndrome progresses, volume depletion becomes significant; patients commonly complain of dizziness and weakness, and manifest tachycardia, dry mucous membranes, and poor skin turgor. A full-blown shock picture can be seen in severe cases.

The presenting mental status correlates most closely with serum osmolality.¹⁸ Roughly one-third of patients presents stuporous or comatose, one-third has normal mentation, and the remaining third is somewhere between these extremes. Hypothermia has been described in DKA and is frequently associated with an underlying infection and a higher mortality rate.¹² Abdominal pain and tenderness are common, and have been attributed to gastric distention or stretching of the liver capsule.¹⁹ Appropriate treatment of the metabolic derangements usually leads to prompt resolution of the pain. Persistent pain should prompt a search for underlying abdominal pathology.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of DKA depends on the patient's presentation. In known diabetics presenting with changes in mental status, the primary diagnostic concern is distinguishing between hypoglycemic and hyperglycemic states, including DKA and hyperglycemic hyperosmolar nonketotic coma (HHNC). This distinction can be made rapidly using bedside glucose assessments, which should be done in all patients presenting with altered mental status.

HHNC generally occurs in older, non-insulin-dependent diabetic patients, and is associated with higher blood glucose levels and greater volume deficits than in DKA. Urine and serum ketone analysis may assist in differentiating between DKA and HHNC, but the distinction is not always clear initially. Significant ketosis may be the result of starvation, alcoholic ketoacidosis (AKA), or isopropyl alcohol ingestion, in addition to DKA. The history, coupled with a blood glucose determination, should assist in sorting through the diagnostic possibilities.

In most cases, a diagnosis is made based on arterial blood gas (ABG) analysis or electrolyte determinations, which demonstrate a metabolic acidosis with increased anion gap. The differential diagnosis includes toxin ingestion (methanol, ethylene glycol, or salicylates), uremia, lactic acidosis, or drug effect (iron, isoniazid, paraldehyde), in addition to AKA or DKA. A careful history and determination of glucose, electrolytes, blood urea nitrogen (BUN), creatinine, lactate, and specific toxin levels direct the clinician to the proper diagnosis.

EMERGENCY DEPARTMENT EVALUATION

Regardless of the patient's presentation, evaluation must begin with an assessment of airway, breathing, and circulation. Most patients with DKA maintain a patent airway; comatose patients, however, may require intubation for airway protection. Assessment of ventilation, oxygenation, and acid-base status commonly requires ABG analysis. Pulse oximetry should be utilized to ensure adequate oxygenation pending ABG results.

Supplemental oxygen should be administered if the saturation is low, or if oximetry is unavailable. The circulatory assessment reveals significant volume depletion in most cases; large-bore, peripheral venous access should be obtained, and volume resuscitation begun with normal saline. Cardiac monitoring and urinary catheter insertion should be considered for patients who appear significantly ill.

A bedside glucose determination should be done on all patients with altered mental status to determine the need for dextrose administration. Naloxone and thiamine can be administered as well, as indicated. Blood loss should be ruled out with a quantitative hemoglobin determination and stool analysis for occult blood. Urinalysis should be performed as soon as a specimen is available; urine dipsticks can detect glucosuria and ketonuria rapidly and accurately. Blood should be sent for glucose, electrolytes, BUN, and creatinine, in addition to the tests mentioned previously.

Once initial stabilization has been accomplished, the physician should elicit a thorough history and perform a careful physical examination, looking for precipitating causes. A detailed review of the timing and dosages of recent insulin administration, as well as a dietary history, are often revealing, as are symptoms identifying recent or intercurrent precipitating illness. Further laboratory evaluation should be guided by the findings of the history and physical examination.

The typical patient with DKA presents with hyperglycemia, glucosuria and ketonuria, and an elevated anion gap metabolic acidosis. A mildly elevated BUN and

hematocrit are consistent with volume depletion, and electrolyte values may reflect volume depletion as well.

Many patients, however, do not present with this “typical” picture, and the clinician must recognize the possible variations in laboratory results in order not to miss the diagnosis. Although initial glucose levels in DKA average 600 mg/dL or more, marked hyperglycemia may be absent if urine flow is adequate to allow glucose to be excreted.²⁴ In addition, many diabetics are also hyperlipidemic, which may result in spurious lowering of glucose levels as well as falsely elevated or depressed electrolyte levels.¹⁶

The degree of acid–base disturbance depends somewhat on the patient's volume status. The classic elevated anion-gap acidosis results from an accumulation of organic acids and an increase in unmeasured anions such as AcAc and BHBA, which cannot be excreted as urine flow decreases. If fluid intake maintains adequate renal perfusion, however, ketoacids are excreted, and chloride is retained to compensate for loss of the bicarbonate buffer, leading to a hyperchloremic, non–anion-gap acidosis.^{11,25} In some cases, when vomiting and volume depletion are severe, loss of hydrogen chloride from the stomach and aldosterone-mediated renal bicarbonate resorption can cause a hypochloremic metabolic alkalosis and can actually result in alkalemia.¹³ The sum of these effects may be a mixed metabolic picture that obscures the diagnosis.

The absence of detectable ketonuria and ketonemia may also confound the physician. Despite consistent increases in blood ketoacid levels, the relative ratio of AcAc and BHBA, which are mutually interconvertible, depending on the patient's redox state, varies from patient to patient. Because the nitroprusside test for qualitative ketones in serum and urine detects AcAc but not BHBA, patients with a high BHBA/AcAc ratio may appear not to be ketotic, and the diagnosis of DKA may be missed.²²

EMERGENCY DEPARTMENT MANAGEMENT

Once the diagnosis is established, treatment requires correction of hypovolemia, reversal of ketoacid production, enhancement of glucose and ketoacid metabolism, replacement of electrolyte losses, and treatment of precipitating causes. Normalization of the metabolic state should occur gradually to avoid complications such as volume overload, hypoglycemia, hypokalemia, and cerebral edema.²⁴

Volume replacement should begin as soon as hypovolemia is recognized. Fluid resuscitation should thus be underway before a definitive diagnosis is established. Fluid deficits in DKA average 5 L²⁸; normal saline effectively restores intravascular volume while avoiding a rapid fall in extracellular osmolality. The initial rate of infusion should be rapid, but moderate rates of infusion (500 mL/h) appear to allow metabolic acidosis to be corrected more rapidly than higher rates (1 L/h).¹

Giving smaller volumes of bicarbonate-free solutions tends to lessen the dilutional effect on existing bicarbonate and avoids excessive washout of ketone bodies, which, if retained, are metabolized to bicarbonate in the presence of insulin. An initial rate of 500 mL/h for 4 hours, followed by 250 mL/h for the next 4 hours, has been shown to be effective in patients without extreme volume deficit.¹ Ultimately, the initial infusion rate is dictated by the patient's hemodynamic stability and response to therapy, as reflected by urine output. Decisions to change to half-normal saline may be left to the admitting physician.

Volume replacement lowers serum glucose and ketone levels and helps correct metabolic acidosis, but insulin must be given for ketogenesis to be reversed, for ketone bodies to be metabolized back to bicarbonate, and for glucose to be utilized as a substrate for cellular energy production. Treatment should begin with a bolus dose of regular insulin, 0.1 U/g. A subsequent continuous infusion of 0.1 U/kg/h lowers serum glucose concentrations reliably and predictably, is as effective as high-dose insulin regimens in decreasing serum glucose and ketone body concentrations, and carries a lesser risk of hypokalemia and hypoglycemia. Continuous intravenous infusion achieves effective steady-state concentrations of insulin more reliably than does intermittent bolus therapy.²⁷ Intramuscular and subcutaneous injections are not recommended in volume-depleted patients.^{9,17,20}

The osmotic diuresis associated with hyperglycemia produces clinically significant deficits in total body potassium, sodium, phosphate, and bicarbonate. Acidosis, insulin deficiency, and hyperosmolality all shift potassium and phosphate extracellularly, often masking the total body deficits.² Whether the initial serum potassium is high, normal, or low, all patients in DKA require potassium replacement. Patients whose potassium levels are elevated initially should receive replacement when the serum potassium level falls to 5. Patients with normal or low serum potassium levels should receive replacement as soon as urine output is confirmed. The administration of fluids and insulin, as well as the correction of acidosis, tend to lower the serum potassium level, placing patients with initially low serum potassium levels at considerable risk for respiratory arrest and cardiac dysrhythmias. An infusion rate of 10 to 40 mEq/h can substantially correct a total body deficit of 300 to 600 mEq within 24 hours.

Most patients in DKA present with hyperphosphatemia, despite total body phosphate depletion.³⁰ With appropriate restoration of volume and administration of insulin, phosphate levels fall, reaching a nadir 24 to 48 hours after the initiation of insulin therapy. Phosphate administration can be associated with undesirable side effects, such as hypocalcemia, and, more importantly, has not been shown to affect the outcome of patients with DKA.^{8,30} Phosphate replacement should be reserved for patients with severe hypophosphatemia, and is not routinely indicated in the initial management of DKA.

Sodium deficits, although significant, are generally corrected by the administration of normal saline. The use of bicarbonate to correct base deficit is controversial. Although systemic acidosis has deleterious effects on cellular function throughout the body, it has been demonstrated that, during DKA, the central nervous system maintains a higher pH than the rest of the body, through a poorly understood buffering mechanism.²³ The administration of bicarbonate increases systemic levels of CO₂, which diffuses freely across the blood–brain barrier and combines with water to form carbonic acid. Because bicarbonate crosses the blood–brain barrier much less readily than does CO₂, cerebrospinal fluid (CSF) acidosis ensues.

Other cellular membranes exhibit this differential permeability to CO₂ and bicarbonate as well, suggesting that bicarbonate administration may cause a paradoxical intracellular and CSF acidosis. Although this paradoxical acidosis has never been demonstrated in clinical investigations involving patients in DKA, it has been shown that the administration of bicarbonate confers no therapeutic benefit in patients with a presenting pH of 6.9 or greater, and may actually increase ketone-body formation or delay the metabolism of ketoacids to bicarbonate.^{10,14,23,26}

Other potential hazards of bicarbonate therapy include tissue hypoxia through shifting of the oxyhemoglobin dissociation curve, hypokalemia, and rebound alkalosis. Overall, it appears that bicarbonate administration, although it may transiently increase serum pH, does not improve clinical outcome and may actually be deleterious in the patient with DKA. Adjunctive bicarbonate therapy should be considered only for those patients presenting with a pH less than 6.9, in order to prevent complications of decreased cardiac contractility, cardiac dysrhythmias, and peripheral vasodilatation commonly associated with severe acidemia.

Initially, the patient's blood glucose should be monitored at least every 1 to 2 hours during treatment. Serum electrolytes should also be monitored closely to ensure that metabolic derangements are being corrected. A fall in blood glucose of 75 to 100 mg/dL/h is a reasonable goal, and insulin infusions should be adjusted accordingly. The serum potassium level generally reaches a minimum 1 to 4 hours after the initiation of therapy.² Although ABG measurement may be necessary to diagnose mixed acid–base disorders in DKA, repeated arterial sampling may not be necessary, because venous pH correlates well with arterial values. Many patients can be followed using venous samples alone.⁴

Ketone monitoring is not helpful and may demonstrate a paradoxical increase in quantitative ketones despite clinical improvement, which occurs as BHBA is oxidized to AcAc (with which nitroprusside reacts) in the presence of insulin.²² While initial blood gas measurement may be necessary to diagnose coexisting acid–base disorders in DKA, repeated arterial sampling is usually unnecessary.⁴ Patients who present with hemodynamic instability or hypokalemia should have continuous cardiac monitoring. Urinary output should be monitored closely. A careful search for underlying precipitating factors should be undertaken, with appropriate diagnostic studies utilized as indicated. The possibility of silent myocardial infarction should be considered in patients without an obvious precipitating cause.

Insulin therapy must be continued for ketonemia and acidemia to be corrected. To avoid hypoglycemia and to reduce osmotic gradients between blood and brain, 5% dextrose should be added to the intravenous infusion (usually half-normal saline at this point) when the blood glucose level reaches 250 mg/dL.² The insulin infusion also is reduced by half at this point.

Complications of therapy for DKA include hypoglycemia,²¹ hypokalemia, and hypophosphatemia, as well as fluid overload and cerebral edema. Careful electrolyte and fluid monitoring and the use of 5% dextrose, as described, reduce the risk of these complications substantially. Vascular thrombosis, rhabdomyolysis, and

disseminated intravascular coagulation are rare but often fatal complications of DKA. [3,15,30](#)

DISPOSITION

Proper management of DKA requires careful monitoring of vital signs and fluid status, as well as repeated assessment of pH, glucose, and electrolytes. The therapeutic plan may have to be altered frequently, especially in the early phase of treatment, and complications tend to occur rapidly, with potentially severe consequences. For these reasons, many patients with DKA require admission to an intensive care setting.

Specialty ward units with monitoring capability and low patient-to-nurse ratios have also been used safely and effectively. [15](#) These units provide a cost-effective alternative to the intensive care unit for patients who do not require cardiorespiratory support. In very unusual circumstances, patients may be treated in the emergency department and released. Such patients should have a mild presentation that responds rapidly to therapy; have no precipitating illness requiring hospitalization; have normal vital signs, pH, and anion gap; have a blood glucose level less than 300 mg/dL and a bicarbonate level greater than 15 mEq/L; should be taking oral fluids well; should be reliable and have good family support; and should have follow-up scheduled with their primary physician within 24 hours.

If needed, transfer to another facility should occur only after vital signs have been stabilized and volume resuscitation is well underway. Personnel capable of providing advanced life support should accompany the patient, who should have continuous cardiac monitoring. The transferring physician should provide a detailed flowsheet of fluid and electrolyte therapy, in addition to the usual transfer documentation.

COMMON PITFALLS

- Failure to administer dextrose to diabetic patients presenting in coma
- Failure to diagnose DKA in patients who are euglycemic, have a negative nitroprusside test, or do not present with a high anion-gap acidosis
- Failure to initiate potassium replacement in patients with normal or high initial potassium levels
- Failure to maintain insulin infusion until the anion gap is normal
- Failure to monitor glucose frequently and add dextrose to the infusion when the blood glucose level reaches 250 mg/dL
- Failure to search diligently for precipitating causes

CHAPTER 167

Hyperosmolar Hyperglycemic Nonketotic Coma

Dana Pope and Leslie S. Zun

[Clinical Setting](#)
[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Hyperosmolar hyperglycemic nonketotic coma (HHNC) is a syndrome of profound dehydration that develops insidiously as a consequence of prolonged osmotic diuresis. Also known as the hyperglycemic nonketotic syndrome, it is commonly defined by a plasma osmolarity greater than 350 mOsmol/kg water, a serum glucose concentration greater than 600 mg/dL, and an absence of ketoacidosis in a patient with a depressed level of consciousness.^{1,9,13,17} In the following discussion, a number of caveats should be kept in mind. The range of serum glucose values seen in HHNC is wide, usually far wider than that seen with diabetic ketoacidosis (DKA).¹⁴ The absence of ketoacidosis or ketonuria is not absolute, and ketones may be present in small amounts.^{1,12,16,25} The patient may not actually be comatose but is more likely to be drowsy or confused.⁴ HHNC is associated with a high mortality^{1,4,9,14} and should be considered a medical emergency.

CLINICAL SETTING

The patient most at risk for developing HHNC is elderly, with an average age of about 60 years.^{1,4,8,14,17} The age range is wide, however, and case reports appear in the pediatric literature.^{14,20,21}

Usually a diabetogenic stress is implicated in precipitating the hyperosmolar state. Chronic renal insufficiency, pneumonia, gram-negative sepsis, myocardial infarction, pancreatitis, and gastrointestinal bleeding are frequently associated with HHNC and contribute to its high mortality. The following have also been implicated in the development of HHNC: thiazide diuretics, corticosteroids, phenytoin, propranolol, chlorthalidone, furosemide, ethacrynic acid, diazoxide, cimetidine, chlorpromazine, *L*-asparaginase, immunosuppressive agents, loxapine, hyperalimentation, peritoneal dialysis and hemodialysis, cardiac surgery, stroke, severe burns, pancreatitis, and heat stroke.^{1,2,4,6,9,16}

There is no history of diabetes mellitus in two-thirds of patients who develop HHNC.^{1,9} The remaining one-third generally have a history of type II, or non-insulin-dependent, diabetes; a few patients are insulin dependent. On recovery, most patients prove to have mild type II diabetes.^{4,13}

Patients with HHNC often have severe concurrent illnesses, which are commonly the precipitating cause of HHNC.¹

HHNC has a reputation for being underrecognized. The high mortality rate of HHNC (20% to 60%)^{1,9,14} is variously explained by delay in establishing the diagnosis,¹³ by failure to treat aggressively from the outset,¹ and by the high incidence of serious underlying disease.^{1,13}

Pancreatic endocrine insufficiency is thought to be an age-related process of progressive cell senescence, the effect of which is exaggerated by circulating catecholamines and adrenergic stimulation at the time of metabolic stress, such as trauma or infection. Furthermore, peripheral resistance to insulin has been demonstrated in HHNC, and hypertonicity itself inhibits secretion of pancreatic insulin.^{7,19} With a decline in renal function, due to age or dehydration, the ability to excrete glucose is impaired and severe hyperglycemia may occur.⁵ Continued osmotic diuresis causes progressive dehydration, which further impairs pancreatic beta-cell function, further decreases glomerular filtration rate, and sets in motion a worsening spiral of metabolic events.

To conceptualize the events that occur in response to hyperglycemic hypertonicity and dehydration due to osmotic diuresis, it is helpful to review the distribution of body water in the intracellular and extracellular spaces. Total body water is about 60% of normal body weight (perhaps 50% in the elderly).²³ Intracellular fluid comprises two-thirds of total body water, and extracellular fluid, one-third. The extracellular space is further subdivided into interstitial fluid, comprising three-fourths of the extracellular space, and plasma, occupying the remaining one-fourth. Because water is freely permeable between the various compartments, total solute concentration in all of the compartments is identical (normal osmolarity is 280 to 300 mOsmol/kg water; however, the solute composition is different).

Extracellular solute is composed primarily of sodium and its anions, and intracellular solute is composed primarily of potassium, magnesium, and phosphate. Unlike a substance such as urea, which is freely permeable across cell membranes and does not create an osmotic gradient, glucose is located only in the extracellular space and is osmotically active. Thus, with hyperglycemia, water moves from the intracellular to the extracellular space. The expanded extracellular space may be reflected in a dilution of the serum sodium concentration but without actual hypotonicity.¹⁴ The serum sodium concentration typically falls 1.3 to 1.6 mEq/L for every 100-mg/dL rise of the serum glucose level above normal.⁷ Sodium is also lost through osmotic diuresis as tubular sodium reabsorption is inhibited, and water is lost in greater amounts than sodium, further increasing the tonicity of the extracellular space and drawing free water from the intracellular space to compensate.¹⁴

Patients presenting with HHNC may have a slight degree of ketosis. In fact, the wide spectrum of glucose and ketoacid concentrations that is seen in practice blurs the distinction between DKA and HHNC.^{1,12,24} The absence of ketosis is most often explained by the production of insulin sufficient to inhibit the release of free fatty acid from adipose tissue, yet insufficient to cause glucose uptake by cells.^{1,10,14} This concept has been questioned. Investigators have found no difference in initial plasma insulin levels between patients with HHNC and DKA. The lack of ketosis has also been explained by the effect of hyperosmolarity itself in suppressing ketone formation and by the finding of lower levels of lipolytic hormones (i.e., growth hormone and cortisol) in HHNC patients compared with those with DKA.⁹

CLINICAL PRESENTATION

Most patients who develop HHNC experience polyuria and polydipsia for days or weeks before seeking medical attention. In these patients, insidious dehydration progresses until mental status is altered. Unresponsiveness has been cited as the most common reason patients are brought for medical attention.¹ In contrast, patients with DKA rapidly develop signs and symptoms from acidosis, bringing them to medical attention before dehydration becomes as severe. One study found that the average duration of symptoms before presentation was 12 days for HHNC and 3 days for DKA.⁹

A few notes of caution are in order when these patients are to be assessed. The standard signs of dehydration (poor skin turgor, dry mucous membranes) are not reliable in elderly patients, and it is not always possible to estimate fluid deficits by clinical or laboratory findings. Neither the serum sodium nor the plasma osmolarity has been found to correlate with the volume of replacement fluid required by patients with HHNC.¹ The advanced state of dehydration may be underestimated if urine output is maintained by osmotic diuresis.¹⁶ On the other hand, renal dysfunction due to diabetic nephrosclerosis or other causes may prevent polyuria from occurring, even with progressively increasing levels of serum glucose.⁵

The severity of mental status changes in HHNC has been found to correlate with the degree of hyperosmolarity and the rate at which hyperosmolarity develops.^{8,17,18} In addition to altered mental status, HHNC can cause a variety of other neurologic findings: seizures, Babinski reflexes, bilateral or unilateral focal deficits, aphasia, muscle fasciculations, central hyperthermia, hemianopsia, nystagmus, visual hallucinations, visual loss, acute quadriplegia, acute urinary retention, and severe dysphagia.^{5,11,16}

As mentioned earlier, HHNC may be found in patients who present with a number of serious associated illnesses, the most frequent being chronic renal insufficiency, pneumonia, gastrointestinal hemorrhage, and gram-negative sepsis.¹

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of HHNC includes DKA; other causes of altered mental status, such as hepatic failure, uremia, cerebrovascular accident, and drug ingestion; and other causes of severe dehydration.

In patients with altered mental status, early diagnosis requires a high index of suspicion. Blood glucose measurement must be performed routinely and immediately in all patients with altered mental status to identify hypoglycemia or hyperglycemia. Patients with DKA often display Kussmaul respirations, and the fruity odor of acetone may be detected on the breath. An elevated anion-gap acidosis, ketosis, and mild-to-marked hyperglycemia are diagnostic. Lactic acidosis is often suspected when patients are gravely ill and display signs of shock. Blood pH determination reveals severe metabolic acidosis, and the anion-gap and lactic acid levels are elevated.

EMERGENCY DEPARTMENT EVALUATION

Basic laboratory evaluation for a patient suspected of having HHNC should include determination of levels of serum electrolytes, glucose, blood urea nitrogen, and creatinine; a complete blood cell count; urinalysis; and arterial blood gas analysis. A search should be made for serious underlying illness. A chest radiograph, electrocardiogram, blood and urine cultures, serum amylase value, liver enzyme studies, coagulation studies, and, in some cases, cardiac enzyme tests should be ordered.

The blood glucose concentration in HHNC is typically greater than 600 mg/dL and may be as high as 4800 mg/dL, with average values of about 1000 mg/dL.^{8,9,14,17} Caution must be exercised in the interpretation of rapid fingerstick readings when the blood sugar concentration is this high.⁹

Serum sodium and potassium concentrations may be low, normal, or high, and the values do not reflect total body losses.¹⁷ If the serum sodium concentration initially is not low, but normal or elevated, significant water loss can be assumed to have occurred.¹⁴ Potassium depletion is the rule, and profound deficits (on the order of 400 to 1000 mEq) may be encountered. If the initial serum potassium concentration is low, profound total body potassium depletion is undoubtedly present.¹⁷

All patients with HHNC are initially azotemic due to both prerenal and renal causes.¹⁷ The blood urea nitrogen–creatinine ratio may exceed 30:1.¹⁴ In one series, the average initial blood urea nitrogen and creatinine values were 87 mg/dL and 5.5 mg/dL, respectively. After treatment, the average values had fallen to 24 mg/dL and 2.0 mg/dL, respectively.¹

The serum osmolarity can be calculated using the following formula:

$$\text{Osmolarity (mOsmol/kg water)} = 2(\text{serum Na}) + (\text{blood glucose})/18 + (\text{blood urea nitrogen})/2.8$$

Although the measured and calculated osmolarity values follow similar trends, there is not always a reliable correspondence between the values.^{8,22}

Because urea is freely permeable across cell membranes, it does not create an osmotic gradient between the intracellular and extracellular spaces. The *effective* osmolarity should also be calculated (by excluding the blood urea nitrogen value from the equation), because azotemia may mask actual hypotonicity of the extracellular fluid. If a patient presents with hyperglycemia and a normal or low effective plasma osmolarity, it is potentially dangerous to administer hypotonic fluids or insulin, because lowering the tonicity of the extracellular fluid too rapidly might lead to cerebral edema.¹⁴

About half of patients with HHNC have a mild metabolic acidosis, with an anion gap about twice normal.¹ Various explanations of the acidosis are offered: accumulation of lactic acid or b-hydroxybutyric acid (not measured by Acetest or Ketostix tests) or acute or chronic renal insufficiency with accumulation of acid metabolites.

The complete blood cell count may show an elevated white blood cell count suggestive of a serious underlying infection. Because of profound dehydration, hemoconcentration can be expected to elevate the hemoglobin and hematocrit, so a patient with an initially normal hematocrit should be suspected of being anemic.¹⁷

The urinalysis may show only modest glycosuria, and ketonuria need not be absent to make the diagnosis of HHNC.¹⁷

EMERGENCY DEPARTMENT MANAGEMENT

The first priority in the treatment of HHNC is to replace volume (sodium) deficits, then to correct hyperosmolarity, and, finally, to manage any underlying illness.

Patients who are hypotensive or who have signs of shock need immediate fluid resuscitation with normal saline.^{10,17} Because average fluid deficits are on the order of 9 to 12 L, it is reasonable to begin emergency treatment of all HHNC patients with normal saline. Central venous pressure monitoring should be considered.^{13,17} One to 2 L of normal saline should be infused rapidly until the patient's blood pressure and urine output are acceptable or the central venous pressure begins to rise. It is then reasonable to switch to 0.5 normal saline, with the goal of replacing half of the estimated volume deficit during the first 12 hours and the remaining estimated deficit during the second 12 hours.¹

Because all patients with HHNC have total body potassium deficits, potassium should be administered as soon as it is certain that the patient is neither hyperkalemic nor oliguric. An intravenous infusion of about 10 mEq/h may be begun even prior to insulin therapy.^{3,17}

The use of insulin in the initial management of HHNC may not be necessary.^{13,25} West and colleagues²⁵ have shown that blood glucose levels decrease by about 25% because of dilution from fluid replacement alone. After volume status has improved, the remaining hyperglycemia may resolve through the metabolism and renal excretion of excess glucose. Insulin should be given, however, if the patient is acidotic, hyperkalemic, or in renal failure.

When insulin is given for HHNC, a low-dose regimen is appropriate: A reasonable approach is to give 0.15 U of regular insulin per kilogram of body weight intravenously as an initial bolus, followed by a continuous intravenous infusion of about 0.1 U/kg/h. This therapy is stopped when the blood glucose concentration has fallen to about 250 mg/dL or the osmolarity has reached 315 mOsmol/kg water.¹⁰ At this point, 5% dextrose should be added to the infusion to avoid hypoglycemia. Another suggested insulin regimen is 14 to 20 U of regular insulin intramuscularly, followed by 5 U intramuscularly every hour until the blood glucose level is about 300 mg/dL.¹⁷

If fluid resuscitation does not improve the urine output, treatment with furosemide should be initiated after making certain that fluid volume has been restored. Initial management may also involve empiric phosphate repletion, anticoagulation with subcutaneous heparin, and broad-spectrum antibiotic prophylaxis.^{13,15,17}

DISPOSITION

All patients with HHNC should be admitted to an intensive care setting. Because of the need for immediate and closely monitored treatment for at least the first 24 hours, it is usually preferable to avoid transfer to another facility until after fluid deficits and hyperosmolarity have been corrected and treatment for any serious underlying illness has been initiated.

COMMON PITFALLS

- Measuring the blood glucose level in all patients with new neurologic abnormalities will avoid a misdiagnosis of cerebrovascular accident and a potentially lethal delay in proper treatment.
- Because there is at least a theoretical concern that treatment of HHNC with hypotonic fluids can cause cerebral edema, it is safest to initiate therapy with normal saline while monitoring central venous pressure.^{11,13,17}

- Giving insulin before fluid deficits are restored may decrease the hypertonicity of the extracellular fluid abruptly and place the patient at risk for cerebral edema, systemic hypoperfusion, and cerebral infarction.^{1,5} Initial therapy should be consistent with the degree of hyperglycemia and the calculated effective osmolarity. Iatrogenic hypokalemia may result from insulin therapy if potassium replacement is not adequate and the serum potassium level carefully monitored.^{9,17}
- Phenytoin should not be used in treating seizures associated with HHNC. It is ineffective in this setting and inhibits the release of endogenous insulin.¹⁷

Diabetes mellitus currently affects approximately 16 million Americans, and this number is likely to reach 20 million by the year 2010. It is a disproportionately expensive disease; patients diagnosed with diabetes accounted for 4.6% of the United States population, yet were responsible for 14.6% of all direct care expenditures in 1994. This chapter focuses on the emergency department evaluation and treatment of the acute and chronic complications of diabetes other than those directly associated with hypoglycemia and severe metabolic disturbances.

Diabetes is a chronic disease that requires long-term medical attention to limit the development of its devastating complications and to manage them when they do occur. Approximately 90% of diabetics have type 2 (or ketosis-resistant) diabetes (DM2), and the remainder have type 1 (ketosis-prone) diabetes (DM1). Although the frequency of the acute and chronic complications of diabetes differs between the two types of patient, both groups are at risk for the microvascular, macrovascular, and neuropathic complications of diabetes.

Microvascular complications of diabetes include retinopathy and nephropathy. Macrovascular complications are peripheral vascular, cerebrovascular, and coronary artery disease. Hypertension eventually occurs in approximately 50% of diabetic patients. Chronic, poorly controlled hyperglycemia, in addition to the metabolic consequences associated with glycosuria, can lead to impaired immune function and delayed wound healing. The development of complications is related to the duration of diabetes and the degree of glycemic control.

EMERGENCY DEPARTMENT EVALUATION

A diabetes-related history is important in assessing any patient with diabetes who presents to an emergency department. The first fact to be determined is which type of diabetes the patient has ([Table 168.1](#)). DM1 generally occurs in younger, lean patients and is characterized by the marked inability of the pancreas to secrete insulin. The distinguishing characteristic of a patient with DM1 is that if insulin is withdrawn, ketosis, and eventually ketoacidosis, develops. These patients are therefore insulin-dependent (i.e., insulin is life-sustaining), because they produce no endogenous insulin.

Characteristic	Type 1 Diabetes (DM1)	Type 2 Diabetes (DM2)
Synonyms	Insulin-dependent diabetes, IDDM	NIDDM
Age at onset	Usually <30 yr; sometimes in older adults	Usually >40 yr; sometimes in younger persons, even children
Genetic predisposition	Moderate; requires environmental factors for expression; only 10% of identical twins develop DM1 if one sibling affected	Strong; 80%–90% of identical twins develop DM2 if one sibling is affected; more common among Native Americans, Hispanics, African Americans
Precipitating factors	Insulin secretion trigger; precipitating autoimmune response	Obesity, age
Findings at diagnosis	80% C-peptide at diagnosis	Most patients had asymptomatic diabetes for 4–7 yr prior to "diagnosis"
Endogenous insulin levels	Very low to none	Present
Insulin resistance	Only present when blood glucose levels high	Almost always present
Response to prolonged fast	Hypoglycemia, ketonuria	Normal blood glucose levels
Response to stress, withdrawal of insulin	Ketosis	Hypoglycemia without ketosis
Response to diet alone	Negative	Always present to some degree
Response to sulfonylurea agents	Absent	Present

IDDM, insulin-dependent diabetes mellitus; NIDDM, noninsulin-dependent diabetes mellitus; C-peptide, C-peptide.

TABLE 168.1. Metabolic and Clinical Characteristics of the Two Major Types of Diabetes Mellitus

DM2 typically occurs in older (greater than 40 years of age) patients who have a family history of diabetes. Patients who develop DM2 have a genetic predisposition to do so and develop peripheral insulin resistance along with insufficient pancreatic b-cell secretion of insulin. Most patients (90%) who develop DM2 are obese, and obesity itself is associated with insulin resistance, which further worsens the diabetic state. Because patients with DM2 retain the ability to secrete some endogenous insulin, those who take insulin rarely develop diabetic ketoacidosis (DKA) when insulin is stopped. Therefore, they are considered insulin-requiring, not insulin-dependent. Moreover, patients with DM2 often do not require treatment with oral antidiabetic medication or insulin if they lose weight or do not eat.

Previously, differentiating between the two types of diabetes was relatively straightforward: If patients developed diabetes in childhood, especially if accompanied by DKA, they were considered to have DM1. Now, however, some patients are developing DM2 at younger ages (sometimes as young as age 6 or 7), and, to make matters more confusing, some present in DKA only to ultimately be controlled on diet or oral antidiabetic agents. Conversely, 30% of patients presenting with new-onset DM1 are more than 30 years old. Defining the type of diabetes can, therefore, be challenging, but a good clinical history often allows one to make the distinction. A lean Caucasian patient without a family history of diabetes who developed diabetes in childhood is likely to have DM1. A history of DKA or the presence of significant ketosis (greater than trace positive urine ketones) at the time of diagnosis of diabetes helps to identify DM1.

A strong family history of DM2, obesity, and Hispanic, African-American, or Native-American heritage all make the diagnosis of type 2 diabetes more likely, regardless of age. Patients who require insulin after a several-year history of treatment with oral agents are much more likely to have DM2. However, no definitive test exists for differentiating between the two types.

The duration of the diagnosis of diabetes is important also, because the chronic complications of diabetes are related to the length of time the patient has had the disease. Patients with DM2 have often had diabetes for 5 to 7 years before the diagnosis is made, however, and can present with the complications of diabetes at the time of diagnosis.¹⁷

Patients should be asked if they self-monitor their blood glucose levels, what their usual blood glucose levels are, and what the recent values have been. Patients should be asked about the types and doses of their diabetes medications. A sense of patients' level of knowledge about managing their diabetes is useful, as is a sense of their degree of compliance with diet and medications. The date and value of the most recent glycosylated hemoglobin determination is a useful indicator of both the quality of glycemic control and the patients' monitoring of their disease.

Symptoms of hypoglycemia and hyperglycemia (polyuria, polydipsia, nocturia, weight loss) should be elicited, with their time course and severity.

Although complications are often diagnosed by physical examination or by laboratory testing, the presence of known complications of diabetes should also be assessed in the patient history. Specifically, a history of retinopathy, nephropathy, vasculopathy (hypertension and coronary, peripheral, and cerebrovascular

disease), neuropathy, or diabetic foot complications (ulcers and amputations) should be sought.

A diabetes-focused physical examination includes the following components: vital signs, funduscopic examination, limited vascular and neurologic examinations, and a foot assessment. Other organ systems should be examined as indicated by the patient's clinical situation.

Vital signs are useful for several reasons. Obviously, it is important to note whether the patient has hypertension or hypotension. Orthostatic vital signs may be useful in assessing volume status, as well as in suggesting the presence of an autonomic neuropathy. If the respiratory rate and pattern suggest Kussmaul respiration, DKA must be immediately considered and appropriate tests ordered.

The funduscopic examination should include a careful view of the retina, including both the optic disc and the macula. If hemorrhages or exudates are seen, the patient should be seen by an ophthalmologist as soon as possible, because nonophthalmologists tend to underestimate the severity of retinopathy, especially if the pupils have not been dilated.

The dorsalis pedis and posterior tibialis pulses should be palpated and their presence or absence noted. This is particularly important among patients with foot infection, because poor lower extremity blood flow can delay healing and increase the risk of amputation.

Documenting lower extremity sensory neuropathy is useful among patients who present with foot ulcers, because decreased sensation limits the patient's ability to protect the feet and ankles. If peripheral neuropathy is found, the patient should be made aware that foot care (including daily foot examinations) is very important for the prevention of foot ulcers and possible subsequent lower extremity amputation.

Diabetes Medications

In addition to sulfonylurea agents and insulin, a variety of new drugs have become available for the treatment of DM2.³⁰ These drugs allow for the use of combination oral therapy, often with improvement in glycemic control. The sulfonylurea agents (e.g., glyburide and glipizide) and meglitinides (e.g., repaglinide) increase insulin secretion. Their most common serious adverse reaction is hypoglycemia. The biguanides (e.g., metformin) decrease hepatic glucose production and insulin resistance. These drugs commonly cause gastrointestinal symptoms such as nausea, abdominal cramping, and diarrhea. Rarely, they can cause severe lactic acidosis, especially among patients with renal insufficiency. The α -glucosidase inhibitors (e.g., acarbose and miglitol) decrease intestinal absorption of carbohydrate, often producing flatulence and, rarely, causing small bowel obstruction. The newest class of drugs are the thiazolidinediones (troglitazone, rosiglitazone, and pioglitazone), which act as insulin sensitizers. Troglitazone has been associated with hepatotoxicity that is usually reversible but has resulted in fulminant hepatic failure. Patients on troglitazone should have monthly measurements of liver enzymes for the first year of use, and the medication should be stopped if transaminases exceed three times the upper limits of normal.

Abnormalities Caused by Hyperglycemia

Acute hyperglycemia, even when not associated with DKA or the hyperglycemic nonketotic syndrome (HNKS), is harmful for a number of reasons. If the blood glucose level exceeds the renal threshold for glucose (greater than 240 mg/dL in a healthy person, but diminished with advancing age, renal insufficiency, and pregnancy), an osmotic diuresis ensues, with loss of glucose, electrolytes, and water. Hyperglycemia impairs leukocyte function through a variety of mechanisms.²² Patients with diabetes have an increased rate of wound infection,⁸ and hyperglycemia may also independently impair wound healing.

Chronic hyperglycemia is associated with an increased risk for the development of the microvascular and neuropathic complications of diabetes, as elegantly demonstrated in the Diabetes Control and Complications Trial (DCCT) for DM1¹² and the United Kingdom Prospective Diabetes Study (UKPDS) for DM2.^{25,26} In the DCCT, intensive therapy designed to maintain normal blood glucose levels greatly reduced the development and progression of retinopathy, microalbuminuria, proteinuria, and neuropathy as assessed over a 7-year period. Intensive therapy was not associated with increased mortality or major macrovascular events and did not decrease the quality of life, although it did increase the likelihood of severe hypoglycemic episodes. In the UKPDS, aggressive treatment of blood glucose levels and hypertension was shown to decrease the risk of microvascular complications in patients with DM2.

Among patients with known diabetes that is poorly controlled, there is no absolute level of blood glucose elevation that necessitates admission to the hospital or the administration of insulin. Patients with DM1 who cannot tolerate oral fluids require hospitalization. Likewise, if the patient is severely symptomatic or the precipitating cause of hyperglycemia cannot be adequately treated in the emergency department, the patient needs to be admitted. Generally, lowering the blood glucose level in the emergency department does not correct the underlying cause of hyperglycemia and has no long-term impact on the patient's blood glucose levels. Therefore, a plan must be formulated as to how the patient's blood glucose level will be lowered and how it will subsequently be monitored. The adequacy of follow-up is an extremely important consideration. Whether to give insulin in the emergency department is of lesser consequence and can be decided on an individual basis.

EMERGENCY DEPARTMENT MANAGEMENT

New-Onset Diabetes

Most patients with diabetes have DM2, and most of those are asymptomatic at diagnosis. The initial treatment for patients with newly discovered, asymptomatic diabetes is a trial of diet therapy. Therefore, if an asymptomatic patient is noted incidentally to have an elevated blood glucose level in the emergency department, this can be followed up by the patient's outpatient physician. Patients who have mild-to-moderate symptoms of poorly controlled diabetes but have not previously been diagnosed can usually be treated on an outpatient basis, often with the initiation of low-dose oral antidiabetic agent therapy.

Controversy exists over the management of markedly symptomatic patients with newly discovered DM2 and blood glucose levels over 400 mg/dL. If close follow-up can be arranged, these patients can be started on maximal doses of a sulfonylurea agent and treated as outpatients. Generally, the patient feels better within 1 to 2 days, and, within a week, the blood glucose levels are markedly lower. These patients can often have their sulfonylurea agent dose tapered as they comply with diet therapy, and, in some cases, diabetes can subsequently be controlled by diet alone. However, patients who cannot drink adequate amounts of fluid, who have serious coexisting medical conditions (e.g., myocardial infarction [MI] or systemic infection), or who do not have reliable follow-up should generally be hospitalized for initiation of therapy.

Patients with new-onset DM1 need to be started on lifelong insulin therapy. Many present in DKA. An occasional patient with new-onset DM1 who presents with mild manifestations and is judged to be very compliant can begin on insulin as an outpatient. This kind of treatment, however, requires close follow-up and the capability to provide immediate and thorough education concerning the use of insulin; the signs, symptoms, and treatment of hypoglycemia; and self-monitoring of blood glucose levels.

Management of Hyperglycemia during Medical Illness and Surgery

Serious medical illness and surgery produce a state of increased insulin resistance and relative insulin deficiency. Hyperglycemia can occur, even in nondiabetic patients, because of stress-induced insulin resistance plus the administration of dextrose-containing intravenous fluids.^{3,18,22} Increases of glucagon, catecholamines, cortisol, and growth hormone antagonize the effects of insulin, and insulin secretion is itself inhibited by the α -adrenergic effect of increased catecholamine levels. The counterregulatory hormones also directly increase hepatic gluconeogenesis.

To maintain normal blood glucose levels, treatment regimens must be modified to compensate for both the decreased caloric intake and increased physiologic stress. Near-normal blood glucose levels should be maintained in medical and surgical patients with diabetes for four basic reasons:

1. To prevent the development of ketosis in patients with DM1
2. To prevent electrolyte abnormalities and volume depletion secondary to osmotic diuresis
3. To prevent the development of impaired leukocyte function that occurs when blood glucose levels are elevated
4. To prevent the impaired wound healing that occurs when blood glucose levels are elevated

A variety of approaches have been described for the management of patients with diabetes who undergo surgery^{18,22} or are otherwise unable to maintain oral caloric

intake. Patients with DM1 must have insulin and carbohydrate given at all times to prevent the development of ketosis. For seriously ill patients and those undergoing general anesthesia, the optimal regimen involves continuous intravenous infusions of dextrose and insulin. This technique requires that the blood glucose level be measured with a glucose meter every hour, and that the insulin and dextrose infusion rates be adjusted accordingly to prevent hypoglycemia or persistent hyperglycemia (Table 168.2).

A. Start infusion of a solution containing 5% dextrose at a rate of 125 mL/h.

B. Start intravenous insulin infusion as follows:

Whole Blood Glucose (mg/dL)	Insulin Infusion Rate (U/h)
<100	None
101-150	1
151-200	2
201-300	3
>350	4*

C. Measure blood glucose level with a glucose meter every 2 hours before and after surgery and hourly during surgery.

a. Do not change insulin infusion rate if blood glucose level ranges between 100 and 300 mg/dL.

b. Increase insulin infusion rate by 0.5 U/h if blood glucose level is >180 mg/dL.

c. Hold dextrose infusion if blood glucose level >350 mg/dL. Restart once blood glucose level <250 mg/dL.

d. Decrease insulin infusion rate by 0.5 U/h if blood glucose level is <100 mg/dL, and increase dextrose infusion rate by 50 mL/h. Once blood glucose level increases to >100 mg/dL, decrease dextrose infusion rate back to 125 mL/h.

*Dextrose infusion is held until blood glucose level <200 mg/dL.
From Peters AL. Prevention and treatment of glucose emergencies. *Intensiv Diabetol*. Munich: Elsevier; 1993:1042.

TABLE 168.2. Suggested Intravenous Insulin Infusion Adjustment during Surgery

Frequent blood glucose monitoring is not always possible for every patient, and patients with less serious illness or those undergoing minor surgery may do just as well with subcutaneously injected insulin. In patients going to surgery who have not received a dose of intermediate-acting insulin that day, an injection of half of the patient's total daily dose as NPH insulin before surgery is often effective. At the same time, an intravenous infusion containing 5% dextrose should be started at a rate of 125 mL/h. Blood glucose levels should be checked every 2 hours during surgery, and small doses of regular or lispro (Humalog) insulin given if values are greater than 250 mg/dL.

The same principles of providing a constant source of insulin and carbohydrate apply to patients with DM1 who are not going to surgery but who must remain NPO due to other medical reasons. One approach is to give sliding-scale regular insulin every 4 hours, the dose based on the patient's blood glucose level. To avoid hypoglycemia, the regular insulin should not be given more frequently than every 3 to 4 hours, because the previous dose will peak in 2 to 4 hours and last up to 6 hours. Lispro insulin can be given every 3 hours.

Patients with DM2 who are on insulin can follow similar guidelines. However, because patients with DM2 secrete some endogenous insulin and do not develop ketosis, they can often be managed for brief periods without either insulin or dextrose. However, if the blood glucose is less than 80 mg/dL, or more than 250 mg/dL, appropriate treatment is required.

Patients who have been taking sulfonylurea agents or other oral antidiabetic agents should have their blood glucose levels monitored when oral intake is not allowed, and intravenous dextrose with or without insulin should be given to keep blood glucose levels between 100 and 250 mg/dL.

The presence of cardiovascular disease and renal dysfunction increases surgical morbidity and mortality in patients with and without diabetes.²⁹ In addition, diabetic autonomic neuropathy increases the likelihood of cardiovascular instability.⁵ The emergency physician caring for the diabetic patient who requires emergent surgery must notify the surgeon and the anesthesiologist of the patient's condition, obtain medical consultation when appropriate, and promptly initiate a thorough medical evaluation so as not to delay surgery.

Acute Disturbances

Infections

Infections cause considerable morbidity and mortality among patients with diabetes. Infections may precipitate metabolic derangements, and, conversely, the metabolic derangements of diabetes may facilitate infection. Depending on the population studied, infections have been identified as the precipitant in 26% to 77% of cases of DKA.⁶ A few infections, such as malignant otitis externa, rhinocerebral mucormycosis, and emphysematous pyelonephritis, occur almost exclusively in patients with diabetes. Certain infections, such as staphylococcal sepsis, occur more frequently and result in greater mortality among patients with diabetes, while others, such as pneumococcal pneumonia, affect diabetic patients no differently than the general population.

Although diabetes can compromise all aspects of host defenses against infection, all diabetic patients are nevertheless not equally susceptible to infection. Impairments in humoral immunity and polymorphonuclear leukocyte and lymphocyte function^{3,22} are exacerbated by hyperglycemia and acidemia but are substantially, if not entirely, reversed by normalization of pH and blood glucose levels. Although the exact level above which impaired leukocyte function occurs has not been well defined, *in vitro* evidence suggests that glucose levels above 250 mg/dL impair leukocyte function.²

Patients with long-standing diabetes also tend to develop microvascular and macrovascular disease, with resulting poor tissue perfusion and an increased risk of infection. The ability of skin to act as a barrier to infection may also be compromised when the diminished sensation of diabetic neuropathy results in unnoticed injury.

Ear, Nose, and Throat Infections. Two head and neck infections that are associated with high morbidity and mortality, malignant otitis externa and rhinocerebral mucormycosis, are seen almost exclusively in diabetic patients.

Malignant or necrotizing otitis externa principally occurs in diabetic patients older than 35 years of age and is almost always caused by *Pseudomonas aeruginosa*. The infection starts in the external auditory canal and spreads to the adjacent soft tissue, cartilage, and bone. Patients typically present with severe ear pain and otorrhea; and although they often have a preexisting otitis externa, the progression to invasive disease is usually rapid. Examination of the auditory canal may reveal granulation tissue, but spread of infection to the pinna, the preauricular tissue, and the mastoid often makes the diagnosis apparent. Involvement of cranial nerves, particularly the facial nerve, is common; when there is extension to the meninges, the outcome is often fatal. Computed tomography (CT) is useful to define the extent of disease.

Prompt surgical consultation is mandatory for malignant otitis externa, because surgical debridement is often an essential part of therapy. Intravenous antipseudomonal antibiotic therapy should be started at once in patients with invasive disease. Diabetic patients with severe otitis externa but no evidence of invasive disease can be treated with an otic antibiotic drop and oral ciprofloxacin, but they require close follow-up.

Mucormycosis is the name given collectively to the infections caused by various ubiquitous molds. Invasive disease occurs in poorly controlled diabetic patients, especially in conjunction with DKA. In these patients, the organism colonizes the nose and paranasal sinuses, spreading into adjacent tissues by invading blood vessels and causing soft-tissue necrosis and bony erosion. Patients usually present with periorbital or perinasal pain and various degrees of swelling and induration. There may be a bloody nasal discharge. Involvement of the orbits, with lid swelling, proptosis, and diplopia, is common. The nasal turbinates may appear dusky red or frankly necrotic. The appearance of black necrotic tissue is an important visual clue. As the illness progresses, there is invasion of the cranial vault through the cribriform plate, which may result in cerebral abscess, cavernous sinus thrombosis, or internal carotid artery thrombosis. Wet smears of the necrotic tissue often reveal broad hyphae and distinguish mucormycosis from a severe facial cellulitis.

CT helps to delineate the extent of disease. Treatment consists of control of the predisposing hyperglycemia and acidemia, intravenous amphotericin B, and immediate surgical debridement. Until the diagnosis is confirmed, treatment with antistaphylococcal antibiotics is appropriate.

Urinary Tract Infection. Patients with diabetes have an increased risk for cystitis and, more importantly, for serious upper urinary tract infection. Intrarenal bacterial

infection should be considered in the differential diagnosis of any patient with diabetes who presents with flank or abdominal pain.

The treatment of cystitis is essentially the same as in nondiabetic patients, although individuals with a neurogenic bladder due to diabetic neuropathy may not empty the bladder well and may require urologic referral. Sulfonamide antibiotics can cause hypoglycemia among patients taking sulfonylurea agents by displacing the sulfonylurea agents from their binding sites and increasing their hypoglycemic effect.

The principles of treatment of pyelonephritis do not differ for diabetic patients, but a lower threshold for hospital admission is appropriate for at least two reasons. First, pyelonephritis makes control of diabetes more difficult by causing insulin resistance; in addition, nausea may limit the patient's ability to maintain normal hydration. The ensuing hyperglycemia further compromises the immune response. Second, diabetic patients are more susceptible to the complications of pyelonephritis, including renal abscess, emphysematous pyelonephritis, renal papillary necrosis, and gram-negative sepsis.

In one series, 36 of 52 patients with renal abscess had diabetes, and more than 70% of cases of emphysematous pyelonephritis occur in patients with diabetes.⁷ The latter is an uncommon necrotizing infection of the kidney caused by *Escherichia coli*, *Klebsiella pneumoniae*, or other organisms capable of fermenting glucose to carbon dioxide. The presentation is usually similar to that of uncomplicated pyelonephritis. The diagnosis is established by identifying renal gas on plain radiography, ultrasonography, or noncontrast helical CT urography, and surgical intervention is indicated once the diagnosis is made.

Skin and Soft-Tissue Infection. Sensory neuropathy, atherosclerotic vascular disease, and hyperglycemia all predispose diabetic patients to skin and soft-tissue infections. These can affect any skin surface but most commonly involve the feet. Even the smallest wound can be complicated by cellulitis, lymphangitis, and, more ominously, staphylococcal sepsis. Minor wound infections and cellulitis are typically caused by *Staphylococcus aureus* or hemolytic streptococci and can be treated with a penicillinase-resistant synthetic penicillin or a first-generation cephalosporin.¹⁵

Outpatient treatment of minor infections is appropriate if the patient is reliable, performs self-monitoring of blood glucose levels (and urine ketones for DM1 patients), and has close follow-up available. Wounds and, in particular, cutaneous ulcers can also be complicated by necrotizing infections of the skin, subcutaneous tissues, fascia, or muscle. These infections are typically polymicrobial, involving group A streptococci, enterococci, *S. aureus*, Enterobacteriaceae, and various anaerobes. Radiographs should be taken of any spreading soft-tissue infection in a diabetic patient to look for the soft-tissue gas that characterizes these infections. Surgical debridement is necessary for necrotizing infections. Gram stains and surface cultures are not helpful; antibiotic coverage should reflect the range of potential pathogens.

Osteomyelitis. Contiguous spread of a polymicrobial infection from skin ulcer to adjacent bone is common in diabetic patients. In one study, osteomyelitis was found underlying 68% of diabetic foot ulcers, and physical examination and plain radiographs each failed to make the diagnosis in one half of patients.²¹ Unfortunately, these are typically the only diagnostic modalities available in the emergency department, and, often, the diagnosis is suspected but cannot be established. If osteomyelitis is apparent by radiograph or physical examination (e.g., if wounds are deep enough to expose tendons or bone), the patient should be admitted for intravenous administration of antibiotics. If osteomyelitis is suspected but admission is not necessitated by the soft-tissue infection or metabolic disturbances, the patient can be discharged to have an outpatient workup.

Other Infections. Although cholecystitis is probably no more common in patients with diabetes than in the general population, severe fulminating infection, especially with gas-forming organisms, is. The early clinical manifestations of emphysematous cholecystitis are indistinguishable from those of usual cholecystitis. The diagnosis can be made by finding gas in the gallbladder lumen, wall, or surrounding tissues. Even with immediate surgery, mortality is high. Clostridial species are found in over 50% of cases.

Diabetic patients have a greater incidence of staphylococcal and *Klebsiella pneumoniae* than do persons without diabetes. Diabetes is also a risk factor for reactivation of tuberculosis. Cryptococcal infections and coccidioidomycoses are more virulent in diabetic patients.

Ophthalmologic Abnormalities

Diabetes is the leading cause of blindness in the United States; therefore, visual complaints by diabetic patients should be taken very seriously. Diabetes can affect the lens, the vitreous, and the retina, causing visual symptoms that may prompt the patient to come to the emergency department. Visual blurring may develop acutely as the lens changes shape with marked changes in blood glucose concentrations.⁹ This effect, which is caused by osmotic fluxes of water into and out of the lens as the blood glucose concentration varies, usually occurs as hyperglycemia increases, but it may also be seen when high blood glucose levels are lowered rapidly. In either case, recovery to baseline visual acuity can take up to a month, and some patients are almost completely unable to read small print or do close-up work during this period.

Rarely, patients with DM1 who are in extremely poor control (e.g., those with frequent episodes of DKA) can acutely develop a "snowflake" (or "metabolic") cataract. Named for their snowflake or flocculent appearance, these cataracts can progress rapidly and create total opacification of the lens within a few days. Surgery is often required to restore vision. Patients with diabetes also tend to develop senile cataracts at a younger age than do persons without diabetes, although not in relation to the degree of glycemic control.

Some degree of diabetic retinopathy can be expected to develop in more than 90% of patients with DM1 and in 40% to 60% of patients with DM2 who have had the disease for 15 years or more. Patients with DM2 may already have diabetic retinopathy at the time their diabetes is diagnosed.¹⁷ There are five stages in the progression of diabetic retinopathy:

1. Dilation of the renal venules and formation of retinal capillary microaneurysms
2. Increased vascular permeability
3. Vascular occlusion and renal ischemia
4. Proliferation of new blood vessels on the surface of the retina
5. Hemorrhage and contraction of the fibrovascular proliferation and the vitreous

Patients with DM2 do not develop proliferative retinopathy as often as those with DM1.

The first two stages of diabetic retinopathy are known as "background" or nonproliferative retinopathy. Initially, there is dilatation of the renal venules, followed by the appearance of microaneurysms, which appear as tiny red dots on the retina and cause no visual impairment. However, as the microaneurysms or retinal capillaries become more permeable, hard exudates appear, reflecting the leakage of plasma. These are sharply defined yellow deposits composed mostly of lipid material. Rupture of intraretinal capillaries results in hemorrhage. If these ruptures occur deep in the retina, they appear as "dot blot" hemorrhages that can be difficult to distinguish from microaneurysms. If a more superficial capillary ruptures, a flame-shaped hemorrhage appears. Hard exudates are often found in partial or complete rings (circinate pattern), which usually include multiple microaneurysms. These rings usually mark an area of edematous retina.

Many patients with macular edema are unaware of its presence. No change in visual acuity may be noted by the patient, unless the center of the macula is involved. Macular edema can cause visual loss, however, so it is extremely important to refer patients with suspected macular edema to an ophthalmologist for evaluation and possible laser therapy. Laser therapy is very effective in decreasing macular edema and preserving vision, but it is less effective in restoring vision once it is lost.

Preproliferative and proliferative diabetic retinopathy are the next stages in the progression of the disease. Cotton-wool spots can be seen in preproliferative retinopathy. These represent retinal microinfarcts due to capillary occlusion and are off-white to gray patches with poorly defined margins.

Proliferative retinopathy is characterized by neovascularization, the development of networks of fragile new vessels that are often seen on the optic disc or along the main vascular arcades. The vessels undergo cycles of proliferation and regression. During proliferation, fibrous adhesions develop between the vessels and the vitreous. Subsequent contraction of the adhesions can result in traction on the retina and retinal detachment. Contraction also tears the fragile new vessels, which hemorrhage into the vitreous.

Often, the first hemorrhage is small and is noted by the patient as a fleeting, dark area, or "floater," in the field of vision. Because subsequent hemorrhages can be larger and more serious, the patient should be referred immediately to an ophthalmologist for possible laser therapy. Patients with retinal hemorrhage should be

advised to limit their activity and keep their head upright (even while sleeping), so that the blood settles to the inferior portion of the retina, thus obscuring less central vision.

Patients with active proliferative diabetic retinopathy are at increased risk for retinal hemorrhage if they receive thrombolytic therapy, so this is a relative contraindication to the use of thrombolytic agents.

Diabetic Nephropathy

Diabetic nephropathy occurs eventually in 30% to 40% of patients with DM1 (and, although less well studied, probably occurs with the same prevalence in patients with DM2).²⁸ All patients with diabetes should be considered to have the potential for renal impairment unless proven otherwise. Thus, extreme care should be exercised when using any nephrotoxic agent in a patient with diabetes. The use of contrast media can precipitate acute renal failure in patients with underlying diabetic nephropathy, and, although most recover within 10 days, some develop irreversible renal failure. Patients with diabetes who must undergo contrast medium-enhanced studies should be well hydrated before, during, and after the procedure and should have careful monitoring of renal function.²⁹ A better solution is to get equivalent clinical information by using an alternative study that does not require contrast medium administration (e.g., ultrasonography or noncontrast helical CT urography).

Potentially nephrotoxic drugs should be avoided whenever possible. Renally excreted or potentially nephrotoxic drugs should be given at reduced dosage as appropriate to the patient's serum creatinine level or creatinine clearance.

Because chronic blood pressure elevation contributes to the decline in renal function, it is extremely important that patients with diabetes who are found to be hypertensive be referred for chronic blood pressure management. If antihypertensive therapy is to be started in the emergency department, an angiotensin converting enzyme (ACE) inhibitor is a good choice,¹⁹ because these agents have been found to reduce the rate of decline in renal function, independent of their effect on blood pressure. They also decrease proteinuria among patients with diabetic nephropathy. It should be kept in mind, however, that ACE inhibitors tend to increase the serum potassium level and should thus be used with caution in patients with renal serum insufficiency or somewhat elevated serum potassium levels.

Diabetic Neuropathy

Diabetic neuropathy is common. Distal symmetric sensorimotor polyneuropathy (in a "glove and stocking" distribution) is the most frequent pattern.²⁷ In addition to the pain often experienced in its early stages, this type of neuropathy eventually leads to loss of sensation. The combination of decreased sensation and peripheral arterial insufficiency often leads to foot ulceration and eventual amputation.

A variety of acute-onset neuropathies occur in diabetic patients, including acute cranial mononeuropathies, mononeuropathy multiplex, focal lesions of the lumbosacral plexus, and radiculopathies. Among cranial neuropathies, third oculomotor nerve palsy is the most common, followed by sixth (abducens) and fourth (trochlear) nerve palsies. All can present with diplopia and eye pain. In diabetic third-nerve palsy, the pupil is usually spared, whereas in third-nerve palsy due to intracranial aneurysm or tumor, the pupil is affected in 80% to 90% of cases. It is important to consider nondiabetic causes for cranial nerve palsies, because 42% have been found to be due to causes other than diabetes. Evaluation should therefore include either nonenhanced and contrast medium-enhanced CT or magnetic resonance imaging of the optic nerve. Neurologic consultation is generally recommended. Acute cranial nerve mononeuropathies usually resolve within 2 to 9 months. These neuropathies are thought to be caused by acute thrombosis or ischemia of the blood vessels supplying the nervous system structure involved.

Autonomic dysfunction can involve any part of the sympathetic or parasympathetic chains and produces myriad manifestations. Patients likely to seek care in the emergency department include those with diabetic gastroparesis and vomiting, those with severe diarrhea, and those with bladder dysfunction and urinary retention. Symptoms tend to wax and wane over time. Treatment is only symptomatic. Patients with gastroparesis may benefit from the use of metoclopramide, cisapride, or erythromycin. Alleviating the functional abnormalities associated with the autonomic neuropathy is often difficult and frustrating for both doctor and patient. The patient's primary physician, and often an appropriate subspecialist, should be involved in devising a long-term treatment plan.

The Diabetic Foot

Fifty percent to 70% of all nontraumatic lower extremity amputations occur in diabetic patients.⁴ At one clinic, however, the rate of amputation was halved after the institution of a program that ensured that patients removed their shoes for a foot examination at every clinic visit.⁴ Although foot care is a lifelong challenge for the diabetic patient, the emergency physician can play an important role in this process. This is most obvious in the case of the acutely injured or infected limb, but extends to the recognition of feet at risk and appropriate referral for podiatric care.

The insensate, poorly perfused foot is at risk for ulcers from pressure necrosis or inflammation from repeated skin stress and unnoticed minor trauma. Either can evolve into cellulitis, osteomyelitis, or nonclostridial gangrene and end in amputation.

Wounds, infections, or ulcers of the feet demand particular attention in the diabetic patient. In addition to appropriate use of antibiotics, it is mandatory to avoid further trauma to the healing foot through use of crutches, a wheel chair, or bed rest. If bone or tendon is visible, osteomyelitis is present, and hospitalization for intravenous antibiotics is often necessary. Many patients need a vascular evaluation in conjunction with local treatment of the foot ulcer, because, in some cases, a revascularization procedure may be required to provide adequate blood flow for wound healing. For patients who may be discharged, every attempt should be made to ensure frequent follow-up or, if necessary, home nursing visits. If such follow-up is not available, hospitalization may be necessary for initial treatment. Follow-up care by a podiatrist or an orthopedist with experience in the care of a diabetic foot is optimal.

Because curing ulcers and foot infections is so difficult, it is better to prevent them. The emergency physician can facilitate this by briefly inspecting the feet of each patient with diabetes and educating the patient about the need for proper foot care. Patients with distal sensory neuropathy to pinprick or light touch, decreased peripheral pulses, moderate-to-severe onychomycosis, or impending skin breakdown deserve referral to a podiatrist for foot care.

Macrovascular Complications

Macrovascular disease is the leading cause of death in patients with diabetes. It is responsible for approximately 75% of deaths in patients with diabetes, compared with approximately 35% of deaths in the general population.³¹ The presence of diabetes causes a twofold increase in MI in males and a fourfold increase in females that is in addition to the other known risk factors. The risk of stroke is doubled, and the risk of developing peripheral vascular disease is increased fourfold. Although the disease process itself is the same as in patients without diabetes, atherosclerosis develops earlier and follows a more malignant course among patients with diabetes. Patients with DM1 are predisposed to develop coronary artery disease at a younger age than are patients without diabetes; it is not rare for patients in their 30s and 40s to die of ischemic heart disease. Hypertension is twice as common among patients with DM2, which also increases the risk of atherosclerosis. *In fact, it has been shown that patients with DM2 who have never had an MI have the same risk of having an MI as nondiabetic patients who have had a prior MI.*¹⁶ Patients with diabetes must therefore have their hypertension and lipid abnormalities treated aggressively to lessen their risk of developing atherosclerotic vascular disease.

Patients with diabetes have been said to have an increased incidence of silent ischemia. However, silent ischemia is common in many patients with coronary artery disease, and the apparent higher incidence among patients with diabetes may simply be related to the fact that they are more likely to have coronary artery disease to begin with. Nevertheless, it is prudent to order an electrocardiogram on patients with diabetes who have a serious illness or who present with generalized weakness, malaise, or other nonspecific symptoms that are not generally expected to be due to myocardial ischemia.

COMMON PITFALLS

- Failure to provide patients who have DM1 with a continuous source of insulin and glucose when they are unable to receive oral intake
- Failure to keep the blood glucose levels of patients with wounds or active infections below 250 mg/dL, which leads to poor healing
- Underestimating the severity of diabetic retinopathy on fundoscopic examination through undilated pupils. Any patient with lesions near the macula should be referred urgently to an ophthalmologist.
- Failure to provide adequate hydration to patients with mild diabetic nephropathy before contrast material is given, precipitating acute renal failure
- Failure to examine the feet; overlooking small ulcers or underestimating their seriousness

- Failure to consider myocardial ischemia in patients with nonspecific symptoms

CHAPTER 169

Hypoglycemia

Scott R. Votey and Anne L. Peters

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Hypoglycemia is defined as a plasma glucose value less than 50 mg/dL, accompanied by signs and symptoms of adrenergic excess (sweating, nervousness, tachycardia, shakiness) or alterations in mental status, or both, that are relieved by the administration of carbohydrate. The glucose concentration at which clinical hypoglycemia occurs varies. Completely healthy women may have glucose levels less than 45 mg/dL during a fast without symptoms of hypoglycemia. Conversely, adrenergic symptoms of “hypoglycemia” may occur in patients without low blood glucose levels. Therefore, the diagnosis of hypoglycemia must be based on the presence of both biochemical hypoglycemia and concomitant hypoglycemic symptoms.

Although there are many causes of hypoglycemia, the vast majority of episodes encountered in the emergency department (ED) occurs as complications of the treatment of diabetes with insulin or an oral antidiabetic agent. Hypoglycemia is an important and growing concern for the approximately 16 million individuals with diabetes in the United States. The publication of the Diabetes Treatment and Control Trial (DCCT) ⁴ in 1993 and the United Kingdom Prospective Diabetes Study (UKPDS) ¹³ in 1998 have proven that tight control of blood glucose delays the development and progression of complications in patients with both type 1 and type 2 diabetes. From these has come a greater emphasis on maintaining euglycemia.

Unfortunately, tight control also increases the frequency of hypoglycemia, especially in patients treated with insulin. ⁵ Although mild episodes of hypoglycemia (defined as episodes recognized and treated by the patient) are not harmful and should not dissuade patients from adequately treating their diabetes, recurrent severe episodes (involving altered mentation and requiring assistance to treat) may be associated with progressive cognitive decline. ⁸ Goals for emergency physicians in the management of hypoglycemia are (1) recognition of each episode of hypoglycemia, (2) prompt and adequate treatment, (3) identification of the cause of the episode, and (4) establishment of a plan to prevent future episodes.

A balance between glucose utilization and production maintains normal blood glucose levels. In health, preprandial blood glucose levels are usually 70 to 100 mg/dL, with a small postprandial rise peaking 1 hour after eating and returning to baseline within 4 hours. The major glucose-requiring tissues are the brain, muscle, and red blood cells. During fasting, glucose production occurs through hepatic glycogenolysis (breakdown of glycogen) and gluconeogenesis. Insulin levels are high in the postprandial period and fall with fasting.

Glucoreceptors in the hypothalamus sense low blood glucose levels and cause the secretion of counterregulatory hormones. Glucagon is the primary counterregulatory hormone in nondiabetic patients. Patients with type 1 diabetes lose their glucagon response to hypoglycemia within the first 5 years of disease.

The onset of action of glucagon is rapid, and it acts by enhancing glycogenolysis and gluconeogenesis. If glucagon is not present, epinephrine serves as the major counterregulatory hormone. It also has a rapid onset of action, and acts by inhibiting glucose utilization by muscle, increasing gluconeogenesis, and inhibiting insulin secretion. Cortisol and growth hormone are secreted as part of normal hypoglycemic counterregulation, but their release is delayed and they do not contribute to the acute recovery from hypoglycemia.

CLINICAL PRESENTATION

The signs and symptoms of hypoglycemia fall into two categories: adrenergic (those caused by increased activity of the sympathetic autonomic nervous system) and neuroglycopenic (those caused by depressed activity of the central nervous system [CNS]) ([Table 169.1](#)). Although there is much individual variation, the adrenergic symptoms of hypoglycemia typically start at approximately 60 mg/dL, and evidence of neuroglycopenia occurs at approximately 50 mg/dL. Symptoms vary from person to person but, within an individual, remain fairly constant from episode to episode.

Adrenergic	Neuroglycopenia
Weakness	Headache
Tremor	Mental dullness
Sweating and warmth	Confusion
Tachycardia and palpitations	Amnesia
Nervousness	Incoordination
Irritability	Visual disturbances
Tingling of face and fingers	Seizures
Hunger	Coma
Nausea	Focal neurologic deficits

TABLE 169.1. Signs and Symptoms of Hypoglycemia

Not all patients experience the adrenergic symptoms of hypoglycemia. ⁷ Autonomic neuropathy, which occurs in more than 25% of patients with long-standing (more than 10 years) type 1 diabetes, can diminish adrenergic symptoms. ³ Patients who are chronically hypoglycemic, particularly patients with tightly controlled type 1 diabetes, accommodate to hypoglycemia and may not have adrenergic symptoms until the blood glucose is less than 50 mg/dL and neuroglycopenic symptoms develop. This phenomenon, termed *hypoglycemia-associated autonomic failure*, is the combined result of a downregulation of the adrenergic response to hypoglycemia, due to intensive insulin therapy or recent hypoglycemia, and autonomic dysfunction. Patients who lack adrenergic symptoms often fail to recognize impending hypoglycemia and are at increased risk for severe neuroglycopenia.

Because the CNS is almost entirely glucose-dependent for function, hypoglycemia manifests neurologically within minutes. Measurable cognitive deficits commonly begin at blood glucose levels less than 50 mg/dL, but some patients remain awake and alert at much lower levels. ⁹ Patients may fail to perceive their cognitive dysfunction and deny having any CNS symptoms. The blood glucose at which seizures occur varies, but a seizure at a glucose greater than 40 mg/dL should prompt investigation for an alternative cause. Focal neurologic deficits, including hemiparesis, are the presenting symptoms in a small percentage of patients.

Long-term cognitive deterioration is a function of the severity, duration, and number of hypoglycemic episodes. ⁸ Mild episodes consisting only of adrenergic symptoms do not result in CNS injury. Severe episodes, particularly those resulting in loss of consciousness or seizures, are damaging. Time to recovery and completeness of recovery depend on the severity and duration of hypoglycemia. Elderly patients and those with a history of prior CNS injury, such as a stroke, appear to be at higher risk for a prolonged or incomplete recovery.

DIFFERENTIAL DIAGNOSIS

Although chronic treatment of diabetes with insulin or a sulfonylurea agent is the root cause of the vast majority of hypoglycemic episodes encountered in the ED, there is invariably an acute precipitant perturbing the patient's usual glucose homeostasis. The key to preventing future hypoglycemic episodes is the identification

of the precipitant of the current episode. A good history is the principal tool in achieving this goal, and will identify the precipitant in approximately 50% of cases. Common precipitants can be grouped according to their physiologic mechanisms ([Table 169.2](#)). Inadequate glucose availability is the most commonly identified cause of hypoglycemia, followed by increased caloric utilization, medication error, and diminished excretion.

INADEQUATE GLUCOSE AVAILABILITY
Decreased caloric consumption: missed or delayed meal, fasting
Decreased hepatic gluconeogenesis: suppression by alcohol, hepatic failure
Insufficient counterregulatory hormones: glucagon, epinephrine, cortisol
INCREASED CALORIC UTILIZATION
Exercise
Illness and injury
MEDICATIONS: INCREASED INSULIN EFFECT
Accidental overdose: poor vision, misunderstanding, change in syringe size, change in insulin concentration, pharmacy error
Intentional overdose
MEDICATIONS: DIMINISHED EXCRETION OR METABOLISM
Renal insufficiency: insulin and sulfonylurea agents are renally excreted.
Hepatic failure: sulfonylureas undergo hepatic metabolism

TABLE 169.2. Precipitants of Hypoglycemia in Patients with Diabetes

Patients who take oral sulfonylurea agents can have prolonged periods of hypoglycemia (sometimes lasting up to a week) because of the long elimination half-life of many of these agents; this phenomenon occurs particularly in elderly patients and those with renal insufficiency or hepatic failure.¹² The possibility of declining renal function should be assessed in any patient who develops recurrent unexplained episodes of hypoglycemia while taking these agents. These individuals often require admission to the hospital, continuous intravenous administration of dextrose, and frequent blood glucose monitoring until blood glucose levels stabilize. In addition, even small doses of sulfonylurea agents may produce severe hypoglycemia in young children, and any sulfonylurea ingestion in this age group should be taken seriously.¹¹

Repaglinide (Prandin) is a new short-acting oral agent of the meglitinide class that, like the sulfonylurea agents, increases insulin secretion and may cause hypoglycemia. The hypoglycemia associated with repaglinide is expected to be of shorter duration than that caused by the sulfonylurea agents. On the other hand, metformin (Glucophage), the α -glucosidase inhibitors (acarbose [Precose], miglitol [Glyset]), and the thiazolidinediones (troglitazone [Rezulin], rosiglitazone [Avandia], and pioglitazone [Actose]) do not increase insulin secretion and rarely cause hypoglycemia when used alone. In combination with insulin or a sulfonylurea, however, these drugs may exacerbate an episode of hypoglycemia.

Some patients, particularly the elderly, are not aware that they are being treated for diabetes. Therefore, it is helpful to review all medications the patient is currently taking when investigating the cause of an unexplained episode of hypoglycemia. Surreptitious use of medication is a consideration in healthy-appearing patients with unexplained hypoglycemia, especially if it is severe or recurrent.

Aside from insulin and sulfonylurea agents, a number of other drugs can precipitate hypoglycemia, either at therapeutic doses or in overdose ([Table 169.3](#)). Patients taking β blockers are at increased risk for severe hypoglycemia both because of a blunted counterregulatory response and diminished adrenergic symptoms when hypoglycemia does develop. Salicylate overdoses occasionally precipitate hypoglycemia, particularly in children.

FASTING
Healthy-Appearing Individuals
Drugs
Exogenous insulin
Oral hypoglycemic agents: sulfonylurea agents, repaglinide
β -Adrenergic blocking agents
Salicylates
Disopyramide
Quinine
Fenfluramine
Others
Ethanol and other alcohols
Insulinomas and non- β -cell tumors
Inherited disorders of metabolism
Ill-Appearing Individuals
Hepatic failure: depleted glycogen stores and impaired gluconeogenesis
Renal failure
Adrenal insufficiency
Sepsis
Shock
Malnutrition, including anorexia nervosa
Congestive heart failure, especially severe right heart failure
Pregnancy
FEED (REACTIVE)
Impaired glucose tolerance
Alimentary
Idiopathic, reactive

TABLE 169.3. Selected Causes of Hypoglycemia

Many serious illnesses may result in hypoglycemia; the most common are renal failure, hepatic failure, malnutrition (including anorexia nervosa), and sepsis.⁶ Others include severe right heart failure and malignancy. The etiology is often multifactorial. Adrenal insufficiency itself rarely causes symptomatic hypoglycemia, but it may be a contributing factor during times of physiologic stress. Cortisol is necessary for gluconeogenesis, and, without it, glucose levels (especially fasting levels) fall (see [Chapter 172](#)).

Ethanol ingestion can precipitate hypoglycemia in patients with or without diabetes by suppressing gluconeogenesis, usually in association with inadequate intake of food. This phenomenon occurs most commonly in children, malnourished chronic alcoholics, binge drinkers, and diabetics who neglect to eat adequately when consuming alcohol.

Insulinomas are a rare cause of hypoglycemia. Patients with these tumors have recurrent episodes of hypoglycemia, typically presenting with neuroglycopenic rather than adrenergic symptoms; insulinomas often go undiagnosed for years. Weight gain from eating large amounts of food to self-treat the hypoglycemia is common. Non- β -cell tumors, including mesenchymal tumors, hepatocellular carcinomas, adrenal carcinomas, and others, can also produce hypoglycemia.

Newborns, especially premature infants, are at risk for hypoglycemia during times of physiologic stress due to small glycogen stores and limited hepatic gluconeogenesis. In addition, several inborn errors of metabolism can cause hypoglycemia in children. These include glucose-6-phosphatase deficiency, galactosemia, hereditary fructose intolerance, and carnitine deficiency. Inborn errors of metabolism usually present in the first year of life. Infants experiencing unexplained hypoglycemia should be hospitalized and evaluated for these disorders.

Although hypoglycemia occurs most commonly in the fasting state, there are several causes of fed or reactive hypoglycemia. Alimentary hypoglycemia occurs in patients who have undergone gastrointestinal surgery, most commonly gastrectomy. Patients have symptoms of hypoglycemia 30 to 120 minutes after eating. The hypoglycemia is thought to occur because of a more rapid emptying of food into the duodenum, leading to both an accelerated absorption of glucose and an exaggerated insulin response.

Some patients with “mild” diabetes, including patients treated with diet alone and those with risk factors for type 2 diabetes but who have not yet been diagnosed as having diabetes, experience postprandial hypoglycemia. The insulin response to food is initially delayed; the enhanced insulin secretion that follows produces postprandial hypoglycemia.

Idiopathic reactive hypoglycemia is a rare disorder that is substantially overdiagnosed, particularly in young women. In general, patients with this diagnosis have adrenergic symptoms on fasting or postprandially, but are rarely documented to have a glucose less than 50 mg/dL.

EMERGENCY DEPARTMENT EVALUATION

In the ED, the biochemical diagnosis of hypoglycemia is usually made by using a bedside glucose meter. A blood glucose level should be checked immediately on any patient presenting with adrenergic or neuroglycopenic symptoms, including behavioral abnormalities, decreased level of consciousness, and acute focal deficits. An immediate check should be done on patients with syncope and trauma patients in whom hypoglycemia as a precipitant may be overlooked.

Whole blood levels are approximately 5% to 10% lower than plasma levels, although some newer meters are calibrated to report a higher value that is equivalent to the plasma level. In addition, arterial blood has a glucose level 5% to 10% higher than that of venous blood. Test strips and meters are highly sensitive for the diagnosis of hypoglycemia, but may give falsely *high* readings in the setting of severe anemia and acetaminophen overdose.^{2,10,15} Test strip accuracy also deteriorates with prolonged storage, so strips should not be used beyond their printed expiration date.

Laboratory confirmation of hypoglycemia diagnosed by bedside testing is usually not necessary, however. Laboratory glucose levels measured by the glucose oxidase method (and presumably test strips and meters, which also rely on this reaction) may be falsely low in the setting of high levels of ascorbic acid, levodopa, tolbutamide, and bilirubin.¹⁰

When the patient has recovered adequately, a focused history should be taken, investigating the cause of the episode, including the timing and doses of medications, food eaten, and activity. For diabetic patients, the history should include an assessment of diabetic control, whether home glucose monitoring is performed, usual values, and the frequency and severity of hypoglycemic episodes. The presence of comorbidities, including renal insufficiency and liver disease, should be ascertained.

Additional laboratory testing, including measurements of the serum creatinine or hepatic transaminases, is necessary only if the history fails to reveal the cause of the episode and contributory comorbidities are suspected.

Nondiabetic patients who are suspected of having hypoglycemia, but for whom the diagnosis was not established in the ED, can be referred for an outpatient diagnostic workup.

EMERGENCY DEPARTMENT MANAGEMENT

Hypoglycemia should be considered in every patient with an altered sensorium or any acute neurologic deficit. Ideally, a fingerstick blood glucose level should be obtained to confirm the diagnosis before treatment with glucose is initiated, but glucose should be given empirically if the level cannot be obtained immediately. Although animal studies and retrospective human studies have found a correlation between hyperglycemia and poor neurologic outcome among patients with stroke and severe brain injury, there is no evidence that the doses of glucose given to correct hypoglycemia are harmful. Only 15 to 20 g of carbohydrate is generally required to restore euglycemia, although, occasionally, more is required. Glucose can be administered orally or intravenously, depending on the patient's level of consciousness.

The initial treatment for a confused or comatose adult with hypoglycemia is a 50-mL bolus of 50% glucose intravenously. Less concentrated glucose solutions are recommended for children (25%) and neonates (10%) due to concerns about hyperosmolality. The mean increase in the serum glucose level following this bolus is 150 mg/dL, but it varies greatly and is not predictable.¹ The bolus should be followed by the continuous infusion of 5% or 10% glucose at a rate sufficient to keep the glucose level over 100 mg/dL until the patient is capable of eating. If there is any reason to suspect thiamine deficiency, thiamine 100 mg intravenously should be given concomitantly with glucose to avoid precipitating Wernicke-Korsakoff syndrome.

Patients who are alert enough to eat may be treated with glucose tablets or paste, orange juice, hard candy, or any form of concentrated sugar. If a patient is taking an α -glucosidase inhibitor, absorption of oral carbohydrate may be inhibited. These patients must be treated with dextrose (which is in glucose tablets) as opposed to sucrose (which is in table sugar). They can also be effectively treated with milk, because the drug does not inhibit lactase.

Adults with hypoglycemia who are unable to eat and in whom intravenous access cannot be secured can be given glucagon 1 mg intramuscularly.¹⁴ Children should receive 0.5 mg. Available data have shown glucagon to be safe and effective in restoring euglycemia, with neurologic recovery occurring generally within 10 minutes.

Adrenergic symptoms respond to glucose therapy within minutes. The time to recovery of neuroglycopenic symptoms is more variable, ranging from minutes to (in rare cases) days.⁹ A patient failing to show clear signs of neurologic recovery within 10 minutes should have the glucose level rechecked to verify that euglycemia has been restored, because an additional bolus of glucose is occasionally needed. Alternative etiologies should be considered if there are no signs of neurologic recovery within 30 minutes.

To prevent recurrence, a meal or snack should be given after treatment. The simple carbohydrate given to raise the blood glucose level quickly does not produce a sustained elevation of blood glucose (50 mL of D50 and an 8-oz glass of orange juice contain only about 100 calories each), so a more complete meal, containing protein, fat, and complex carbohydrate, should be given to produce a more sustained rise in blood glucose levels. If hypoglycemia is due to administration of a long-acting insulin or an oral hypoglycemic drug, low glucose levels will typically last for an extended time. It is important to continue treatment and close observation to prevent relapse.

Long-term therapy depends on the cause of the hypoglycemia. If the hypoglycemia is secondary to a disorder such as hepatic failure or adrenal insufficiency, treatment of the underlying disorder is necessary to prevent recurrent hypoglycemia.

Dietary therapy is the treatment of choice for reactive and alimentary hypoglycemia. Patients should avoid sugars and eat frequent small snacks that contain a mixture of carbohydrate, fat, and protein. Restricting carbohydrate intake to 40% of total calories also may help.

In insulin-treated patients who become hypoglycemic, whether the usual insulin dose should be adjusted depends on the severity of the reaction. If the reaction is minor (easily detected and treated by the patient) and there is an explanation for the reaction (e.g., a missed meal or increased exercise), no insulin dose adjustment is indicated. However, if the reaction is more severe or is unexplained, or if there is a pattern of hypoglycemia occurring at the same time each day, the insulin dose should be decreased. Close monitoring of blood glucose levels is necessary to prevent hypoglycemia or hyperglycemia when the insulin dose has been changed.

Recurrent hypoglycemia acutely downregulates the adrenergic response to additional episodes of hypoglycemia. A moderately severe episode of hypoglycemia on day 1 will induce hypoglycemia unawareness on day 2, resulting in a more severe episode on the second day. Therefore, on the day following a moderate-to-severe hypoglycemic episode, the insulin dose should be reduced by 25%.

DISPOSITION

Most patients seen in the ED for hypoglycemia meet discharge criteria ([Table 169.4](#)). Hospital admission is indicated for patients failing to meet these criteria.

Brief episode
Full neurologic recovery
Able to eat
No major comorbidities that require hospital admission
Cause of the episode found and addressed
Treatment plan to prevent future episodes understood by the patient
Hypoglycemia accidental
Relapse unlikely—no long-acting insulin or oral agent, nor prolonged excretion or metabolism
Ability to do home glucose monitoring*
Responsible person to be with the patient*
Follow-up arranged*

*Imperative for severe episodes requiring assistance for recovery.

TABLE 169.4. Discharge Criteria Following a Symptomatic Hypoglycemic Episode

Patients who are discharged should receive specific instructions on how best to avoid recurrent episodes (most commonly by increasing caloric intake or decreasing the insulin dose), should be instructed to perform self-monitoring of blood glucose, and should carry some form of oral glucose at all times. Family members of patients who have experienced a severe episode requiring assistance should be instructed in how to recognize and treat hypoglycemia.

COMMON PITFALLS

- Failure to consider hypoglycemia in all patients with acute neurologic or psychiatric symptoms, regardless of any history of diabetes
- Failure to consider hypoglycemia in any physiologically stressed infant
- Waiting for laboratory results before administering glucose
- Failure to feed the patient following a response to intravenous glucose
- Failure to follow a bolus of intravenous glucose with a continuous glucose infusion in patients who remain unable to eat
- Failure to administer glucagon to any hypoglycemic patient with neuroglycopenic symptoms who is unable to take oral glucose and in whom intravenous access has failed
- Prematurely discharging a patient whose episode of hypoglycemia is due to a long-acting insulin or a sulfonylurea agent
- Failure to consider intentional overdose as the cause of hypoglycemia
- Failure to reinforce the need for self-monitoring of blood glucose and, in particular, failure to discuss the need for monitoring blood glucose levels prior to driving
- Discharging a patient following an episode of hypoglycemia without establishing that the patient understands how to avoid future episodes

CHAPTER 170

Alcoholic Ketoacidosis

Stephen L. Adams and Laura J. Bontempo

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Alcoholic ketoacidosis (AKA) is characterized by a metabolic acidosis with an elevated anion gap due to an accumulation of ketone bodies. Typically, it occurs after an episode of binge drinking, followed by a period of abstinence and starvation.^{5,6,7,15} Ketosis is attributed to multiple factors: direct damage of hepatic mitochondria by alcohol, diminished hepatic glycogen stores, a relative insulin deficiency, increased hepatic ketone formation, decreased gluconeogenesis, rapid lipolysis with increased free fatty acid formation (subsequently serving as a substrate for ketones), and decreased peripheral ketone utilization.^{4,5,6,7,8,11,15}

In addition to the metabolic acidosis, there may be a con- current metabolic alkalosis, respiratory alkalosis, or other acid–base disturbances.^{6,7,16} AKA is reversible and is associated with a low mortality rate.^{5,7} If death occurs, it is generally related to associated disorders rather than to AKA itself.^{15,16}

CLINICAL PRESENTATION

AKA generally occurs in people with a history of chronic alcohol abuse. The patient is typically a binge drinker who has recently stopped drinking.^{6,15} There may be alcohol detectable on the breath or in the serum, dependent on the amount of alcohol ingested and how recently intake was discontinued before the patient's presentation to the emergency department (ED). In one series, 40% of patients in whom the blood alcohol level was measured had levels consistent with intoxication.¹⁶

There is usually no history of diabetes, and men and women are affected equally.^{7,11} The most common presenting symptoms include nausea, vomiting, and abdominal pain.⁷ Cessation of alcohol intake is usually occasioned by the onset of these symptoms rather than an effort to abstain from alcohol.⁶ There is typically also a history of anorexia, with poor fluid and caloric intake.⁷ The abdominal pain may be due to liver disease, pancreatitis, alcoholic gastritis, or other diseases that may or may not be related to alcohol intake.^{1,7,8,12} There is a broad spectrum of severity.

On physical examination, the odor of ketones is almost always present.¹⁰ There may be profound orthostasis and other signs of volume depletion resulting from vomiting, decreased oral intake, and diaphoresis. Tachycardia and tachypnea are common, and the respirations may be deep and rapid (Kussmaul).⁵ Patients may complain of dyspnea.¹¹

Fever is not usually a part of the syndrome, even in patients who eventually prove to have a significant infection.¹⁶ Mental status is usually normal, but an abnormality in orientation or level of consciousness has been reported in up to 15% of patients and may be attributable to a concomitant problem, such as alcohol intoxication, severe infection, hypoglycemia, or cerebrovascular accident.^{7,16} Obtundation and coma have, however, been reported.¹⁴

The abdominal examination may reveal diffuse tenderness.⁷ Distention, diminished bowel sounds, ascites, and rebound are uncommon, and are usually seen only when other processes, such as pancreatitis or sepsis, also are present. Other associated conditions include alcohol withdrawal, upper gastrointestinal bleeding, seizure, myopathy, hepatitis, chronic liver disease, gastritis, and small bowel obstruction. Physical examination may also reveal spider angiomas, as well as other markers of liver disease and chronic alcohol abuse.^{1,7,8,14}

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of AKA includes the other causes of an elevated anion-gap metabolic acidosis (see [Chapter 165](#)).^{1,13} Of the several causes of ketoacidosis to be considered, the most common is diabetic ketoacidosis (DKA). It may be difficult to distinguish AKA from DKA based on clinical signs and symptoms alone. Polydipsia and polyuria are variable but may be present in both groups.^{7,9} However, an elevated HbA1c level is consistent with ketosis due to diabetes mellitus.⁹

Methanol and ethylene glycol ingestions must also be considered in the chronic alcoholic with an elevated anion-gap metabolic acidosis. Patients with methanol ingestion may complain of visual changes and central nervous system (CNS) symptoms, including headache and vertigo.⁷ Ethylene glycol ingestion may be suggested by the presence of calcium oxalate crystals in the urine.⁷ Other entities that may cause a ketotic state include hyperemesis gravidarum and starvation.¹ Cyanide poisoning has also been associated with ketonemia.¹ Isopropyl alcohol (rubbing alcohol) causes ketosis by being metabolized to acetone, but does not cause an acidosis.¹

The many causes of abdominal pain that could be associated with the patient's symptom complex must also be considered, including such disorders as pancreatitis, gastritis, gastrointestinal bleeding, hepatitis, cirrhosis, and urosepsis, among others.¹⁶

EMERGENCY DEPARTMENT EVALUATION

In addition to the clinical history, the diagnosis hinges on the laboratory finding of an elevated anion-gap metabolic acidosis. Hyperchloremic acidosis had been reported, and the presence of concomitant lactic acidosis is also common.¹⁶ Metabolic alkalosis (due to persistent vomiting and volume depletion) and respiratory alkalosis (as a result of liver disease, alcohol withdrawal, or infection) may be present as well.^{6,7,8,12} Some series note that between one-sixth and one-third of patients with AKA are actually alkalemic.^{6,16} Due to a mixed acid–base disturbance or a compensatory hyperventilation, arterial blood gas analysis may show less severe acidemia than would be expected on the basis of the anion gap.

By definition, patients with AKA are ketotic. There are three types of ketone bodies: acetone and the ketoacids beta- hydroxybutyrate (BHB) and acetoacetate (AcAc). The nitroprusside reaction, which is commonly used to detect ketones in blood and urine, may be misleading in indicating the degree of ketosis, because only AcAc and acetone cause a positive reaction, whereas BHB does not.^{6,7,15}

The ratio of BHB to AcAc depends on the ratio of reduced to oxidized nicotinamide adenine dinucleotide (NADH/NAD). In AKA, this ratio is high because the metabolism of ethanol generates NADH; the BHB/AcAc ratio averages 6:1.^{7,15} A negative or trace-positive nitroprusside reaction may thus be inappropriately interpreted as indicating the absence of ketones. Therefore, the diagnosis of AKA should not be eliminated on the basis of an initially negative or minimally positive nitroprusside reaction.

As the patient is treated and AKA begins to resolve, the NADH/NAD ratio changes to favor the conversion of more BHB to AcAc, and the test for ketones may become more strongly positive.⁷ A similar phenomenon has been described in the course of treatment of severe DKA, when, as the patient clinically improves with the administration of insulin and fluids, the test for ketones “worsens.”⁷ In one series of patients in whom ketones were measured, 4% had a negative semiquantitative reaction for serum AcAc and 10% had negative ketones on urine dipstick testing. This occurred more commonly in patients with higher blood alcohol levels.¹⁶

Although the classic presentation of AKA is one of ketoacidosis without marked hyperglycemia, the glucose concentration may be low, normal, or minimally elevated.^{7,8,9,10,14} Ten percent of patients in one series had a serum glucose value of more than 250 mg/dL, but there was no history of diabetes mellitus, and no

subsequent clinical evidence of glucose intolerance was found after treatment.^{9,16} However, in another study, patients with ketoacidosis, hyperglycemia, and an elevated HbA1c were likely to have concurrent diabetes.⁹

Electrolyte disorders are common. These may include hyponatremia, hypokalemia, hypophosphatemia, hypocalcemia, and hypomagnesemia.⁷ Hyperkalemia is seen in 15% of patients and is correlated with low pH.¹⁶ Hyperphosphatemia, if present, resolves rapidly with therapy.^{7,16} Liver enzymes, amylase, blood urea nitrogen, and false-positive creatinine levels may be elevated, but reflect dehydration and underlying chronic medical problems rather than being a direct result of AKA.^{7,14}

An increased osmolar gap, even after accounting for any ethanol or other toxic alcohols, has been described in some patients with AKA.^{2,3} Although the nature of the gap is unclear, it appears to be attributable, at least partly, to the presence of acetone, its metabolite acetol, 1,2-propanediol, and glycerol.^{2,3}

Anemia and thrombocytopenia are common in AKA but are usually mild. Leukocytosis appears to be primarily a marker of volume depletion and demargination due to physical stress, rather than an infection, although leukopenia is often a marker of a severe underlying disease.

EMERGENCY DEPARTMENT MANAGEMENT

The treatment of AKA is relatively straightforward. Volume repletion and provision of glucose are the mainstays of therapy.^{7,11} Saline, besides normalizing volume status, promotes the renal excretion of the ketone bodies BHB and AcAc.¹⁴ The volume of saline required depends on the initial degree of dehydration and the patient's underlying clinical condition.⁷ Glucose stimulates endogenous insulin secretion, decreasing the generation of ketone bodies.^{5,7,12,15}

In the absence of shock or severe hepatic insufficiency, BHB and AcAc are rapidly converted back to bicarbonate in the liver, and acidosis resolves quickly. In a controlled study that compared the use of normal saline alone with that of saline plus glucose, patients in the glucose-treated group corrected their acidosis within 12 hours. The administration of exogenous bicarbonate or insulin was not necessary. Patients treated with normal saline alone also had favorable outcomes, although not as rapidly.¹²

Dextrose-containing solutions should probably be avoided in those patients who present with severe hyperglycemia.¹⁶ Appropriate doses of insulin should be provided for patients who are known to be diabetic. However, insulin does not appear to play a role in the treatment of the normoglycemic patient with AKA.

Potassium repletion should be initiated in patients who are hypokalemic and in those with normokalemia who are acidemic, assuming there is no problem with renal function. This should be done with appropriate monitoring and frequent reassessments. Magnesium repletion is indicated, in the absence of renal insufficiency, not only to restore calcium homeostasis, but also to forestall alcohol withdrawal. Hypophosphatemia occurs in approximately 20% of patients with AKA, but routine repletion does not appear to improve morbidity and mortality.^{10,16}

The use of bicarbonate in this disease, as in many others marked by acidosis, has been controversial.^{1,8,11,12,16} However, in the absence of complicating features, the response of *even severe* AKA to volume repletion and glucose is such that the administration of bicarbonate is usually not necessary.¹¹

Thiamine should be administered for the prevention of Wernicke's encephalopathy.^{6,7,11} Vitamin supplements should be administered as indicated.

DISPOSITION

Many patients with AKA can be discharged home from the ED after receiving appropriate treatment. One series reported only a 54% admission rate.¹⁶ Patients should not be discharged until they have demonstrated the ability to tolerate fluids, have had their volume status normalized, and have shown resolution of metabolic abnormalities. Underlying or precipitating illness must have resolved or been ruled out.

Admission is indicated for those who cannot tolerate oral hydration because of persistent nausea and vomiting, for those in whom a significant metabolic acidosis or electrolyte abnormality persists, and for those in whom the cause of abdominal pain is unclear or an associated illness complicated the picture. Admitted patients can often be treated on a general medical floor or in a short-term observation unit.

Close follow-up after discharge should be arranged. Many patients may benefit from referral to an alcohol rehabilitation program.

COMMON PITFALLS

- Misdiagnosis of AKA as DKA in the patient with ketosis, Kussmaul respiration, and minimally elevated blood glucose level
- Failure to consider AKA in the patient presenting with complaints of abdominal pain who does not offer a history of ethanol ingestion or binge drinking
- Failure to make use of the olfactory clue of a strong ketotic odor
- Assuming a patient is not ketotic because a serum or urine nitroprusside reaction is negative or only trace-positive
- Failure to appreciate the presence of a mixed acid–base disorder
- Failure to treat with dextrose-containing solutions
- Failure to consider other causes of nausea, vomiting, and abdominal pain in the alcoholic patient. Because the alcoholic is predisposed to a multitude of diseases, a careful history and physical examination must be done in even the most apparently straightforward of cases.

THYROID FUNCTION TESTS

In the emergency department, the diagnosis of hyperthyroidism or hypothyroidism depends on clinical assessment and is supported and confirmed by thyroid function testing.

Thyroid hormone concentration depends on the rate of production by the thyroid gland and on utilization or metabolism at extrathyroidal sites ([Fig. 171.1](#)).¹⁵ Thyroid hormone is secreted in response to stimulation of the thyroid gland by thyroid-stimulating hormone (TSH) produced in the anterior pituitary gland. TSH release, in turn, is promoted by thyrotropin-releasing hormone (TRH) derived from the hypothalamus, and is further modulated by intrapituitary T_3 concentration.

Figure 171.1. Major features of the hypothalamic–anterior pituitary–thyroid–target tissue axis. TBP, thyroid hormone–binding protein.

Thyroxine, T_4 , is produced solely by the thyroid gland and is deiodinated in various parts of the body to the biologically active triiodothyronine, T_3 , or to the inactive reverse T_3 . In addition, small amounts of T_3 are produced by the thyroid gland. The vast majority of thyroid hormone is carried by various proteins; the most important clinically is thyroxine-binding globulin, TBG. Changes in the amount of carrier proteins or in their binding capacity can alter the concentration of total and free thyroid hormones. Free unbound T_4 and T_3 are physiologically active fractions and best correlate with the clinical status.

The best means of assessing thyroid hormone activity is measurement of the free T_4 level. Generally, the degree of reduction of the free T_4 below normal levels is proportionate to the severity of hypothyroidism, and the degree of elevation above normal levels is proportionate to the severity of thyrotoxicosis. Direct measurement of free T_4 is technically demanding and not readily available, but the commonly available free T_4 assays are accurate in most clinical situations and are less expensive. Free T_4 can also be assessed by using the less reliable free T_4 index, which is the product of the *total* T_4 concentration and the T_3 resin uptake. The latter reflects alterations in protein binding of hormone due to nonthyroidal illness and other conditions. Unfortunately, the term is sometimes confused with total T_3 .

Sensitive assays of TSH have become the single most helpful measurements of thyroid function. The level of TSH reflects the pituitary's perception of thyroid hormone action. In thyroid gland failure (primary hypothyroidism), the basal TSH level is elevated. The TSH is suppressed with almost all causes of thyrotoxicosis, but now TSH assays are sensitive enough to distinguish euthyroid patients from those with hyperthyroidism.^{2,12,15} Sensitive TSH assays have eliminated the need to perform TRH stimulation tests to evaluate questionably thyrotoxic patients and have made possible more precise thyroid hormone-replacement therapy.

The combination of free T_4 assay and a sensitive TSH assay is the primary means of assessing thyroid status in all patients. A single TSH assay may be an effective screening tool in some settings, but both tests are needed in the emergency department or in acutely ill patients. When the clinical picture suggests thyrotoxicosis, the finding of an elevated free T_4 and a suppressed (unmeasurable) TSH confirms the diagnosis.

Additional thyroid function tests are rarely used to establish a diagnosis of thyrotoxicosis in the emergency setting. Total T_3 and free T_3 assays are available. Their major use is in identifying so-called T_3 -toxicosis, an unusual condition in which T_3 rather than T_4 is responsible for hyperthyroid effects and in which, as might be expected, TSH is suppressed but free T_4 is low or normal.

Direct assessment of increased thyroid gland function can be obtained by measurement of thyroid radioactive iodine uptake. This nuclear medicine test quantitates the uptake of iodine by the thyroid gland and generally reflects thyroid hormone production. Because this test is strongly influenced by the patient's total iodine pool, recent exposure to iodine-containing contrast agents or medications may confuse the interpretation of test results. An exogenous iodine load expands the iodine pool and dilutes the radioactively labeled iodine, producing a spuriously low radioactive iodine uptake. The test is used chiefly to determine the etiology of hyperthyroidism. It has no place in the evaluation of the hypothyroid patient.

COMMON PITFALLS

- Thyroid function tests can be influenced by nonthyroidal illness, drugs, and a variety of other clinical states, such as pregnancy. Acute illness can affect the secretion and metabolism of thyroid hormone and can alter the equilibrium between free and protein-bound hormone, making interpretation of thyroid testing extremely difficult. Acutely ill hospitalized patients do not benefit from routine thyroid function testing.⁷
- Although by far the most common cause of a low TSH is thyrotoxicosis, TSH levels can be suppressed in hypopituitary or hypothalamic disease, in the first trimester of pregnancy, in acute psychiatric illness, in patients with nonthyroidal illness, and in patients receiving dopamine or high doses of glucocorticoids.⁴ The most sensitive assays can distinguish some of these entities from ordinary thyrotoxicosis, in which the TSH is unmeasurable.¹⁸ Conversely, the TSH can be elevated from causes other than hypothyroidism. Levels have been reported to be increased in the recovery stage after nonthyroidal illness and after the use of certain cholecystographic contrast agents.⁴ Nevertheless, when the TSH is combined with a free T₄ assay and a knowledge of the clinical setting, it is possible to make a correct interpretation in the majority of patients.
- Severe systemic illness, as well as the use of a number of medications, can lead to a confusing array of thyroid function test abnormalities in which patients may have a biochemical picture of either hyper or hypothyroidism.³ In addition, patients with the “sick euthyroid syndrome” may appear to be clinically hypothyroid in the setting of acute nonthyroidal illness, but have normal free T₄ and a decreased T₃ level due to decreased peripheral conversion of T₄ to T₃. Thus, emergency department patients with mild or questionable signs and symptoms of either hyperthyroidism or hypothyroidism are best managed without immediate treatment.

THYROID STORM

Thyroid storm is a rare, life-threatening complication of thyrotoxicosis. It occurs most often in patients with undiagnosed or undertreated thyrotoxic Graves disease and, occasionally, in patients with toxic multinodular goiter. It is reported in 1% to 2% of patients who are hospitalized for hyperthyroidism. Although thyroid storm occurs in both sexes and at any age, it is more common in women during the middle decades. Its pathogenesis is unknown.

The onset of thyroid storm is usually abrupt. If untreated, it is usually fatal. The overall mortality is 10% to 20%, with underlying illness being the cause of death in many instances.

A precipitating event can be identified in 50% to 75% of cases. The causes most commonly implicated are infection (especially pulmonary), trauma, vascular accident, diabetic complications, and nonthyroidal surgery. Preoperative preparation of hyperthyroid patients and the use of antithyroid drugs, iodine, and propranolol in treatment have virtually eliminated thyroid storm in patients undergoing thyroid surgery for hyperthyroidism.

CLINICAL PRESENTATION

The criteria for a diagnosis of thyroid storm are a temperature higher than 37.8°C (100°F); tachycardia out of proportion to the fever; dysfunction of the central nervous system (CNS), cardiovascular system, and/or gastrointestinal (GI) system; and exaggerated peripheral manifestations of thyrotoxicosis.

Thyroid storm is a clinical diagnosis. The presence of thyrotoxicosis is a prerequisite for the development of storm, but determining the point at which thyrotoxicosis becomes thyroid storm is a matter of judgment and semantics.

Fever is an invariable finding and may be as high as 41.1°C (106°F), with or without concurrent infection. Marked diaphoresis is also present and can lead to significant insensible fluid loss.

CNS dysfunction occurs in 90% of patients with thyroid storm. Symptoms range from restlessness, anxiety, and emotional lability to delirium, obtundation, and coma. Neuromuscular manifestations include tremor and muscle weakness.

Cardiovascular abnormalities are present in 50% of patients. Sinus tachycardia is usual. Atrial fibrillation, premature ventricular contractions, and, rarely, complete heart block can occur. The pulse pressure is characteristically widened (one series reported an average pulse pressure of 80 mm Hg), with increased stroke volume, cardiac output, and myocardial oxygen consumption. Congestive heart failure is common in thyroid storm and may be the presenting manifestation. Progressive cardiac dysfunction leads to pulmonary edema and cardiogenic shock as terminal events.

GI dysfunction is also prominent in most patients with storm. Marked weight loss has often occurred in the preceding weeks or months, and storm may be heralded by diarrhea and hyperdefecation. During storm, anorexia, nausea, vomiting, and crampy abdominal pain may simulate an acute abdomen. Jaundice and tender hepatomegaly are occasionally additional GI manifestations.

DIFFERENTIAL DIAGNOSIS

The diagnosis of thyroid storm is a clinical one.¹⁷ In general, storm should be suspected in any thyrotoxic patient with either a fever or the other cardinal manifestations discussed previously. Additional factors to consider include a history of Graves disease, a palpable goiter, or any eye signs suggestive of Graves ophthalmopathy.

Exaggerated symptoms of hyperthyroidism distinguish storm from routine thyrotoxicosis. When thyroid storm is suspected, therapy should generally be initiated immediately.

Additional disease entities that may be confused with thyroid storm are those that manifest with a hyperkinetic state, hyperpyrexia, or dysfunction of the previously described organ systems ([Table 171.1](#)).

Disease Entity	Manifestations
Anxiety states	Agitation, sleeplessness, emotional lability, weight loss
Psychosis	CNS dysfunction, tachycardia
Cocaine toxicity	Agitation, confusion, tachycardia, arrhythmias, weight loss, hyperthermia
Pheochromocytoma	Sweating, palpitations, nervousness, tremor, weight loss, heat intolerance
Heat stroke	Confusion, tachycardia, hyperthermia, prostration
Neuroleptic malignant syndrome	Hyperthermia, tachycardia, CNS dysfunction
Diabetes mellitus, out of control	Confusion, vomiting, weight loss, abdominal pain, tender hepatomegaly
Chronic obstructive pulmonary disease, end-stage	Confusion, tachycardia, hyperthermia, arrhythmias, pulmonary infection
Acute abdomen	Vomiting, abdominal pain, hyperthermia
Congestive heart failure	Cardiovascular dysfunction, arrhythmias, tender hepatomegaly
Alcoholic complications	Confusion, vomiting, restlessness, tremor, fever, jaundice, abdominal pain, tender hepatomegaly

TABLE 171.1. Differential Diagnosis of Thyroid Storm

EMERGENCY DEPARTMENT EVALUATION

Some historic information, if available, can be of great help in making the diagnosis. A history of goiter, increased sweating, rapid heart rate, severe weakness, heat intolerance, or weight loss despite an increased appetite suggests antecedent thyrotoxicosis. A history of eye complaints (stare, bulging eyes, conjunctivitis, periorbital swelling, corneal ulceration, diplopia, decreased visual acuity) suggests Graves disease. The medication history may provide important clues; the patient should be asked about thyroid hormone preparations, iodine-containing compounds, and recent radiographic studies with iodine-containing contrast materials.⁹

The physical examination is of increased importance when a history is unobtainable. Fever, tachycardia, widened pulse pressure, and CNS dysfunction are evident from the outset. Cardiovascular examination often shows arrhythmias, especially atrial fibrillation, or signs of congestive heart failure. Eye signs such as stare, lid lag,

and Graves ophthalmopathy may be found. Examination of the thyroid gland almost always reveals a goiter, often with a thrill or a bruit. Muscle tremor and evidence of weakness, especially of the proximal muscle groups, should be sought.

Thyroid function tests do not distinguish uncomplicated thyrotoxicosis from thyroid storm because of an overlap in values,³ and, in any event, these laboratory values are not normally available to the emergency physician quickly enough to affect initial management.

Nonspecific laboratory abnormalities of the complete blood count, electrolytes, and liver function studies are often noted, and hyperglycemia is common. Hypercalcemia may occur in 25% of patients with storm. Plasma cortisol levels have been observed to be inappropriately low for the degree of stress.

EMERGENCY DEPARTMENT MANAGEMENT

The treatment of thyroid storm must not be delayed once the diagnosis is suspected. The thyrotoxic patient who is treated unnecessarily for thyroid storm should do well. Specific therapeutic goals can be divided into five areas: general supportive care, inhibition of thyroid hormone synthesis, retardation of thyroid hormone release, blockade of peripheral thyroid hormone effects, and identification and treatment of precipitating events.

General Supportive Care

Adequate hydration with intravenous fluids and electrolytes must be ensured in order to replace GI and insensible losses. Supplemental oxygen should be provided because of increased oxygen consumption. Continuous cardiac monitoring to identify cardiac arrhythmias is indicated. Fever should be controlled with antipyretics and a cooling blanket.

Congestive heart failure must be treated in the usual fashion. Congestive heart failure due to thyrotoxicosis may be refractory to digitalis, however. Glucocorticoids equivalent to 300 mg of hydrocortisone per day should be administered intravenously. Occasionally, specific therapy is required to reduce unacceptably high levels of blood glucose or calcium. Finally, the patient's clinical status and response to treatment must be followed closely by frequent monitoring of vital signs and repeated physical examination.

Inhibition of Thyroid Hormone Synthesis

The antithyroid drugs propylthiouracil (PTU) and methimazole block the synthesis of thyroid hormone through inhibition of the organification of tyrosine residues. PTU (900 to 1200 mg orally as an initial loading dose, followed by 300 to 600 mg/d) should be administered until thyrotoxicosis is controlled. Methimazole is an alternative to PTU (dose: 90 to 120 mg orally initially, followed by 30 to 60 mg/d). A nasogastric tube may be required, because these medications are available only in oral form.

Antithyroid drugs begin to act during the first hour after administration, but full therapeutic effect is not achieved for 3 to 6 weeks. PTU is preferred over methimazole, because it produces a more rapid clinical response and also inhibits the peripheral conversion of T_4 to T_3 .

Inhibition of Thyroid Hormone Release

Iodide administration immediately retards the release of stored thyroid hormones from the thyroid gland. Iodide should not be administered until 1 hour after the loading dose of an antithyroid drug to avoid worsening hyperthyroidism by increasing the pool of iodine available for incorporation into thyroid hormone before organification has been inhibited. It may be given as Lugol's solution, 30 drops orally per day, or as sodium iodide, 1 g every 8 to 12 hours by slow intravenous infusion. An alternative is lithium carbonate, 300 to 450 mg orally three times a day as an initial dose and then titrated by blood lithium level. Although lithium effectively blocks thyroid hormone release, it has a narrow margin of therapeutic safety.

Blockade of Peripheral Thyroid Hormone Effects

Adrenergic blockade is a mainstay of therapy for thyroid storm. Propranolol is the drug of choice. Given intravenously (1 mg/min to a total dose of 10 mg), it begins to control the cardiac and psychomotor manifestations of thyroid storm within minutes. Oral propranolol (20 to 120 mg or more every 4 to 6 hours) begins to be effective in about 1 hour.

Intravenous propranolol has been associated with cardiac arrest in rare instances, and the usual precaution of avoiding use of the drug in patients with bronchospastic disease and heart block should be considered. To detect the latter problem, electrocardiographic findings should be checked before the drug is administered.

In patients with thyrotoxic congestive heart failure, the use of propranolol is controversial.⁸ Heart failure can be caused by tachycardia, especially in the presence of atrial fibrillation. The benefit of slowing the ventricular response in atrial fibrillation must be weighed against the risk of depressing myocardial contractility. Digitalis should be administered before propranolol in this clinical setting.

Guanethidine and reserpine also provide effective autonomic blockades and are alternatives to propranolol. Both act to deplete catecholamine stores, and guanethidine also blocks their release. Guanethidine can be given in a dose of 1 to 2 mg/kg/d orally. Reserpine is administered in an initial dose of 1 to 5 mg intramuscularly, followed by 1.0 to 2.5 mg every 4 to 6 hours.

Other Therapeutic Modalities

Symptomatic improvement should occur within hours of the initiation of therapy, but resolution of thyroid storm requires the degradation of circulating thyroid hormones. Because the biologic half-life of T_4 is 6 days and that of T_3 is 22 hours, thyroid storm may persist for days. Alternative therapeutic modalities such as exchange transfusion, plasmapheresis, and charcoal hemoperfusion have been used in the treatment of thyroid storm refractory to other measures.

DISPOSITION

Patients suspected of having thyroid storm require admission to an intensive care unit. An endocrinologist or an internist should be consulted. Treatment of thyroid storm should not be delayed pending consultation, however. When it is necessary to transfer a patient to another facility, transport must be effected by an advanced life-support unit with an intravenous line, supplemental oxygen, and continuous cardiac monitoring.

COMMON PITFALLS

- The most common pitfalls for the emergency physician center around diagnosis of this endocrine emergency. Because of the rarity and variable presentation of thyroid storm, the clinician may fail to consider it as the diagnosis. The diagnosis must be suspected based on the constellation of the patient's presenting signs and symptoms. Fever in a thyrotoxic patient does not necessarily imply thyroid storm. It is the exaggerated symptoms of hyperthyroidism that distinguish thyroid storm from routine thyrotoxicosis.
- Apathetic thyrotoxicosis is a distinct form of thyrotoxicosis that most often occurs in the elderly without the usual hyperkinetic manifestations. This diagnosis is frequently missed and should be considered in the elderly patient who presents with weight loss, proximal muscle weakness, slowed mentation, placid facies, congestive heart failure, or atrial fibrillation. Undiagnosed and untreated, these patients may quietly lapse into a coma and die. When signs and symptoms referable to dysfunction of one organ system dominate and obscure the underlying diagnosis of thyrotoxicosis, "masked" thyrotoxicosis is said to exist.

MYXEDEMA COMA

Myxedema coma is the ultimate life-threatening expression of severe hypothyroidism. It occurs most often during the winter months in elderly women who have long-standing hypothyroidism that is undiagnosed or undertreated. A precipitating stressful event can be discovered in most patients who develop this complication of

hypothyroidism.

Myxedema coma is rare. It occurs in patients with hypothyroidism, which is usually a result of surgical or radioiodine ablative therapy for Graves disease, idiopathic hypothyroidism, or Hashimoto thyroiditis.¹⁴ The pathophysiology of myxedema coma is unknown, but metabolic complications, intercurrent illness, and thyroid hormone deficiency *per se* have been implicated.

Hypothyroidism is generally a progressive, insidious disease.¹⁴ Patients who develop hypothyroidism after subtotal thyroidectomy most often do so 12 to 15 months following surgery. Of patients treated with radioactive iodine, 40% to 70% develop hypothyroidism within 10 years. A patient with undiagnosed hypothyroidism may present with coma as the initial manifestation of the disease. More often, the disease progresses over a period of years, and coma occurs when the patient is stressed with an additional precipitating event. Of these, infection, especially pulmonary infection, is the most common. Exposure to a cold environment, cerebrovascular or cardiovascular events, hemorrhage, and trauma have also been identified as precipitants. In addition, because hypothyroid patients metabolize drugs slowly, even normal doses of sedatives, analgesics, or anesthetics can induce prolonged coma in a patient with severe hypothyroidism. More than 50% of patients who develop myxedema coma do so after admission to the hospital. Drugs, nosocomial infections, and the rigors of diagnostic and therapeutic procedures are the most likely causative factors. If untreated, myxedema coma is fatal.

CLINICAL PRESENTATION

All patients who develop myxedema coma are hypothyroid and have signs and symptoms of hypothyroidism. Patients with moderate-to-severe hypothyroidism develop myxedema—a nonpitting, dry, waxy swelling of the skin and subcutaneous tissues due to accumulation of mucopolysaccharides, resulting in characteristic puffy facies (Fig. 171.2). Additional cutaneous clues to the diagnosis include thinning of the eyebrows and scant body hair. Other frequent complaints are fatigue, weakness, cold intolerance, muscle cramps, constipation, and weight gain. Women often have a history of menometrorrhagia. A deepened voice and a thick, enlarged tongue may be noted.

Figure 171.2. Myxedema.

DIFFERENTIAL DIAGNOSIS

The differentiation of myxedema coma from other entities rests on the clinical recognition of myxedema. Severely ill, elderly patients with hypothermia, respiratory failure, hyponatremia, or hypoglycemia may have myxedema coma or precoma. Because T_3 and T_4 may be depressed in an acutely ill euthyroid patient, and, in any event, are not usually available to the emergency physician, treatment must be based on a history and physical examination that clearly support the diagnosis of myxedema.

The clinical picture of myxedema superficially resembles that of chronic renal failure and nephrotic syndrome. Chronic renal failure can present with mental impairment or coma, sallow complexion, puffy face and extremities, seizures, and hyponatremia, but the patient with renal failure has an elevated serum creatinine. Patients with nephrotic syndrome may present with normal renal function but often appear pale and have anasarca. The serum T_4 may be low in these patients because of a loss of TBG in the urine, but the free T_4 and TSH are normal. Although mild proteinuria may occur with hypothyroidism, it is of a much lesser degree than in nephrotic syndrome.

EMERGENCY DEPARTMENT EVALUATION

A history of hypothyroidism, treatment for Graves disease, or discontinuation of replacement thyroid hormone therapy is helpful, if elicited.

Paresthesias, ataxia, and delay of the relaxation phase of the deep tendon reflexes may occur with hypothyroidism. Seizures (in 25% of those who develop myxedema coma) and mental disturbances are more severe neurologic manifestations. Coma is a terminal expression of neurologic dysfunction in myxedema.

Cardiovascular clues to hypothyroidism are bradycardia, cardiomegaly, and low voltage on electrocardiogram (ECG). Systolic blood pressure is usually less than 100 mm Hg, but mild hypertension may be observed. Pericardial effusion is present in up to 30% of patients; echocardiography is often required to confirm the presence of effusion.

Patients with severe hypothyroidism commonly have abdominal distention that may be due to ascites, paralytic ileus, or fecal impaction. Acquired megacolon is almost uniformly observed; bowel obstruction and pseudoobstruction have been reported.

Normal thermogenesis is impaired in hypothyroidism; hypothermia, unassociated with sweating or shivering, is a typical finding. A normal or elevated temperature in this clinical setting may indicate underlying infection.

Respiratory failure is common in myxedema coma.²⁰ Respiratory assistance may be required to treat hypercapnia and hypoxemia. Serum sodium levels of less than 120 mEq/L occur in up to two-thirds of patients with myxedema coma.^{5,16}

Seventy percent of patients with myxedema coma have a temperature less than 37°C (98.6°F), and 15% less than 29.5°C (85°F). The systolic blood pressure is less than 100 mm Hg in 50% of cases, and bradycardia is common. A scar may be seen over the thyroid area. A distended urinary bladder is sometimes noted.

Thyroid function tests confirm the diagnosis of hypothyroidism but are not usually available during emergent evaluation. The free T_4 is low. The TSH level is elevated in primary hypothyroidism but may be low or normal in pituitary–hypothalamic disease. Hyponatremia, hypochloremia, and hypoglycemia may be present on routine laboratory testing. Additional laboratory abnormalities include hypercholesterolemia and occasional striking elevations of muscle enzymes such as creatine kinase, serum glutamic-oxaloacetic transaminase, and lactate dehydrogenase. When lumbar puncture is performed, the cerebrospinal fluid (CSF) pressure may be increased, and the CSF protein level is usually elevated.

Radiographic abnormalities in hypothyroidism may include an enlarged cardiac silhouette on chest radiograph or ileus on abdominal flat plate. Typical ECG findings consist of sinus bradycardia, low voltage, prolongation of the PR interval, and inversion of the T waves. The presence of a myocardial effusion may be confirmed by echocardiography.

EMERGENCY DEPARTMENT MANAGEMENT

The diagnosis of myxedema coma must be based on a clinical impression, and treatment should not be delayed once the diagnosis is made. However, the decision to

treat must be made with extreme caution, because the administration of large doses of thyroid hormone can be fatal to the euthyroid or mildly hypothyroid patient. Every attempt to attribute coma to its proper cause should be made first.

Respiratory failure should be treated with oxygen administration and ventilatory support as needed. Hypothermic patients should be gradually rewarmed passively with blankets; hypothermic patients typically respond quite slowly. Aggressive rewarming techniques are hazardous.¹¹ Drugs that may further depress respiratory or metabolic function should be avoided. Hyponatremia should be treated with water restriction or, when hyponatremia is severe, with hypertonic saline and furosemide.¹² Hypoglycemia requires intravenous glucose infusion. Hypotension should be treated with isotonic fluid administration and thyroid hormone replacement. Vasopressors should be used only when hypotension is refractory to initial therapy. Glucocorticoids equivalent to 300 mg of hydrocortisone per day should be given to ensure adequate cortisol activity, because adrenal insufficiency may be a concomitant finding. Frequent vital signs, cardiac monitoring, and sequential physical examination are important to monitor the patient's status and response to treatment.

Thyroid hormone replacement is the most critical and specific aspect of therapy for myxedema coma. L-thyroxine is the recommended preparation.¹³ An initial dose of 400 to 500 µg is given by slow intravenous infusion. (If cardiac arrest following intravenous L-thyroxine has occurred, the dose should be reduced in the face of cardiac ischemia.) The initial dose should be followed by 50 to 100 µg/d intravenously. Once the patient is able to take an oral dose, 100 to 200 µg/d can be started orally. Initiation and adjustment of this oral dose depend on the results of thyroid function testing.⁶

Triiodothyronine (T₃) is four times as potent pharmacologically as thyroxine (T₄). However, it was previously available only in tablet form, and its use was not favored because it had to be crushed and given by a nasogastric tube in many patients. There was also concern that absorption would be reduced because of myxedema-induced gastrointestinal dysfunction. Intravenous L-triiodothyronine is now available.¹⁰ An initial intravenous dose of 25 to 50 µg is recommended for emergent treatment of myxedema coma or precoma in adults. The dose should be lowered to 10 to 20 µg for patients with known or suspected cardiovascular disease. Subsequent dosage is 65 to 100 µg per 24 hours in three to four divided doses, or half of this amount in patients with cardiovascular disease. Contraindications and drug interactions of intravenous T₃ are identical to those of T₄. With either drug, clinical improvement should be apparent within 24 to 36 hours.

A final aspect of treatment of myxedema coma is the identification and treatment of any precipitating event. Those factors previously mentioned should be sought and treated when present. Care should be taken not to place any additional metabolic demands on these precariously compensated patients.

DISPOSITION

All patients treated for myxedema coma require admission to an intensive care unit. Consultation with an endocrinologist or an internist should be arranged. Patients who require transfer to another facility should be transported in an advanced life-support unit in which supplemental oxygen and continuous cardiac monitoring are available.

COMMON PITFALLS

- Failure to consider the diagnosis of myxedema coma is a common pitfall. Because myxedema coma is rare and because the associated metabolic problems may distract attention from the underlying diagnosis, coma may be attributed to hypothermia, CO₂ narcosis, hyponatremia, hypoglycemia, drug overdose, or other causes. Unless the underlying thyroid failure is diagnosed and treated, therapeutic efforts will not be successful.
- Fever can occur in a patient with myxedema coma who has an underlying infection. The absence of hypothermia does not preclude a diagnosis of myxedema coma.

ADRENAL INSUFFICIENCY

Adrenal insufficiency results when the adrenal cortices fail to produce adequate quantities of cortisol and aldosterone.^{1,5} The disorder results from a primary failure of hormone production because of loss of adrenal tissue (Addison disease) or from a failure of the pituitary to produce sufficient adrenocorticotrophic hormone (ACTH) to stimulate the adrenal glands.

Primary adrenal insufficiency is an uncommon disorder, affecting approximately 100 persons per million.^{1,3} Over 90% of the gland must be destroyed before symptoms become apparent. The most important cause is “idiopathic autoimmune adrenalitis,” with lymphocytic infiltration of the adrenal gland and antiadrenal antibodies. This disorder is more common in women, usually arising between the third and fifth decades, and is sometimes associated with other autoimmune diseases, such as early ovarian failure, hyperthyroidism and hypothyroidism, insulin-dependent diabetes, hypoparathyroidism, vitiligo, and pernicious anemia.

Various other causes of primary adrenal insufficiency are listed in [Table 172.1](#). Primary adrenal insufficiency is also seen in patients with the acquired human immunodeficiency virus (HIV),^{6,10} usually due to disseminated cytomegalovirus (CMV) infection. Up to 84% of patients with CMV show evidence of CMV adrenalitis,^{7,12,16} which can be treated with ganciclovir.^{14,18} Other causes of adrenal insufficiency in patients with HIV include Kaposi’s sarcoma or drug therapy. Drugs such as metyrapone, mitotane, aminoglutethimide, ketoconazole, fluconazole, and possibly rifampin may also decrease adrenal steroidogenesis.⁹

Metastatic cancer
Lung
Breast
Leukemia
Infectious bacterial diseases
Meningococemia
Pneumococemia
Infectious granulomatous diseases
Tuberculosis
Blastomycosis
Coccidioidomycosis
Histoplasmosis
Viral diseases
Cytomegalovirus (especially in HIV patients)
Herpes simplex virus
Infiltrative diseases
Sarcoidosis
Amyloidosis
Hemochromatosis
Hemorrhage
Anticoagulant therapy
Abdominal trauma
Congenital adrenal hyperplasia
Adrenoleukemia
Adrenal infarction
Emboli of adrenal veins
Overwhelming sepsis (Waterhouse-Friderichsen syndrome)

TABLE 172.1. Causes of Primary Adrenal Failure

In an otherwise healthy person, acute primary adrenal failure is exceedingly rare. Most primary adrenal insufficiency appears to result from diseases that develop over a period of years and progresses slowly to complete destruction of the adrenal glands.

The most common cause of *secondary* adrenal insufficiency (inadequate pituitary ACTH reserve) is suppression of the hypothalamic–pituitary–adrenal (HPA) axis by exogenous glucocorticoids. This suppression occurs after as little as 1 to 2 weeks of glucocorticoid therapy, with rapid withdrawal of glucocorticoids precipitating signs of adrenal insufficiency. Depending on the dose and duration of therapy, it may require several months to 1 year after withdrawal of glucocorticoids before the HPA axis again functions normally.

Secondary adrenal insufficiency is otherwise caused by disorders that destroy or compromise pituitary or hypothalamic integrity, such as pituitary or parasellar tumors (prolactinoma, acromegaly, meningioma, craniopharyngioma), hypothalamic tumors, head trauma, infarction (“pituitary apoplexy”), infiltrative or inflammatory processes, and hemorrhage (Sheehan syndrome). With the exception of trauma, infarction, and hemorrhage, pituitary and hypothalamic disease tends to result in gradual rather than sudden loss of function. Aldosterone secretion is usually normal in secondary adrenal insufficiency.

CLINICAL PRESENTATION

The clinical presentation of adrenal insufficiency depends on how rapidly adrenocortical function is lost. Acute adrenal failure (“addisonian crisis”) is a medical emergency that requires rapid intervention. It usually occurs in an individual with underlying chronic adrenal insufficiency that experiences an acute stress, such as severe infection, sepsis, alcohol withdrawal, trauma, surgery, or myocardial infarction. Thus, it is important that the physician try to identify an intercurrent illness that could have precipitated the acute episode. There may also be a history of other autoimmune disorders.

The clinical syndrome includes weakness, fatigue, anorexia, nausea and vomiting, abdominal pain, diarrhea, dizziness, musculoskeletal pain, and weight loss. The patient may be disoriented, confused, or comatose. There is tachycardia, as well as hypotension with orthostatic changes. The skin is cool and dry, and the urine output is decreased. The patient may have a low-grade fever but can also be hypothermic. The classic physical finding in primary adrenal failure is hyperpigmentation, which is present in 98% of patients and is described as “suntan that doesn’t fade.” There is pigmentation of skin creases or folds that are not exposed to the sun; the nails, buccal mucosa, and gingiva may also be hyperpigmented. In Blacks, the tongue may appear darker. Vitiligo may be present, the scalp hair may be prematurely gray, and calcification of the ear lobes may be noted. Commonly, the presenting complaint is related to the gastrointestinal tract (e.g.,

constipation, nausea and vomiting, vague abdominal pain). Personality changes, irritability, and restlessness can also be noted.

Patients with secondary adrenal insufficiency may have additional symptoms and signs related to hypothalamic or pituitary disease, such as loss of sexual performance and libido, menstrual disturbances, headache, visual disturbances, galactorrhea, features of acromegaly, or evidence of head trauma. Hyperpigmentation is rare, because circulating levels of ACTH and related peptides are low. Loss of ACTH is often accompanied by loss of thyroid-stimulating hormone (TSH) secretion, so signs of hypothyroidism may be present. In patients with HIV, the most common complaint is fatigue.¹⁵

The most sensitive laboratory finding of adrenal insufficiency is hyperkalemia, although, classically, hyponatremia, hypercalcemia (with a normal ionized fraction), mild metabolic acidosis, and hypoglycemia are described. The hyperkalemia is secondary to aldosterone deficiency, whereas the hyponatremia results from renal sodium loss and free water retention. The blood cell count may show lymphocytosis or eosinophilia. The urine sodium value is inappropriately high for a state of hypoperfusion. In secondary adrenal failure, the potassium level may be normal because mineralocorticoid function is intact and aldosterone is present. However, hyponatremia may still be present.

DIFFERENTIAL DIAGNOSIS

Acute adrenal failure may present as hypovolemic shock, hypoglycemia, or both. The diagnosis should be pursued in any patient with a history of chronic glucocorticoid use, because medication may be stopped or an intercurrent stress may arise to precipitate the crisis. The differential diagnosis of acute adrenal crisis includes other causes of cardiovascular collapse and shock: myocardial infarction, heart failure, hypovolemia, sepsis, pulmonary embolism, and so forth. The diagnosis should be considered in all patients with dehydration, hypotension, orthostasis, or obtundation. Hyperpigmentation and typical laboratory abnormalities suggest adrenal insufficiency.

Chronic adrenal insufficiency is difficult to diagnose because the symptoms may develop over months to years. It is often confused with a "flu-like" illness because many of the complaints are nonspecific: fatigue, weakness, abdominal discomfort, poor appetite, and musculoskeletal complaints. The examination is often unremarkable. Laboratory evaluation may not be particularly revealing in all cases, especially with secondary insufficiency.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

After attention has been given to the ABCs, a thorough history and physical examination should be performed, noting altered mental status, fever, tachycardia, hypotension or orthostatic changes, abdominal discomfort, cutaneous and oral hyperpigmentation, or vitiligo.

The first step of treatment is to reverse shock. Normal saline and vasopressors are administered as needed. Central venous lines for hemodynamic monitoring may be necessary, and cardiac monitoring should always be instituted. Laboratory studies are ordered as necessary, including electrolytes, glucose, creatinine, and baseline plasma ACTH, and serum cortisol. Because plasma ACTH is extremely labile, the blood sample must be placed on ice before being transported to the laboratory. The results of these tests can often take days to become available, so if adrenal insufficiency is suspected, treatment should be initiated promptly, particularly because the condition can progress rapidly to circulatory collapse and death. If no apparent cause for cardiovascular collapse is apparent, blood cultures, urine culture, and chest radiography should be performed to seek evidence of occult infection.

In severe cases, it may be necessary to treat the hyperkalemia immediately. The total body potassium level is often low, however, and the serum potassium value can be expected to decrease after glucocorticoids are administered. Symptomatic hyponatremia should also be treated. The next step is to administer glucocorticoids (e.g., dexamethasone, 6 to 8 mg i.v.). Dexamethasone is recommended because it will not interfere with the cosyntropin test, which may be used to try to establish the diagnosis. If the cause of adrenal insufficiency is pituitary failure, treatment with levothyroxine is also indicated. Desmopressin may also be necessary if diabetes insipidus is present.

Patients with known chronic adrenal insufficiency require three to four times their normal glucocorticoid replacement dose during illness and stress. Patients with illnesses severe enough to require hospitalization may need an even higher dose. Those receiving exogenous steroids as therapy for other illnesses must be given adequate doses during surgery, illness, or stress ([Table 172.2](#)).

1. Correct electrolyte levels, blood pressure, and hydration if necessary.
 2. Give hydrocortisone phosphate or succinate, 100 mg i.m., on call to operating room.
 3. Give hydrocortisone phosphate or succinate, 50 mg i.m. or i.v. in recovery room and every 6 hours for the first 24 hours.
 4. If progress is satisfactory, reduce dosage to 25 mg every 6 hours for 24 hours; then taper to maintenance dosage over 3 to 5 days. Resume previous 9 α -fluorocortisol dose when patient is taking oral medications.
 5. Maintain or increase cortisol dosage to 200 to 400 mg/24 h if fever, hypotension, or other complications occur.
- From Felig P, et al. *Endocrinology and metabolism*, 2nd ed. New York: McGraw-Hill, 1987:594.

TABLE 172.2. Corticosteroid Coverage for Surgery

Although not necessary in the emergency department, evaluation of adrenocortical function may be performed with the short ACTH (cosyntropin) test. Immediately after a baseline serum cortisol and plasma ACTH level are drawn, ACTH 0.25 mg is administered intravenously, and a serum cortisol value is obtained 60 minutes later. If prednisone or hydrocortisone has been administered, it will interfere with this test; however, dexamethasone does not interfere with the assay and, furthermore, has no acute effect on the response of the adrenal gland to ACTH.

After the short ACTH test, glucocorticoid replacement is continued with hydrocortisone (100- to 200-mg i.v. bolus, then 20 to 25 mg/h as a continuous infusion). Alternatively, one may give 100 to 200 mg of hydrocortisone every 6 hours as an intravenous infusion over 30 minutes ([Table 172.3](#)). Fluids and vasopressors are administered as needed. The clinical picture of shock should improve within 6 to 12 hours. When the acute adrenal crisis resolves, the infusion can be replaced with an oral regimen of hydrocortisone, 20 mg at 8 a.m. and 10 mg at 2 p.m. Three to four times this dose is needed for patients under continuing stress. Replacement of mineralocorticoid, if necessary, is accomplished with fludrocortisone acetate (Florinef), 0.1 mg daily.

1. Cortisol, 100 mg i.v., every 6 hours for 24 hours. Reduce to 50 mg every 6 hours if progress is satisfactory, and then taper to oral maintenance dose by day 4 or 5. Maintain or increase dosage to 200 to 400 mg/24 h if complications persist or occur.
 2. Intravenous saline and glucose
 3. Correction of precipitating factors
 4. General supportive measures
- From Felig P, et al. *Endocrinology and metabolism*, 2nd ed. New York: McGraw-Hill, 1987:594.

TABLE 172.3. Treatment of Acute Adrenocortical Insufficiency (Adrenal Crisis)

The hallmark of adrenal insufficiency is loss of adrenal reserve, and the diagnosis cannot always be made on the basis of a single cortisol level, which may be in the normal range. A low baseline cortisol level, especially in the presence of physiologic stressors, however, suggests adrenal failure: primary adrenal insufficiency if the ACTH level is high, and secondary adrenal insufficiency if both cortisol and ACTH levels are low.

DISPOSITION

After treatment for shock and glucocorticoid deficiency is begun in the emergency department, all patients with *acute* adrenal insufficiency should be admitted to an intensive care unit. Subspecialty consultation should be requested. The short ACTH test may be performed at this time. Patients in whom *chronic* adrenal insufficiency is suspected should be admitted to the hospital for evaluation.

COMMON PITFALLS

- Because adrenal insufficiency is uncommon and the symptoms are often nonspecific, the emergency physician may fail to consider the diagnosis.
- Patients may be potassium depleted even when the serum potassium concentration is high. The serum potassium value may drop substantially with glucocorticoid replacement and must be monitored closely during treatment.
- Patients with pituitary failure may not show evidence of diabetes insipidus until after deficiencies of glucocorticoids and thyroid hormone have been corrected.
- Patients receiving exogenous steroid therapy should always have the dose increased (to two to four times the usual replacement regimen) when there is intercurrent illness or stress.
- The clinician should not fail to institute appropriate fluid resuscitation and steroid replacement while performing the ACTH stimulation test.

CUSHING SYNDROME

Cushing syndrome, also known as hypercortisolism, occurs whenever there is symptomatic glucocorticoid excess, regardless of the cause of that excess. The syndrome as originally described by Harvey Cushing in 1932 includes truncal obesity, hypertension, weakness, and edema. The most common cause of Cushing syndrome is prolonged exogenous steroid administration.

Cushing disease refers to the situation in which this syndrome is specifically due to excessive ACTH secretion from the pituitary; this accounts for 70% of individuals with naturally occurring Cushing syndrome.²² Cushing disease typically occurs in women between 20 and 40 years of age, is of gradual onset and slowly progressive, and produces only mild symptoms. Most of these patients have pituitary microadenomas; macroadenomas can develop, however, and may present as headaches or visual changes due to pressure on the optic chiasm.

Cushing syndrome can also be caused by an ACTH-secreting carcinoma (e.g., small-cell bronchogenic carcinoma, pancreatic cancer, bronchial carcinoid, or carcinoma of the thymus). The peak incidence is in men between the ages of 40 and 60; the typical course is very rapid, and the tumor is usually advanced when discovered.

Adrenal neoplasms are another cause of Cushing syndrome, comprising about 20% of cases. Typically, these tumors produce signs and symptoms of glucocorticoid excess, but not of androgen excess; they are usually unilateral, and approximately 50% are malignant. Adrenal carcinoma has a rapid onset and rapid progression, with hypokalemia and abdominal pain as common symptoms. Benign adrenal tumors have a slow, progressive course.

CLINICAL PRESENTATION

Obesity and weight gain are the main symptoms. Seventy-five percent of patients have deposition of fat in the face, described as “moon facies,” and around the neck and shoulders, known as a “buffalo hump.” Other fat accumulation occurs within the mesentery, producing truncal obesity. There also may be atrophy of the skin; half of patients have abdominal striae. The face can appear red and flushed. Patients also complain of fatigue and weakness; a proximal myopathy can be detected in about 60% of patients.

Osteoporosis develops from mobilization of calcium, resulting in vertebral compression and pathologic fractures. Glucose intolerance and insulin resistance are other features, but overt diabetes is seen in only about 20% of patients. Delayed wound healing and cutaneous fungal infections may also be noted. Hypertension is common. Women show signs of increased androgens: increased facial hair, acne, and amenorrhea, with the latter present in 75% of premenopausal women ([Table 172.4](#)).

From Felig P, et al. *Endocrinology and Metabolism*, 2nd ed. New York: McGraw-Hill, 1987:466.

TABLE 172.4. Clinical Features of Cushing's Syndrome

Laboratory findings are generally nonspecific in the patient with Cushing syndrome. There may be glucose intolerance due to insulin resistance. The hemoglobin and hematocrit are high-normal, and the white blood cell count usually shows a leukocytosis that is predominantly a neutrophilia. Electrolytes are often normal, but a hypokalemic metabolic acidosis may be present in cases of extreme excess. In some elderly patients, the diagnosis is made in the workup for persistent hypokalemia, with no other signs or symptoms present.³

DIFFERENTIAL DIAGNOSIS

Because many features of Cushing syndrome, such as obesity, hypertension, amenorrhea, and weakness, are common for other reasons, and thus nonspecific, the diagnosis can be difficult to make. Random measurements of serum cortisol have little diagnostic value, because the serum cortisol exhibits substantial diurnal variation, but the diagnosis can be made using low-dose and high-dose dexamethasone suppression testing. Because the performance and interpretation of the dexamethasone suppression test is complicated, it is important to refer these patients to their primary care physician or to an endocrinologist for testing and follow-up.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

One should not expect to make a firm diagnosis of Cushing syndrome in the emergency department, but should promptly refer those patients with a constellation of symptoms consistent with the syndrome to an endocrinologist.

Treatment of Cushing syndrome requires reversal of hypersecretion of hormone, whether it is at a pituitary or an adrenal level. The treatment for microadenomas and macroadenomas is partial hypophysectomy or irradiation of the sella turcica. Complications of this treatment that may be seen in the emergency department include

postoperative diabetes insipidus and hypothyroidism; however, hypothyroidism may take some time to present. Patients who undergo bilateral adrenalectomy may develop Nelson syndrome, the effect of an enlarging pituitary tumor that secretes high levels of ACTH; this syndrome presents as visual changes due to tumor encroachment on the optic chiasm. Ten percent to 20% of patients undergoing bilateral adrenalectomy develop Nelson syndrome within 10 years of surgery.

COMMON PITFALLS

- Because the symptoms are common and nonspecific, the clinician may fail to consider the diagnosis of Cushing syndrome.
- Excess glucocorticoid activity may permit the dissemination of viral disease such as herpes and chickenpox and may allow reactivation of tuberculosis and fungal infections. Most important, fever and other systemic signs of infection may be masked.

PHEOCHROMOCYTOMA

Chromaffin cells in the adrenal medulla are responsible for the release of epinephrine and norepinephrine into the circulation. These cells may form tumors called pheochromocytomas. The pheochromocytoma is known as the “10% tumor”: 10% are bilateral, 10% are extraadrenal, and 10% are malignant. Most pheochromocytomas produce norepinephrine as the predominant catecholamine, but epinephrine, dopamine, and other vasoactive substances can also be secreted.

The incidence of pheochromocytoma is less than 1% in hypertensive patients. However, the diagnosis is important because it is a potentially treatable cause of hypertension. Moreover, the tumor can be malignant or may result in fatal paroxysms of hypertension. In one autopsy series, as many as 75% of cases were not correctly diagnosed before death, demonstrating the difficulty of making the diagnosis.²⁰ Pheochromocytomas are also associated with multiple endocrine neoplasia (MEN) syndromes. MEN-2a, the best known, is Sipple syndrome (pheochromocytoma, medullary carcinoma of the thyroid, and parathyroid adenoma).

CLINICAL PRESENTATION

When these tumors secrete norepinephrine and epinephrine, they are responsible for signs and symptoms of catecholamine excess. The most common of these effects is hypertension, occurring in 90% of patients.¹¹ The hypertension may be persistent but is reported as episodic in approximately 50% of patients. The sudden paroxysms of hypertension may cause the patient to feel a throbbing palpitation or headache. These symptoms may be transient, lasting minutes or several hours, or they may occur once a month or several times a week, but they usually increase in frequency as the tumor grows. Actions that put pressure on the tumor, such as the Valsalva maneuver or exercise, may precipitate attacks. Bladder wall tumors may produce symptoms with micturition. The 10% to 15% of patients who do not have hypertension are thought to have tumors that secrete dopamine or other vasodilating substances.²

Other symptoms of catecholamine excess may be more subtle and persistent. These may include heat intolerance, increased sweating, weight loss, and hyperglycemia. Chronic constriction of the arterial and venous beds may decrease the total intravascular volume, resulting in orthostatic symptoms despite the baseline increase in blood pressure. The heart rate may be increased, but most patients have a reflex bradycardia secondary to hypertension.²

DIFFERENTIAL DIAGNOSIS

Approximately one in 1000 hypertensive patients harbors a pheochromocytoma.² Unusual lability of blood pressure may provide a clue. Episodic symptoms thought to be hot flashes in perimenopausal women or preeclampsia during pregnancy may be due to pheochromocytoma. Other causes of hypertensive crisis may be in the differential diagnosis, especially in patients with refractory hypertension. Ninety percent of patients with pheochromocytoma report spells of headache, palpitations, or sweating.⁸ The combination of uncontrolled hypertension and orthostatic hypotension should suggest the diagnosis.

The definitive diagnosis is established by demonstration of increased catecholamines and their metabolites in a 24-hour urine collection. The urine should be collected for vanillylmandelic acid (VMA), metanephrines, and free catecholamines. A wide variety of drugs (most antihypertensives) and common foods (e.g., bananas, caffeine, and chocolate) can interfere with the test, however. Because results will not be readily available in the emergency department, these tests have no place in emergency department evaluation and management.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The major priority for the emergency physician is treatment of hypertensive emergency, if present, and volume expansion. Initial management with sodium nitroprusside (starting at 1 to 3 µg/kg/min) helps to control hypertension through its arterial and venous dilating effects. If pheochromocytoma is suspected or hypertension is resistant to treatment with nitroprusside, alpha blockade can be achieved with intravenous phentolamine (1- to 4-mg bolus, followed by a continuous infusion titrated to effect). Beta blockade is used to treat arrhythmias and resistant hypertension but should be used only after alpha blockade has been accomplished, to avoid paradoxical hypertension from unopposed alpha effects. Low doses usually suffice. Both nifedipine (10 to 20 mg) and labetalol (20 mg) are useful in treating hypertensive crisis in these patients as well.¹⁷

DISPOSITION

Typically, patients with uncontrolled hypertension and symptoms suggesting hypertensive crisis require admission. Stable patients who are asymptomatic should be referred for prompt follow-up with an endocrinologist for further evaluation and testing.

The recurrence rate after surgical resection is less than 10%; the 5-year survival rate after surgery is approximately 95%. Approximately 25% of patients continue to have hypertension after removal of the pheochromocytoma; the cause is believed to be irreversible vascular damage from previous uncontrolled catecholamine excess or underlying essential hypertension. Hypertension in these patients is usually readily controlled with standard antihypertensive regimens.

COMMON PITFALLS

- A number of commonly used medications can cause catecholamine release and may result in uncontrolled hypertension in patients with pheochromocytoma.^{4,19} These medications include glucagon, droperidol, histamine, tyramine, metoclopramide, saralasin, tricyclic antidepressants, phenothiazines, and naloxone.
- Pheochromocytoma should be considered in patients who complain of transient symptoms that have resolved by the time of emergency department evaluation. These patients may benefit from appropriate referral and outpatient evaluation.
- Because patients with pheochromocytoma are often hypo- volemic, sudden blood loss or sudden loss of vascular tone can result in precipitous and severe hypotension.

HYPOPITUITARISM

Any lesion that destroys the pituitary or hypothalamus or that interferes with releasing and inhibiting factors that act on the anterior pituitary can result in pituitary insufficiency, or hypopituitarism. The pituitary hormones potentially involved include growth hormone, prolactin, the gonadotropic hormones follicle-stimulating hormone and luteinizing hormone, TSH, and ACTH. If the neurohypophysis is involved, vasopressin may also be decreased. The causes of hypopituitarism are summarized in [Table 172.5](#).

The serum sodium concentration and serum osmolality are normally maintained within a narrow range by homeostatic mechanisms involving thirst, antidiuretic hormone (ADH), and renal handling of sodium.

Sodium and chloride ions are normally separated from the glomerular filtrate in the ascending limb of the loop of Henle, leaving behind a hypotonic filtrate and resulting, in the absence of ADH, in the net excretion of free water. Increases in serum osmolality above the normal range of 280 to 300 mOsmol/kg are detected by osmoreceptor neurons in the hypothalamus and cause an increase in thirst and in circulating levels of ADH. ADH acts on the collecting ducts of the renal tubules, increasing free-water reabsorption from the glomerular filtrate into the hypertonic interstitium of the renal medulla; this results in the excretion of low volumes of urine of relatively high osmolality and a return of the serum osmolality toward normal. ADH is also secreted in response to decreases in intravascular volume and (although to a lesser degree) in response to noxious stimuli such as pain, fear, nausea, and hypoxia.²

Sodium balance is regulated independently of ADH by changes in the degree of sodium reabsorption in the proximal tubule. Hypovolemic states such as those caused by hemorrhage or dehydration are associated with increased sodium absorption in the proximal tubule and decreased delivery of sodium to the tubular diluting sites. Conversely, increases in intravascular volume and glomerular filtration rate suppress proximal tubular sodium reabsorption, resulting in increased delivery of sodium to diluting sites.

Disorders of water balance can be traced to abnormalities of thirst or water acquisition, glomerular filtration rate, renal sodium transport, or ADH metabolism.

HYPONATREMIA

CLINICAL PRESENTATION

Hyponatremia is physiologically significant only insofar as it reflects a state of extracellular hypoosmolality in which free water shifts from the vascular space to the intracellular space. Although the resulting cellular edema is well tolerated by most tissues, the brain is very sensitive to changes in cell volume. The clinical manifestations of hyponatremia, usually associated with serum sodium levels below 130 mEq/L, are therefore related primarily to cerebral edema. Symptoms include headache, difficulty in concentrating, confusion, lethargy, agitation, nausea, vomiting, and seizures. Anorexia and muscle cramps are also common.

The incidence and severity of manifestations increase not only with the degree of hyponatremia, but also with the rate at which it develops. When the serum sodium level falls gradually over a period of days or weeks, the brain can compensate by extruding solutes and fluid into the extracellular space.¹² Serum sodium values as low as 110 mEq/L may thus be reached with minimal symptomatology. However, a *rapid* fall in the serum sodium level, from a normal level to levels below 125 mEq/L, exceeds the capacity of these compensatory mechanisms and can lead to profound cerebral edema, to the point of coma or brainstem herniation.²

DIFFERENTIAL DIAGNOSIS

The diagnosis of hyponatremia rests entirely on the ability to obtain and measure accurately the concentration of sodium in the patient's serum. Therefore, the possibility of erroneous sampling should always be considered, especially when the reported value does not seem consistent with the clinical situation. Was the specimen properly labeled? Was it drawn from a venous site proximal to an infusion of hypotonic saline or dextrose 5% in water (D5W)? Is there an error in laboratory measurement or recording? When an error of some kind is suspected, a fresh sample should be obtained and tested before diagnostic or therapeutic procedures are initiated.

There are several clinical conditions in which an accurately measured, low serum sodium concentration does not represent a true hypoosmolar state. The most common is moderate-to-severe hyperglycemia. Extracellular glucose accumulation causes movement of free water into the extracellular space, resulting in hyponatremia yet a normal or even increased serum osmolality. The serum sodium value decreases by approximately 1.6 mEq/L for each 100-mg/dL increase in the serum glucose value.³ This hyponatremia is not physiologically significant, and it resolves as normoglycemia is reestablished. This phenomenon, termed *hypertonic hyponatremia*, is also noted in patients treated with mannitol or glycerol to control intracranial hypertension or acute glaucoma.

Pseudohyponatremia refers to a falsely low serum sodium measurement in patients whose plasma contains excessive amounts of lipid or protein. In this situation, the plasma water in which sodium is dissolved occupies a smaller proportion of the blood specimen. Laboratory methods that measure sodium content per unit of plasma thus report low sodium levels, even though the concentration of sodium in serum water is normal. This situation occurs when the serum sodium concentration is measured by the flame emission spectrophotometry or indirect potentiometry method, but not with direct potentiometry.³ Because the serum osmolality is normal, water metabolism is completely undisturbed. Hyperlipidemia severe enough to produce pseudohyponatremia is almost always associated with a lipemic appearance of the serum. Hyperproteinemia of a sufficient degree to cause pseudohyponatremia is most commonly due to multiple myeloma or administration of intravenous immune globulin.⁷

EMERGENCY DEPARTMENT EVALUATION

The emergency department evaluation of true hyponatremia has two goals. The first is to define the chronicity of the hyponatremic state, which must be based primarily on historic clues. In general, patients with a paucity of symptoms despite sodium levels less than 125 mEq/L are very likely to have chronic hyponatremia. Acute hyponatremia is much less common than chronic hyponatremia and should be suspected in patients with a history of sudden free-water loading (e.g., patients with psychogenic polydipsia, infants given only tap water for 1 to 2 days, and postoperative patients who have been given hypotonic intravenous fluids or who have absorbed hypotonic bladder irrigation fluids).¹

The second goal in the evaluation of the hyponatremic patient is to establish the cause. Hyponatremia can be classified as hypovolemic, euvolemic, or hypervolemic based on the history and physical examination ([Fig. 173.1](#)). Hypovolemic patients demonstrate signs of volume depletion, such as tachycardia, orthostasis, dry

mucous membranes, diminished skin turgor, oliguria, or azotemia. A low fractional excretion of sodium (less than 0.5%) plus low fractional excretion of urea (less than 55%) may be helpful in identifying subtle cases of hypovolemia.⁹ Hypervolemia is manifested by the presence of congestive heart failure, peripheral edema, or ascites. Patients who appear neither volume depleted nor volume overloaded are classified as having euvolemic hyponatremia.

Figure 173.1. Algorithm for diagnosis and treatment of hyponatremia.

Hypovolemic Hyponatremia

Patients with hypovolemic hyponatremia have decreased total body sodium stores. Nonrenal causes of sodium depletion include vomiting, diarrhea, fistulas, gastrointestinal drainage tubes, excessive sweating, and third-spacing of fluids from peritonitis, pancreatitis, or burns. Renal causes of sodium loss include osmotic diuresis and salt-wasting nephropathies such as medullary cystic disease and obstructive uropathy. Thiazide diuretics are one of the most common causes of severe hyponatremia, especially in the elderly population, but hyponatremia appears more often to be the result of significant potassium depletion and of inhibition of free-water generation in the loop of Henle than of volume depletion *per se*.⁵

In general, the nonrenal causes of hypovolemic hyponatremia are associated with a urine sodium value of less than 20 mEq/L, while renal causes are associated with a urine sodium value of more than 20 mEq/L. As a general principle, hyponatremia does not develop unless free-water intake exceeds free-water excretion. In these hypovolemic conditions, hyponatremia is maintained by low glomerular filtration rates that preclude adequate free-water excretion and by high levels of ADH secreted in response to hypovolemia.

Hypervolemic Hyponatremia

Hyponatremic patients with clinical signs of total body sodium excess, usually as evidenced by the presence of edema, are classified as having hypervolemic hyponatremia. Two situations are associated with inappropriate increases in body sodium stores. The first is renal retention of sodium in response to states of decreased effective intravascular volume (e.g., congestive heart failure, cirrhosis, and the nephrotic syndrome). The second is an inability of the kidney to excrete ingested sodium loads because of acute or chronic renal insufficiency.

In patients with hypervolemic hyponatremia, the evaluation should include a search for signs of decreased cardiac output, increased portal vein pressure, nephrotic range proteinuria, or renal insufficiency. Patients with decreased effective vascular volume due to heart failure, cirrhosis, and nephrotic syndrome typically have urine sodium values that are less than 20 mEq/L; those with renal insufficiency typically have values greater than 20 mEq/L.

Euvolemic Hyponatremia

Patients who appear neither dehydrated nor edematous are considered to have euvolemic hyponatremia. As with the other types of hyponatremia, the low serum sodium concentration implies that free-water intake has occurred at a rate that exceeds the kidneys' ability to excrete it. This can occur in patients with psychogenic polydipsia (who, if renal function is normal, must drink at least 15 L of water per day), but it has also been noted in patients who have been given tap water enemas, in infants given tap water bottle feedings, and in hospitalized patients who have been given large amounts of hypotonic fluids. This group is identified by the history of excessive free-water administration and by a urine osmolality that is appropriately low, generally less than 100 mOsmol/L.² Hyponatremia in association with a grossly normal volume status may also be seen in some patients with renal failure who have ingested more free water than can be promptly excreted, given their decreased glomerular filtration rate.

An often considered but somewhat uncommon cause of eu-volemic hyponatremia is the syndrome of inappropriate ADH secretion, or SIADH (Table 173.1), in which ADH is secreted in excessive amounts despite the presence of hyponatremia and adequate intravascular volume. This syndrome is associated with a variety of pulmonary and central nervous system conditions, with malignancy, with the acquired immunodeficiency syndrome (AIDS), and with the use of a number of medications (Table 173.2).¹¹ The diagnostic criteria for SIADH are

DISEASES OF THE CENTRAL NERVOUS SYSTEM	METABOLIC
Infection	Acute porphyria
Trauma	NEOPLASMS
Neoplasm	Lung
Vascular	Pancreas
Degenerative diseases	Duodenum
Psychosis	Lymphoma
PULMONARY DISEASE	Ureter
Pneumonia	Ewing sarcoma
Active tuberculosis	Prostate
Abscesses	STRESS
Asthma	Trauma

TABLE 173.2. Drugs Associated with Hyponatremia

Hypotonic hyponatremia
Inappropriately concentrated urine (UOsmol greater than 100 mOsmol/L)
Normal renal excretory function
Normal adrenal and thyroid function
Absence of hypovolemia and dehydration
Absence of edema

Interestingly, measurement of ADH levels is not helpful in making the diagnosis, because the ADH level is also commonly elevated when hyponatremia is due to other causes.

Two additional causes of euvolemic hyponatremia must be ruled out before one makes the diagnosis of SIADH or exogenous water toxicity–hypothyroidism and cortisol deficiency. Hyponatremia due to cortisol deficiency is rarely associated with a serum sodium level less than 120 mEq/L, and it corrects promptly after glucocorticoid replacement. Hypothyroidism has been associated with sodium levels as low as 110 mEq/L and is treated by thyroid hormone replacement. The mechanism of hyponatremia in these conditions remains incompletely understood.

EMERGENCY DEPARTMENT MANAGEMENT

The treatment of hyponatremia depends on the severity of symptoms and the rate at which hyponatremia has developed. It is important to distinguish between acute and chronic hyponatremia, because the pathophysiology and appropriate treatment are quite different.

Patients with acute hyponatremia (i.e., developing in less than about 48 hours) are at risk for severe central nervous system effects, such as obtundation and seizures, at levels of 125 mEq/L or less. Cerebral edema develops as free water shifts from the vascular space to the intracellular space within a period too short to allow the neurons to compensate by extruding cellular solutes. Cardiopulmonary arrest may occur secondary to brainstem herniation.² First, the source of excess free water must be identified and eliminated. Patients with obtundation or seizures should receive hypertonic (3%) saline to increase the serum sodium rapidly, but only enough to arrest the progression of symptoms. An increase of 4 to 6 mEq/L is usually sufficient to stop hyponatremic seizures. Further correction, using normal saline, should proceed at an overall rate of no more than 0.5 mEq/L/h, and serum sodium levels should be closely monitored. In theory, *acute* hyponatremia can be corrected more rapidly without risk of adverse consequences, but, in practice, it is usually difficult to be certain of the time course over which hyponatremia developed and the degree of cellular compensation that may already have occurred.

Chronic hyponatremia must be managed especially carefully. Overaggressive therapy is potentially more dangerous than the condition itself. In these patients, the brain cells have had time to reduce their solute content to match that of the hypoosmotic serum and are relatively protected from cerebral edema. When patients such as these have the serum sodium concentration increased rapidly, a significant number develop central pontine myelinolysis (CPM), an entity characterized by focal myelin destruction in the pons and extrapontine areas.⁶ Symptoms begin 1 to 3 days after rapid correction of the serum sodium and consist of dysarthria, dysphagia, seizures, altered mental status, quadriparesis, and hypotension.⁶ The condition is typically associated with permanent sequelae. The risk of CPM appears to be quite low in patients whose *chronic* hyponatremia is corrected at a rate of less than 0.5 mEq/L/h until levels in the normal range are reached.⁶ Myelinolysis is not associated with rapid correction of hyponatremia of less than 24 hours' duration.⁵

Hypertonic saline is indicated only for the initial correction of severely symptomatic acute or chronic hyponatremia. The appropriate volume of hypertonic saline required to produce a given change in the serum sodium level may be calculated using the following formula:

$$\text{Required volume} = \frac{(\text{Na}_{\text{desired}} - \text{Na}_{\text{current}})(\text{TBW})}{(\text{Na}_{\text{IV fluid}} - \text{Na}_{\text{current}})}$$

Thus, for a 50-kg woman with 60% total body water and serum sodium of 113 mEq/L, the volume of 3% NaCl (513 mEq/L) required to raise the serum sodium by 4 mEq/L would be

$$\frac{(4 \text{ mEq/L})(50 \text{ kg} \times 0.6)}{(513 - 117)} = 0.3 \text{ L or } 300 \text{ mL}$$

One might give 300 mL of 3% NaCl over the first 1 to 2 hours until resolution of seizures and then proceed with other steps to increase the serum sodium by a total of less than 12 mEq/L over the first 24 hours. Furosemide may be given in addition to hypertonic saline to produce a net negative water balance, as well as to lessen the risk of sodium overload.

In patients *without* severe manifestations, such as seizures or coma, the treatment of hyponatremia should be directed at the underlying cause. Hypovolemic hyponatremia should be treated with normal saline. Hypervolemic hyponatremia is often difficult to treat, because the underlying disorders are usually not readily reversible. Sodium and water restriction is usually the best alternative. Diuretics may result in transient loss of sodium and water but may ultimately decrease glomerular filtration rate and thereby limit free-water excretion. Patients with euvolemic hyponatremia should have their free-water intake restricted, and any identifiable underlying cause should be treated. Diuretic-induced hyponatremia responds to withdrawal of the offending medication, liberalized sodium intake, and repletion of total body potassium.

COMMON PITFALLS

- Do not overlook the possibility of sampling error, hyperglycemia, hyperlipidemia, or hyperproteinemia before making the diagnosis of hypotonic hyponatremia.
- Always consider the diagnosis in groups at high risk for severe hyponatremia, including elderly patients on diuretics, psychiatric patients, infants given only tap water, postoperative patients receiving hypotonic intravenous fluid therapy, and patients with malignancy or AIDS.
- Acute symptomatic hyponatremia should be recognized and treated quickly in order to avoid cerebral edema and brainstem herniation syndrome. Chronic hyponatremia should be corrected at an overall rate less than 0.5 mEq/L/h or 12 mEq/L/d in order to minimize the risk of central pontine myelinolysis.

HYPERNATREMIA

Hypernatremia is considerably less common than hyponatremia, because even a small increase in the serum sodium concentration is a potent stimulus to thirst. Elevated serum sodium levels develop only in patients who are unable to experience thirst or are unable to gain access to water. Hypernatremia is most often seen at extremes of age.

CLINICAL PRESENTATION

Hypernatremia reflects a state of intravascular hyperosmolarity that results in the efflux of water from the intracellular space to the extracellular space. Signs and symptoms are primarily related to central nervous system dehydration. Mental status changes range from irritability to lethargy, confusion, delirium, seizures, and coma. Muscle tone tends to be increased, as are deep tendon reflexes. Central nervous system hemorrhage into the subarachnoid, intracerebral, or subdural space is seen in severe cases and is thought to be caused by tearing of bridging veins as they are stretched by shrinkage of brain tissue.⁴

As with hyponatremia, the severity of symptoms correlates both with the severity of hypernatremia and the rate at which it develops. When the serum sodium value increases gradually over several days or weeks, neurons respond by retaining excess quantities of osmotically active solutes. This minimizes the efflux of free water from the cells and delays the onset of symptoms until relatively extreme levels of hypernatremia are achieved. When hypernatremia develops rapidly (in less than 48 hours), this adaptive mechanism is overwhelmed, and symptoms develop.

EMERGENCY DEPARTMENT EVALUATION

It is helpful to classify hypernatremia as hypovolemic, hypervolemic, or euvolemic on the basis of clinical signs of dehydration or volume overload. Classification helps to narrow the list of causes and aids in the selection of therapy (Fig. 173.2).

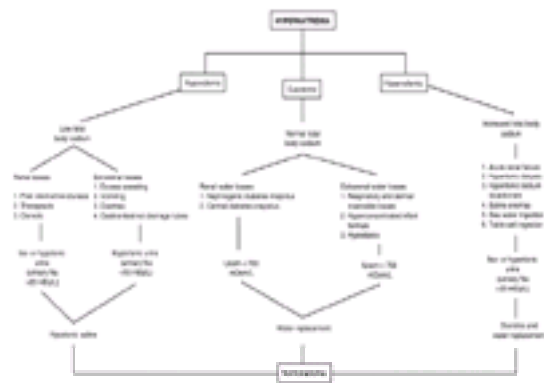

Figure 173.2. Algorithm for diagnosis and treatment of hypernatremia.

Hypovolemic Hypernatremia

Patients with hypovolemic hypernatremia exhibit signs of dehydration such as tachycardia, orthostasis, dry mucous membranes, diminished skin turgor, oliguria, and azotemia. Hypovolemia implies that total body sodium stores are decreased, and hypernatremia implies that free water has been lost to a greater degree than sodium. There are nonrenal and renal causes. Nonrenal causes of hypovolemia include excessive sweating, protracted vomiting, diarrhea (hyperosmotic nasogastric feedings, acute gastroenteritis, lactulose), and gastrointestinal drainage tubes; the urine sodium concentration is less than 10 mEq/L. Renal causes include postobstructive, osmotic, or therapeutic diuresis; the urine sodium is greater than 20 mEq/L. Notably, to achieve a hypernatremic state, the loss of hypotonic fluids must be coupled with inadequate free-water replacement.

Hypervolemic Hypernatremia

Patients with signs of fluid overload (e.g., pulmonary edema or peripheral edema) are classified as having hypervolemic hypernatremia. This group has increased total body sodium stores, with a smaller increase in total body free water. The differential diagnosis includes acute renal failure, use of hypernatremic dialysate solutions, seawater ingestion, and excessive administration of sodium in the form of hypertonic saline, sodium bicarbonate, or saline enemas or emetics. An enteral overdose of as little as 4 teaspoons of table salt can result in a serum sodium concentration of 160 mEq/dL in the average adult. Patients who have taken an overdose of table salt but have had no intake of water may not have overt signs of hypervolemia. The urine sodium value is more than 20 mEq/L in these cases.

Euvolemic Hypernatremia

Patients who appear neither dehydrated nor edematous are considered to have euvolemic hypernatremia, implying appropriately normal total body sodium stores and an isolated loss of free water. This may occur in comatose or intubated patients whose insensible free-water losses are not adequately replaced. It is especially common in those whose insensible losses are accelerated because of tachypnea or fever. Euvolemic hypernatremia is also seen in infants whose powdered formula is inadequately diluted or, rarely, in persons with an intrinsic defect in the hypothalamic thirst drive, a condition known as essential hypernatremia. In all of these cases, the urine osmolality is appropriately greater than 700 mOsmol/L during water deprivation.

Diabetes insipidus causes euvolemic hypernatremia due to inappropriate loss of free water in the urine. In this condition, there is an inability to maximally concentrate urine during periods of water deprivation. This inability may be due to inadequate hypothalamic secretion of ADH (central diabetes insipidus) or an inability of the kidneys to respond adequately to circulating ADH (nephrogenic diabetes insipidus). In either case, hypernatremia is accompanied by inappropriately dilute urine (UOsmol less than 700 mOsmol/L³), even during water restriction.

EMERGENCY DEPARTMENT MANAGEMENT

As with the treatment of hyponatremia, it is important to distinguish between acute hypernatremia (less than 48 hours' duration) and chronic hypernatremia (greater than 48 hours' duration), because cell physiology and the response to therapy are quite different.

Acute hypernatremia is much less common and usually develops in the setting of inadvertent sodium administration. Severe neuronal dehydration develops and the cells are unable to rapidly adapt by retention of additional cellular osmoles. Subarachnoid, intracerebral, and subdural hemorrhage may occur. Therefore, acute hypernatremia should be corrected rapidly, using D5W or oral administration, until acute manifestations begin to improve. Diuretics should be added for patients with clinical signs of volume overload.

More commonly, hypernatremia develops over several days or even weeks because of slower loss of hypotonic fluid or insensible free-water loss. The neurons adapt by retaining cellular solutes, minimizing movement of free water out of the cell. Rapid administration of hypotonic saline or D5W in these patients carries a risk of cerebral edema. Chronic hypernatremia should be normalized at a steady rate over 48 to 72 hours.¹⁰

The free-water deficit can be calculated using the following formula:

$$\text{Water deficit} = \text{TBW} \frac{(\text{Na}_{\text{actual}} - \text{Na}_{\text{desired}})}{\text{Na}_{\text{actual}}}$$

where total body water is 60% of the usual body weight. This can be administered as D5W or oral water, with 30% given over the first 24 hours and 70% over the next 48 hours.⁹ Hypovolemic patients should receive 0.9% normal saline (154 mEq/L) until they are euvolemic and can then be started on hypotonic fluids. Hypervolemic patients with chronic hypernatremia may require diuretic therapy in addition to free-water replacement.

COMMON PITFALLS

- Always consider the possibility of hypernatremia in high-risk patients: infants and demented, comatose, or intubated patients without access to free-water replacement.
- Chronic hypernatremia should be corrected gradually over 48 to 72 hours in order to minimize the risk of cerebral edema.

Normally, total body potassium amounts to about 50 mEq/kg, or 3500 mEq in a person weighing 70 kg.⁸ Ninety-eight percent of it is within the intracellular space, and 2% is in the extracellular space. The normal serum potassium concentration is between 3.5 and 5.0 mEq/L in most laboratory assays. Because of the relatively small percentage of total body potassium in the extracellular space, the serum potassium level does not always reflect total body potassium. The average 70-kg person has a total extracellular potassium content of only 70 mEq; therefore, potentially dangerous hyperkalemia may occur during overly rapid potassium administration because of a delay in the redistribution of potassium from the extracellular to the intracellular space.

PHYSIOLOGY AND PATHOPHYSIOLOGY AT THE CELLULAR LEVEL

The ratio of extracellular to intracellular potassium concentration is the major determinant of the cellular membrane resting potential, which affects the function of neurons, cardiac myocytes, smooth muscle cells of the gut, and skeletal muscle cells. Dysfunction of these cells causes most of the clinical manifestations of hyperkalemia and hypokalemia. [Table 174.1](#) outlines the factors that affect transcellular potassium distribution.^{1,2,4,5 and 6,10,23}

FACTORS INCREASING SERUM POTASSIUM CONCENTRATIONS	FACTORS DECREASING SERUM POTASSIUM CONCENTRATIONS
Acidemia	Alkalemia
Insulin deficiency	Insulin
Beta blockers	Beta-adrenergic agonists
Alpha-adrenergic agonists	Sodium-potassium-ATPase activity
Hyperosmolarity	(cellular sodium-potassium pump)
Aldosterone deficiency	Aldosterone

TABLE 174.1. Extrarenal Factors Affecting Transcellular Potassium Distribution

PHYSIOLOGY AND PATHOPHYSIOLOGY AT THE ORGAN AND SYSTEM LEVEL

Total body potassium content is determined by the difference between potassium intake and potassium excretion. About 90% of potassium excretion occurs in the urine, about 10% in feces, and a very small amount in sweat. Therefore, renal potassium excretion is the major determinant of the total body potassium content and potassium homeostasis. [Table 174.2](#) outlines the factors that affect renal potassium excretion.

FACTORS INCREASING RENAL POTASSIUM EXCRETION	FACTORS DECREASING RENAL POTASSIUM EXCRETION
High-potassium diet	Low-potassium diet
Aldosterone and other mineralocorticoids	Aldosterone deficiency
Natriuresis	Oligoanuria
Chronic metabolic alkalosis	
Chronic metabolic acidosis	
Chronic respiratory acidosis	
Glucocorticoids	
Anions such as penicillin salts	

TABLE 174.2. Factors Affecting Renal Potassium Excretion

HYPERKALEMIA

CLINICAL PRESENTATION

Hyperkalemia is most common in patients with chronic renal insufficiency. Clinical manifestations of hyperkalemia are most evident in the cardiovascular and neuromuscular systems.²⁰ Cardiac manifestations of hyperkalemia ([Table 174.3](#)) are most common and are often not heralded by any other symptoms before the onset of life-threatening dysrhythmias and cardiac arrest.²⁰ Neuromuscular manifestations are rarely clinically evident but can include decreased deep tendon reflexes, weakness, and respiratory muscle insufficiency. The clinical manifestations of hyperkalemia are potentiated by concomitant hyponatremia or hypocalcemia and tend to be more severe when the serum potassium concentration has risen rapidly.

EARLY CHANGES
Tall peaked (tented) T waves Shortened QT interval
LATER CHANGES
Widened QRS complex Increased PR interval Low-amplitude P waves Elevation or depression of ST segment
ADVANCED CHANGES
Absent P waves Marked QRS complex widening Sine wave pattern Ventricular fibrillation Asystole

*There is only a rough correlation of ECG changes with serum potassium concentration. Life-threatening dysrhythmias can occur at even mildly elevated serum potassium concentrations.

TABLE 174.3. Electrocardiographic Manifestations of Hyperkalemia ^a

DIFFERENTIAL DIAGNOSIS

There are four general causes of a high serum potassium level: artifactual hyperkalemia, excessive potassium intake, decreased renal potassium excretion, and transcellular maldistribution. [Table 174.4](#) outlines the differential diagnosis and etiologies of hyperkalemia. ^{3,7,10,12,13} and ^{14,18,20}

ARTIFACTUAL HYPERKALEMIA
Hyperkalemia in vitro or due to sample error Excessive leukocytosis or thrombocytosis Rapid tourniquet inflation during venipuncture Inadequate mixing of sample in anticoagulant Clot retraction
EXCESSIVE POTASSIUM INTAKE
Oral or intravenous potassium supplements Prescription potassium salts Over-the-counter potassium Dietary potassium Cation exchange Renin-inhibitor or diuretic treatment Excessive use of diuretics or radiation
DECREASED RENAL POTASSIUM EXCRETION
Acute renal failure Chronic renal insufficiency Hypokalemia Etiology Diagnosis Treatment Prognosis Prevention Differential diagnosis
TRANSCELLULAR MALDISTRIBUTION
Acidemia Hypokalemia secondary to metabolic acidosis Hypokalemia secondary to metabolic alkalosis Hypokalemia secondary to hypomagnesemia Hypokalemia secondary to hypocalcemia Hypokalemia secondary to hypophosphatemia Hypokalemia secondary to hypoparathyroidism

TABLE 174.4. Etiologies and Differential Diagnosis of Hyperkalemia

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of hyperkalemia should be suspected in patients with any of the predisposing conditions listed in [Table 174.4](#), especially chronic renal insufficiency or acute renal failure. The presumptive diagnosis of hyperkalemia is based on electrographic (ECG) changes (see [Table 174.3](#)) in a clinical setting that predisposes to hyperkalemia (see [Table 174.4](#)). If these presumptive diagnostic criteria are met, continuous cardiac monitoring and specific emergent therapy for hyperkalemia should be instituted before laboratory confirmation. The definitive diagnosis of hyperkalemia is established by determining a serum, plasma, or whole blood potassium concentration.

Artifactual hyperkalemia should be suspected in an appropriate clinical setting (see [Table 174.4](#)) when the patient does not have symptoms, signs, or ECG changes compatible with hyperkalemia. Continuous cardiac monitoring should be maintained while the potassium concentration is measured on a second blood sample.

Measurement of the plasma potassium level may be needed to confirm artifactual hyperkalemia that is due to extreme leukocytosis or thrombocytosis; the elevated *serum* potassium concentration in this case is due to release of potassium from platelets or leukocytes during clotting. ^{3,11}

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Because ECG changes correlate only roughly with serum potassium levels, continuous cardiac monitoring is advisable whenever the serum potassium level is elevated, although dangerous effects usually do not occur below a level of 6.5 mEq/L. Specific therapy is indicated when associated ECG changes are present. ^{13,17,20,21}

For mild potassium elevations in the absence of clinical and ECG manifestations of hyperkalemia, management should be directed at determining the most likely etiology of hyperkalemia and taking steps to correct any identified predisposing factors. This might include, for instance, discontinuing oral potassium supplements or drugs known to produce hyperkalemia. Spurious hyperkalemia should, of course, be ruled out. Provided there is no reason to believe that the serum potassium level will rise further, the patient can be discharged and outpatient follow-up arranged for a repeat potassium determination and further evaluation within 48 to 72 hours. In other cases, however, admission to the hospital is advisable. Patients with greater elevations of the serum potassium level require admission to a monitored bed.

When ECG or clinical manifestations of hyperkalemia are present, continuous cardiac monitoring and specific emergent therapy are indicated. These patients should be admitted to an intensive care unit with continuous cardiac monitoring.

Except in the setting of digoxin toxicity, calcium is the first-line therapy for severe hyperkalemia because its therapeutic effect is almost immediate, with a duration of about 30 to 60 minutes. Calcium does not alter the extracellular or total body potassium content but acts by electrophysiologically stabilizing cell membranes. ^{13,20} The adult dose is one ampule (10 mL) of a 10% calcium gluconate solution (4.6 mEq/10 mL), ^{13,20} or one ampule (10 mL) of a 10% calcium chloride solution (13.6 mEq/10 mL). This is given over at least 2 minutes by a peripheral vein and repeated in 5 to 10 minutes if necessary. ^{13,20} Intravenous calcium should be reserved for treatment of severe hyperkalemia and cardiac manifestations requiring immediate intervention. It is relatively safe, although it may cause transient hypercalcemia with its attendant adverse effects.

Intravenous sodium bicarbonate has a therapeutic effect that begins within minutes and lasts about 2 hours. ^{9,17} Like calcium, it is a temporizing measure, causing a shift of potassium from the extracellular to the intracellular space without altering total body potassium. The dose is one or two ampules (about 50 mEq per ampule) given intravenously over about 5 minutes and repeated after 15 minutes, if necessary. ^{9,17} Potential complications of NaHCO₃ include significant alkalemia, hypernatremia, hyperosmolality, hypervolemia, shift of the oxyhemoglobin dissociation curve to the left, and precipitation of hypocalcemic tetany.

Glucose and insulin act together to shift potassium from the extracellular to the intracellular space, but also do not change the total body potassium content. They thus provide another means of buying time until definitive therapy can be instituted. Therapeutic effects begin within 30 to 60 minutes and last 4 to 6 hours.

Unless the patient is hyperglycemic, glucose and insulin should be used in combination, even in the nondiabetic patient, because one cannot always depend on an adequate endogenous insulin response to a glucose load. ²⁰ A common bolus dose is 10 U of regular insulin and 25 to 50 g of glucose. ^{13,17,20} Because bolus therapy causes an acute change in blood osmolality, which may transiently worsen hyperkalemia, some prefer administration by infusion. A typical infusion is 500 mL of D₁₀W with 10 U of regular insulin, infused over 30 to 60 minutes. Potential complications of glucose and insulin therapy include hyperglycemia, hypoglycemia, and hyperosmolality.

Beta-adrenergic stimulation results in movement of potassium into cells, and both epinephrine and albuterol have been investigated for their potassium-lowering

potassium loss.

EMERGENCY DEPARTMENT EVALUATION

Hypokalemia should be suspected in patients with any of the predisposing conditions listed in [Table 174.6](#), especially in those taking a non-potassium-sparing diuretic. An ECG with prominent U waves in multiple leads supports the diagnosis but is nonspecific. Hypokalemia is established by determining a serum, plasma, or whole blood potassium concentration.

The combination of hypokalemia and hypertension in the absence of other obvious predisposing factors suggests primary hyperaldosteronism.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

It is reasonable to admit patients with serum potassium concentrations less than 2.5 mEq/L. A serum potassium concentration of 2.5 mEq/L generally reflects a total body potassium deficit of 200 to 400 mEq.^{9,17,20} Patients with mild hypokalemia (2.5 to 3.5 mEq/L) can usually be managed as outpatients with gradual oral potassium repletion, provided they do not manifest cardiac dysrhythmias, ileus, profound muscle weakness, or other serious effects.

Emergency department management should focus on determining the etiology of hypokalemia, confirming that the patient can tolerate oral potassium repletion, and excluding other serious conditions or complications. Patients who can be sent home with oral potassium supplementation should have follow-up within 48 to 72 hours to check the potassium level and to undergo further diagnostic evaluation, as necessary.

In mild hypokalemia, the oral route for potassium repletion is preferred because of its ease, safety, and economy. Potassium chloride (KCl) at a daily dosage of 40 to 80 mEq, with no more than 40 mEq given as a single dose, is usually effective. KCl may be given as a liquid, in enteric-coated tablets, or in wax matrix tablets. KCl solution is the preparation of choice because it is generally well tolerated and inexpensive. Enteric-coated KCl tablets can cause GI ulceration. Wax matrix KCl tablets cause less GI ulceration and are the preferred alternative for the patient who finds oral KCl solution unacceptable because of its taste.

When metabolic acidosis accompanies hypokalemia (as may occur with severe diarrhea), potassium bicarbonate, potassium citrate, or potassium gluconate is preferred over KCl. Potassium-sparing diuretics do not, in themselves, replete total body potassium deficits, and they should generally not be used concurrently with oral potassium supplements, because severe hyperkalemia can result.

For more severe hypokalemia (K^+ less than 2.5 mEq/L), the total body potassium deficit can be profound, and potassium repletion is more urgent. Patients should have an intravenous line and should be monitored for rhythm disturbances or the development of other symptoms. In the absence of clinical or ECG manifestations, potassium repletion can be accomplished by the oral route while close observation and continuous cardiac monitoring are continued. Otherwise, repletion generally should begin with combined intravenous and oral administration of KCl.

Intravenous KCl should not be given at a rate greater than 40 mEq/h through a peripheral intravenous line, but it may be given through a femoral line at a rate of up to 60 mEq/h for emergent treatment of hypokalemia-induced paralysis or malignant ventricular arrhythmias.^{9,13,14} and ^{15,20} For rates above 10 mEq/h, continuous cardiac monitoring and a constant infusion pump should be used to avoid accidental overinfusion.

Because intravenous KCl can cause local vein irritation and phlebitis, some clinicians recommend infusion into a central vein, but this practice seems to increase the potential for cardiac dysrhythmias. Simultaneous oral and intravenous potassium repletion, although effecting improvement more rapidly, carries a higher risk of hyperkalemia.

Patients with gastric acid loss from persistent vomiting often develop "hypokalemic contraction alkalosis." The dehydration and metabolic alkalosis from gastric acid loss cause the kidney to conserve sodium and chloride and to increase potassium and bicarbonate excretion. In addition to potassium supplementation, these patients require rehydration, usually with intravenous sodium chloride, to correct their hypokalemia.

Hypokalemic patients with any of the following conditions should be admitted to an intensive care unit with continuous cardiac monitoring: malignant cardiac dysrhythmias, digitalis toxicity, profound weakness with impending respiratory insufficiency, a serum potassium concentration below 2.0 mEq/L, rhabdomyolysis, or hepatic encephalopathy.

COMMON PITFALLS

- Replacing potassium too rapidly without appropriate cardiac and laboratory monitoring
- Overcorrecting hypokalemia into the hyperkalemic range by excessive potassium administration, especially when hypokalemia is due to transcellular maldistribution rather than a total body potassium deficit (e.g., hypokalemic periodic paralysis)

Disorders of calcium, magnesium, and phosphorus metabolism can result in life-threatening emergencies that have nonspecific presentations resembling those of many other disease processes. However, emergency department (ED) testing for the presence of these disturbances must be selective. Such testing must be guided by an understanding of the pathophysiology of these disorders and the clinical settings in which they are likely to occur. Once a diagnosis is made, this same understanding makes it possible for the physician to choose effective and appropriate therapy.

CALCIUM

About 40% of the serum calcium is protein-bound, an additional 10% to 15% is chelated with other anions, and the physiologically active, ionized component makes up the remaining 45% to 50%. Serum calcium levels are regulated primarily by interactions between parathyroid hormone (PTH) and vitamin D. PTH increases bone resorption and renal tubular calcium resorption. Vitamin D is responsible for regulating intestinal calcium absorption, and has an additional bone resorptive effect.

The normal total serum calcium level ranges from 8.5 to 10.5 mg/dL, and the free ionized level from 4.0 to 4.8 mg/dL. Raising the pH increases calcium binding to serum proteins, lowering the free ionized fraction without altering the total plasma calcium level. Ionized calcium changes by about 1.7 mg/dL for every change of 0.1 pH units. Alterations in serum protein also affect the measured Ca^{2+} ; that is, decreasing the serum albumin by 1 g/dL lowers the total serum calcium by about 0.8 mg/dL.¹ Measurement of ionized Ca^{2+} may be warranted in patients with suspected hypocalcemia who are hypoalbuminemic or alkalotic.

HYPERCALCEMIA

CLINICAL PRESENTATION, EMERGENCY DEPARTMENT EVALUATION, AND DIFFERENTIAL DIAGNOSIS

The severity of the manifestations of hypercalcemia depends on the serum calcium level, the rate of rise from normal values, and the presence of concurrent medical conditions.⁴ Central nervous system (CNS) manifestations, ranging from weakness, lethargy, depression, and confusion to obtundation or coma, are prominent. Gastrointestinal (GI) manifestations such as anorexia, nausea, vomiting, abdominal pain, and constipation are also typical. In the kidney, hypercalcemia causes an inability to concentrate the urine, leading to polyuria and dehydration. Chronic hypercalcemia may be associated with nephrocalcinosis and renal failure.¹

ED evaluation should include at least serum electrolytes, calcium (total and ionized), and an electrocardiogram (ECG). The most common ECG correlate of hypercalcemia is shortening of the Q-T interval, but more severe effects include dysrhythmias and heart block; ultimately, asystole can occur. Hypercalcemia can also exacerbate digoxin toxicity.

The major causes of hypercalcemia are listed in [Table 175.1](#). Among these, primary hyperparathyroidism and malignancy (especially carcinoma of the breast and lung) are the most common. The combination of CNS and GI symptoms and shortened QT in the setting of existing malignancy should suggest hypercalcemia. However, other causes of multisystem dysfunction, such as infection, or primary CNS or GI system dysfunction, should also be considered.

ENDOCRINE DISORDERS
Hyperparathyroidism
Hyperthyroidism
Adrenal insufficiency
Phenothiazines
MALIGNANCY
Solid tumors
Breast, lung, colon, stomach, cervix, ovary, kidney, bladder, head, and neck
Hematologic
Multiple myeloma
Lymphoma
GRANULOCYTOSIS DISEASES
Sarcoidosis
Tuberculosis
Histiocytosis, eosinophilic myositis
DRUGS
Thiazides
Lithium
Vitamin D intoxication
Vitamin A intoxication
MISCELLANEOUS
Dehydration or prolonged immobilization
Enanthelidism ingestion
Metabolic syndrome

TABLE 175.1. Causes of Hypercalcemia

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Symptomatic hypercalcemia or a serum calcium level above 15 mg/dL requires immediate intervention. Forced saline diuresis is the first-line treatment; 1 to 2 L of isotonic saline is given initially, followed by 200 to 500 mL/h, depending on the level of volume depletion. Intravenous furosemide (20 to 40 mg every 6 to 8 hours) is

given to enhance urinary output and decrease calcium reabsorption in the loop of Henle once intravascular volume has been repleted. ^{4,20}

Additional treatment should be considered when the serum calcium level does not respond rapidly to saline diuresis. Calcitonin (2 to 4 IU/kg intramuscularly or subcutaneously every 12 hours) causes a rapid fall of the serum calcium level in most patients and is appropriate for those who respond suboptimally to saline diuresis or for whom saline loading and diuresis are not practical (e.g., patients with congestive heart failure). ^{4,18}

Although mithramycin (25 µg intravenously) can also be used to lower the serum calcium level, the effect is not apparent for at least 12 hours. ⁴ Dialysis is occasionally necessary if rapid control of the serum calcium level is critical. ^{5,9}

Hydrocortisone (100 to 150 mg intravenously every 12 hours) is effective mainly in hypercalcemia due to hematologic malignancy. ¹⁶ Several other agents, among them gallium nitrate, etidronate, and pamidronate, have controlled the hypercalcemia of malignancy; all act by inhibiting bone resorption, but because of the slow onset of effect, they are inappropriate for emergency therapy.

Intravenous phosphate can decrease serum calcium levels rapidly, but should not be given because of the risk of metastatic calcification and resulting organ damage, including dysrhythmias. Intravenous sodium EDTA should also be avoided because of dangers associated with its use. ⁷

The disposition of patients from the ED depends on the presence or absence of symptoms. Patients with symptomatic hypercalcemia need close monitoring in a telemetry unit to continually assess for cardiovascular complications, especially pulmonary edema. Serum calcium, potassium, and magnesium levels must also be checked regularly. In patients with asymptomatic hypercalcemia, discharge with close outpatient follow-up (less than 1 week) is appropriate. Prior to discharge from the ED, obtaining a serum PTH level may facilitate the outpatient workup.

COMMON PITFALLS

- Common complications of saline diuresis include congestive heart failure and fluid overload.
- A common error is to give a loop diuretic before intravascular volume repletion; this tends to deplete volume further, decreasing the glomerular filtration rate, and may exacerbate hypercalcemia.
- Frequent monitoring of calcium, magnesium, and potassium levels (and appropriate replacement) is necessary during treatment.
- Thiazide diuretics should be discontinued, because they can increase the serum calcium level. ²⁰

HYPOCALCEMIA

CLINICAL PRESENTATION, EMERGENCY DEPARTMENT EVALUATION, AND DIFFERENTIAL DIAGNOSIS

Hypocalcemia should be considered in patients who have renal failure, chronic malabsorption, or a history of neck surgery or neck irradiation ([Table 175.2](#)). It should also be considered in those who display the cardinal signs or symptoms of hypocalcemia, primarily neuromuscular irritability. Hypocalcemia is also a feature of disorders in which intravascular calcium is chelated by any of a number of anions, such as rhabdomyolysis (phosphates), ethylene glycol poisoning (oxalate), hydrofluoric acid exposure (fluoride), and pancreatitis (fats). Lastly, it is found in settings of overdoses of two frequently used medications: beta blockers and calcium channel blockers.

HYPOPARATHYROIDISM
Neck surgery Neck irradiation
RENAL FAILURE
MEICATIONS
Anticonvulsants Corticosteroid overdose Chromatographic agents
GASTROINTESTINAL
Malabsorption syndromes Vitamin D deficiency Acute pancreatitis
OVERDOSE
Calcium channel blocker Beta blocker
MISCELLANEOUS
Hypophosphatemia Adrenal insufficiency Ethylene glycol Hydrofluoric acid Inorganic arsenite, selenite, selenic acidosis Ethanol Magnesium deficiency Hypomagnesemia (normal ionized fraction)

TABLE 175.2. Causes of Hypocalcemia

Clinical symptoms depend on both the ionized calcium level and the rapidity of its fall from normal values. Patients with hypocalcemia frequently complain of circumoral and distal extremity paresthesias, although nonspecific symptoms such as weakness, fatigue, irritability, or altered mental status may predominate. The classic manifestations of carpopedal spasm, hyperreflexia, muscle cramping, and tetany are more troubling, and laryngospasm, seizures, or precipitation of congestive heart failure can be life-threatening. Trousseau's sign (carpopedal spasm after arterial occlusion of the arm for 3 minutes) and Chvostek's sign (contraction of the facial muscles after percussion over the facial nerve) may indicate subclinical hypocalcemia.

The typical ECG manifestation of hypocalcemia is prolongation of the Q-T interval. Inverted T waves, sinus bradycardia, complete heart block, ventricular dysrhythmias, and ventricular fibrillation have also been reported.

Hypocalcemia must be differentiated from other conditions presenting in a similar manner, including hypomagnesemia, severe alkalosis, strychnine poisoning, and tetanus.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

CaCl₂ is the drug of choice for acutely symptomatic patients with severe hypocalcemia, as 1 ampule (10 cc) delivers 13.6 mEq (272 mg) of Ca²⁺, compared with 4.6 mEq (93 mg) provided by 10 cc of Ca²⁺ gluconate. Some clinicians recommend the routine use of calcium gluconate, as opposed to calcium chloride, in the absence of cardiovascular collapse, because it is less irritating to veins. Standard doses are 5 to 10 cc of CaCl₂ or 5 to 10 cc of calcium gluconate, up to a total one-time dose of 20 cc. In special situations (e.g., severe calcium channel blocker overdose), repeating the CaCl₂ may be beneficial. Furthermore, an infusion of 1 to 2 mg/kg/h is often necessary after bolus dosing. Continued cardiac monitoring and serial calcium levels are indicated. The infusion should be terminated if bradycardia or a shortening of the QT interval develops.

All symptomatic patients require admission to a telemetry or intensive care unit. For asymptomatic patients, oral calcium (1 to 4 g/d in divided doses), with or without vitamin D, is appropriate. Outpatient follow-up should be emphasized to evaluate the underlying etiology.

COMMON PITFALLS

- Refractory hypocalcemia that does not respond to intravenous calcium may be due to hypomagnesemia. ¹
- Calcium should be given cautiously to patients on digitalis, as digitalis toxicity may be precipitated or exacerbated. ²⁴
- If hyperphosphatemia is present, calcium administration may result in calcium phosphate precipitation in soft tissues.
- Calcium should not be given in the same intravenous line as sodium bicarbonate, or precipitation will occur. ¹

MAGNESIUM

Like calcium, serum magnesium is made up of fractions that are protein-bound (30%) and chelated (15%); the rest is the physiologically active, ionized component. The normal serum magnesium concentration is 1.5 to 2.5 mEq/L.

HYPERMAGNESEMIA

CLINICAL PRESENTATION, EMERGENCY DEPARTMENT EVALUATION, AND DIFFERENTIAL DIAGNOSIS

Because the kidney is efficient in excreting excess magnesium, hypermagnesemia is uncommon, except in the presence of renal insufficiency or severe dehydration. In patients with normal renal function, hypermagnesemia has been reported after parenteral administration of magnesium in the therapy of toxemia,¹³ magnesium salt enemas, bladder irrigation with hemiacidrin,⁸ and oral ingestion of magnesium preparations in the presence of a perforated viscus.²⁵

Hypermagnesemia causes cardiac and neuromuscular depression. Lethargy, nausea, vomiting, flushing, and mental confusion are common but nonspecific manifestations. Depression of deep tendon reflexes is often noted as levels exceed 4 mEq/L. At higher levels, marked muscle weakness, paralysis, and respiratory insufficiency develop; dysrhythmias and cardiac arrest occur at even higher levels. The ECG manifestations of hypermagnesemia include prolongation of the P-R interval, QRS complex, and the Q-T interval, but these findings are variable and nonspecific.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

The treatment of hypermagnesemia begins with removal of the source of exogenous magnesium. In symptomatic patients, 10 mL of 10% calcium gluconate or calcium chloride solution can be given intravenously¹; calcium transiently reverses hypermagnesemia effects by acting as a direct membrane antagonist. In patients with adequate renal function, intravenous normal saline and furosemide are given to promote a brisk diuresis and enhance urinary magnesium excretion. In patients with very high magnesium levels or in those with renal failure, emergency peritoneal dialysis or hemodialysis may be necessary.

ED disposition will vary based on the level of supportive care required. Relatively asymptomatic patients should be monitored on telemetry if renal function is abnormal or if ECG changes are evident. Magnesium levels below 5 mEq/L do not usually require aggressive treatment, and patients are generally asymptomatic. Such patients may be discharged with outpatient follow-up once dehydration is corrected and any source of supplemental magnesium is eliminated.

COMMON PITFALLS

- Magnesium-containing antacids and laxatives should be avoided in patients with renal failure and in those with a decreased glomerular filtration rate.
- Hypermagnesemia should be suspected in patients presenting with neuromuscular depression in a clinical setting potentially associated with hypermagnesemia. This is unlikely to occur unless there has been rapid and massive magnesium administration or renal function is impaired.

HYPOMAGNESEMIA

CLINICAL PRESENTATION, EMERGENCY DEPARTMENT EVALUATION, AND DIFFERENTIAL DIAGNOSIS

Hypomagnesemia can result from many causes (Table 175.3), but is most commonly seen in the ED in association with alcoholism, diuretic use, or malnutrition. The measured serum magnesium concentration may not accurately reflect the patient's total body magnesium status. Alcoholics and patients with renal disease may have depleted total body magnesium stores but a normal or even an elevated serum level. Up to 40% of patients with other electrolyte deficiencies are magnesium-deficient as well, whether or not symptoms are present.²²

DIETARY
Alcoholism Malnutrition
GASTROINTESTINAL
Malabsorption syndromes Chronic diarrhea
RENAL
Tubular dysfunction
DRUGS
Diuretics
DRUGS CAUSING INTRACELLULAR SHIFT
Insulin treatment of diabetic ketoacidosis
ENDOCRINE/METABOLIC
Diabetic or alcoholic ketoacidosis Hypokalemia Bazins Sepsis

TABLE 175.3. Causes of Hypomagnesemia

Hypomagnesemia may be responsible for a variety of psychiatric, neuromuscular, GI, and cardiovascular effects.^{6,16} Many of the symptoms and signs may be due to other associated disorders, such as hypocalcemia and hypokalemia.²² Psychiatric complaints can range from apathy and depression to delirium and coma. Neuromuscular effects are similar to those of hypocalcemia, ranging from extremity tremors to convulsions.²¹ Nausea, anorexia, and abdominal pain may be noted. Cardiovascular effects, including atrial and ventricular dysrhythmias (especially torsades de pointes), are potentially immediately life-threatening.²¹

The ECG changes associated with hypomagnesemia may be related to an interaction with other abnormalities of calcium and potassium.²² Although acute changes in magnesium levels may result in peaked or flattened T waves, chronic changes are associated with P-R prolongation, QRS widening, and, most commonly, Q-T prolongation.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Emergent therapy and hospitalization are warranted when severe hypomagnesemia is associated with cardiac dysrhythmias, marked CNS manifestations, or other severe symptoms. ECG monitoring is mandatory, and there should be frequent evaluation of the deep tendon reflexes.

Magnesium therapy is indicated for arrhythmias associated with a prolonged Q-T interval. It is the drug of choice for torsades de pointes, in a dose of 2 g pushed intravenously. For other cardiac indications, the data are less clear. Although several studies appeared to show decreased mortality when Mg²⁺ was used in the treatment of myocardial infarction, this was not confirmed by the largest prospective study, the ISIS 4 trial.³ Mg²⁺ may be helpful for supraventricular arrhythmias, if associated with hypokalemia, hypomagnesemia, or alcohol withdrawal.

For seizures, tetany, or malignant ventricular dysrhythmia, 2 g of magnesium sulfate may be given intravenously over several minutes, followed by 5 g intravenously over 6 hours. Dysrhythmias due to hypomagnesemia may be unresponsive to conventional antidysrhythmic therapy, but they respond well to intravenous magnesium.

In general, patients with serum magnesium levels below 1 mEq/L should be hospitalized: Most are symptomatic, and repletion typically takes several days. Repletion can be initiated with intravenous doses of 2 to 5 g given over several hours, followed by oral supplementation of up to 6 g/d until stable normal serum levels are restored. Most administered magnesium is rapidly excreted in the urine, and only a fraction is taken up by the cells. Doses should be withheld if the serum level rises

above 1.5 mEq/L at any time, or if deep tendon reflexes are lost, indicating hypermagnesemia. Magnesium supplementation is also appropriate for patients with alcohol withdrawal and for those with hypokalemia or hypocalcemia that is unresponsive to the usual corrective measures.

Recent studies, however, do not support the routine use of Mg²⁺ for alcoholic patients presenting to the ED.¹¹ Nevertheless, intravenous Mg²⁺ is recommended for those being treated for withdrawal, as it has been shown to decrease the risk of seizures, as well as decrease arrhythmias during withdrawal. It takes 5 to 7 days to replete total body stores.

Other clinical settings in which treatment with magnesium may be indicated are digitalis toxicity, eclampsia, and cocaine-induced myocardial infarction. Mg²⁺ opposes the effect of digitalis on the resting membrane potential of myocardial cells, thereby decreasing spontaneous depolarizations. Mg²⁺ is the treatment of choice for eclampsia, because it blocks Ca²⁺-mediated vasospasm. This may also be the mechanism for its beneficial effect in cases of cocaine-induced myocardial ischemia.

Patients with mild or chronic hypomagnesemia can be treated with oral supplementation (magnesium oxide or enteric-coated magnesium chloride¹⁷) and an adequate diet. These patients generally exhibit minimal symptoms and can be discharged from the ED with outpatient follow-up (less than 1 week). Oral magnesium can cause diarrhea, however, and the dose should be decreased if this occurs. Treatment should always include correction of the underlying cause of the hypomagnesemia.

COMMON PITFALLS

- The degree of hypomagnesemia generally correlates only roughly with the degree of total body magnesium depletion.
- Most administered magnesium is rapidly excreted in the urine, so correction of magnesium depletion requires days to weeks of supplementation.
- Hypokalemia or hypocalcemia refractory to the usual corrective measures may be due to underlying hypomagnesemia, correction of which allows correction of the other electrolyte disorder(s).

PHOSPHORUS

Eighty percent to 85% of total body phosphorus is found in bone; almost all of the remainder is in skeletal muscle and soft tissue.⁹ Because most of the body's phosphorus is intracellular, serum phosphate concentrations do not necessarily reflect total body stores. Normal serum levels in adults range from 2.7 to 4.5 mg/dL. Fifteen percent of the phosphorus in serum is protein-bound; the remaining 85% is in the form of HPO₄⁽⁻²⁾ and H₂PO₄⁽⁻⁾ in a molar ratio of 4:1 at a pH of 7.4.

Phosphate homeostasis is under the control of vitamin D and PTH. The former stimulates bone resorption in some mineral-deficiency states and stimulates phosphate absorption in the GI tract; the latter acts in the proximal renal tubule to increase phosphate excretion.¹⁵ Other hormones, such as insulin, estrogen, and thyroid hormone, may also modify renal tubular handling of phosphate.

HYPERPHOSPHATEMIA

CLINICAL PRESENTATION, EMERGENCY DEPARTMENT EVALUATION, AND DIFFERENTIAL DIAGNOSIS

The most common cause of hyperphosphatemia is acute or chronic renal failure,¹⁹ and severe hyperphosphatemia is rare unless renal function is at least moderately impaired. Other etiologies include hypoparathyroidism, excess human growth hormone, rhabdomyolysis, and cytotoxic therapy (as part of the tumor lysis syndrome). Exogenous causes of hyperphosphatemia include overtreatment of hypophosphatemia and the use of phosphate-containing laxatives and enemas ([Table 175.5](#)).

1 g MgSO ₄ = 8.12 mEq Mg
1 mEq Mg = 0.5 mmol Mg = 12.3 mg
1 mEq/dL Mg = 1.2 mg/dL
1 g MgSO ₄ = 98 mg of elemental Mg
1 Mg oxide tablet = 111 mg = 9 mEq Mg
1 10-cc ampule of 50% MgSO ₄ = 5 g of Mg or 40.6 mEq Mg

Not all ampules contain the same amount of Mg²⁺.

TABLE 175.4. Key Magnesium Conversions

ENDOGENOUS
Renal failure
Hypoparathyroidism
Excess growth hormone
Tumor lysis syndrome
Rhabdomyolysis
EXOGENOUS
Phosphate enemas
Phosphate laxatives
Overtreatment of hypophosphatemia

TABLE 175.5. Causes of Hyperphosphatemia

The clinical manifestations of hyperphosphatemia, if any, result from its effect on calcium homeostasis.¹⁹ If phosphate and calcium concentrations reach levels at which the solubility product is exceeded, calcium-phosphate crystal deposition can occur in the heart, kidney, lungs, and other soft tissues. Acute hypocalcemic symptoms can also occur.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Treatment of hyperphosphatemia *per se* should rarely be necessary in the ED. Any treatment these patients receive is directed at the underlying associated illness. For refractory hyperphosphatemia, hemodialysis may be required.

Phosphate-binding antacids containing calcium are used chronically by renal failure patients to control serum phosphate levels; oral phosphate intake is also restricted.¹⁵

COMMON PITFALL

Specific treatment for hyperphosphatemia *per se* is rarely indicated. Instead, therapy is directed at the underlying associated disorders.

HYPOPHOSPHATEMIA

CLINICAL PRESENTATION, EMERGENCY DEPARTMENT EVALUATION, AND DIFFERENTIAL DIAGNOSIS

As with magnesium and calcium, altered states of phosphate homeostasis often go unrecognized. The causes of hypophosphatemia are varied ([Table 175.6](#)); those related to alcohol and diabetes are most commonly seen in the ED.¹⁵ Alcoholism is associated with hypophosphatemia because of dietary insufficiency and urinary phosphate losses, as well as several other postulated mechanisms.¹⁵

DECREASED INTAKE OR ABSORPTION
Decreased dietary phosphate intake
Diarhea, malabsorption
Vitamin D deficiency
Phosphate-binding antacid therapy for renal failure
INCREASED LOSS
Hyperparathyroidism
Renal tubular defects
Prolonged diuresis
TRANSCELLULAR MOVEMENT
Insulin administration
Respiratory alkalosis
Alcohol withdrawal
Treatment of diabetic ketoacidosis

TABLE 175.6. Causes of Hypophosphatemia

Patients with diabetic ketoacidosis (DKA) are usually hyperphosphatemic on initial presentation, although their total body phosphate level is depleted due to urinary losses.¹⁶ After treatment with fluids and insulin, phosphate falls due to transcellular shifts and continuing urinary losses. Although the benefit of phosphate repletion in DKA remains controversial,²⁴ phosphate administration is recommended if hypophosphatemia is moderate (less than 1.5 to 2.0) or severe (less than 1.0 mg/dL).²³

Unless hypophosphatemia is severe, most patients remain asymptomatic. With severe hypophosphatemia, which is associated with chronic total body phosphate depletion, there may be clinical effects on neurologic, pulmonary, and cardiac function. Patients may present with paresthesias, weakness, dysarthria, depressed reflexes, or altered mental status.¹⁵ Severe hypophosphatemia affects diaphragmatic contractility² and can therefore contribute to respiratory failure. Cardiomyopathy has been described in severely hypophosphatemic patients,¹⁴ as have rhabdomyolysis and hemolytic anemia.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Mild-to-moderate hypophosphatemia is asymptomatic and can be corrected with 1 to 3 g of phosphate supplementation daily.¹⁵ Oral preparations such as skim milk, Neutra-Phos, or Phospho-Soda can be used. Severe or symptomatic hypophosphatemia is rarely encountered in ED patients; if it is, intravenous phosphate salts are required.¹² In these rare severe cases, therapy can be begun with 0.5 to 1.0 mL/h of K_2PO_4 for the average 70-kg patient, where 1 mL of K_2PO_4 contains 4.4 mEq K^+ and 3 mmol (93 mg) $PO_4^{(-)}$. A simple way to administer this is to put 2 cc K_2PO_4 in 1: of fluid and run it at 250 cc/h.

The rare patient with severe symptomatic hypophosphatemia needs intensive care monitoring.

COMMON PITFALL

The administration of intravenous phosphate is rarely required. Its use may be associated with hypocalcemia and tissue deposition of phosphate salts, and thus is strongly discouraged.

the renal vasculature (e.g., malignant hypertension), or the tubules (e.g., ATN).¹⁹

ATN accounts for up to 85% of intrinsic renal failure in adults.¹⁹ It is frequently self-limited and often reversible. Etiologies include ischemic insults to the kidney (e.g., shock, hemorrhage), administration of drugs (e.g., aminoglycosides, intravenous contrast agents), and pigment nephropathy (e.g., myoglobinuria occurring secondary to limb ischemia, cocaine use, hyperthermia, or crush injuries). In ATN, the tubules lose the ability to concentrate urine and to reabsorb sodium. The urine tends to have a specific gravity similar to that of serum (1.010), and the urinary sodium concentration tends to be greater than 40 mEq/L.¹⁹ On microscopic urinalysis, granular casts and tubular epithelial cells are noted in about 80% of patients.¹² ATN may be either oliguric or nonoliguric, the nonoliguric variety having a better prognosis.¹⁹

AIN accounts for about 10% of intrinsic renal failure in adults.¹⁹ It is usually caused by a drug hypersensitivity reaction, but can also be due to infection, immune-mediated disease, or other causes.¹⁵ Many drugs have been implicated in AIN, including beta-lactam antibiotics, sulfonamide drugs, and NSAIDs.¹⁵ Patients with AIN may present with fever, rash, arthralgias, eosinophilia, and eosinophiluria (the latter detectable by Hansel's stain of the urine). However, these findings are frequently absent, making differentiation of AIN from other causes of ARF difficult.¹⁵

Postrenal azotemia results from obstruction of the renal collecting system at the level of the ureters, bladder, or urethra. For renal failure to develop, ureteral obstruction must be bilateral (except in patients with a single functioning kidney). Among the common causes of obstruction are prostatic hypertrophy or carcinoma, cervical carcinoma, neurogenic bladder, and urethral stricture. Ureteral obstruction may also occur as a result of blood clots, tumors, calculi, retroperitoneal fibrosis, or malignancy.¹⁰ It is important to note that patients with obstructive, postrenal failure may present with anuria, oliguria, or normal urinary output. Because the renal parenchyma is unaffected, microscopic urinalysis may reveal hematuria but is otherwise essentially normal.

EMERGENCY DEPARTMENT EVALUATION

The emergency department (ED) evaluation of the patient with ARF requires a two-step approach. The physician should immediately determine whether life-threatening complications exist, and then attempt to determine the cause of ARF so that potentially reversible causes can be corrected.

A detailed history should be obtained, including recent exposure to new medications (especially diuretics, NSAIDs, and ACE inhibitors), intravenous contrast material, chemicals, animal venoms, unusual plants or foods, or illicit drugs.^{2,19} A history of recent hospitalization, surgery, or other intercurrent illness that might be associated with renal hypoperfusion (e.g., cirrhosis, aortic or vascular disease, or congestive heart failure) should also be sought. A history of malignancy is especially important, as these patients are at risk of ARF from obstruction, radiation nephritis, or chemotherapy. Urinary retention in such patients, especially in conjunction with back pain or neurologic symptoms, should prompt immediate evaluation for spinal cord compression. Bone pain in the elderly should suggest multiple myeloma. Recent onset of paroxysmal nocturnal dyspnea or orthopnea may suggest volume overload.

Physical examination should begin with an assessment of volume status. Hypertension, rales, peripheral edema, or jugular venous distention suggests fluid overload. Resting tachycardia, orthostatic hypotension, dry mucous membranes, or poor skin turgor points to hypovolemia. Signs of uremia should be sought, including asterixis, alteration in mental status, and pericardial friction rub. Skin examination may reveal generalized rash in AIN, livedo reticularis in atheroembolic renal failure, or palpable purpura with vasculitis.

Laboratory analysis should include a complete blood count, electrolytes, glucose, calcium, phosphorus, blood urea nitrogen (BUN), and creatinine. The urine should be sent for microscopic analysis, specific gravity, osmolality, and sodium and creatinine concentrations. Urine specific gravity, rapidly available in the ED, is a reasonable estimate of urine osmolality, except when solutes such as glucose or radiocontrast media are present. Anemia and thrombocytopenia may suggest thrombotic thrombocytopenic purpura (TTP) or HUS. A pregnancy test should be done in women of childbearing age because of the unusual but important causes of ARF that are associated with pregnancy, including preeclampsia and septic abortion,¹⁴ and because radiography may be used during the workup. A chest x-ray aids in the determination of volume status. An electrocardiogram (ECG) should be performed to evaluate for hyperkalemia. An arterial blood gas (ABG) analysis may be helpful, especially if acidosis, reflected in a low serum bicarbonate, is severe.

After ruling out immediately life-threatening complications, the patient should be evaluated for evidence of urinary tract obstruction. A prostate examination in men and a pelvic examination in women are mandatory. Percussion of the suprapubic area, or bedside ED ultrasonography, may reveal an enlarged bladder. Costovertebral angle tenderness may suggest ureteral obstruction. A Foley catheter should be passed to exclude bladder outlet obstruction and to monitor urine output, even in patients without oliguria.

If bladder catheterization does not reveal evidence of distal obstruction and another etiology for ARF is not readily apparent, attention must be directed at ruling out bilateral ureteral obstruction. Renal ultrasound can detect hydronephrosis with a sensitivity of 98% to 99% and a specificity of 75% to 80%.⁵ Despite this high sensitivity, nondilated obstructive uropathy can occur early after obstruction, in cases due to malignancy or retroperitoneal fibrosis and in patients who are severely dehydrated.¹² Noncontrast computed tomography (CT) of the renal collecting system may be helpful if ultrasonography is inconclusive or if the etiology of the obstruction is unclear.⁵

The gold standard for diagnosing obstruction is retrograde pyelography, which avoids contrast-induced nephrotoxicity but requires urologic consultation. Intravenous pyelography (IVP) is contraindicated because of the real risk of nephrotoxicity due to contrast agent.³

If obstruction is not the cause of ARF, urinary electrolytes should be evaluated to determine whether renal failure is pre-renal or renal.⁷ As previously noted, urinary sodium is frequently less than 20 mEq/L in prerenal azotemia,¹² while, in intrinsic renal failure, tubular reabsorption of sodium is compromised and the urinary sodium concentration often exceeds 40 mEq/L.¹⁹ In addition, in prerenal failure, enhanced sodium and water reabsorption results in increased passive reabsorption of urea, elevating the BUN out of proportion to the serum creatinine. Hence, a BUN/creatinine ratio greater than 20:1 suggests prerenal azotemia. The most accurate index for differentiating between prerenal and renal failure is the fractional excretion of sodium (FE_{Na}),⁷ which measures the percentage of sodium presented to the renal tubules that is not reabsorbed:

$$FE_{Na} = [U_{Na}/P_{Na}]/[U_{Cr}/P_{Cr}]$$

In prerenal azotemia, the FE_{Na} is usually much less than 1%, whereas in ATN or AIN, it is elevated, often to above 3%. Urinary sodium and FE_{Na} are increased in patients who have received diuretics.

Microscopic urinalysis provides further information.¹⁹ In prerenal azotemia, the urinalysis is unremarkable; occasional hyaline casts may be all that is noted. With intrinsic renal causes of ARF, one can expect to see a more "active" sediment. In ATN, the urine contains granular casts and tubular epithelial cells, individually or in casts.¹² In AIN, there is often eosinophiluria and white cell casts. Patients with acute glomerulonephritis often have dysmorphic red cells and red cell casts.¹⁹ [Table 176.2](#) lists laboratory features useful in distinguishing between prerenal azotemia and ATN.

	Prerenal Azotemia	Acute Tubular Necrosis
BUN/creatinine ratio	>20:1	<10:1
Urinary sodium	<20 mEq/L	>40 mEq/L
Urinary osmolality	>500	<350
Urine-specific gravity	>1.020	<1.010
FE_{Na}	<1%	>2%
Urinalysis	Normal sediment or hyaline casts	Granular casts, tubular epithelial cells

TABLE 176.2. Distinguishing between Prerenal Azotemia and Acute Tubular Necrosis

EMERGENCY DEPARTMENT MANAGEMENT

Volume overload and hyperkalemia are the most common causes of early death in ARF patients. Fluid overload is best avoided by accurate initial assessment of volume status, judicious administration of fluids, and constant reassessment of oliguric or anuric patients. Patients who present in pulmonary edema benefit from traditional therapy (i.e., oxygen, morphine, and diuretics, with particular attention paid to the use of nitrates to reduce preload) until hemodialysis is available.⁹

Hyperkalemia is a life-threatening emergency that may become manifest abruptly in ARF, particularly in patients whose renal failure is due to rhabdomyolysis. The management of this entity is discussed in [Chapter 179](#).

Hypertension requiring immediate treatment may be managed with intravenous nitrates or sodium nitroprusside.¹¹ The latter agent should be used for only relatively brief periods in patients with renal failure due to the risk of thiocyanate toxicity. Adjuvant oral medications with a relatively rapid onset of action include labetalols, β blockers, α_2 agonists, and calcium channel blockers.¹¹

Once potentially life-threatening complications of renal failure have been addressed, the next priority is to identify the cause of renal dysfunction and to reverse it, if possible. If the etiology appears to be postrenal, prompt relief of the obstruction can prevent further renal injury. Bladder outlet obstruction is almost always relieved by passage of a Foley catheter. Clamping the Foley catheter when large volumes of urine are released from the bladder, once a common practice, is unnecessary, even if the patient develops gross hematuria.¹⁰ If obstruction persists after bladder catheterization, or if a Foley catheter cannot be placed, urologic imaging and consultation are indicated.

If the cause of renal insufficiency appears to be prerenal, intravascular volume should be replenished with intravenous crystalloid or blood. If prerenal azotemia occurs in the face of normal or increased total body sodium (e.g., congestive heart failure), efforts must be made to correct the underlying disorder to improve renal perfusion. Invasive monitoring may be necessary to monitor volume status.

The efficacy of diuretics and dopamine in oliguric patients with ARF is the subject of controversy.^{6,12,17,19,21} There are no data to support the routine use of dopamine (which can cause tachyarrhythmias, cardiac ischemia, and digital and gut necrosis) in patients with adequate cardiac output.^{6,17,19,20} and ²¹ Similarly, there is no evidence that diuretics decrease morbidity, mortality, or progression to end-stage renal disease in patients with ARF.^{17,19,21} Moreover, the routine use of diuretics in the initial care of ARF patients poses a number of risks. Administering a diuretic to a patient who is already volume contracted may precipitate ischemic ATN, and administering a diuretic to a patient with obstructive uropathy might increase hydrostatic damage to the kidneys. Administering mannitol to an anuric patient can cause intravascular volume expansion and pulmonary edema. For patients with myoglobinuric renal failure, however, mannitol is recommended, in combination with volume replacement and sodium bicarbonate.¹

A number of life-threatening emergencies associated with ARF may require emergent dialysis. Nevertheless, treatments or temporizing measures are available for each and should be instituted while arrangements are made for dialysis or transfer. The indications for acute dialysis can be remembered using the mnemonic AEIOU: severe acidosis, electrolyte abnormalities (especially hyperkalemia and hyponatremia), ingestions (ethylene glycol, methanol, lithium, theophylline, salicylate, and others), volume overload, and uremia. Central venous access with a large-bore catheter is required for hemodialysis, and percutaneous peritoneal access must be secured for peritoneal dialysis. Should emergent dialysis be necessary, direct consultation with a nephrologist is essential to coordinate timely intervention.

DISPOSITION

Although the initial evaluation and management of the patient with ARF can generally be performed in the ED, the patient with ARF is best managed in the hospital. If the etiology is clearly postrenal, consultation with a urologist is mandatory, as emergent surgical decompression may be indicated. For metabolic or uremic complications of renal failure, whether acute or chronic, nephrology consultation in the ED is prudent.

Most patients presenting to the ED with ARF should be admitted to the hospital for further evaluation. A possible exception is the patient with prerenal azotemia secondary to an easily correctable cause such as diarrhea or diuretic therapy. Such a patient can sometimes be discharged with close follow-up if fluid resuscitation is carried out in the ED and urine output is reestablished. Nonazotemic patients with acute urinary outflow tract obstruction corrected by bladder catheterization can, in many cases, also be discharged with an indwelling catheter. In this case, urine should be cultured and close urologic follow-up arranged.

Transfer to a tertiary care facility should be considered for any patient with renal failure if dialysis is not available at the primary facility. Because potentially life-threatening complications of renal failure can develop rapidly, the emergency physician should not wait until complications appear before arranging for transfer. In rare cases, the patient must be transferred to an out-of-hospital dialysis unit. In these cases, the ED physician must ensure that the accepting physician will be immediately available upon the patient's arrival. All available and appropriate modalities should be instituted before transfer, and the patient should be transported by an advanced life-support unit.

COMMON PITFALLS

- Failing to recognize and initiate therapy for life-threatening complications before continuing with any workup. An ECG should always be checked if hyperkalemia is possible.
- Failing to assess volume status adequately. Fluid replacement may be all that is necessary in order to reverse prerenal insufficiency.
- Forgetting the simple things: a prostate examination in men and a pelvic examination in women, and insertion of a Foley catheter to rule out bladder outlet obstruction, which can occur even in the patient who is voiding.
- Failing to appreciate that the serum creatinine is not an accurate measure of renal function in the ARF patient.
- Giving diuretics to the hypovolemic oliguric patient, which only further increases volume contraction, potentially worsening renal perfusion.
- Delaying appropriate transfer to a center where dialysis can be performed, even though most life-threatening uremic complications can be treated before emergency dialysis is initiated.

ACKNOWLEDGMENT

The authors gratefully acknowledge the work of Dr. Robert Rosenthal, who contributed significantly to this chapter in previous editions.

familial kidney disease, such as polycystic kidney disease or Alport syndrome, may also be helpful.

Laboratory abnormalities such as anemia, acidosis, hyperkalemia, hypocalcemia, and hyperphosphatemia can occur with *acute* renal failure as early as 10 days after its onset, but they tend to be better tolerated in patients with chronic renal disease. Findings on urinalysis are usually not helpful. Attention must be directed toward potentially reversible factors (e.g., volume depletion or obstruction), as they may represent the only opportunity to reverse the patient's disease rather than simply to manage its effects (Table 177.3).

REVERSIBLE FACTORS
Hypovolemia
Congestive heart failure
Pericardial tamponade
Severe hypertension
Catabolic state/protein loads
Nephrotoxic agents
Obstructive disease
Reflex disease

TREATABLE CAUSES
Renal artery stenosis
Malignant hypertension
Acute interstitial nephritis
Hypercalcemic nephropathy
Multiple myeloma
Vasculitis (e.g., systemic lupus erythematosus, Wegener granulomatosis, periarthritis nodosa)
Obstructive nephropathy
Reflex nephropathy

TABLE 177.3. Reversible Factors and Treatable Causes of Chronic Renal Failure

DIALYSIS

Patients with ESRD are often sustained on chronic hemodialysis or chronic ambulatory peritoneal dialysis (CAPD). Although usually seen regularly by their nephrologists and nurse specialists, they continue to be relatively frequent visitors to emergency departments, being subject to those complications of chronic renal failure that are not corrected by dialysis, to the manifestations of underlying systemic diseases, and to complications of the dialytic therapy itself. ^{7,18,19 and 20}

Compared with other patients, dialysis patients are less able to tolerate the stresses of intercurrent illness or trauma. Moreover, there is a significant potential for iatrogenic illness due to inappropriate fluid or drug administration. Even apparently innocuous agents, such as antacids and enemas, can cause serious problems. Physicians caring for patients with ESRD should thus have ready access to a reference compendium containing guidelines for the adjustment of drug dosages in renal failure.²

A number of serious problems are commonly encountered both in dialysis patients and in those with chronic renal failure who have not yet undergone dialytic therapy. The approach is similar in the two patient groups. The two major dialysis modalities, hemodialysis and CAPD, are themselves associated with specific complications with which the emergency physician should be familiar.

Hemodialysis

In hemodialysis, the patient's heparinized blood passes through an extracorporeal dialyzer circuit in which it is in contact with an artificial dialysis membrane. Water and solutes from the blood diffuse across this membrane to normalize blood volume and correct metabolic abnormalities. The amount of fluid transferred depends on the pressure under which blood is pumped through the dialyzer. Hemodialysis is usually performed several times a week for 3 to 5 hours per treatment. The high blood-flow rates that are necessary to make this an efficient process necessitate special access to the patient's circulation, generally through a surgically created arteriovenous fistula or through an artificial vascular graft, both of which are usually placed in the arm.

The vascular access device must be treated with care to avoid causing thrombosis or bleeding or introducing infection. The blood pressure should never be taken in the involved arm, and a tourniquet should never be applied. Unless absolutely essential, one should avoid drawing blood from the access or placing an intravenous line in it. However, if no other site is available and it is essential to obtain blood samples (e.g., if blood is needed immediately for crossmatch in a patient with serious bleeding), the fistula or graft can be used. Careful skin cleansing and sterile technique are mandatory, and firm but nonocclusive pressure should be applied to the site for 10 minutes after the puncture. The presence of a thrill both before and after the procedure should be documented.

Likewise, if intravenous access is critical but otherwise impossible, an intravenous line may be placed in the access, but with similar infection precautions and continuous observation during the infusion. Special care should be taken not to puncture the back wall of the access. An automated infusion pump is necessary to control the infusion rate, particularly when using the relatively high-pressure vessels in artificial arteriovenous grafts. With the low pressure typical of mature dilated fistulas, an infusion pump is still advisable.

Hemodialysis patients may present to the emergency department with a variety of complaints relating to the vascular access. Hemorrhage from a recent puncture site is usually easily managed with continuous, firm, but nonocclusive pressure over the site. Thrombosis, signaled by the loss of the thrill in the access, requires immediate consultation with a vascular surgeon, who may elect to perform a radiocontrast fistulogram, to infuse a thrombolytic agent, or to revise the access surgically. Forceful irrigation attempts are inadvisable.

The most common access-related problem is access infection, which is a serious concern in these patients because of the associated risk of bacteremia and metastatic infection, as well as the risk that the access may have to be removed because of persistent infection or impaired function. Infection is more likely to occur in an artificial graft than in a native fistula.

Most access infections are staphylococcal; contamination with skin flora at the time of puncture is believed to be the most likely cause. The diagnosis of access infection is not always obvious. When there is warmth, redness, tenderness, or local induration over the area and the patient is febrile, there is little cause for confusion, but some patients lack definite local signs and may present with repeated episodes of bacteremia or with fever and no obvious source of infection. In this situation, one should suspect access infection, draw blood cultures, and begin antibiotic therapy promptly.

A commonly used regimen is vancomycin 1 g, given intravenously as a single loading dose. Vancomycin is not hemo-dialyzable and needs to be given only once every 5 to 7 days, making it an attractive choice for staphylococcal coverage; in addition, its major toxicity is renal. A third-generation cephalosporin or an aminoglycoside can be added to this regimen if infection with a gram-negative organism is suspected. Local practice may vary, however, and emergency physicians should be familiar with the regimens in common use in their own institutions. Although a febrile illness may prove to be of viral etiology, it is prudent to treat such patients on the presumption of bacterial illness, because they can deteriorate rapidly and do have a high risk of access infection.

Not all febrile dialysis patients need to be admitted to the hospital. After intravenous antibiotic loading, a reliable patient who otherwise feels and looks relatively well may be sent home with careful instructions to return if there is any clinical deterioration. This decision is best reached in conjunction with the consulting nephrologist.

Peritoneal Dialysis

In CAPD, the patient's own peritoneum serves as the membrane across which diffusion of water and solutes occurs. Sterile dialysis fluid is infused into the peritoneal cavity through a surgically implanted Tenckhoff catheter; after a dwell period of 4 to 8 hours, it is exchanged for fresh fluid. Exchanges are performed by the patient at home, usually four times a day, 7 days a week, using a sterile exchange technique. Osmotic forces generated by high concentrations of glucose in the dialysis fluid ensure adequate removal of fluid volume from the blood; this is in contrast to hemodialysis, in which the amount of fluid removed is controlled by adjusting the pressure under which blood is introduced into the dialyzer coil. CAPD offers several advantages over hemodialysis: greater patient independence, smoother control of excess volume and hypertension, and avoidance of rapid solute shifts and intermittent anticoagulation.

As with hemodialysis, many of the emergency problems encountered by the patient on CAPD are related to access devices, in this case the peritoneal catheter. By far, the most common problem is peritonitis, caused by inadvertent contamination of the peritoneal cavity when exchanges are performed or by direct invasion of organisms from an infected catheter exit site. Peritonitis in these patients is, as a rule, less severe than other types of peritonitis. In fact, these infections are usually treated on an outpatient basis, despite the fact that they involve the presence of a foreign body. Occasionally, if infection cannot be eradicated with antibiotic therapy, the catheter must be removed surgically and hemodialysis initiated pending placement of a new catheter after the infection has cleared.

About two-thirds of episodes of peritonitis are due to gram-positive organisms, predominantly staphylococci. In most of the remainder, assorted gram-negative organisms are responsible; a small percentage are due to fungal infection, which is usually considered an indication for catheter removal. Polymicrobial infection suggests a communication with the bowel or genitourinary tract.

The diagnosis of peritonitis is usually based on the patient's observation of cloudiness in the dialysate effluent at the time an exchange is performed. This is generally the earliest sign of peritonitis; thus, patients are instructed to seek medical attention immediately when they notice it. Abdominal pain and fever often develop if treatment is not initiated promptly. Hospital admission becomes necessary if there is high fever, hypotension, severe abdominal pain, or nausea and vomiting, or if the patient cannot continue to carry out exchanges at home.

In the emergency department, the diagnosis of peritonitis is confirmed by the finding of organisms on Gram stain of the peritoneal fluid or of a cell count of more than 100 white blood cells/ μ L (predominantly neutrophils). This cell count corresponds approximately to the level at which cloudiness begins to be grossly detectable. Even in patients who have not noted cloudiness of the peritoneal effluent but who have fever, abdominal pain, or vague malaise, it is advisable to obtain a sample of fluid for examination, because the presentation of peritonitis can initially be subtle.

The fluid is obtained using meticulous sterile technique. Some is put into an open Vacutainer tube and sent for cell count and differential. The remainder, still in the syringe, should be sent to the microbiology laboratory for Gram stain and culture.

CAPD-related peritonitis can usually be treated on an outpatient basis.⁸ In general, treatment decisions should be made in conjunction with the patient's nephrologist or the CAPD nurse specialist, because these individuals usually are aware of the patient's overall medical condition, the types of infection recently experienced, and any psychosocial considerations that might affect outpatient management.

A common treatment regimen is vancomycin 30 mg/kg intraperitoneally at the time of diagnosis, followed by once-weekly intraperitoneal dosing. Heparin 1000 U may be added to each bag for the first few days of treatment in an effort to decrease the risk of fibrin's obstructing the catheter. A third-generation cephalosporin or an aminoglycoside can be added to the regimen for gram-positive coverage if there is reason to suspect infection with gram-negative organisms (e.g., positive Gram stain, recent gram-negative infection). These are typically given as an intraperitoneal loading dose, followed by a once-daily intraperitoneal maintenance dose. Arrangements should be made for the patient to be seen within 2 days to make sure the infection is responding to treatment and to check culture results and adjust therapy accordingly. Again, because practice may vary in different settings, emergency physicians should be familiar with the regimens in common use in their own institutions.

Several important caveats should be noted regarding the diagnosis of peritonitis. Other acute abdominal processes, such as pancreatitis, diverticulitis, or ruptured viscus, may present with a picture similar to that expected for peritonitis, and thus may not be diagnosed if the physician's suspicion is not aroused.¹⁶ To confuse the picture further, the finding of intraabdominal free air on radiograph may be the result of its inadvertent introduction during dialysis exchanges and does not necessarily indicate perforation.⁹ (The finding of brownish or fecal material in the dialysate mandates immediate surgical consultation.)

Several other problems related to the peritoneal dialysis procedure occasionally bring the CAPD patient to the emergency department. An exit site infection or an infection of the subcutaneous catheter tunnel may present as tenderness, warmth, or induration or simply as a painless purulent exudate. Any exudate should be subjected to Gram stain and culture. Treatment can be started with an oral antibiotic active against skin flora, but intensive local cleansing and skin care are also a critical part of management. Closed infections of the subcutaneous tunnel may be difficult to appreciate, and they respond poorly to medical therapy unless they are drained. If the patient should develop a leak of dialysis fluid from the tubing, bag, or catheter, or from around the catheter, evaluation and treatment should proceed as with peritonitis. The leaking elements must be replaced, if possible, or surgical intervention arranged.

Difficulties with inflow or outflow of the dialysis fluid also occur occasionally. After ruling out straightforward problems such as kinked tubing or closed clamps, the physician must consider more troublesome mechanical causes, including obstruction of the catheter lumen, in which case, surgical or nephrologic consultation is necessary. Radiographic visualization with a contrast catheterogram may help to direct specific intervention. Fibrinolytic agents are sometimes helpful with obstructed catheters, but catheter replacement is often required.

CLINICAL PRESENTATION

Infection

Infections are a major cause of death in dialysis patients, and vascular access infection and peritonitis are the most common infections in hemodialysis patients and CAPD patients, respectively. Most infections are due to usual pathogens rather than to opportunistic organisms. The challenge for the clinician arises from the fact that classic findings may not be obvious.

Some manifestations of infections may be attributed to chronic renal failure *per se*, to the effects of dialysis, or to other underlying medical illness. For instance, pneumonia may present as dyspnea alone, which is easily attributed to volume overload or to the effects of chronic anemia. Urinary tract infection can occur even in patients who are essentially anuric⁴; upper urinary tract infection, presenting as renal colic or with symptoms typical of pyelonephritis, is most common in patients with polycystic kidney disease. These and other infections are generally treated according to the same principles that apply to other patients,¹⁵ but antibiotic dosages must be adjusted for ESRD and the dialysis modality.

Hypotension

Hypotension commonly occurs in hemodialysis patients during or immediately after the dialysis procedure, but it usually resolves spontaneously or responds readily to fluid infusion. It is usually the result of rapid fluid and electrolyte shifts. CAPD patients are not subject to this cause of hypotension, but they, too, can become volume depleted if intake does not keep up with fluid losses that occur through dialysis. Other potentially lethal causes of hypotension must also be considered. Sepsis, drug effects, myocardial dysfunction, dysrhythmia, myocardial infarction, and pericardial tamponade are important considerations in patients treated by either dialysis modality; acute electrolyte disturbances, vascular instability, anaphylactoid reaction, and air embolism are considerations primarily in hemodialysis patients.

Pericardial tamponade may develop acutely when there is bleeding into the pericardial sac or when volume depletion allows a previously subclinical effusion to produce significant circulatory compromise. Although tamponade in this setting generally presents with the expected physical findings, coexistent cardiac or pulmonary disease may make the diagnosis difficult. Echocardiography is useful in detecting pericardial fluid; the size of an effusion does not correlate well with the presence of tamponade, however.

Many dialysis patients have effusions (of varying size) that do not appear to cause clinical difficulties. Echocardiographic demonstration of right ventricular collapse is a much better indicator of tamponade. Emergency pericardiocentesis may be necessary if the patient's condition deteriorates rapidly and tamponade is thought likely; it can establish the diagnosis and buy time until definitive surgical therapy can be undertaken. Another temporizing measure that is useful when tamponade has been precipitated by volume depletion is intravenous saline infusion to raise filling pressures.

Dyspnea and Volume Overload

Dyspnea in the dialysis patient is most commonly due to volume overload. In the hemodialysis patient, it usually develops during the interval between dialyses. Physical examination is not always reliable in detecting volume overload in these patients; even chest radiographic findings may be misleading.¹⁰ The most reliable

clue is a history of recent weight gain.

The definitive treatment of volume overload is dialysis, but several temporizing measures are available ([Table 177.4](#)).^{6,13} Oxygen should be administered and the patient kept in the sitting position. Sublingual nitroglycerin can be administered quickly and does not require intravenous access; it often provides very rapid relief by reducing preload and afterload. Intravenous nitroglycerin and nitroprusside are additional useful options and can be titrated to effect; thiocyanate toxicity can result from prolonged use of nitroprusside in patients with renal failure, however.

Dialysis
Hemodialysis
Hemofiltration
Peritoneal dialysis
Oxygen
Nitroglycerin (sublingual or intravenous)
Nitroprusside
Nifedipine
Morphine
Loop diuretics

TABLE 177.4. Treatment of Pulmonary Edema in Renal Failure

Oral afterload reducers such as nifedipine provide a simpler option in patients who can get by without aggressive intravenous therapy.¹³ Morphine can also be given, as in nondialysis patients. Intravenous furosemide produces rapid pulmonary venodilation but, of course, has a minimal diuretic effect in most dialysis patients.¹⁴ Finally, the use of continuous positive airway pressure devices may make it possible to avoid intubation in some patients who would otherwise require it.

Although volume overload is the most likely cause of shortness of breath in the dialysis patient, dyspnea can also be the result of cardiac impairment of any cause, hypotension, infection, pleural or pericardial effusion, or any of the other causes of dyspnea in nondialysis patients.

Another potentially adverse effect of volume overload is severe hypertension, because, in most dialysis patients, blood pressure is at least partly volume dependent. For hypertensive crisis (i.e., hypertension, usually severe, with evidence of acute end-organ dysfunction), therapy should include not only sodium nitroprusside by intravenous infusion, but also prompt initiation or intensification of dialysis to lower blood volume.

Chest Pain

Chest pain in a dialysis patient should always suggest coronary artery disease. A significant proportion of dialysis patients die of cardiovascular causes,³ and most patients have risk factors such as hypertension, hyperlipidemia, and carbohydrate intolerance. Added to this are the effects of chronic anemia and intermittent or chronic volume overload. The hemodialysis procedure itself is often the occasion for additional ischemic stress to the myocardium because of transient hypoxemia and hypotension.

Initial interventions for suspected ischemic chest pain are similar to those for other patients, but particular attention should be directed toward such correctable factors as volume overload, hypertension, and anemia. The diagnosis of myocardial infarction by standard electrocardiographic and enzyme criteria is generally not affected by the abnormalities of ESRD.^{11,12} Although baseline cardiac enzyme levels may be somewhat higher than in the nondialysis population, when infarction occurs, the pattern of enzyme changes is not affected. Decisions as to the most appropriate reperfusion therapy for dialysis patients with acute coronary syndromes should be made in concert with a cardiologist and the patient's nephrologist.

Chest pain may, of course, be due to any of the other commonly incriminated causes, but pericarditis should always be a consideration in the dialysis patient once myocardial ischemia has been excluded. Pericarditis (and tamponade) may occur even in well-dialyzed patients. The signs and symptoms are the same as those noted in nondialysis patients. Based on experience in undialyzed uremic patients, it has traditionally been taught that increased or intensified dialysis hastens resolution of pericarditis or prevents the development of tamponade or pericardial constriction, although this remains an open question. For many patients with pericarditis, indomethacin provides prompt relief of pain. Intrapericardial instillation of corticosteroids, or pericardial stripping, is ultimately necessary in others.

Bleeding

Bleeding is relatively common in dialysis patients; it is, at least in part, related to platelet dysfunction (which is not completely corrected by dialysis) and, in hemodialysis patients, to transient anticoagulation. It is important to ascertain what the bleeding patient's usual hemoglobin level has been. Erythropoietin is now administered routinely to almost all dialysis patients, but untreated, the baseline hemoglobin level may be 6 to 7 g/dL. Moderately severe anemia may present with increased angina or dyspnea. Other symptoms, sometimes life-threatening ones, may be caused by occult bleeding into particular anatomic sites; spontaneous intracranial, intraocular, pericardial, and retroperitoneal bleeding have been reported.

Treatment of acute bleeding episodes follows standard principles. It should also be established that dialysis has been adequate. Because correction of severe anemia (hematocrit less than 25%) improves bleeding time (probably by a rheologic effect), red cell transfusion should be considered, and additional acute treatment with desmopressin (0.3 µg/kg intravenously or subcutaneously) or conjugated estrogens (0.6 mg/kg intravenously) should be begun. For life-threatening bleeding, cryoprecipitate infusion and platelet transfusions are recommended.⁵

Neurologic Dysfunction

Neurologic dysfunction in the form of *disequilibrium syndrome* is common during and just after the hemodialysis procedure. Typical mild manifestations are headache, nausea, and muscle cramps; more severe cases may cause altered mental status and grand mal seizures. Disequilibrium is presumed to be due to the rapid fluxes of fluid and solutes that occur with dialysis: It coincides with the removal of large volumes of fluid or the correction of marked metabolic and electrolyte abnormalities with hemodialysis (it does not occur with CAPD); it usually resolves within a few hours after the treatment is completed; and symptoms often respond promptly to intravenous infusion of mannitol or hypertonic saline during dialysis.

However, because there are many other potential causes for neurologic dysfunction in these patients (not the least of which are intracranial bleeding, hypertensive encephalopathy, infection, and untoward drug effects), it is unwise to attribute any acute neurologic abnormality to the disequilibrium syndrome without carefully considering other causes. If findings are focal, appear suddenly, or fluctuate or become worse after a reasonable period of observation, attention should be directed to all of the other potential causes. Similarly, the presence of fever, papilledema, or severe hypertension should suggest more serious etiologies.

Electrolyte Abnormalities

Hyperkalemia is a common life-threatening emergency in undialyzed patients with acute or chronic renal failure, but it is seldom a serious problem in the dialyzed patient. When hyperkalemia does occur, it is usually due to noncompliance with dietary restrictions or dialysis treatments. On occasion, it may also be the result of intercurrent disorders such as rhabdomyolysis, sepsis, or severe acidosis. Hyperkalemia is particularly dangerous because it is generally completely asymptomatic until dangerous cardiac effects develop. Although many dialysis patients chronically tolerate moderate hyperkalemia (6 to 7 mEq/L) with no apparent problem, a potassium level in this range must still be considered potentially dangerous, because severe effects can develop fairly rapidly. Moreover, the electrocardiogram is occasionally completely normal even when hyperkalemia is severe,¹⁷ and it cannot be relied on to exclude any danger of serious hyperkalemic complications developing. Thus, the serum potassium level should always be checked.

The treatment of hyperkalemia is outlined in [Chapter 174](#). The guidelines for treatment in dialysis patients follow those for treatment in other patients, but particular attention must be directed to avoiding volume overload, symptomatic hypocalcemia, or other potential complications of therapy and to instituting or reinstating dialysis as promptly as possible. A particularly convenient and effective method of decreasing the serum potassium level is by the administration of nebulized albuterol in a dose four to eight times as great as that used in the typical asthmatic. This intervention provides rapid and sustained improvement in the serum potassium concentration for at least several hours and appears to be associated with few side effects. ¹

A dialysis patient in cardiac arrest should be presumed to be hyperkalemic and should receive intravenous calcium and intravenous bicarbonate (through separate lines to prevent precipitation). This is one group of patients to whom these two drugs should still be administered routinely despite the recent revisions of advanced cardiac life-support guidelines.

Other electrolyte abnormalities can occur in ESRD patients under a variety of conditions, but the most important and the most common are hypocalcemia and hypermagnesemia. Hypocalcemic symptoms may occur in patients who have not been treated with vitamin D and calcium supplementation, particularly when intravenous bicarbonate is given to treat hyperkalemia or severe acidosis. Symptomatic hypocalcemia should be treated with intravenous calcium gluconate or calcium chloride.

Mild hypermagnesemia is common in ESRD, but symptoms do not usually occur until magnesium levels are high, generally over 4 mg/dL. Symptomatic hypermagnesemia is almost always due to inadvertent ingestion of magnesium-containing antacids or laxatives. Intravenous calcium acts as a direct antagonist to the neuromuscular effects of hypermagnesemia, but in the absence of the renal route of excretion, removal of excess magnesium from the body requires emergent dialysis.

DISPOSITION

A critical decision commonly facing the emergency physician is whether emergency dialysis is necessary for patients presenting to the emergency department with acute clinical problems. Some patients may have deteriorated between hemodialysis treatments or despite continuing CAPD; others may have failed to undergo scheduled dialyses. The most common indication for emergency dialysis ([Table 177.5](#)) is severe volume overload or pulmonary edema; available temporizing measures for managing the patient until dialysis can be effective have already been described. Appropriate temporizing measures also may be employed to manage malignant hypertension, severe electrolyte disturbances, or severe acidosis while awaiting the definitive treatment afforded by dialysis.

Pulmonary edema
Severe uncontrollable hypertension
Hyperkalemia
Other severe electrolyte or acid-base disturbances
Some overdoses
? Pericarditis

TABLE 177.5. Indications for Emergency Dialysis

Uremic symptoms (e.g., lethargy, confusion, asterixis, nausea, and vomiting) indicate that dialysis is needed but are not, in themselves, indications for *emergency* dialysis. Similarly, serum creatinine and blood urea nitrogen levels correlate only roughly with uremic symptoms or life-threatening metabolic disturbances and do not, in themselves, indicate an urgent need for dialysis. The appearance of pericarditis, with or without pericardial tamponade, is often considered an indication for urgent or intensified dialysis, but pericarditis can occur even in well-dialyzed patients and it is not clear that there is an increased risk of clinical deterioration if it is not treated aggressively.

A key component of the emergency department management of all types of problems in the dialysis patient must always be consultation with the patient's nephrologist or dialysis nurse, both to take advantage of these specialists' expertise in caring for these patients' complicated problems and to ensure optimal continuity of care. However, the emergency physician has a responsibility to be familiar with the evaluation of and therapy for acute problems in dialysis patients so that emergency interventions can be performed promptly when necessary.

COMMON PITFALLS

- Failing to identify treatable factors in patients who may have a reversible component of their chronic renal insufficiency
- Causing iatrogenic illness through inappropriate fluid or drug administration
- Allowing the vascular access to be used for taking blood pressure or drawing blood, or for intravenous infusion
- Failing to consider vascular access infection in hemodialysis patients, or peritonitis in CAPD patients, because of lack of specific findings on history and physical examination
- Failing to consider the diagnosis of tamponade because the patient does not demonstrate all of the classic signs and symptoms
- Failing to treat volume overload because of a lack of specific findings
- Overlooking anemia as a cause of increased angina or shortness of breath
- Inappropriately attributing any neurologic dysfunction to disequilibrium syndrome
- Failing to seek evidence of hyperkalemia by blood test or electrocardiogram
- Inducing symptomatic hypocalcemia by ill-advised bicarbonate therapy

CHAPTER 178

The Patient with a Renal Transplant

Louis G. Graff

- Medications
- Complications of Transplant Surgery
- Renal Dysfunction
- Fever or Infection
- Abdominal Pain
- Immunizations
- Disposition
- Common Pitfalls
- Chapter References

The kidney is the most commonly transplanted organ in the United States: More than 10,000 are transplanted each year.¹⁴ In contrast to dialysis, transplantation allows the patient to live a normal life and has thus become the preferred treatment for patients with end-stage renal disease. Transplant patients do not need a treatment (dialysis) three times a week, need not restrict their diets (potassium, sodium, and fluid intake), and can have children.¹⁵

The transplanted kidney is obtained from a living related donor or from a cadaver. At surgery, it is connected to the common iliac vein and artery in the pelvic fossa, and the ureter is anastomosed to the bladder. The transplanted kidney is placed in the pelvic area not only because it is anatomically convenient for anastomosis to the vasculature and the bladder, but also because it is accessible there for direct palpation, biopsy, or removal. The patient and transplanted organ are matched for the human leukocyte antigen major histocompatibility gene complex to minimize the risk of transplant rejection, and the patient is given immunosuppressive drugs (e.g., corticosteroids, azathioprine, cyclosporine, tacrolimus). Graft survival is 95% at 1 year for properly matched, living related donors and 90% for cadaveric donors.^{7,16,14} Patient survival is higher (greater than 98% at 1 year for living related donors and 95% for cadaveric donors), as the patient can go back on dialysis if the transplant fails.

The unique aspects of caring for the patient with a transplanted kidney must be kept in mind when such a patient presents to the emergency department. Evaluation and management of even minor problems is often complicated by the patient's immunosuppressed state and the presence of a transplant. Transplant patients often have a limited ability to tolerate intercurrent illness, trauma, or other physiologic stresses. Moreover, chronic immunosuppression places them at increased risk for severe infectious disease, and often makes it difficult to evaluate emergent problems such as abdominal pain or fever. The status of the transplanted kidney must always be a concern as well. Patients may present with complications of the transplant surgery or with subtle signs and symptoms of graft rejection.

MEDICATIONS

Once a problem is identified, treatment is often more complicated in the transplant patient, because certain medications may have adverse effects or be frankly contraindicated in these patients (Table 178.1). For example, potassium-sparing diuretics can cause severe hyperkalemia in patients on cyclosporine. Nephrotoxic drugs can act synergistically with cyclosporine and contribute to renal dysfunction. Lovastatin can cause a severe myopathy in patients taking cyclosporine. Also, a number of medications can increase or decrease cyclosporine and tacrolimus levels² and thus affect drug effectiveness and toxicity (see Table 178.1).

NEPHROTOXINS Cisplatin, foscarnet, vancomycin, cimetidine, ranitidine, all sulfonamides, amphotericin B, ketoconazole, meprobamate, trimethoprim-sulfamethoxazole, aztreonam
DRUGS THAT DECREASE CYCLOSPORINE EFFECTIVENESS Rifampin, phenobarbital, phenytoin, carbamazepine, succinylcholine
DRUGS THAT INCREASE CYCLOSPORINE EFFECTIVENESS AND TOXICITY Ethinacem, nifedipine, verapamil, diltiazem, trimethoprim, metoprolol, ranitidine, fluconazole, clarithromycin, erythromycin, meprobamate, succinylcholine, oral contraceptives
DRUGS THAT INCREASE TACROLIMUS EFFECTIVENESS AND TOXICITY Ethinacem, nifedipine, verapamil, diltiazem, trimethoprim, metoprolol, ranitidine, fluconazole, clarithromycin, erythromycin, meprobamate, succinylcholine, oral contraceptives
DRUGS THAT DECREASE TACROLIMUS EFFECTIVENESS Carbamazepine, phenobarbital, phenytoin, rifabutin, rifampin, valproic acid
DRUGS THAT INHIBIT AZATHIOPRINE METABOLISM Allopurinol
POTASSIUM-SPARING DIURETICS Amiloride, spironolactone, triamterene
LOVASTATIN (MAY CAUSE MYOPATHY)

TABLE 178.1. Some Drugs to Avoid in the Renal Transplant Patient

Emergency physicians should be familiar with the adverse effects of medications routinely prescribed to the transplant patient. Cyclosporine, tacrolimus, and azathioprine increase the patient's susceptibility to infection, particularly by opportunistic organisms. The patient's risk of cancer (especially lymphoma, cervical cancer, and skin cancer) is 3% or 4%.⁶ Because azathioprine causes leukopenia in more than 50% of patients, close monitoring of the blood count is necessary. Both drugs can also cause hepatotoxicity, so liver enzymes should be checked in patients with symptoms consistent with hepatitis. Also, liver failure can decrease the metabolism of cyclosporine and cause cyclosporine nephrotoxicity. Corticosteroids can contribute to the development of peptic ulcer disease, hypertension, accelerated coronary artery disease, diabetes, osteoporosis, aseptic necrosis of the hip, impaired healing, cataract, hemorrhagic pancreatitis, and candidal pharyngitis. Additional immunosuppressive agents (e.g., mycophenolate mofetil, rapamycin, anti-interleukin-2 receptor monoclonal antibodies) are being developed and brought into clinical practice. These agents have their own side effects and adverse interactions with other medications.²⁰

COMPLICATIONS OF TRANSPLANT SURGERY

Early after transplantation, complications of the surgery may bring patients to the emergency department. There may be acute tubular necrosis, especially if the graft preservation time before surgery was prolonged. Vascular complications, such as renal artery stenosis or thrombosis or renal vein thrombosis, can cause graft dysfunction or localized pain. Ureteral stenosis can cause decreased graft function as well.

Local hematoma or lymphocele can cause pain or compromise graft function by mass effect. The immunosuppressive drugs given to prevent graft rejection also inhibit wound healing and the normal response to infection. At least 20% of patients develop a wound infection, and many others develop other infections. Most patients with surgical complications present within days or weeks of transplantation, although some complications (e.g., ureteral stenosis, smoldering infection) may have a delayed presentation.

RENAL DYSFUNCTION

Evidence of renal dysfunction should always be sought in the patient with a renal transplant, and any reversible cause of renal failure must be identified and treated promptly (Table 178.2). Apparently, small changes in the serum creatinine level may indicate important changes in renal function. For example, an increase in the serum creatinine level from 1 to 2 mg/dL represents a 50% decrease in renal function. During the first days after transplant surgery, the most common causes of renal failure are acute tubular necrosis, hyperacute rejection, urinary tract obstruction, urine leak, compression of the graft or renal artery by hematoma, and hypovolemia. During the first 12 weeks after transplant surgery, the patient may experience acute rejection, renal artery stenosis, or urinary tract obstruction. Renal failure more than 3 months after surgery is usually due to acute rejection, chronic rejection, recurrence of underlying renal disease, or new renal disease.

Meningitis can present very subtly in the transplant patient. Classic signs of meningitis (e.g., fever or meningismus) may not be present. Headache, which may suggest other serious disease, such as temporal arteritis or subarachnoid hemorrhage,⁹ is the most common symptom. Opportunistic organisms such as *Cryptococcus* are more likely to cause disease than are the usual pathogens.¹³ The emergency physician must have a high level of suspicion and a low threshold for performing a diagnostic lumbar puncture.

Trimethoprim–sulfamethoxazole prophylaxis has become the standard in renal transplant patients because of the high risk of infections.⁸ *Pneumocystis carini* pneumonia ordinarily develops in up to 12 % of patients, but it is eliminated with prophylaxis. In addition, prophylaxis with trimethoprim–sulfamethoxazole for the first 6 months reduces the risk of urinary tract infection from greater than 50% to 5%.⁸

ABDOMINAL PAIN

Evaluation of abdominal pain in the transplant patient is challenging because immunosuppressive medications can mask the signs and symptoms of disease. In one series of transplant patients with abdominal pain, 10% developed an acute abdomen, and half of them required surgery for perforation or bowel obstruction.¹¹ Of those who required surgery, only 29% had fever and only 29% had leukocytosis. Because of the subtle presentation and difficulty in diagnosis, delays before surgery were substantial (ranging from 18 to 96 hours), and 71% of patients had suffered perforation by the time of surgery. Notably, 43% had signs of perforation on plain abdominal radiographs.

The most common causes of an acute abdomen in transplant patients are similar to those in the general population: gastroduodenal bleeding or perforation, colonic bleeding or perforation, bowel obstruction, appendicitis, cholecystitis, volvulus, and ovarian torsion.^{4,11} Patients with polycystic kidney disease may have abdominal pain because of hemorrhage or infection in the cysts, if their own kidneys have not been removed. Ultrasound may be helpful in evaluating these patients. Because both azathioprine and cyclosporine can cause hepatitis with abdominal pain, liver enzymes should be measured in transplant patients with abdominal pain. The transplant patient has an increased risk of developing lymphoma, probably because of chronic immunosuppression. Abdominal computed tomography scanning can identify enlarged retroperitoneal nodes or tumor mass.

Pancreatitis occurs infrequently (1%) in renal transplant patients. When it does occur, it is quite serious, with 80% to 100% mortality.¹⁶

IMMUNIZATIONS

Killed and antigen-based vaccines (tetanus, diphtheria, rabies, influenza, and pneumococcal vaccines) can be safely used in transplant patients. There is no contraindication to treatment with immunoglobulin. Live or attenuated vaccines are contraindicated in the immunosuppressed patient, because they can cause serious infection.

DISPOSITION

The threshold for hospitalizing the transplant patient should be very low. One must always suspect a pathologic process, even in patients who seem to have only minor complaints. When a transplant-related problem is identified, the emergency physician should not hesitate to seek appropriate consultation or to arrange transfer of the patient to a facility with the resources to manage transplant patients. Nevertheless, the emergency physician can manage most acute problems in renal transplant patients if a thorough and meticulous approach is used.

COMMON PITFALLS

- Prescribing potentially nephrotoxic drugs in the renal transplant patient
- Failing to realize that a small rise in the transplant patient's creatinine level may represent a relatively large decrement in renal function, necessitating aggressive evaluation
- Assuming that a normal urine output excludes obstruction as the cause of acute renal failure
- Failing to remember that the immunosuppressed transplant patient often does not show classic signs or laboratory findings of infection
- Failing to remember that certain drugs may decrease cyclosporine or tacrolimus levels and lead to transplant rejection; likewise, certain drugs may increase these drug levels and lead to toxicity
- Failing to provide increased doses of steroids when transplant patients taking corticosteroids undergo major stress, such as surgery, myocardial infarction, major trauma, or sepsis
- Giving a blood transfusion without a clear indication, because stimulation by exogenous antigens may lead to rejection
- Overlooking the fact that the transplant patient may have three kidneys (two original, one transplanted), all of which may become infected or be injured

The goals of management are to treat the underlying cause or causes of rhabdomyolysis, to identify and treat complications, and to prevent acute renal failure.

Rhabdomyolysis may continue to proceed or may be exacerbated by excessive exertion, agitation, fighting of restraints, seizures, or abnormal posturing. These should be controlled by aggressive sedation, with a benzodiazepine, in order to prevent further muscle breakdown. Rarely, pharmacologic paralysis with nondepolarizing neuromuscular agents and intubation may be required. Hyperthermia, if present, should also be aggressively treated.

Patients with hyperkalemia require continuous cardiac monitoring and aggressive intervention. Hypocalcemia is generally self-limited and rarely requires specific treatment; the same is true of hyperphosphatemia. As noted previously, the patient should be monitored for the development of compartment syndrome. Coagulopathy can generally be addressed by treating the underlying disease process.

Several uncontrolled studies suggest the efficacy of early, aggressive isotonic fluid administration in preventing acute renal failure in crush-related or traumatic rhabdomyolysis.^{2,10,15} This treatment results in increased renal tubular flow rates, which facilitate the excretion of substances that may injure or obstruct the renal tubules. A target urine flow rate of 200 to 300 cc/h has been suggested.

Many experts also recommend the use of intravenous sodium bicarbonate to alkalinize the urine, because myoglobin is toxic to the kidneys in acid urine. There have been no prospective randomized studies, however. Retrospective, uncontrolled trials suggesting benefit have been confounded by the concurrent use of saline loading. One small nonrandomized study has questioned the benefit of bicarbonate (and mannitol), suggesting that saline expansion alone is sufficient to prevent renal failure.⁸

The role of diuretics such as mannitol and furosemide is also unclear. Mannitol should probably be considered if urine output is inadequate despite saline infusion, because it may convert oliguric renal failure to nonoliguric renal failure, which has a better prognosis. Acute renal failure unresponsive to the aforementioned measures may require dialysis, but the prognosis for ultimate recovery is good.

DISPOSITION

Patients with rhabdomyolysis generally require admission to the hospital, as it is not possible to predict which individuals will develop complications. Patients with hyperkalemia, metabolic acidosis, or evidence of renal failure, and those with other serious comorbid conditions, require hospital admission. Patients with hyperkalemia require admission to a monitored setting, and nephrology consultation is indicated if renal insufficiency develops or if metabolic abnormalities are unresponsive to usual medical treatment. Dialysis is required for some individuals. If renal consultation and dialysis are not available at the treating institution, transfer to a facility with those capabilities should be initiated.

COMMON PITFALLS

- Failure to consider rhabdomyolysis in patients with alcoholism, unconsciousness, prolonged immobilization, seizures, hyperthermia, or infection
- Failure to identify and treat hyperkalemia associated with rhabdomyolysis
- Failure to pharmacologically control agitation, seizures, or abnormal posturing in patients who are at risk for rhabdomyolysis
- Failure to evaluate for compartment syndrome
- Failure to realize that the diagnosis of rhabdomyolysis cannot be ruled out on the basis of the serum or urine myoglobin alone
- Failure to provide adequate hydration and to prevent or treat acidosis in patients with rhabdomyolysis

CHAPTER 180

Hematuria

James P. d'Etienne and Steven A. Godwin

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management and Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Hematuria is defined as the presence of an abnormal number of red blood cells in the urine. Specifically, more than 3 to 5 red blood cells per high-powered field on microscopic examination of a spun urine specimen is considered abnormal.

CLINICAL PRESENTATION

Gross hematuria can be quite startling and often brings the patient immediately to the emergency department for examination. Microscopic hematuria is usually discovered as an incidental finding during an evaluation for an unrelated complaint.

Rapid screening can be done simply with a urine dipstick analysis. Dipstick urinalysis is reported to have a sensitivity of 86% to 100%, a specificity of 65% to 99%, a false-negative rate of 3% to 24%, and a false-positive rate of 10% to 15% for detecting hemoglobin and myoglobin in urine. ^{2,5,16} The dipstick test depends, however, on lysis of intact erythrocytes to release free hemoglobin and does not differentiate between hemoglobin and myoglobin. ⁷

False-positive reactions may also occur as a result of oxidizing contaminants (e.g., bacterial peroxidases, povidone). More commonly, false-positive results are due to menstrual blood, traumatic catheterization, and improper collection techniques. Pigments in the urine from medications (e.g., Pyridium) and bilirubin, as well as improper handling of the urine specimen, may also result in inaccurate readings. False-negative reactions are often due to reducing agents (e.g., ascorbic acid).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hematuria is broad. Studies evaluating men age 50 or older for hematuria have found that the most common diagnoses, excluding trauma and exercise-induced hematuria, are benign prostatic hypertrophy (BPH), neoplasm, infection, nephrolithiasis, and unknown causes. ^{8,9,15,16} Neoplasm is a prime concern in adults. Population-based studies suggest that patients over 40 with hematuria should be aggressively investigated. ^{3,4,6}

In pediatric patients, the reported incidence of gross hematuria is approximately one in 1000 emergency visits. A cause can be found in approximately 60% of cases, the most frequent diagnoses (in descending order) being urinary tract infection, perineal irritation, meatal stenosis with ulceration, trauma, recent surgical procedure, clotting abnormalities, nephrolithiasis, and glomerulonephritis. ¹²

Hemorrhagic cystitis should be suspected when hematuria is accompanied by dysuria, urinary frequency, suprapubic pain, leukocytosis, or pungent-smelling urine. Severe flank pain that radiates to the groin may indicate a ureteral calculus. Although hematuria is often associated with renal colic, up to 15% of cases may be dipstick-negative for hematuria. ¹¹ Exercise-induced hematuria, trauma, neoplasm, prostatic hypertrophy, and hemorrhagic cystitis present as lower tract disease devoid of proteinuria and casts. Hematuria may also be caused by trauma to the flaccid posterior bladder wall, transient renovascular vasoconstriction, or direct renal trauma. ¹

Hematuria is symptomatic of a variety of systemic diseases. Poststreptococcal glomerulonephritis occurs 1 to 2 weeks after a sore throat; it may present solely with hematuria or as a florid nephritic syndrome with hematuria, edema, hypertension, and renal insufficiency. Immunoglobulin A (IgA) nephropathy (Berger disease), thought to be an immune-complex-related disorder, is often asymptomatic, presenting with hematuria and proteinuria several days after an upper respiratory tract infection. Hematologic conditions such as sickle cell disease, sickle-thalassemia, and bleeding dyscrasias; autoimmune disorders; and vasculitides may also present with hematuria. Symptoms of Henoch-Schönlein purpura include arthritis, rash, hematuria, and abdominal pain in children. Goodpasture syndrome, primarily a pulmonary disease, may present as gross hematuria associated with symptoms of hemoptysis, dyspnea, cough, and fatigue in a young adult man. Schistosomiasis, the most common cause of hematuria worldwide, may be present in patients who have lived in or traveled to Africa or the Middle East.

Anticoagulant therapy alone should not be considered a cause of hematuria. One prospective study found that 30% of anticoagulated patients who presented with hematuria had significant urinary tract disease. ¹⁸ Similarly, BPH may result in hematuria but should not be assumed to be the cause of bleeding, as many patients have other associated urologic problems of potentially greater significance. ⁶

EMERGENCY DEPARTMENT EVALUATION

A common error in the evaluation of hematuria is failing to obtain a complete history and perform a thorough physical examination. The importance of a thorough evaluation is highlighted by the broad list of causes illustrated in [Fig. 180.1](#). The large number of diagnostic possibilities makes the diagnosis of hematuria difficult if it is not approached in a systematic fashion.

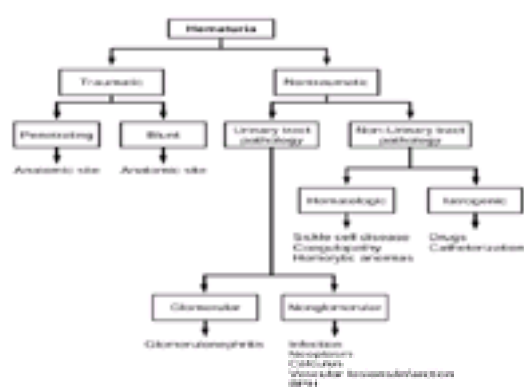

Figure 180.1. Causes of hematuria.

As noted, dipstick evaluation is a fast, reliable method to screen for hematuria. Both myoglobinuria and hemoglobinuria present with heme-positive dipstick findings but no red cells on microscopic examination. Hemoglobinuria is usually associated with a characteristic pink color of the serum, whereas myoglobin tends to be cleared from the blood very rapidly. Microscopic urinalysis should be performed to look for formed red and white blood cells and casts. Hematuria of renal origin is classically associated with red cell casts and significant proteinuria; dysmorphic red cells may also be noted. Hematuria arising from the ureters, bladder, and urethra results in the presence of formed erythrocytes in the urine and no proteinuria or casts.

Proteinuria of 100 to 300 mg/dL or more, corresponding to 2+ to 3+ on dipstick analysis, should not be attributed to simple hematuria. It requires evaluation for

glomerulonephritis.²

The history should address the onset and duration of symptoms, preceding illnesses, level of physical activity, travel history, medication history, and family history of renal, urologic, or hematologic disorders. Hematuria noted on initiation of the urinary stream indicates a possible urethral source, while hematuria only late in the stream suggests a source in the bladder or prostate. Blood noted throughout the entire stream indicates a renal, ureteral, or bladder source. The patient's blood pressure and history of hypertension should be noted, as hypertension is a common indicator of occult renal disease. An abdominal examination should be done to look for suprapubic or flank tenderness, masses, and bruits.

A history and physical examination consistent with renal colic may prompt further evaluation. Available diagnostic modalities include an intravenous pyelogram (IVP), a non-contrast-enhanced helical computed tomography (CT) scan, or an ultrasound to search for calculi, obstruction, or dilatation of the ureter or renal pelvis. Non-contrast-enhanced helical CT has been shown to be an excellent tool for the evaluation of nephrolithiasis. The potential nephrotoxicity associated with intravenous contrast material is eliminated, making this the imaging study of choice in patients with renal disease. CT can also define other abdominal abnormalities, such as abdominal aortic aneurysm or masses involving the kidneys or urinary tract.^{17,19} CT can delineate renal vascular pathology, but the definitive diagnosis usually requires arteriography or venography.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

The need for acute management of hematuria is limited. Nontraumatic hematuria does not cause life-threatening bleeding, with the rare exception of spontaneous rupture of a renal artery aneurysm or renal infarction secondary to an arterial embolus.⁴ In these two conditions, aggressive fluid resuscitation and close hemodynamic monitoring are necessary.

Further evaluation, necessary for patients with asymptomatic hematuria, can usually be performed on an elective basis in consultation with a primary care physician, urologist, or nephrologist. The emergency department evaluation may be supplemented later by cystoscopy, IVP, CT scanning, and renal biopsy, depending on the laboratory and clinical presentation.¹² The patient should be counseled on the risk of significant disease, particularly with increasing age. Management of patients at risk for neoplasm may change dramatically, as rapid immunochromatographic qualitative assays for detection of transitional cell tumors become readily available.^{10,13}

Patients in pain, like that due to renal calculi, should be given parenteral analgesics before the diagnosis is established. Patients with renal calculi should be admitted if they have uncontrolled pain, protracted vomiting, obstruction of a solitary kidney, or evidence of significant associated infection.¹⁴ Relative indications for admission include high-grade ureteral obstruction, a large calculus, or preexisting impaired renal function. Urologic consultation should be requested for these patients.

When uncomplicated infection is the cause of hematuria, patients may be treated on an outpatient basis. For more seriously ill patients, intravenous antibiotics should be started promptly. Admission should be strongly considered for infected patients with malignancy, diabetes mellitus, in-dwelling Foley catheters, or known stone disease.

Patients with newly diagnosed or suspected disease of the renal vessels should be admitted to an intensive care unit, with surgical consultation. Patients with hematuria associated with glomerulonephritis are often admitted if the diagnosis is new or if the risk of complications (e.g., severe hypertension, oliguria, volume overload, pulmonary edema, or electrolyte imbalance) is thought to be significant.

COMMON PITFALLS

- Attributing hematuria to a benign condition that may be an incidental finding (e.g., BPH) may result in a serious misdiagnosis, particularly in patients over age 40.
- Ruling out nephrolithiasis because of a negative urine dipstick examination
- Failing to perform a complete history and physical examination to identify possible systemic causes of hematuria
- Failure to ensure follow-up for patients with hematuria, particularly those over age 40

FOLLICULITIS AND CUTANEOUS ABSCESS

Folliculitis is an inflammation of hair follicles due to infection, overhydration, chemical irritation, or physical injury of the skin.¹⁶ The most common sites of involvement are the apocrine areas of the upper back, chest, buttocks, hips, and axillae, but folliculitis can occur in any hair-bearing region of the body. The most common infecting organism is *Staphylococcus aureus*, but streptococci and gram-negative organisms are implicated in many cases. *Pseudomonas aeruginosa* has been reported after exposure to hot tubs as well as ordinary baths and showers.³ The individual lesion of folliculitis is a 2- to 5-mm dome-shaped pustule with a central hair shaft surrounded by a rim of erythema. Superficial folliculitis is often primarily pruritic rather than painful, and heals without scarring. If inflammation progresses deeper into the follicle, pain and tenderness develop, and scar formation is more likely to occur with healing.

Pseudofolliculitis is a foreign-body reaction caused by close shaving in persons of African descent. The hair shaft becomes trapped below the follicle exit, and, because of its propensity for tight curling, grows into the follicular wall. Sycosis barbae is a deep infectious progression of pseudofolliculitis that, if untreated, can lead to significant facial scarring.

An untreated follicular infection, or one that does not resolve on its own, can evolve into a *furuncle* or *carbuncle*.⁸ Furuncles are single, deep cutaneous nodules involving the hair follicle. These nodules often go on to suppurate. The bacteriology is the same as that of folliculitis. Carbuncles are formed by multiple interconnecting furuncles that drain through several skin openings. Common locations of carbuncles include the chin, back of the neck, and scalp.

Cutaneous abscesses can originate in any part of the body through local breaks in the skin. Patients with conditions such as diabetes, inflammatory bowel disease, and immune disorders are at greater risk. Involvement of the head and neck is often due to obstruction and infection of a sebaceous gland or cystic acne. Pure *S. aureus* is cultured in 25% of abscesses; streptococci, gram-negative organisms, and anaerobes are recovered in other cases, often as polymicrobial cultures.³ Approximately 5% of abscesses are sterile, most commonly in association with parenteral drug abuse.¹⁴

A cutaneous abscess presents as a red, painful, usually fluctuant mass. The patient typically experiences discomfort and swelling for several days before presentation for care. Systemic symptoms (fever, chills, tachycardia, malaise) are unusual but can occur if the abscess is extensive, is surrounded by significant cellulitis, or extends along a mucous membrane such as the rectum or oral cavity.

Cutaneous abscesses are frequently associated with other conditions. Hidradenitis suppurativa is a recurrent, suppurative, and scarring disease of the apocrine glands, most commonly involving the axillae and pubic regions of persons of African descent. Their greater concentration of apocrine glands leaves these persons more susceptible to infection from chemicals (deodorants, depilatories), trauma (shaving), or poor hygiene. Hidradenitis can be divided into acute and chronic phases. In the acute phase, when burning and itching predominate, single abscesses can develop. In the chronic phase, sinus formation and honeycombed scarring can be seen. Multiple and recurring abscesses are not uncommon.

Abscesses of the buttock and perineum can arise from multiple sources.^{1,3} An abscess in the proximal buttock crease is often associated with pilonidal disease. This condition generally afflicts hirsute young males, but its origins are unclear.¹⁶ Ingrown hair or, possibly, congenital remnants of hair follicles and squamous epithelium at the sacrococcygeal junction predispose to abscess formation.

When an abscess arises close to the anus, careful differentiation has to be made between a true perianal and a simple buttock lesion. Perianal abscesses originate from anal crypts, are very painful on rectal examination, and are often associated with systemic symptoms such as fever, malaise, and anorexia.¹³ If left untreated, they can dissect proximally into the ischioanal space and become perirectal abscesses. Recurrent or persistent buttock and perianal abscesses can originate from fistulous tracts created by inflammatory bowel disease.

Bartholin gland abscess is a common problem that can arise from duct obstruction and infection with vaginal flora. The Bartholin glands are located within the vaginal vestibule at the 4 o'clock and 8 o'clock positions. A cyst or infection manifests as a mass medial to and often including the labium minus. The predominant organisms are anaerobic, including *Bacteroides fragilis* and peptostreptococci, and are associated with a variety of gram-negative enteric organisms in mixed culture. Ten percent to 15% of these abscesses are due to *Neisseria gonorrhoeae*.⁹

DIFFERENTIAL DIAGNOSIS

When considering folliculitis, the differential diagnosis includes impetigo, cutaneous fungal infections, skin infestations (scabies), insect bites, and viral disorders (herpesvirus). The lesions of a systemic bacterial infection (*P. aeruginosa* and *N. gonorrhoeae*) can appear like scattered follicular disease. Abscesses have to be differentiated from other nodular lesions, such as uninfected cutaneous cysts, malignant tumors, nodular fungal lesions, and foreign-body granulomas.

EMERGENCY DEPARTMENT EVALUATION

When assessing a patient for folliculitis, furuncles, or a cutaneous abscess, the most important differentiation is between those lesions that contain pus and those that do not. Folliculitis and early furuncles are nodular, whereas abscesses have a soft or "fluctuant" center. Fluctuance indicates the presence of pus and, therefore, usually the need for incision and drainage. Buttock and breast abscesses are often mistaken for simple cellulitis because the large amount of fibrous tissue can obscure the presence of fluctuance. Whenever there is doubt, the lesion should be aspirated with an 18-gauge needle attached to a small syringe (3 to 10 mL). If pus is discovered, incision and drainage should follow.

An assessment of underlying conditions is necessary to determine the overall risk to the patient. Patients with diabetes, immunosuppression, blood dyscrasia, altered white blood cell function, or valvular heart disease are at greater risk from cutaneous infections. The presence of systemic signs such as malaise, fever, and tachycardia indicates a more widespread involvement of the cutaneous infection and requires a somewhat more extensive emergency department evaluation.

Gram stain and culture are unnecessary in healthy patients with simple cutaneous abscesses. A stain and culture may be useful, however, in managing patients who

are at higher risk, who have systemic signs, or to whom systemic antibiotics have been administered. The results can guide future management decisions, particularly if resolution is slow or inadequate.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Treatment for folliculitis depends on the extent and depth of follicular involvement. For uncomplicated common folliculitis, hot tub folliculitis, and pseudofolliculitis, removing the offending agent and a gentle regimen of once or twice-daily skin cleansing with a mild hand soap often suffices.¹⁵ This regimen can be supplemented by topical applications of antibiotics such as bacitracin and polymyxin B (Polysporin) or mupirocin (Bactroban). If the offending agent is a razor, special commercially available razors (PFB foil-guarded razor, Remington and Norelco electric razors for men of African descent) can be recommended.

If the folliculitis is painful or more extensive and involves the deep portions of the follicle, a 5- to 7-day course of oral antibiotics is added to the aforementioned measures (Table 181.1). Patients with recurrent folliculitis should seek follow-up for consideration of prophylactic measures, such as the prolonged administration of an oral antibiotic or intranasal mupirocin to eliminate an *S. aureus* carrier state.⁵

Condition	Antibiotic	Dose	Interval
Folliculitis, furuncles, abscesses, localized cellulitis/erysipelas	Cephalexin	250-500 mg	q6h
	Dicloxacillin	250-500 mg	q6h
	Erythromycin	250-500 mg	q6h
	Azithromycin	500 mg (day 1); 250 mg (days 2-5)	q24h
Hot tub folliculitis	Ciprofloxacin	250-500 mg	q12h
Bartholin abscess	Ceftriaxone	250 mg IM plus Doxycycline 100 mg	b.i.d.

TABLE 181.1. Oral Antibiotic Regimens for Adults with Uncomplicated Cutaneous Infections

Untreated folliculitis can progress to a furuncle. If the furuncle has yet to suppurate, as demonstrated by the inability to obtain pus on needle aspiration, a regimen of warm soaks and antibiotics is recommended (see Table 181.1). For the buttock and perineal area, warm soaks or sitz baths are recommended at least twice a day. Patients should be seen within 48 to 72 hours for follow-up, at which time, surgical drainage can be performed if the furuncle has suppurated. Carbuncles are more likely to present as obvious suppuration that will require surgical drainage.

Incision and drainage is indicated for most cutaneous abscesses. Appropriate analgesia, sedation, and anesthesia should be provided. For most small (less than 5 cm) superficial abscesses, local anesthesia of the skin over the abscess usually suffices. For very small abscesses, ethyl chloride spray can be followed by immediate incision. Local anesthesia can be supplemented by administering a parenteral opioid before intervention. For large or deep abscesses or those located in particularly sensitive areas, such as the perineal region, consideration can be given to intravenous administration of short-acting sedative and analgesic agents with appropriate monitoring.

Before incision, the abscess is cleansed with povidone-iodine or a similar skin cleanser. The incision is made with a no. 11 surgical blade attached to a knife handle. To provide for maximum drainage and access, the length of the incision should be at least two-thirds the diameter of the actual cavity to allow for digital or gentle instrument probing and disruption of loculations and pockets in the irregularly shaped cavity. Probing is followed by saline irrigation with a soft-tipped catheter attached to a syringe. Probing and irrigation are terminated when the effluent is pus free and blood tinged.

The cavity is lightly packed with gauze tape (one-fourth or one-half in.) to encourage further drainage. Excessive packing can result in obstruction of drainage. A bulky dressing is usually necessary to absorb continuing secretions. The packing can most often be removed at follow-up in 48 to 72 hours. This is followed by a regimen of warm soaks or sitz baths at least two times a day until drainage ceases. An abscess cavity takes 10 to 14 days to heal. Large abscesses take longer to heal and may need to be repacked once or twice at 48-hour intervals.

Special considerations apply to the management of Bartholin abscess. The incision is made on the medial portion of the abscess, close to the vaginal introitus, to avoid excessive bleeding. Instead of gauze packing, a small balloon-tipped (Word) catheter is recommended for drainage.¹⁸ This is followed by once- or twice-daily sitz baths. The catheter is left in place for 4 to 6 weeks to produce epithelialization of the incision and drainage site and to reduce the risk of abscess recurrence.

Early consultation should be considered for patients with facial, perianal, pilonidal, and Bartholin abscesses, as well as infection secondary to parenteral drug abuse. For cosmetic reasons, the approach to drainage of facial abscesses (e.g., needle aspiration, mucosal approach) should be discussed with a consultant. Perianal abscesses often require general anesthesia in an operative setting. Patients with pilonidal and Bartholin disease require appropriate follow-up because of the potential for recurrence. Soft-tissue infections in parenteral drug users can be deceptively extensive and involve the deep soft tissue; these patients are also at risk for systemic and cardiac valvular disease. They often require hospital admission for evaluation and treatment.

Ordinarily, cutaneous abscesses need not be treated with systemic antibiotics.¹¹ Antibiotics are indicated, however, under certain conditions. Relative indications include systemic toxicity as manifested by fever and chills; cellulitis extending well beyond the abscess cavity; underlying comorbid conditions (e.g., diabetes, immunosuppression); location (e.g., facial, Bartholin gland); and failure to respond to incision and drainage.¹ Table 181.1 lists the possible antibiotic choices for oral outpatient therapy. Intravenous antibiotic regimens for patients who require hospitalization are summarized in Table 181.2. The duration of treatment is usually 5 to 7 days.

Condition	Antibiotic	Dose	Interval
Abscesses	Ampicillin/sulbactam	1.5-3 g	q6h
Cellulitis			
Suspected Streptococcus	Cefazolin	1-2 g	q6h
Staphylococcus	Erythromycin	500-1,000 mg	q6h
Suspected Haemophilus influenzae	Ampicillin/sulbactam	1.5-3 g	q6h
	Cefazolin	0.75-1.5 g	q6h
	Trimethoprim/sulfamethoxazole	8 mg/kg*	q6h
Suspected gram-negative bacteria, diabetes	Ticarcillin/clavulanate	3.0 g	q4-6h
	Clindamycin plus ciprofloxacin	300-600 mg	q6h
200-400 mg			q12h
Deep cutaneous infections (abscess, abscess), diagnosis uncertain	Ampicillin/sulbactam	1.5-3 g	q6h
	Ticarcillin/clavulanate	3.0 g	q4-6h
	Clindamycin plus gentamicin	300-600 mg	q6h
Clindamycin		1-1.2 mg/kg	q6h
Gentamicin		4 mg	q6h
Chloramphenicol		25 mg/kg	q6h

*Based on trimethoprim content.

TABLE 181.2. Intravenous Antibiotic Regimens for Adults with Serious or Complicated Cutaneous Infections

Manipulation of an abscess can cause bacteremia in 30% of cases but is most relevant in patients with preexisting cardiac valve disease. These patients must be given adequate antibiotic prophylaxis, as recommended by the American Heart Association guidelines, before intervention.²

COMMON PITFALLS

- Mistaking an abscess for a small area of cellulitis or a furuncle and failing to carry out needle aspiration
- Making an abscess incision that is too small to permit adequate drainage
- Mistaking a perianal abscess for a buttock abscess
- Removal of the catheter prematurely from a Bartholin abscess
- Failure to consider the possibility of coexisting cardiac valve disease and to provide antibiotic prophylaxis when draining an abscess
- Failure to refer patients with recurrent cutaneous infections for consideration of prophylaxis

CUTANEOUS CELLULITIS

Cellulitis is an acute, spreading infection of the skin and subcutaneous tissue characterized by warmth, swelling, and erythema. It is most often caused by group A *Streptococcus* and *S. aureus*.^{15,16} The first sign of common cellulitis is local skin discomfort, which is followed by frank tenderness and erythema. Within 24 hours, there is noticeable expansion of the process, even though the margins themselves are indistinct. The terms *very hot*, *red*, and *swollen* apply. In many cases, lymphangitis or “streaking” can be observed proximally from the site of cellulitis. Soon afterward, there is involvement of local and regional lymph nodes that become swollen and tender. Ultimately, systemic symptoms such as fever, malaise, and tachycardia can occur. In the preantibiotic era, this progression was known as “blood poisoning” and not uncommonly led to death.

Erysipelas is a distinctive form of cellulitis caused almost exclusively by group A streptococci, although occasional cases are due to *S. aureus*. Erysipelas is most common in infants and young children, but it occurs in adults as well.¹⁷ It can begin as a result of minor skin trauma, surgical intervention, or a preexisting skin condition. In adults, it is likely to occur in the setting of venostasis, lymphedema, diabetes, or alcohol abuse. In contrast to common cellulitis, the lesion of erysipelas is sharply demarcated, indurated, and easily palpable. Characteristically, it is also shiny red. It is usually associated with fever and an elevated white blood cell count. Untreated lesions can form bullae that break down and leave raw, weeping surfaces.

A serious form of cellulitis seen in children, and occasionally in adults, is caused by *Haemophilus influenzae* type B. Although most commonly involving the face and the periorbital tissues, *H. influenzae* cellulitis can also involve the arms and legs. In adults, it may originate as a respiratory infection and then involve the neck and chest. In children, the cellulitis often takes on a blue-red to purple-red appearance. In both adults and children, *H. influenzae* cellulitis is associated with systemic toxicity and a significant risk of sepsis and secondary site involvement.

Aeromonas hydrophila and *Vibrio vulnificus* are two water-related organisms that can cause uncommon forms of cellulitis.^{4,6} The skin infection of *A. hydrophila* follows local trauma and exposure to fresh water; early infections are indistinguishable from streptococcal cellulitis but often progress to bullae, abscess formation, and foul-smelling exudate. *V. vulnificus* cellulitis occurs after trauma and exposure to salt water. The infection can range from mild cellulitis to an aggressive infection associated with vesicles, bullae, and myositis that can mimic gas gangrene.

DIFFERENTIAL DIAGNOSIS

Cellulitis can be difficult to distinguish from other cutaneous conditions. The most serious condition to be considered is thrombophlebitis, particularly when the lower extremity is involved. Cellulitis can be differentiated by the presence of fever, lymphangitic streaking, an advancing margin, and an elevated white blood cell count, although these findings are not consistently present.

Viral and drug-related exanthems can be localized, but usually are associated with recognizable precipitants and specific syndromes.

Dermatitis can appear red and somewhat warm but is usually associated with considerable itching and scaling. Secondary infection of dermatitic lesions, however, is not uncommon.

Insect stings, particularly due to *Hymenoptera*, can cause significant local reactions that can be confused with cellulitis, and these reactions can persist up to 7 days.¹⁹ As compared with cellulitis, insect stings produce more pain than tenderness, cause more edema and less erythema, and are pruritic.

Fungal infections of the skin, particularly with *Candida*, appear in characteristic locations (often intertriginous), have a distinctive appearance (moist, bright red), and can be identified by potassium hydroxide staining.

EMERGENCY DEPARTMENT EVALUATION

Common cellulitis and erysipelas, when localized to a small area in an otherwise healthy patient, need no invasive or laboratory testing. With more extensive cellulitis, a white blood cell count is performed to check for signs of systemic involvement and to gauge the severity of infection. Because of the low bacterial count in the lesions of cellulitis, aspiration of the advancing margin for Gram stain and culture yields an organism in only 25% of cases.¹² In any event, these tests do not aid in immediate treatment decisions.

In compromised hosts and in patients in whom *H. influenzae* infection is suspected, a more extensive workup is indicated. The incidence of bacteremia ranges from 5% in toxic streptococcal cellulitis to 90% in *H. influenzae* cellulitis. Gram stain and culture, while of low yield, can be performed in an attempt to identify the causative organism. Older patients and those with underlying conditions such as diabetes or immunocompromised states should be evaluated for metabolic derangements and any evidence of other sites of involvement. Outlining the margins of the cellulitis with a marker can aid in the monitoring and follow-up of patients with cellulitis by indicating lesion progression or regression.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Common, localized cellulitis and mild, uncomplicated erysipelas in patients without risk factors can be treated as outpatients. Oral antibiotics (see [Table 181.1](#)) are begun, and close (48- to 72-hour) follow-up is arranged. Antibiotics are continued for 3 days after the resolution of clinical findings (i.e., a total course of 6 to 10 days). (Because of its unique pharmacology, azithromycin is given only for 5 days, however.) Although oral ciprofloxacin is often prescribed as a first-line agent for cellulitis, it has only moderate activity against streptococcal organisms and poor activity against *S. aureus*.

Hospital admission and infectious disease consultation should be considered under the following conditions: when there are signs of systemic toxicity; underlying illnesses such as diabetes; specific involvement of areas such as the face, orbit, hand, perineum, or lower extremity (particularly with preexisting edema); presumed *H. influenzae* infection; or suspected gram-negative organisms or mixed infections. Patients who require admission should be treated with intravenous antibiotics (see [Table 181.2](#)).

COMMON PITFALLS

- Failure to instruct the patient about elevation and care of the involved area
- Misdiagnosing deep vein thrombosis as lower extremity cellulitis
- Failure to arrange follow-up in 48 to 72 hours for patients with cellulitis
- Unnecessarily treating insect stings with antibiotics

DEEP CUTANEOUS AND NECROTIZING SOFT-TISSUE INFECTIONS

Deep cutaneous and necrotizing soft-tissue infections often constitute a threat to life and limb, yet they can be deceptively benign in appearance.¹⁰ Early in their clinical course, attempts at separating the various types of infections into discrete syndromes are made difficult by the fact that they share many characteristics. However, it is recognition of these characteristics that alerts the clinician to a potentially emergent condition:

1. These infections occur in settings that include trauma, foreign-body penetration, contamination with soil, surgical intervention, ischemia, or diabetes.
2. Tissue involvement is extensive, but classic signs of common cellulitis (heat, redness, induration) are often not present.
3. As the infection progresses, blebs, maceration, and exudate appear.
4. The hallmark of these infections, which, however, is not always present, is crepitance secondary to gas formation.

Specific deep cutaneous infections are summarized in [Table 181.3](#).

Characteristics	Clostridial Cellulitis	Synergistic Necrotizing Cellulitis	Necrotizing Fasciitis	Clostridial Myonecrosis	Clostridial Myonecrosis
Preexisting conditions	Wounds, ulcers, peripheral vascular disease, diabetes	Diabetes, obesity, advanced age	Diabetes, obesity, advanced age	Wounds, ulcers, peripheral vascular disease, diabetes	Wounds, ulcers, peripheral vascular disease, diabetes
Onset	Gradual	Subacute	Acute	Gradual	Acute
Site	Extremities	Extremities	Extremities	Extremities	Extremities
Systemic toxicity	Mild to moderate	Mild to moderate	Severe	Mild to moderate	Severe
Exudate	Thin, dark, foul-smelling	Thin, dark, foul-smelling	Thin, dark, foul-smelling	Thin, dark, foul-smelling	Thin, dark, foul-smelling
Gas formation	Minimal	Minimal	Abundant	Minimal	Abundant
Muscle involvement	No	No	Yes	No	Yes
Common pathogens	<i>Clostridium perfringens</i> , <i>Clostridium septicum</i> , <i>Clostridium novyi</i>	<i>Bacteroides</i> , <i>Streptococcus</i> , <i>Peptococcus</i> , <i>Peptostreptococcus</i>	<i>Streptococcus</i> , <i>Staphylococcus</i> , <i>Peptococcus</i> , <i>Peptostreptococcus</i>	<i>Clostridium perfringens</i> , <i>Clostridium septicum</i> , <i>Clostridium novyi</i>	<i>Clostridium perfringens</i> , <i>Clostridium septicum</i> , <i>Clostridium novyi</i>

TABLE 181.3. Deep Cutaneous and Necrotizing Soft-Tissue Infections

Crepitant cellulitis occurs most commonly in the setting of preexisting, lower extremity, peripheral arterial disease; decubitus ulcer; or a moderately severe traumatic wound. Also known as nonclostridial anaerobic cellulitis, this is a gas-forming infection that results from the synergistic interaction of anaerobic bacteria (*Bacteroides* species and peptostreptococci) and of gram-negative bacteria of enteric origin. In spite of its seriousness, it is usually gradual in onset, with mild local tenderness, and is not likely to cause serious systemic toxicity. In the area of involvement, the skin is minimally discolored and may appear grayish to brown, depending on local vascularity. The exudate, if present, is dark and foul smelling. The hallmark of this infection is crepitance and abundant gas formation, as seen on radiographs. The infection remains localized to the skin and subcutaneous tissues without extending to muscle.

Synergistic necrotizing cellulitis has also been called nonclostridial gangrene and nonclostridial anaerobic myonecrosis. Fournier gangrene of the male genitalia and perineum is a variant of this condition. Synergistic necrotizing cellulitis occurs most often in older patients with serious underlying disease, such as diabetes, congestive heart failure, or renal failure, and in the setting of obesity and perirectal infections. Gram-positive streptococci (both aerobic and anaerobic), gram-negative enteric bacilli, and anaerobes (*B. fragilis*), interacting synergistically, have been implicated in this infection. The onset can be acute or subacute, but the infection rapidly progresses to severe local and systemic toxicity with high fever. There is often severe pain at the site of infection, and the skin is blue-gray. Necrosis of the fascia and muscle occurs. Twenty-five percent of cases have clinical crepitance and gas evident on radiographs. The exudate is thin and foul smelling and has the appearance of dish water. Bacteremia occurs in 50% of cases, and mortality has been reported to be as high as 75%.

Necrotizing fasciitis is predominantly a disease of the subcutaneous tissue and fascia, with early sparing of the skin and very late involvement of the muscle.¹⁷ This condition can occur after trauma or abdominal surgery, or with perirectal infections, cutaneous ulcers, intravenous drug abuse, and infections of the head and neck. A wide range of organisms, including gram-negative enteric bacilli, gram-positive streptococci (aerobic and anaerobic), and other anaerobes, has been implicated. Although the infection is usually mixed, it can also be caused by single organisms, such as group A *Streptococcus*. The onset is acute, and the patient develops severe systemic toxicity. In the early stages, the skin appears erythematous and is minimally painful. Later, as the subcutaneous tissue becomes involved, there is mottling, discoloration, marked edema, and bleb formation as a result of interruption of the blood supply to the skin. The exudate is foul smelling and seropurulent, but not abundant. Although gas can be seen on radiographs, clinical crepitance is unusual.

Clostridial cellulitis, also known as clostridial anaerobic cellulitis, is most commonly a result of traumatic wounds. The presence of foreign debris, soil, and necrotic tissue allows rapid growth of clostridial organisms, including *C. perfringens*, *C. septicum*, and *C. novyi*. It is distinguished from clostridial myonecrosis (gas gangrene) by the lack of muscle involvement. Unlike gas gangrene, the onset is gradual, and systemic toxicity is only mild to moderate. Skin changes are minimal, but there is a thin, dark, occasionally foul-smelling exudate at the site of the wound. The most prominent feature of the wound site is crepitance and gas formation that often extends well beyond the actual area of cellulitis. The gas tends to appear on a radiograph as aggregates of bubbles in the subcutaneous tissues.

Clostridial myonecrosis, or gas gangrene, almost always results from a deep injury to skeletal muscle that causes ischemia and tissue necrosis. The same organisms that cause clostridial cellulitis are responsible for this disorder. The incubation period can range from 7 hours to 6 weeks,¹⁸ but once symptoms begin, severe deterioration can occur within 6 hours. Muscle swelling and severe pain are prominent features. Systemic toxicity, as a result of the many toxins elaborated by the clostridial organisms, is profound and leads to tachycardia and an altered sensorium, although fever is not a prominent feature. The involved skin has a yellow or bronze appearance, and the skin involvement progresses to bulla formation and green or black patches of necrosis. A serosanguineous discharge can develop with a characteristic “mousy” odor. Gas formation is minimal at the onset but extends throughout the muscle in a feathery pattern as it dissects through muscle fibers and bundles. Intravascular hemolysis, with thrombocytopenia, is often present. *These patients can die within hours.*

DIFFERENTIAL DIAGNOSIS

There is little difficulty in recognizing the picture of full-blown deep cutaneous and necrotizing soft-tissue infections. Occasionally, they can be confused with such conditions as dry ischemic vascular gangrene, pressure necrosis of a limb, acute deep venous thrombosis, and preexisting changes of venous insufficiency. Air can be introduced into the skin by traumatic lacerations and occasionally can cause some diagnostic concern.

It is important to emphasize, however, that these infections can be missed when they are not full blown. This is where difficulty can arise for the patient presenting to the emergency department in the early stages of infection.

EMERGENCY DEPARTMENT EVALUATION

The presence of a suspected deep cutaneous infection mandates an extensive and aggressive evaluation. This must be initiated promptly and carried out while any resuscitative or stabilizing interventions are in progress. Standard hematologic, biochemical, and clotting profiles are obtained, as well as arterial blood gas studies, a chest radiograph, and an electrocardiogram. A type and crossmatch may be indicated to correct blood loss or anemia.

A wound culture is taken and a Gram stain performed immediately, particularly if a clostridial etiology is suspected. The presence on Gram stain of gram-positive rods with few white blood cells indicates a clostridial infection. A finding of many white blood cells on the smear is more suggestive of a synergistic or mixed bacterial infection. Radiographs of anatomic areas of concern are obtained to look for soft-tissue gas. Because the infection can advance up to 6 in. an hour, the area of involvement should be outlined with a marker and checked at frequent intervals.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Because it can progress so rapidly, clostridial myonecrosis is a true emergency. Concurrent with emergency department evaluation, planning and execution of intervention is carried out in consultation with a surgeon. A combination of hyperbaric oxygen (HBO), surgery, and antibiotics provides optimal treatment.⁷ If immediately available, HBO is initiated to arrest the advance of the hemolytic, necrotizing, and potentially lethal tissue toxins. HBO produces a tissue level of 300 mm Hg, which is 50 mm Hg in excess of that required to cause bacteriostasis and halt production of tissue toxins. HBO significantly reduces the need for extensive debridement and amputation and assists the surgeon in demarcating clearly necrotic from viable tissue. If necessary, however, a fasciotomy can be performed before

HBO is done in order to relieve compartmental swelling and pressure.

In clear cases of clostridial myonecrosis or cellulitis, high-dose penicillin is still the antibiotic of first choice. Chloramphenicol can be used in b-lactam-sensitive patients. If the diagnosis is uncertain, the antibiotics listed in [Table 181.2](#) are also appropriate choices. Antitoxin therapy has never proven efficacious.

The primary treatment for other deep cutaneous infections consists of antibiotics and surgical intervention.¹⁶ Patients with an immunocompromised state or rapidly spreading infection can significantly benefit from adjunctive HBO; this intervention should be considered for all patients with these infections, especially Fournier gangrene.⁷ Broad-spectrum antibiotics are usually initiated empirically in the emergency department (see [Table 181.2](#)).

COMMON PITFALLS

- Failure to recognize a deep cutaneous infection because of a lack of classic skin changes of cellulitis
- Failure to perform a Gram stain in the emergency department
- Failure to take radiographs and thus missing subcutaneous gas
- Initiating only limited-spectrum antibiotics
- Delaying surgical consultation
- Failure to consider HBO therapy early in the patient's management

CHAPTER 182

Tetanus

James J. Mathews and Kaveh Ilkhanipour

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Prevention](#)
[Common Pitfalls](#)
[Chapter References](#)

Tetanus is a rare disease in the United States, having an incidence of less than one case per million per year. The current rate may increase in the future, as more than 10% of the population is not adequately immunized, including immigrants from underdeveloped countries, elderly patients who have lost immunity, and an increasing population of immunocompromised patients who do not have an adequate response to routine immunization. ^{1,4,5,8}

Many countries do not mandate routine immunization, and, in these areas, this disease remains a major public health problem. Most deaths in underdeveloped areas result from the neonatal form of tetanus, and are secondary to unhygienic practices involving the umbilical stump and circumcision. ^{2,12} When immunization is mandated and hygienic practices are used, this disease is virtually eliminated. ^{11,15}

Tetanus is caused by *Clostridium tetani*, an organism with worldwide distribution in soil and feces. ⁷ *C. tetani* is a gram-positive, spore-forming organism with a characteristic drumstick appearance. The organism is motile and is an obligate anaerobe. Although *C. tetani* is killed by heat and various antiseptic agents, its spores are highly resistant and survive in extremely hostile environments.

The clinical syndrome of tetanus develops when *C. tetani* is introduced into the body and the spores germinate and multiply. Proliferation occurs only in anaerobic conditions. Tetanus-prone wounds are wounds with foreign debris or necrotic tissue, or wounds that have been heavily contaminated with soil or feces.

Once established, *C. tetani* releases two exotoxins, tetanolysin and tetanospasmin. Tetanolysin causes hemolysis *in vitro*, but appears to have little clinical effect. Tetanospasmin produces the signs and symptoms of tetanus, and is one of the most potent neurotoxins known. This toxin diffuses into local tissue and eventually into the bloodstream. Tetanospasmin is taken up preferentially by motor neurons, with little initial effect on neuronal function. When the toxin crosses the cleft to presynaptic spinal inhibitory interneurons, decreased amounts of inhibitory substances are released. This effect results in increased muscle tone, decreased coordination, and simultaneous contractions of agonist and antagonist muscle groups, producing tetanic spasms.

CLINICAL PRESENTATION

Tetanus is clinically divided into four separate types. Generalized tetanus, the most common, presents with generalized skeletal muscle spasm. Localized tetanus is associated with persistent localized muscle rigidity at the site of spore inoculation. This can often be a prodrome to the development of generalized tetanus. Cephalic tetanus is characterized by localized involvement of the cranial musculature. Finally, neonatal tetanus presents within the first several weeks of life as generalized tetanus secondary to infection of the umbilical stump.

Tetanus generally occurs 10 to 15 days after injury, and the clinical signs arise over a 2- to 5-day period. ⁷ The length of time between the initial symptoms and the development of the first generalized spasm is a reliable prognostic indicator. Patients tend to have severe disease if the time of onset of generalized spasms is less than 48 hours. The most common presenting symptom is trismus. Associated complaints may be pain or stiffness of the neck, excessive pain in the injured area, and dysphagia. Rarely, tetanic spasms are the initial manifestation.

As the disease progresses, more muscle groups are involved, and the spasms become exquisitely painful. The effect on the back muscles is extremely profound; tetanic spasms of this muscle group produces opisthotonos, in which only the back of the head and the heels rest on the bed. The violence of these spasms can be so severe as to completely rupture the rectus abdominalis muscles and to fracture vertebrae. Spasms may involve the muscles of respiration, producing a fixed chest wall and eventual asphyxia.

Systemic symptoms in mild cases are often minimal, but, in severe cases, marked autonomic disturbances are seen, with tachycardia, wide swings in blood pressure, hyperpyrexia, and cardiac dysrhythmias. These manifestations appear to be due to excessive catecholamine release and are the most common cause of death from tetanus. ^{7,13} Trivial stimuli may trigger not only severe spasms, but also wide swings in vital signs.

DIFFERENTIAL DIAGNOSIS

The only differential diagnosis for the established case of tetanus is strychnine poisoning. Muscle spasms associated with strychnine poisoning may resemble those of tetanus, but there are several important differences. The muscles of the jaw are not involved early in the course of strychnine poisoning or may be spared completely. In tetanus, the jaw muscles are involved early in the course, and trismus is almost always present. Also, in a patient with strychnine poisoning, muscle rigidity disappears completely between spasms.

The early stages of tetanus may be confused with psychoneurotic complaints and with dystonic reactions from such agents as phenothiazines. Dystonic reactions can be rapidly and safely treated, and therefore ruled out, by the administration of benztropine or diphenhydramine. Dental infections may produce trismus, but there is no progression, and signs of local infection are almost always present.

EMERGENCY DEPARTMENT EVALUATION

Laboratory testing is of little value in diagnosing tetanus. ⁹ Routine studies should be obtained, including blood cell counts, electrolyte levels, a chest x-ray, an electrocardiogram (ECG), arterial blood gases, and a vital capacity. Vital capacity and arterial blood gas analysis should be done at frequent intervals to ensure that the patient does not progress to ventilatory failure. If the vital capacity is less than 50% of predicted, paralysis and mechanical ventilation are indicated. ¹³

The site of infection should be located, and appropriate treatment initiated. It must be remembered that a skin wound is not required for tetanus to occur. In underdeveloped countries, otitis media is a common source of *C. tetani* infection. Other sources include the tonsillar crypts, the lower gastrointestinal tract, septic abortion, and chronic wounds. Superficial abrasions and burns, and even corneal lesions, have been implicated in the development of tetanus.

EMERGENCY DEPARTMENT MANAGEMENT

The management of tetanus is supportive and symptomatic. ^{7,13,14} Initial attention should always be directed toward the establishing and supporting of an adequate airway, which may require rapid-sequence orotracheal intubation using a sedative and a paralytic agent. Benzodiazepines should be initiated in an aggressive fashion to help minimize muscle spasm and rigidity. ³ Large doses of intravenous (i.v.) diazepam, lorazepam, or midazolam are generally required. When benzodiazepines are not effective in controlling muscle spasms, generalized motor paralysis with nondepolarizing neuromuscular blocking agents such as pancuronium or vecuronium should be considered.

Autonomic instability secondary to sympathetic overactivity should also be monitored and treated aggressively. Agents providing both α - and β -adrenergic blockade (e.g., labetalol) are optimal in this setting. ⁶ Hypertension refractory to labetalol can be treated with a titratable agent such as sodium nitroprusside. Patients who are

hypotensive should receive i.v. crystalloids and pressors, as needed. Bradycardia should be treated with cardiac pacing.

Human tetanus immunoglobulin (TIG) should be given (1,000 U i.v. and 2000 U intramuscularly). Antibiotic therapy with penicillin (4 million U i.v. every 6 hours), tetracycline (250 mg i.v. every 6 hours), metronidazole (500 mg orally every 6 hours), or erythromycin (500 mg i.v. every 6 hours) should be initiated. Wounds should be surgically debrided after i.v. instillation of TIG so that any toxin that is released by debridement is bound. An attack of tetanus does not provide immunity. Active immunization should be done during the recovery period.

DISPOSITION

Any patient with tetanus should be admitted to the intensive care unit. Although mild cases can be managed in the community setting, the patient with moderate-to-severe disease should be transferred to a tertiary care facility. As the degree of severity is difficult to predict in the early stages of the disease, it is reasonable to transfer all patients with this diagnosis to a tertiary care center. In a review of 106 cases of tetanus in Victoria, Australia, the most important element identified in the management of these patients was the level of nursing care and expertise,¹³ especially for those patients with long-term paralysis requiring mechanical ventilation.

Where this practice has been instituted, the mortality rate from tetanus has been reduced to 10%. Patients with suspected tetanus should be accompanied during transport by personnel skilled in advanced cardiac life support and airway management. The airway should be secured before transfer if the patient is showing a decreasing vital capacity or if transfer is delayed or will be of long duration.

PREVENTION

The most important factors in the reduction of tetanus have been the enforcement of mandated immunization, improved hygiene, and better wound management.^{10,15} The emergency physician can affect all of these areas. All wounds should be carefully cleansed and debrided. Antibiotic prophylaxis should be given when indicated. Patients should receive careful instructions as to wound management and how to avoid wound contamination.

Appropriate tetanus prophylaxis should be given (Fig. 182.1). In many patients, particularly those who have migrated to the United States from underdeveloped countries, it is safest to give both the toxoid and TIG. Immunocompromised and certain elderly patients should also receive both agents.

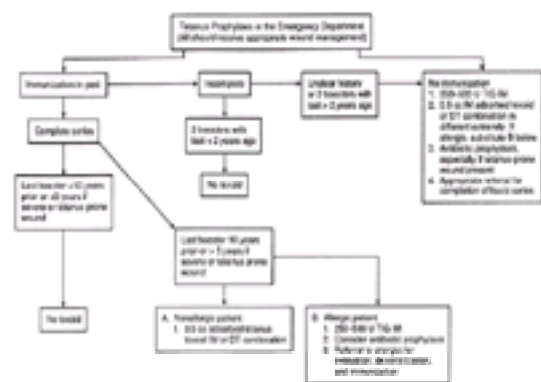

Figure 182.1. Appropriate tetanus prophylaxis.

Many patients claim that they are allergic to the toxoid because they previously experienced a local reaction at the site of the injection. This type of reaction is not an allergic response, and it is safe to administer the toxoid. Patients with a true allergy to the toxoid should be given TIG and antibiotic prophylaxis. This treatment does not impart lasting immunity, but it will prevent the development of tetanus. The allergic patient should be referred to an allergist for desensitization and immunization.

Some patients may refuse to receive tetanus toxoid because they have read of severe neurologic disorders occurring after injection of it, either alone or in combination with other products. Careful epidemiologic studies have not conclusively demonstrated this association.¹⁶ If, after discussion, the patient remains unwilling to receive the toxoid, TIG and appropriate prophylaxis should be given and referral made to the patient's personal physician to discuss adequate immunization.

COMMON PITFALLS

- It is unlikely that a full-blown case of tetanus will go unrecognized. Early cases may be misdiagnosed as a psychoneurotic disorder or dystonic reaction. Careful history and physical examinations will avoid this error.
- Even though tetanus is a rare disorder in the United States, the causative organism, *C. tetani*, is ubiquitous in the environment. Every wound must be considered as possibly contaminated.
- Prevention of tetanus is a responsibility of the emergency physician. Tetanus immunization status should be documented on all patients with wounds, and appropriate prophylaxis given (see Fig. 182.1).

CHAPTER 183

Meningitis and Encephalitis

Raymond J. Roberge and Richard Mark Kaplan

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Lumbar Puncture](#)
[Cerebrospinal Fluid Parameters](#)
[Emergency Department Management](#)
[Chemoprophylaxis](#)
[Common Pitfalls](#)
[Chapter References](#)

Meningitis and encephalitis are infectious and inflammatory processes occurring in the leptomeninges (meningitis), brain structures (encephalitis), or both (leptomeningitis). These disorders are discussed together because of considerable clinical and etiologic overlap.

By convention, meningitis is classified as either bacterial or, when due to any other cause, the aseptic meningitis syndrome. Untreated bacterial meningitis carries a mortality rate of greater than 90%. The aseptic meningitis syndrome, a generally self-limited symptom complex of fever, headache, and nuchal rigidity with characteristic cerebrospinal fluid (CSF) findings (lymphocytosis, variable protein elevation, and normal glucose), is primarily of viral origin. Aseptic meningitis may have many other causes, however, including certain bacteria (*Mycobacterium tuberculosis*, *Leptospira* species, *Treponema pallidum*, *Borrelia* species, *Nocardia*, and partially treated pyogenic infections), fungi, rickettsiae, *Mycoplasma*, parasites, parameningeal infections, malignancy, autoimmune diseases, and miscellaneous causes, such as intrathecal injections, heavy metal poisonings, nonsteroidal antiinflammatory agents, and antibiotics. With the advent of the acquired immunodeficiency syndrome (AIDS) epidemic and the growing numbers of other immunosuppressed individuals in the population, emergency physicians are more likely to see meningitis secondary to some of these previously rarer causes.

Although rapid diagnostic tests and effective antimicrobial agents are available, case fatality rates of greater than 20% are noted for bacterial meningitis in the United States, and significant residual neurologic deficit is noted in many survivors.¹⁹ Early diagnosis and the rapid institution of appropriate antimicrobial therapy are the keys to decreasing this significant morbidity and mortality. Emergency physicians are often the first clinicians to evaluate the patient with meningitis, and their diagnostic acumen may have a significant impact on the ultimate clinical course of this disorder. Nonetheless, a review by a major medical malpractice insurance carrier has identified the missed diagnosis of bacterial meningitis as accounting for 9.4% of all malpractice dollar claims against emergency physicians.⁹

Two bacterial species, *Streptococcus pneumoniae* and *Neisseria meningitidis*, currently account for approximately three-fourths of all cases of bacterial meningitis.¹⁹ *S. pneumoniae* is the most common agent in adults. *N. meningitidis*, responsible for up to 30% of cases of meningitis, is most frequently noted in children and adolescents but accounts for only 10% of bacterial meningitis in patients older than 45 years of age. *Listeria monocytogenes* is implicated in 5% of cases and is generally found in elderly or immunocompromised individuals. *Haemophilus influenzae*, previously a significant cause of childhood meningitis prior to institution of type B vaccine, is responsible for 1% to 3% of adult meningitis. Staphylococcal species and gram-negative bacilli are rarer causes of meningitis in adults. Meningitis due to anaerobic species is quite rare; its presence should suggest brain abscess.¹⁶

Although the aseptic meningitis syndrome remains overwhelmingly a disorder of viral etiology, with enteroviruses and the mumps virus accounting for more than 85% of reported cases,¹⁸ it is important to bear in mind the numerous other causes of this syndrome, because many are amenable to antimicrobial therapy. With polioviruses and herpes simplex as notable exceptions, most viral meningitides are relatively benign, whereas some nonviral causes of the aseptic meningitis syndrome (e.g., syphilis, tuberculosis) are capable of causing significant morbidity and mortality.

Risk factors associated with meningitis include age (the very old and the very young), gender (men more often than women), nasopharyngeal colonization, chronic disease, immunosuppression, and lower socioeconomic status. Specific host risk factors may offer a clue to likely pathogens. For pneumococcal meningitis, risk factors include certain infectious processes (e.g., otitis, sinusitis, pneumonia), trauma (head injury), and immunocompromised states (e.g., sickle cell disease, Hodgkin disease, immunoglobulin deficiency, renal or bone marrow transplantation).

Overcrowded living conditions (e.g., college dormitories, military barracks, skid rows) and poverty increase the risk of contracting meningococcal meningitis. Close association with victims of meningococcal meningitis increases the risk of developing this illness by a factor of 500 to 800. Risk factors for listerial meningitis include the immunocompromised state and the ingestion of *Listeria*-contaminated foods. Adults who develop *H. influenzae* meningitis should be evaluated for anatomic defects such as dermal sinus tracts, previous head trauma with CSF leaks, or infectious processes (e.g., otitis, sinusitis).

Staphylococcal infection should be suspected in patients who have sustained penetrating skull injuries or who have undergone neurologic or otolaryngologic procedures. Gram-negative meningitis is noted after neurosurgical procedures or in association with other nosocomial infections. Chronic immunosuppression from a variety of causes, including human immunodeficiency virus (HIV) infection and organ transplantation, is an increasingly recognized risk factor for fungal meningitis. Because the majority of reported cases of viral meningitis are due to enteroviruses, and because these are spread by the oral-fecal route, poor hygienic habits are associated with an increased risk. The viral inoculum size is also an important risk factor.²⁵

Acute encephalitis is generally a viral-related illness in which the brain matter (cerebral hemispheres, brainstem, or cerebellum) is injured either as a direct result of viral invasion or as a hypersensitivity reaction to a systemic viral illness. Occasionally, encephalitis occurs shortly after vaccination for measles, rubella, chickenpox, or rabies and is thought to represent a disordered immune reaction.

Although the list of viral agents capable of causing encephalitis is extensive, in North America enteroviruses, arboviruses, herpes simplex, mumps, and lymphocytic choriomeningitis account for the overwhelming majority of cases. Many other agents (e.g., rickettsiae, bacteria, fungi, parasites) and disorders (e.g., neoplasia, vascular disease, sarcoid, Behçet syndrome) can also cause encephalitic syndromes.

Increasingly, HIV encephalitis is being recognized. In 1991, 1103 cases of encephalitis were reported to the Centers for Disease Control,⁵ but these figures reflect such factors as underreporting or the inherent difficulty in differentiating mild acute encephalitis from aseptic meningitis. The diagnosis of encephalitis should be considered in all patients who present with fever, headache, nuchal rigidity, and such neurologic findings as altered level of consciousness, seizures, or focal neurologic signs. The overall mortality rate for acute viral encephalitis ranges from 5% to 20% of afflicted individuals, and approximately 20% more suffer some residual neurologic deficit. However, some specific viral encephalitides (e.g., herpes simplex, eastern equine) carry mortality rates as high as 40% to 50%. Timely diagnosis is therefore essential, because specific therapies are available for some agents causing encephalitis (e.g., herpes simplex, syphilis).

CLINICAL PRESENTATION

The triad of fever, headache, and nuchal rigidity constitutes the classic presentation of meningitis, and any patient with these findings warrants a prompt evaluation for the presence of central nervous system (CNS) disease. This same triad is generally noted with encephalitis, coupled with signs and symptoms of brain parenchymal involvement (e.g., altered level of consciousness, seizures, and focal neurologic signs).

Focal findings reflect the portion of the brain that is involved (e.g., hemiparesis, cranial nerve abnormalities, aphasia, ataxia). Any of the encephalitides may demonstrate hypersomnia as an acute symptom. Fever is commonly noted with either condition but is not invariably present, especially in the elderly and the immunocompromised, as a result of decreased immune responses to circulating bacterial and viral antigens. Headache is occasionally absent early in the course of disease and in elderly patients. Nuchal rigidity, noted in more than 80% of patients with bacterial meningitis,⁴ is considered the most characteristic finding in patients with meningeal irritation and is observed in patients with encephalitis in which there is concurrent meningeal involvement (meningoencephalitis). Nausea and vomiting, reflecting CNS inflammation and raised intracranial pressure, can be observed in either condition.

Three clinical signs are characteristic of meningeal irritation but cannot always be elicited. The Brudzinski sign occurs when flexion of the neck results in flexion of the knees and hips. The Kernig sign is elicited by extending the knee with the hip flexed; stretching of the lumbar roots causes pain in the hamstring and paraspinal muscles. The contralateral Brudzinski sign is described as flexion of the contralateral hip and knee during examination for the Kernig sign.

Petechiae, purpura, and morbilliform rash are commonly noted in association with meningococcal meningitis.¹⁵ Similar rashes may be noted occasionally in association with meningitis due to *Staphylococcus*, *H. influenzae*, and *S. pneumoniae*, as well as some viral meningitides, especially echoviruses.

An in-depth neurologic examination is obviously of paramount importance in the evaluation of any patient thought to harbor a CNS infectious process. Mental status or behavioral changes (sometimes quite subtle) are commonly noted with encephalitis and occasionally are the only clues to meningitis in the elderly patient. Seizures noted in association with encephalitis are most commonly focal; either focal or generalized seizures may be noted in as many as 30% of patients with meningitis and may reflect the infectious process itself or associated complications (e.g., fever, electrolyte imbalances, hypoxia).

Seizures are uncommon in meningococcal meningitis, whereas they may be the sole presenting sign of encephalitis. Cranial nerve abnormalities, especially the ocular variety, are often a feature of viral encephalitides and occur in 10% to 20% of cases of meningitis. A careful funduscopic examination may reveal papilledema, the presence of which should arouse suspicion of a brain abscess or encephalitis. Acute deafness is occasionally the presenting complaint of adults with meningitis. Neurologic sequelae of meningitis are not uncommon, and some forms of viral encephalitis (e.g., herpes simplex, eastern equine) result in serious neurologic deficits in as many as 50% of cases.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of meningitis and encephalitis includes infectious, neurologic, toxicologic, metabolic, environmental, and behavioral disorders. Infectious disorders include encephalopathy without actual invasion of the brain substance, brain abscesses, septic emboli, and cortical septic thrombophlebitis. Various noninfectious neurologic disorders, such as migraine and other vascular headaches, prolonged postictal states, and new-onset seizures, share some features common to both encephalitis and meningitis.

Drug ingestion (e.g., phencyclidine, salicylates) often presents in the form of febrile, mind-altered states and must be considered in the differential diagnosis. Metabolic disturbances (e.g., electrolyte imbalances, hypoglycemia, and hyperglycemia) and acute environmental toxicity (e.g., heat stroke) must also be considered. Behavioral alterations (e.g., psychosis, mania) should never be considered to be purely of psychological origin without an evaluation for the possibility of underlying organic causes such as meningitis and encephalitis.

EMERGENCY DEPARTMENT EVALUATION

The majority of patients with meningitis or encephalitis who present to the emergency department display classic complaints of severe headache and fever. Nuchal rigidity can be noted with meningitis and meningoencephalitis, and patients with encephalitis generally demonstrate some symptoms and signs of direct brain involvement. The astute emergency physician is aware that up to 20% of cases of meningitis may present in an atypical fashion and that the key to diagnosis in groups likely to display an atypical presentation (e.g., the elderly or immunocompromised) is a high index of suspicion coupled with a low threshold for performing a lumbar puncture.

Identification of risk factors may aid in the diagnosis of meningitis and assist in directing antibiotic therapy. Most risk factors can be identified with a few questions guided by the six I's:

*I*nfection (e.g., antecedent or concomitant upper or lower respiratory tract infection, sinusitis, otitis)
*I*mmunosuppression (e.g., splenectomy, sickle cell disease, corticosteroids, Hodgkin disease, myeloma, organ transplant, AIDS)
*I*njury (head trauma, neurologic or otolaryngologic procedures)
*I*ndwelling (catheters, shunts, ventricular reservoirs)
*I*mbiber (alcoholic)
*I*dentification (close contacts, such as spouses, roommates, and paramedics)

Many of the more common viruses causing outbreaks of encephalitis demonstrate characteristic seasonal and geographic distributions. For example, arbovirus and enterovirus infections tend to occur in summer and early fall, mumps in winter and spring, and lymphocytic choriomeningitis in fall and winter. Eastern equine encephalitis occurs in the eastern United States, and Venezuelan equine encephalitis is generally found in Florida and the southwestern United States, whereas herpes simplex encephalitis demonstrates no characteristic geographic pattern. Some important data to be elicited in suspected cases of encephalitis can be summarized through the use of the six V's:

Vacation/travel (to endemic areas, foreign or domestic)
Veterinary or other animal contact (rabies)
Vectors (recent mosquito or tick bites)
Viral infections (recent or concurrent)
Vaccinations (recent for measles, varicella, rubella, rabies)
Vital statistics (contact local or national health agencies regarding outbreaks)

The physical examination should focus on likely sites of infection, namely, the oropharynx, ears, and sinuses in the case of meningitis. Similarly, the chest examination should focus on evidence of pulmonary or cardiac sources of infection. The entire body should be scrutinized for the presence of any rashes. Funduscopy is mandatory to rule out papilledema. The neurologic examination must be performed in a timely, but meticulous, fashion. With encephalitis, only subtle clues of neurologic dysfunction (e.g., inattention or drowsiness) are sometimes found.

If papilledema or other evidence of increased intracranial pressure is noted, control measures (e.g., mannitol, hyperventilation) should be undertaken, and the patient should undergo computed tomography of the brain. If meningitis is suspected, but the patient is unable to undergo computed tomography, or if a space-occupying lesion is noted on computed tomography, cultures should be obtained from blood and infectious sites, and antibiotics administered without delay. In cases of suspected encephalitis, antibody titers, cultures, polymerase chain reaction, or fluorescent antibody studies should be obtained, and stool cultures ordered.

Computed tomography or magnetic resonance imaging may also demonstrate changes consistent with disorders such as herpes encephalitis and HIV encephalitis. Suspicion of herpes simplex encephalitis mandates rapid institution of intravenous acyclovir. Intravenous access should be obtained and blood sent for a complete blood cell count, glucose analysis (preferably an initial bedside glucose determination), electrolyte determinations, and liver function studies. Urine and sputum cultures are also warranted. Consideration should also be given to obtaining a toxicology screen. After this, if not contraindicated, lumbar puncture is carried out.

Lumbar Puncture

Lumbar puncture, a safe and rapidly performed procedure with a low complication rate, is the key to confirming the diagnosis of meningitis and many treatable cases of encephalitis. Although there has been concern over the possibility of inducing meningitis by the lumbar puncture itself,²³ the differentiation of spontaneously occurring meningitis from that induced by the procedure is difficult, if not impossible.¹⁰

Two definite contraindications to lumbar puncture are infection at the site of the puncture and evidence of obstructive (noncommunicating) hydrocephalus. Papilledema, anticoagulant use, and the presence of a space-occupying lesion in the brain are relative contraindications. In the event that lumbar puncture is required in a patient with papilledema, a small-bore (22- or 24-gauge) needle should be employed and only a small amount of fluid withdrawn. Whether it is always necessary to perform computed tomography of the head before lumbar puncture is an ongoing controversy.

Cerebrospinal Fluid Parameters

Gram Stain

The visualization of the responsible organism on a Gram stain of fresh CSF is pathognomonic of bacterial meningitis or some nonviral causes of encephalitis. Gram-stained, centrifuged samples of CSF demonstrate bacterial organisms in 80% to 90% of culture-proven cases of bacterial meningitis.¹ CSF counts are highest in pneumococcal and *H. influenzae* meningitis. Patients with listerial meningitis or those who have received previous antimicrobial therapy demonstrate bacteria on Gram stain approximately 60% of the time.³ *L. monocytogenes* is occasionally identified on the Gram stain as a “diphtheroid” contaminant.^{1,3}

In patients with fungal meningitis or encephalitis, successful detection of pathogens requires the examination of a large volume of fluid, because only a small number of fungal organisms are typically present in the CSF. India ink preparations for the detection of fungal elements in CSF are positive in as few as one-half of cases. Similarly, acid-fast smears of CSF for diagnosing tuberculous meningitis are not consistently sensitive. In any event, tests for fungal or tuberculous meningitis or for encephalitis should not be routinely ordered unless there is a good clinical indication for doing so.

Glucose

Normally, the ratio of CSF to serum glucose concentration is 0.60. Hypoglycorrhachia—a CSF glucose level of less than 50 mg/dL, or a CSF/serum glucose ratio of less than 0.50—is noted in more than 50% of cases of bacterial, fungal, and tuberculous meningitis, and is not uncommon in mumps encephalitis and meningitis, lymphocytic choriomeningitis, and herpes simplex meningitis. Normal CSF glucose levels are generally noted in most viral meningitides and encephalitides, as well as in the early stage of pyogenic or tuberculous meningitis.

Protein

Normal protein levels in the CSF range from 15 to 45 mg/dL. Subarachnoid space infection results in increased protein permeability of the choroid plexus, ependyma, and pia mater. Marked protein elevations are observed in bacterial, fungal, and tuberculous meningitis. Viral meningitides or encephalitides generally manifest normal or only moderately elevated levels of protein.¹⁷ Levels of 1000 mg/dL or more must raise the serious suspicion of impending or actual subarachnoid block. Blood (e.g., subarachnoid bleed, traumatic lumbar puncture) increases the CSF protein by 1 mg for each 1000 red blood cells if the protein and cell counts are measured from the same tube.

Cell Count and Differential

Normal CSF contains no red blood cells and has a white blood cell count of less than 5 cells/ μ L, all of which are mononuclear. Red blood cells, at times numbering in the thousands, and xanthochromia are sometimes noted with herpes encephalitis, owing to the hemorrhagic nature of the lesions. The finding of a single granulocytic cell when the CSF is concentrated by a centrifuge, considered pathologic by many, should be considered normal if the total CSF white blood cell count is less than 5 cells/ μ L.⁶ Bacterial meningitis is classically described as having CSF cell counts ranging from 100 to 10,000 cells/ μ L, with polymorphonuclear forms predominating early and lymphocytes appearing subsequently. The leukocyte esterase test can be used as a rapid, reasonably sensitive screening test for the determination of CSF polymorphonuclear leukocytes at concentrations of more than 10 cells/ μ L; its use, however, does not obviate the need for performance of the standard cell count and differential.⁷

Viral meningitis characteristically manifests a CSF lymphocytosis with cell counts on the order of 10 to 1000 cells/ μ L. There may be a marked predominance of neutrophils in the earliest stages of infection. Mononuclear cells usually predominate in cases of tuberculous and fungal meningitis, as well as in other causes of the aseptic meningitis syndrome. In the acute stages of viral encephalitis, a mild-to-moderate rise in mononuclear lymphocytes (e.g., 10 to 250 cells) is noted, with higher cell counts suggestive of concomitant meningeal involvement.

There is considerable overlap in the CSF findings of bacterial meningitis, the aseptic meningitis syndrome, and encephalitis. It has been reported that as many as 10% of patients with bacterial meningitis initially demonstrate a CSF lymphocytosis.^{1,17} Moreover, both tuberculous and fungal meningitis may initially manifest CSF neutrophilia, and neutrophils may predominate throughout the course of illness. Patients with viral meningitis occasionally demonstrate CSF leukocytosis of greater than 1,000 cells/ μ L with more than 75% neutrophils, particularly early in their illness, but a second sample obtained within 8 to 24 hours generally shows a significant decrease in the proportion of neutrophils.

Several ancillary CSF tests are available to aid in the differentiation of bacterial from nonbacterial meningitis. The most helpful for use in the emergency setting are those that detect bacterial antigens (by counterimmunoelectrophoresis, latex agglutination, or enzyme-linked immunosorbent assay). These tests should be used without delaying critical antibiotic therapy. CSF lactic acid levels are usually normal in viral meningitis and elevated (greater than 3.5 mEq/L) in bacterial, fungal, and tuberculous meningitis.¹⁴ Elevated CSF lactic acid, coupled with other CSF findings and the history and physical examination, may also be of diagnostic utility in partially treated meningitides.¹¹

CSF obtained very early in the course of bacterial meningitis may be totally devoid of cells and organisms and may demonstrate no glucose or protein abnormalities. Occasionally, even in immunologically competent individuals, the CSF in fulminant meningitis (especially pneumococcal) demonstrates no cells but is teeming with bacteria. Although no single CSF laboratory value can, of itself, make the diagnosis of meningitis when the Gram stain is negative, certain patterns are more closely related to certain etiologic agents. A pattern of CSF neutrophilia, very low glucose (5 to 20 mg/dL), and elevated protein (100 mg/dL) strongly suggests bacterial meningitis. The CSF in tuberculous meningitis generally contains mononuclear cells, normal-to-decreased glucose, and elevated protein. In viral meningitis, there is a predominance of mononuclear cells (except for early in the illness, when polymorphonuclear cells may predominate), a normal glucose concentration, and a slightly to moderately increased protein level.

Cultures

The CSF should be cultured in all cases of suspected meningitis. The diagnosis is made only from the culture in almost 20% of cases, and, in all cases, definitive antimicrobial therapy is guided by these results.^{2,8} Cultures take on even more importance in fungal and tuberculous meningitis, in which the India ink or acid-fast preparations are negative in 50% or more of cases.^{1,22} Cultures for suspected fungal or tuberculous meningitis require large volumes of CSF, because the number of organisms per unit volume is small.

In individuals suspected of having partially treated meningitis, the CSF should be cultured for at least 7 days. The agent responsible for viral encephalitis or meningitis may sometimes be identified by polymerase chain reaction or viral isolation from CSF or brain; its identity can also be inferred from a fourfold or greater increase in viral antibody titers between acute and convalescent sera or by isolation of the virus from the throat or stool.

EMERGENCY DEPARTMENT MANAGEMENT

The patient who presents to the emergency department with headache and fever, with or without nuchal rigidity and with or without neurologic abnormalities, should be considered to have meningitis until proven otherwise. An altered sensorium accompanied by fever and headache should prompt consideration of encephalitis. A rapid but thorough physical examination should be carried out, intravenous access obtained, and appropriate laboratory testing ordered.

If there is concern about a possible mass lesion or increased intracranial pressure, intravenous antibiotics should be promptly administered and a computed tomographic scan obtained. If there are no contraindications, a lumbar puncture is done. In the severely ill patient, antimicrobial therapy should never be withheld pending lumbar puncture or laboratory confirmation of the clinical impression. Antibiotic administration is unlikely to alter CSF parameters within the first few hours.

Because the vast majority of patients with bacterial meningitis are infected with pneumococci or meningococci, empiric therapy should be directed against these organisms, but coverage for *H. influenzae* should be provided as well. Antibiotic therapy can be subsequently tailored to the results of the CSF Gram stain ([Table 183.1](#) and [Table 183.2](#)). If the examination suggests the possibility of herpes encephalitis, intravenous acyclovir is instituted at 10 mg/kg over 1 hour, every 8 hours for 10 days. The identification of nonviral agents of encephalitis (e.g., syphilis, toxoplasmosis, tuberculosis) will guide specific therapy.

Ceftriaxone or cefotaxime (2 g)
 If significant *Streptococcus pneumoniae* resistance in the community, trauma, recent surgery, or shunt, add vancomycin 2 g
 If penicillin/cephalosporin allergic, vancomycin 2 g and chloramphenicol 25 mg/kg
 If concomitant steroid use, ceftriaxone 2 g and rifampin 300 mg
 If suspicion of *Listeria*, add ampicillin (2 g) + gentamicin (if allergic, trimethoprim-sulfamethoxazole)

TABLE 183.1. Empiric Parenteral Antibiotic Therapy for Meningitis

Organism	First-line Antibiotic	Alternative
Gram-positive cocci	Ceftriaxone Cefotaxime	Vancomycin
Gram-negative cocci	Penicillin Ampicillin Ceftriaxone Cefotaxime	Chloramphenicol Rifampin
Gram-positive bacilli	Ampicillin + aminoglycoside Penicillin + aminoglycoside	Trimethoprim-sulfamethoxazole
Gram-negative bacilli	Ceftriaxone + aminoglycoside Cefotaxime + aminoglycoside	Chloramphenicol Aztreosum

TABLE 183.2. Gram Stain-Guided Parenteral Antibiotic Therapy for Meningitis

Once the diagnosis of bacterial meningitis or encephalitis has been established, the patient's private physician or an infectious disease specialist should be contacted to assume responsibility for continuing management. Arrangements should be made for admission to a critical care unit. The emergency physician must insist on timely consultation in these potentially devastating illnesses. An infectious disease consultation should be considered for patients with suspected tuberculous or fungal meningitis.

Patients with clinical evaluation suggestive of viral meningitis, but whose CSF demonstrates a predominant neutrophilia, should have a second lumbar puncture done in 8 to 24 hours, because more than 85% will then show a significant decrease in the proportion of neutrophils. The decision of whether to begin antibiotic coverage before the results of the second lumbar puncture are available must be made by the emergency physician on the basis of the patient's clinical picture, the presence of associated risk factors, and the availability of appropriate staff and facilities to monitor the patient's status closely.

Cases of uncomplicated viral meningitis (except those caused by herpes simplex virus) can be discharged from the hospital when the diagnosis is definite. Therapy consists of antipyretic analgesics to alleviate the headache and fever, as well as supportive care and arrangements for appropriate follow-up.

Chemoprophylaxis

Although no hard and fast rules exist for ascertaining who should receive chemoprophylaxis after exposure to individuals with bacterial meningitis, certain guidelines may be useful. Close contacts (e.g., families, roommates, daycare contacts) of patients with meningococcal and *H. influenzae* meningitis have an increased risk (200- to 1,000-fold) of contracting the disease.²¹ Clearly, such individuals deserve the benefit of chemoprophylaxis. Paramedics and hospital personnel who have had close contact with the patient (e.g., mouth-to-mouth resuscitation) should also receive chemoprophylaxis. Others, including schoolmates, do not require prophylaxis.

Rifampin, 600 mg orally every 12 hours for a total of four doses, is the approved regimen for both *H. influenzae* and meningococcal meningitis. Ciprofloxacin (500-mg single dose) is an alternative regimen for meningococcal prophylaxis.²⁴ Pregnant individuals exposed to *N. meningitidis* should receive an intramuscular dose of ceftriaxone (250 mg) or a single oral dose of azithromycin (500 mg).¹² Individuals at risk for pneumococcal meningitis (e.g., postsplenectomy) should receive oral penicillin, 500 mg every 6 hours for 7 days.¹³ Emergency physicians should use their broad public exposure to promote the use of preventative vaccines where appropriate.

COMMON PITFALLS

- Relying on classic signs and symptoms alone, which results in some cases of meningitis being missed because of atypical presentations
- Failure to appreciate occasional overlap in CSF findings between aseptic and bacterial meningitis
- Delay in starting antibiotic therapy when there is a reasonable suspicion of meningitis. Prior antibiotic administration will not materially affect CSF findings
- Failure to provide prophylaxis to significant contacts of patients with meningococcal or *H. influenzae* meningitis
- Failure to realize that organisms remain detectable on CSF Gram stain in 60% of persons with bacterial meningitis despite antibiotic administration

Intracranial suppurative infections include brain abscess, cranial subdural empyema, and cranial epidural abscess. Although uncommon, they can produce serious morbidity and mortality if their diagnosis is delayed. The emergency physician must consider these conditions when evaluating patients who present with headache, fever, alteration of consciousness, or new neurologic deficits. Early identification and immediate neurosurgical consultation can result in an improved outcome.

BRAIN ABSCESS

Brain abscesses can range from microscopic collections of inflammatory cells to necrosis of an entire hemisphere. Brain abscess is the most common intracranial focal suppurative process but only occurs about 2% as commonly as brain tumors. It accounts for four to ten cases per year on a busy neurosurgical service, or for approximately one in 10,000 hospital admissions.^{4,12} The incidence had been declining due to improved therapy for otic and sinus infections; however, an increase in its incidence may be seen due to enhanced use of neurosurgical procedures, improved imaging techniques, and increased population of immunosuppressed patients.⁴

There is a 2 to 3:1 male-to-female predominance. The age distribution relates to the predisposing condition. Abscess from an otic origin usually occurs in those less than 20 years old or more than 40 years old. With a paranasal sinus focus, most patients are 10 to 30 years of age. Approximately 25% of cases occur in children less than 15 years old and are most commonly due to cyanotic congenital heart disease or otic sources. Abscess rarely occurs in those less than 2 years of age, but when it does, it is often secondary to gram-negative bacillary meningitis.^{4,12}

Brain abscesses arise from either contiguous or hematogenous spread of a suppurative infection. Contiguous spread from craniofacial sites (middle ear, sinuses, dental) account for 19% to 40% of all cases.^{8,11,12} Otitis media (chronic) and mastoiditis classically spread to the temporal lobe (50% to 75% of cases) and the cerebellum (one-third of cases). Approximately 85% to 99% of cerebellar abscesses are from an otic source. Frontal and ethmoidal sinusitis spread to the frontal lobe. Dental sources also tend to affect the frontal lobe.^{4,12} Posttraumatic (penetrating) and postneurosurgical procedure abscesses now account for up to 24% of cases.¹¹ These contiguous infections can lead to abscess formation by two mechanisms: by direct extension through infected bone or by retrograde thrombophlebitis from emissary and diploic veins.^{4,8,12}

About 25% of cases arise from hematogenous spread from a cardiac or pulmonary source, including lung abscess, bronchiectasis, cyanotic congenital heart disease (tetralogy of Fallot), and bacterial endocarditis. Hematogenously spread abscesses tend to be multiple and lie in the distribution of the middle cerebral artery at the gray-white junction where microcirculatory flow is poorest. Other causes include hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease), dental extractions, abdominal or pelvic infections, and following esophageal stricture dilation and endoscopic sclerosis of esophageal varices.^{4,12} In the remaining 10% to 15% of cases, there is no clearly identifiable cause.¹²

Improved microbiologic culture techniques have yielded a better understanding of the microbiology of brain abscesses. The microbiology is location dependent, and over 50% of abscesses involve mixed flora.^{5,10,12} Anaerobes play a large role, with their being isolated in 40% to 60% of cases.⁴ The most commonly isolated anaerobes are *Bacteroides* species (from ear or sinus infection) and anaerobic streptococci (from dental and chronic pulmonary infections). Aerobic and microaerophilic streptococci (*Streptococcus milleri*, *S. viridans*) are the most common bacteria isolated, being found in up to 70% of abscesses.⁴ *Staphylococcus aureus* and *S. epidermis* are frequently isolated from posttraumatic or postsurgical abscesses. Gram-negative bacilli, found in 23% to 33% of cases, are associated with chronic otitis, postoperative infections, and abdominopelvic infection.^{4,12}

The acquired immunodeficiency syndrome (AIDS) epidemic and the increasing use of immunosuppressive drug therapy have led to more atypical, fungal, and protozoal brain abscesses, such as *Nocardia*, *Listeria*, *Cryptococcus*, *Mycobacterium*, *Aspergillus*, and *Candida*. *Toxoplasmosis gondii* is the most common cause of brain abscess in patients with AIDS.^{3,4,7}

CLINICAL PRESENTATION

The triad of fever, headache, and focal neurologic deficit is present in less than half of patients who present with a brain abscess.⁴ There are no other pathognomonic signs; therefore, history and a high clinical suspicion are important features to proper diagnosis.

Headache, the earliest presenting symptom, is present in 70% of patients and is oftentimes severe, hemicranial, and persistent. Fever is absent in more than 50% of patients. Alterations in consciousness, ranging from drowsiness to coma, occur in 50% of cases, as do nausea and vomiting. A focal neurologic deficit is seen in 50% to 75% of patients, and can include aphasia, hemiparesis, visual fields deficits, nystagmus, or ataxia. These physical findings may be helpful in localizing the abscess. Focal or generalized seizures occur in 30% of cases. Unfortunately, papilledema is a late and often absent finding.^{4,9,12,14} The patient with a brain abscess is at risk for three major complications, producing sudden deterioration: uncal or tonsillar herniation, hemorrhage into an abscess, or rupture of abscess into the ventricular or subarachnoid space.^{4,10,15}

DIFFERENTIAL DIAGNOSIS

Primary or metastatic brain tumor can mimic cerebral abscess on a computed tomography (CT) scan. History and CT appearance easily differentiate other infectious diseases, such as viral encephalitis, subdural empyema, epidural abscess, and meningitis. Subarachnoid hemorrhage, cerebral infarction, central nervous system (CNS) vasculitis, and migraines can mimic abscesses.^{4,5,14,15}

AIDS patients account for a large proportion of patients presenting to the emergency department (ED) with intracranial mass lesions. Because of the wide variety of pathologic process involving the CNS of AIDS patients, brain biopsy is often needed for definitive diagnosis and treatment. *T. gondii* is the most commonly found organism and is often targeted when selecting empiric therapy. Other considerations include *Cryptococcus*, *Candida*, lymphoma, Kaposi's sarcoma, and progressive multifocal leukoencephalopathy.^{3,7}

EMERGENCY DEPARTMENT EVALUATION

The history and physical examination should focus on sites of potential infection and the possibility of life-threatening complications. Routine laboratory evaluation is rarely helpful. Leukocytosis may be present, but approximately 30% to 40% of patients will have a normal white blood cell count. An elevated erythrocyte sedimentation rate is seen in 40% of cases; however, the C-reactive protein may help to distinguish abscess from tumor. Blood cultures are positive in about 10% of cases, but should be obtained even if the patient is afebrile. Although lumbar puncture is contraindicated in patients with brain abscess, if performed, the results will be normal or nonspecific (elevated opening pressure, mildly elevated protein and cell count). Cerebrospinal fluid (CSF) cultures rarely identify the causative organism.^{4,5,9} Chest films may reveal a pulmonic source of infection; sinus or mastoid films may identify infection in these areas.

A CT scan of the brain, with and without contrast, should be obtained. CT has a reported sensitivity of 95% to 99%.⁴ CT helps to localize the abscess and stage its evolution. During the “early cerebritis” stage (first 3 days), a CT scan reveals an irregular area of low density. This area does not enhance with contrast and represents the necrotic center of the abscess. In the late cerebritis stage, patchy enhancement is present. As the abscess evolves, a homogenous central area of low density is seen, and a thick, diffuse, ringlike pattern of enhancement is present. This enhancement correlates with formation of the collagen capsule. The ring becomes thinner as the capsular development progresses, and it is narrower on the ventricular surface of the abscess.² Features that help to identify the mass as an abscess include gas within the center of the mass, a thinner rim (less than 5 mm), and ependymal enhancement. Patients given corticosteroids may have diminished enhancement of the abscess ring.⁴

Magnetic resonance imaging (MRI) with gadolinium has become the diagnostic procedure of choice. MRI may not be readily available in most departments and not accessible to critically ill patients; therefore, a CT scan remains a very good alternative. MRI has better sensitivity and specificity than contrast CT. MRI better detects mass effect, edema, petechial hemorrhage, smaller lesions, and multifocal involvement. If clinical suspicion is high and a CT scan is negative, an MRI should be performed.

EMERGENCY DEPARTMENT MANAGEMENT

Initial management of the patient with a suspected brain abscess includes airway control, intravenous access, and maintenance of adequate ventilation and circulation. If signs of elevated intracranial pressure and/or impending herniation are present, one must act rapidly to reduce the pressure. These are, however, only temporizing measures and include intubating and hyperventilating the patient, elevating the head of the bed 30 degrees, and instituting pharmacologic therapy with mannitol and dexamethasone. Immediate neurosurgical consultation is required.

Definitive management includes antibiotic therapy and surgical decompression. Immediate surgical decompression is indicated if there is a deteriorating level of consciousness, increasing neurologic deficit, or signs of increasing intracranial pressure.⁵ Surgical options include drainage, aspiration, or excision of the abscess.¹⁰ Intravenous antibiotics should be initiated in the ED and should be selected to treat likely pathogens. [Table 184.1](#) outlines the choice of empiric antibiotics based on the suspected source of the abscess and pathogens involved.^{4,8,12} Pending culture and sensitivity results, one standard regimen includes a third-generation cephalosporin plus metronidazole (400 to 600 mg intravenously every 6 hours). In postsurgical or posttraumatic abscesses, vancomycin or an antistaphylococcal penicillin should be used to cover *Staphylococcus*. If *Pseudomonas* is thought to be a causative organism, ceftazidime plus an aminoglycoside should be used.¹⁴

Pathologic Condition	Site	Index	Treatment
Otitis media/mastoiditis	Temporal lobe or cerebellum	Streptococci (aerobic or anaerobic), Klebsiella (aerobic), Enterobacteriaceae	Third-generation cephalosporin + metronidazole
Skullitis	Frontal or temporal lobe	Streptococci, Bacitracin spp., Staphylococci, Streptococcus spp., Listeria monocytogenes	Third-generation cephalosporin + metronidazole + vancomycin
Dental	Frontal lobe	Mixed (aerobic/anaerobic) bacteria, Streptococcus spp.	Penicillin + metronidazole
Resolving trauma or postoperative	Isolated or several	Staphylococci, Streptococci spp., Enterobacteriaceae, Clostridium spp.	Third-generation cephalosporin + vancomycin, or antistaphylococcal PCN
Congenital heart disease	NCH distribution	Streptococcus spp., Staphylococci spp.	Penicillin or ampicillin + third- generation cephalosporin
Long disease exposure or abuse	NCH distribution	Acinetobacter, Acinetobacter, Bacteroides, Streptococcus spp., Neisseria	Penicillin + metronidazole + TMP/SMX or third-generation cephalosporin
Bacterial meningitis	NCH distribution	Streptococcus pneumoniae, S. aureus, Streptococcus spp., Klebsiella	Antistaphylococcal PCN, ampicillin, or vancomycin + ampicillin
CSF source	NCH distribution	Enterobacteriaceae	Third-generation cephalosporin

PCN, penicillin; NCH, nuchal rigidity; TMP/SMX, trimethoprim-sulfamethoxazole; G, gram-negative.

TABLE 184.1. Treatments for Brain Abscess Based on Pathogen and Site of Abscess

Corticosteroids are used to reduce cerebral edema and help control intracranial pressure. The standard regimen is dexamethasone 10 to 12 mg intravenously, followed by 4 mg every 6 hours. Because corticosteroids may reduce antibiotic penetration into the abscess cavity and may delay encapsulation, they are indicated only when there is evidence of a significant mass effect, with progressive neurologic deficit or changing level of consciousness.^{4,5,12}

DISPOSITION

All patients diagnosed with a brain abscess in the ED require admission to the hospital. Immediate neurosurgical consultation should be made. If a neurosurgeon is not available, arrangements should be made for transfer to a neurosurgical center after stabilization. Young persons, those without underlying disease, and those without neurologic deterioration or mental status changes have a better prognosis. With early diagnosis, advanced neuroradiologic imaging, and rapid treatment, mortality is less than 30%, but in patients presenting with signs of herniation, mortality is greater than 50%.^{4,10,12} Persistent neurologic deficits, including seizure, intellectual or behavioral impairment, and motor deficits, are seen in 30% to 55% of patients.⁴

CRANIAL EPIDURAL AND SUBDURAL SPACE INFECTIONS

Subdural empyema and cranial epidural abscess are rare, but life-threatening, causes of intracranial suppurative infections. Subdural empyema accounts for 15% to 25% of focal intracranial infections, while cranial epidural abscess is much less common. Subdural empyema is a disease of teen-agers and young adults, with most cases occurring in the 10- to 40-year age group. On the other hand, epidural abscess rarely occurs in young children and has been reported in patients from ages 12 to 68. Both conditions exhibit a 3:1 male-to-female predominance.⁴

Subdural empyema forms between the dura mater and arachnoid mater, while cranial epidural abscess forms outside the dura mater. Both entities share a similar pathogenesis and etiology, and the two infections can coexist. The infections are thought to occur through direct extension or by hematogenous spread through the emissary veins.^{4,12} Paranasal sinus disease, especially frontal and ethmoidal sinusitis, accounts for 60% to 70% of cases. Other causes include cranial osteomyelitis, mastoiditis, otitis media, head trauma, cranial surgery, ventriculoperitoneal shunt, halo traction pins, orbital infections, and chronic subdural hematoma.^{4,6,8} In children, bacterial meningitis is the most common predisposing condition.¹²

The microbiology of these infections can be predicted by the primary source of infection. Aerobic, anaerobic, and microaerophilic streptococci are isolated in the majority of cases due to otorhinogenic origin. *S. aureus* and coagulase-negative staphylococci are found in sinus, otic, postoperative, and posttraumatic cases. Gram-negative bacilli can usually be seen in otic and posttraumatic sources. Polymicrobial infections are common, and a sterile culture may be found in 20% to 30% of cases. In children, the most common causative agents are those responsible for the underlying meningitis (*H. influenzae*, *S. pneumoniae*).^{4,6,12}

CLINICAL PRESENTATION

The clinical presentation of subdural empyema is fever, headache, and nuchal rigidity. The nonspecific symptoms of a sinus or ear infection, fever and malaise, rapidly progress to severe headache and meningismus. A classic presentation is a young male with frontal sinusitis, who develops progressive obtundation and

hemiparesis.⁸ Headache, present in 90% of cases, is focal but then becomes more generalized. Nausea and vomiting are common. Varying degrees of encephalopathy can be seen, ranging from mild confusion to coma. Focal neurologic signs (including hemiparesis, third and sixth cranial nerve palsies, and focal or generalized seizures) are seen in 75% of patients.^{4,12} Postoperative and posttraumatic subdural empyema has a very indolent course due to the slow accumulation of fluid. Headache is often absent, and the disease course is more benign.^{1,4}

The presentation of epidural abscess is more insidious. Symptoms can take weeks to months to develop. Patients often present with a long history of nonspecific symptoms, without focal signs or mental status changes. Once the fluid mass reaches critical size, nausea, vomiting, headache, drowsiness, and lethargy occur. Focal neurologic signs, seizure, and coma do not occur unless the infection spreads to the subdural space or cerebral herniation occurs. A patient with an epidural abscess involving the petrous bone may present with unilateral facial pain and fifth and sixth cranial nerve palsies, leading to lateral rectus weakness (Gradenigo syndrome).^{1,4,6}

DIFFERENTIAL DIAGNOSIS

The initial presentation of subdural empyema and epidural abscess is similar to that of other intracranial processes. Meningitis, brain abscess, subdural hematoma, subarachnoid hemorrhage, herpes encephalitis, venous sinus thrombosis, and tumor should be considered.^{1,4} CT scanning and the more sensitive MRI allow definitive diagnosis in most cases.

EMERGENCY DEPARTMENT EVALUATION

History and physical examination should focus on finding potential sources of infection. A detailed neurologic examination should be performed. Routine laboratory evaluation is of limited value. The white blood cell count may be only mildly elevated and oftentimes is normal. The sedimentation rate may be elevated if osteomyelitis is present.⁶ CSF analysis is usually not helpful and is actually contraindicated, due to the risk of herniation.^{1,4}

CT scanning with intravenous contrast remains the mainstay of ED diagnosis for both subdural empyema and cranial epidural abscess. Subdural empyema reveals a crescent-shaped, hypodense fluid collection in the subdural space, with displacement of the arachnoid. A mass effect is common, and an enhancing rim may be seen. Epidural abscess appears as a poorly defined, lentiform, extraaxial area of low or intermediate density. A hypointense, medial enhancing rim, representing inflamed dura, helps to differentiate it from a subdural collection.¹³ Cranial osteomyelitis may be detected.^{4,12}

MRI with gadolinium is more sensitive in detecting these processes, but may not be readily available in most EDs. MRI advantages include increased delineation between bone, CSF, and brain parenchyma; better ability to localize fluid to the epidural or subdural space; ability to characterize fluid type (blood, pus, or sterile effusion) in the collection; and ready detection of subtle edema and parenchymal abnormalities.^{4,13} MRI should be used when CT scanning is negative in the face of high clinical suspicion.

EMERGENCY DEPARTMENT MANAGEMENT

Once the diagnosis is made, immediate neurosurgical consultation is required. If signs of impending herniation are present, temporizing measures must be employed.

Antibiotic coverage should begin in the ED. The choice of antibiotic should be tailored to the suspected source until culture results are available. A scheme for antibiotic selection is outlined in [Table 184.1](#). If an otogenic source is suspected, a third-generation cephalosporin with metronidazole should be used. In postsurgical or posttraumatic abscesses, nafcillin or vancomycin should be used with a third-generation cephalosporin.^{4,12}

DISPOSITION

All patients require admission. If neurosurgical services are not available, the patient, once stabilized, should be transferred to an appropriate center. Patients with an isolated cranial epidural abscess have an excellent prognosis. Most recover, with good neurologic outcome.

The mortality for subdural empyema ranges from 6% to 20%. Of those that survive, 15% to 44% have a persistent neurologic deficit (seizure disorder, hemiparesis, aphasia). Outcome is directly related to advanced patient age, degree of encephalopathy present, and delay to appropriate therapy.

COMMON PITFALLS

- Failure to order MRI after negative CT scan in patients suspected of having a subdural empyema or cranial epidural abscess
- Inappropriate antibiotic selection because the likely origin of the infection was not considered
- Delay in reducing intracranial pressure and neurosurgical consultation

CHAPTER 185

Gonorrhea

Rodney Smith

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation and Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Gonorrhea (GC) is a sexually transmitted disease caused by the small gram-negative diplococcus *Neisseria gonorrhoeae*. It is the second most frequently reported communicable disease after chlamydia. In 1997, approximately 325,000 cases were reported in the United States, and this figure represents only about half of the estimated number of cases treated.^{4,5} The current epidemic of GC in the United States began in 1960, had a rapid rise in the number of annually reported cases, and peaked in 1975. Overall, there has been a gradual decrease in the annual incidence of GC since 1975, but the incidence has been stable or rising among adolescents.²² There has also been a significant increase in antibiotic-resistant strains of *N. gonorrhoeae* since 1985. Thus, it is likely that gonococcal infections will continue to be a major public health problem.

GC is slightly more common in males, but the highest incidence is in females in the 15- to 19-year-old age group.^{4,21} There is increased prevalence in non-Whites, in urban populations, in patients with lower socioeconomic status, in patients with multiple sex partners, among male homosexuals, and in patients with illicit drug use.¹⁵ There is a seasonal variation, with more cases reported during the summer.⁴

Complications of GC, including pelvic inflammatory disease (PID), epididymitis and/or orchitis, prostatitis, ophthalmitis, septic arthritis, endocarditis, meningitis, and perihepatitis, are not reported separately, and their true incidence is unknown. Chronic sequelae such as infertility, ectopic pregnancy, blindness, urethral strictures, and abdominal adhesions represent a significant cause of morbidity.

Patients presenting to the emergency department with gonococcal disease usually fall into one of three categories: (1) those with symptoms due to localized infection; (2) those with symptoms attributable to disseminated disease; and (3) those who are asymptomatic contacts of partners known to be infected. The role of the emergency physician is to make the diagnosis, obtain suitable specimens for culture, institute appropriate antibiotic therapy, and arrange for timely follow-up.

CLINICAL PRESENTATION

The clinical manifestations of localized disease depend on the sex of the patient, the site of the infection, and the strain of gonococcus causing the infection. In heterosexual men, acute urethritis is the most common presentation. Symptoms begin within 1 to 14 days of exposure and consist of dysuria and a penile discharge. Physical examination reveals meatal erythema and, either spontaneously or with urethral stripping, a purulent urethral exudate. Asymptomatic gonococcal urethritis (GU) is not uncommon in sexually active men. It is estimated that 3% to 10% of newly acquired cases of GC in men may be asymptomatic and that the proportion of asymptomatic disease may approach 60% in some populations.¹⁴ Because these men may not seek medical attention, they can constitute an important reservoir of disease in the community.

Primary GC in women is usually asymptomatic, and, when symptoms do occur, they are usually mild and nonspecific. Women with GC present to the emergency department with complaints of vaginal discharge, abnormal vaginal bleeding, urinary tract symptoms, and abdominal or pelvic pain.^{2,13} Up to 20% of women with GC develop PID, and 33% to 81% of women with PID have GC.²⁰ Other local complications of GC include Bartholin abscess and perihepatitis (Fitz-Hugh-Curtis syndrome).

In patients with GC at any site, the pharynx has been found to be colonized in 3% to 7% of heterosexual men, 5% to 20% of women, 10% to 25% of homosexual men, and 39% to 96% of pregnant women.⁸ Oropharyngeal GC is usually asymptomatic but can present as an acute exudative tonsillitis, a sore throat with minimal objective findings, or an acute ulcerative gingivostomatitis.

Anorectal involvement is common in both heterosexual women and homosexual men. Of women with GC, 26% to 63% may have positive rectal cultures, and most are due to autoinoculation of the rectum from vaginal infections.^{2,15,22} Up to 6% of women have GC of the rectum in the absence of infection at another site.²² In homosexual men, the rate of GC infection is as high as 55%, and half of these have no other site of infection.^{1,22} Anorectal GC is often asymptomatic. When symptoms do occur, they are usually mild and consist of various combinations of pruritus ani, rectal discomfort, tenesmus, dyspareunia, hematochezia, and purulent or mucoid rectal discharge.^{1,22}

Disseminated gonococcal infection (DGI) may complicate the course in 1% to 3% of patients, with the majority of cases occurring in patients with an asymptomatic primary infection.⁵ About 80% of DGI cases occur in women, and about two-thirds of these occur within the first week after the onset of menses.⁵ Pregnant or puerperal women and homosexual men are also at risk for developing DGI. The most common presentations of DGI are the arthritis–dermatitis syndrome, which occurs in approximately 60% of patients with DGI, and acute gonococcal arthritis. These probably represent different stages of a similar process, with a bacteremia leading to the arthritis–dermatitis syndrome, followed by frank suppurative arthritis.⁵ Rare complications of DGI include pericarditis, endocarditis, perihepatitis, pyomyositis, osteomyelitis, and meningitis.⁵

Clinically, the arthritis–dermatitis syndrome presents with fever, chills, polyarticular arthritis or arthralgias, a characteristic rash, and tenosynovitis. The arthritis is migratory and occurs in only 30% to 40% of cases. The most frequently involved joints are the wrists, followed in frequency by the knees, hands, ankles, and elbows.^{5,11} Although painful, the joints are usually not red or warm, and the effusion, if present, is small and usually sterile. The characteristic rash begins as petechiae or painful red papules involving the digits or distal extremities. These lesions either resolve spontaneously or evolve through vesicular and pustular stages to develop gray necrotic centers, often on hemorrhagic bases. There are usually fewer than 20 lesions per patient, and it is generally accepted that they represent septic emboli to small blood vessels during episodes of gonococcemia.¹¹ Skin lesions are seen in 50% to 75% of cases. Tenosynovitis occurs in up to 65% of cases and generally involves the extensor tendons of the hands, the wrists, or the tendons about the ankles.¹¹

Gonococcal arthritis presents as an acute monoarticular or pauciarticular septic arthritis. The joint is red and warm and has an easily demonstrable effusion. The degree of systemic toxicity depends chiefly on the number and size of the joints involved.¹¹

Patients with DGI should have cultures obtained from mucosal sites, as there is a high rate of recovery of GC from these sites.⁵ For example, GC is cultured from the cervix in 90% of women and from the urethra in 50% to 75% of men. Pharyngeal cultures are positive in 20%, and rectal cultures in 15%. On the other hand, cultures of synovial fluid are positive for GC in only 50% of patients with frank arthritis, and in 25% to 30% of all patients with DGI. Blood cultures are positive in only 20% to 30%, and skin lesions in less than 5%.⁵

DIFFERENTIAL DIAGNOSIS

In men with urethritis, the major distinction to be made is between GU and nongonococcal (*Chlamydia trachomatis*) urethritis (NGU). Patients with GU are more likely to be Black, young, and of lower socioeconomic status than are patients with NGU.¹² Symptoms of GU are usually much more acute, and patients are more likely to complain of urethral discharge than are patients with NGU. The discharge in GU is usually purulent, whereas, in NGU, it is more often mucoid and scanty. Diagnosis is based on Gram stain of the urethral discharge. Other causes of NGU include *Ureaplasma urealyticum* (20% to 40%), *Trichomonas vaginalis* (25%), and, occasionally, herpes simplex virus.⁴

In women with symptoms attributable to GC, the differential diagnosis depends on the presenting symptoms. GC should always be considered in women presenting

with a vaginal discharge. In studies of women with uncomplicated GC, no physical finding, including the character of the cervical discharge, reliably distinguishes between patients with GC and those whose symptoms are due to other pathogens.² Moreover, the finding of other pathogens on microscopy does not rule out coexistent GC. In one study, 35% of emergency department patients with GC also had trichomoniasis, and 19% had vaginal candidiasis.² Similarly, the results of urinalysis do not differentiate patients with GC from those whose urinary tract symptoms are due to other pathogens. GC should be considered in patients presenting with abnormal vaginal bleeding when another cause is not readily apparent, and it should always be a diagnostic consideration in sexually active women with complaints of abdominal or pelvic pain.

Gonococcal proctitis should be suspected in homosexual men presenting with rectal symptoms, but no symptoms are specific for anorectal GC. In studies of homosexual men presenting with rectal symptoms to venereal disease screening clinics, only 20% to 30% were found to have GC. Other causes of proctitis, including syphilis, herpes simplex, *Chlamydia*, *Entamoeba histolytica*, *Campylobacter*, anal fissure, anal fistula, and perianal abscess, should also be sought.

The differential diagnosis of patients presenting with signs and symptoms of DGI depends on the clinical manifestations of the process. In patients presenting with the classic arthritis–dermatitis syndrome, the major differential diagnosis is between disseminated *N. gonorrhoeae* and disseminated *N. meningitidis*. Clinical findings suggestive of meningococcemia include a larger number of skin lesions (greater than 100) and leukocytosis.¹⁶ Other diagnostic considerations include acute rheumatic fever and Reiter syndrome. The fever and migratory polyarthralgias of DGI may suggest acute rheumatic fever, but high temperature (greater than 103°F [39.4°C]) is unusual in DGI, and skin lesions, if present, are distinctive. Features of DGI that distinguish it from Reiter syndrome are the more acute onset, increased frequency of migratory polyarthralgias, upper limb predominance, female predominance, and rarity of ocular involvement in DGI.¹¹ In men presenting with urethritis and arthritis, a Gram stain of the urethral discharge may be helpful.

The major differential diagnosis in patients presenting with acute monoarticular or pauciarticular septic arthritis is between gonococcal arthritis and other infectious arthritides. Gonococcal arthritis is the most frequent cause of septic arthritis in young, sexually active patients.⁴ It predominantly affects the wrists and small joints of previously healthy women in the 15- to 35-year-old age group. Other types of infectious arthritis are uncommon in this population, predominantly involve the larger joints of the lower extremities, and affect men with underlying medical problems who are either preadolescent or more than 40 years old. Definitive diagnosis is based on culture and Gram stain.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

In addition to the history and physical examination, the laboratory plays an important role in diagnosing GC. In symptomatic males, the Gram stain of urethral discharge approaches 100% sensitivity and specificity. In females and asymptomatic males, however, the Gram stain is less useful, with sensitivity as low as 45%. Culture for GC is considered the “gold standard,” but proper collection and handling of the specimen is required to ensure accurate results. The specimen should be plated immediately and incubated in 3% to 5% CO₂ at 35°C to 37°C for 48 hours. More recently, nucleic acid amplification tests have been developed with high sensitivity and specificity for GC, and, in many sites, have replaced routine culture for the diagnosis of GC.¹⁰ In addition to standard cervical and urethral specimens, these tests have been able to detect GC in first-voided urine samples, which allows a noninvasive method of screening patients for the disease.^{18,19} In addition, testing for chlamydia can be performed on the same sample. Finally, GC has been detected by polymerase chain reaction in synovial fluid of patients with DGI, even when the culture is negative.⁵

The diagnosis and treatment of men presenting with acute urethritis are based on the results of a Gram stain of the urethral discharge. If a discharge cannot be expressed spontaneously or with urethral stripping, material for Gram stain may be obtained by inserting a calcium alginate swab about 2 cm into the distal urethra and rotating it gently. Patients with a positive Gram stain (polymorphonuclear leukocytes [PMNs] with intracellular gram-negative diplococci) or with a suggestive but nondiagnostic Gram stain (PMNs with extracellular gram-negative diplococci of typical *N. gonorrhoeae* morphology) should be treated for GC as will be outlined later. Patients with negative Gram stains (PMNs with either no organisms or bacteria not morphologically similar to gonococci) should be treated for NGU. If Gram stain is not available, a specimen should be obtained for culture or nucleic acid tests, and the patient treated for GC and *Chlamydia*.

The evaluation of women presenting with vaginal discharge, dysuria, PID, vaginal bleeding, and abdominal pain is discussed elsewhere in this text. The possibility of GC should always be considered, and cultures should be obtained if clinically indicated. Because of the high incidence of GC among adolescents, a GC culture should be obtained routinely whenever pelvic examination is done for whatever reason in this age group. When obtaining cervical cultures for GC, disinfectants and lubricants should not be used on the speculum, because even trace amounts may inhibit the growth of gonococci.¹⁷ Excess cervical mucus should be removed, and a sterile swab should be inserted into the cervical canal and allowed to remain for 15 to 30 seconds. The swab should then be plated immediately onto a selective medium that is at room temperature. Rectal cultures are recommended in all women suspected of having GC, because they increase the diagnostic yield by 4% to 5%.^{2,15,17} Blind rectal cultures may be obtained by inserting an unlubricated cotton-tipped swab past the anal canal into the rectum (about 3 cm) and moving it from side to side to sample the crypts. It should be left in place for 15 to 30 seconds. If there is stool on the swab when it is removed, it should be discarded and a new specimen obtained.

Routine culturing for *N. gonorrhoeae* in patients with pharyngitis is not indicated. Pharyngeal cultures for GC should probably be obtained in high-risk groups: homosexual men and prostitutes with pharyngitis, patients with sore throats and concurrent signs or symptoms of urogenital GC, pregnant women in whom GC is suspected, and patients with a history of exposure to GC and historic or clinical evidence of oropharyngeal involvement.

Homosexual men presenting with anorectal symptoms should have a careful physical examination for perianal erythema, ulcers, vesicles, fissures, tears, fistula, abscess, hemorrhoids, and other causes of their symptoms. An anoscopic examination should be performed in search of mucosal lesions or any exudate (which should be Gram stained). Anoscopy-directed Gram stain has a sensitivity of 60% to 79% in detecting GC.^{1,7} The presence of other diagnostic lesions does not rule out coinfection with GC, and all patients with a negative Gram stain should have rectal cultures for GC.^{1,2 and 3} Patients with acute proctitis after recent anal-receptive intercourse should be treated with ceftriaxone and doxycycline if anal pus is identified or the Gram stain demonstrates PMNs.⁴

Patients with signs or symptoms of DGI often have an asymptomatic primary infection. A careful physical examination for signs of complications should be performed. Cultures of the pharynx, rectum, and urethra or cervix should be obtained before initiating antibiotic therapy. Blood cultures should be obtained, and any joint effusions should be aspirated and specimens sent for cell count, microscopy for crystals, Gram stain, and culture. Pathologic cardiac murmurs or rubs suggest the possibility of endocarditis or pericarditis, and if meningeal signs are present, a lumbar puncture is indicated. Electrocardiographic evidence of myocarditis or pericarditis should be sought if clinically indicated.

Asymptomatic sexual contacts of patients with known cases of GC should be examined, have samples cultured, and undergo empiric treatment.⁴ To await culture results before initiating therapy unnecessarily exposes these patients to the risks of complications. Up to 7% of women with untreated asymptomatic GC may develop PID during the 24 to 72 hours required to obtain culture results and have the patient come back for treatment.¹⁵

Current Centers for Disease Control and Prevention (CDC) guidelines for the treatment of GC are outlined in [Table 185.1](#). There has been extensive clinical experience with ceftriaxone that documents its efficacy against anal, genital, and pharyngeal GC, and resistance has not been identified. Its disadvantages are the added pain and expense of injection and the unavailability of vials of less than 250 mg. Pain on injection may be minimized by using 1% lidocaine as the diluent. Quinolone-resistant GC has rarely been reported in the United States, but a cluster of GC with reduced sensitivity to quinolones has been reported in the Cleveland, Ohio, area.^{3,9} Spectinomycin (2 g intramuscularly) may be used in patients unable to take cephalosporins or quinolones, but, like the quinolones, it is ineffective against incubating syphilis.⁴

TABLE 185.1. Treatment of Gonococcal Infection

All patients treated for GC should have blood samples drawn for syphilis serology. Patients with incubating syphilis are likely to be cured by ceftriaxone or any of the regimens that include a 7-day course of doxycycline or erythromycin.⁴ Patients with positive serologies should be treated as discussed in the section on syphilis. Because of a reported high incidence of human immunodeficiency virus (HIV) infection in patients presenting with sexually transmitted disease, it is recommended that these patients also be offered serologic testing for HIV, as well as appropriate counseling.

DISPOSITION

Patients with uncomplicated GC may be managed as outpatients and do not require follow-up evaluation for test of cure. Patients treated for GC should be advised to refrain from sexual activities until they and their sex partner or partners have completed antibiotic therapy and are completely asymptomatic.⁴ Patients who are symptomatic after treatment have usually been reinfected, but they should be carefully evaluated for other sexually transmitted diseases or other causes of their symptoms, and should have culture of mucosal sites to look for resistant strains of GC.

The control of GC is highly dependent on contact tracing. Patients should be strongly encouraged to refer sexual contacts for treatment or to provide health-care personnel with the identities of exposed partners. The CDC recommends evaluation and treatment of persons who have had sexual contact with symptomatic patients within 30 days preceding onset of symptoms. If the index case is asymptomatic, sexual contacts within the preceding 60 days should be treated.⁴ If the contact was before these time periods, the most recent sex partner should be treated. Special effort should be made to identify contacts of women with PID, because 20% to 60% of the infected sexual partners of these women may be asymptomatic.¹⁴ Emergency physicians should be aware of and comply with state and local health department sexually transmitted disease-reporting guidelines.

Although hospitalization is recommended for patients with DGI, several centers routinely and successfully manage individuals with uncomplicated arthritis-dermatitis syndrome as outpatients. Only reliable patients with a typical presentation and ready access to follow-up care should be considered for outpatient treatment. It is imperative that these patients understand that anything other than a prompt response to therapy (definite improvement within 24 to 48 hours and essentially complete remission of symptoms within 72 hours of the initiation of therapy) necessitates an immediate return for further evaluation and possible hospitalization. Failure to respond rapidly to one of the recommended treatment regimens suggests either an alternative diagnosis or, rarely, infection with an antibiotic-resistant strain of GC. Patients in whom the diagnosis is uncertain, who have purulent synovial effusions, or whose psychosocial situation may make compliance unlikely or follow-up difficult should probably not be considered candidates for outpatient therapy. Patients with meningitis or endocarditis should be treated with ceftriaxone (1 to 2 g intravenously every 12 hours),⁴ and infectious disease consultation should be requested.

COMMON PITFALLS

- The most common error in the management of GC is failure to diagnose. A significant proportion of men with GC remain asymptomatic, and the mild, nonspecific symptoms of primary GC in women require a high index of suspicion on the part of the emergency physician. This is especially true of adolescents, who have increasing rates of infection and often lack access to health care.²¹ A detailed sexual history should be obtained from all patients presenting with urogenital or rectal complaints, and there should be a low threshold for obtaining cultures and instituting antibiotic therapy.
- The absence of symptoms should never lead the clinician to withhold antibiotics in a patient with known exposure to GC.
- Although a positive urethral or cervical Gram stain is highly specific for GC, the sensitivity is low in asymptomatic patients. Thus, a negative Gram stain should never be used to justify withholding therapy if there is a suspicion of GC.

[Chapter References](#)

Syphilis has been a public health problem since the fifteenth century, when thousands died in a European epidemic. Over the years, syphilis evolved into an indolent disease manifested primarily by neuropsychiatric sequelae (20% of the patients in U.S. mental institutions in the 1920s had tertiary syphilis). The incidence of the disease dropped dramatically in the 1940s with the development of serologic screening programs and the introduction of penicillin. Between 1985 and 1990, a syphilis epidemic, due to the practice of “sex for drugs,” in crack cocaine users occurred throughout the United States. [1,2,11](#)

Since 1990, syphilis rates have declined each year. The incidence of syphilis is highest in large metropolitan areas with relatively large minority populations. It remains substantially more common among Blacks than among other ethnic groups and continues to be concentrated in the southern region of the United States. Because the emergency department is the only access to health care for many high-risk patients, emergency physicians have a unique opportunity to detect cases of syphilis and aid in the public health effort to control and eradicate this disease. [6](#)

Syphilis infection occurs when *Treponema pallidum*, a spirochete, is disseminated through the body via the bloodstream or lymphatics. The primary pathologic lesion of syphilis is a focal endarteritis. *T. pallidum* is transmitted, most often during sexual activity, by contact between infectious lesions and sites of minor trauma. The risk of transmission varies significantly with the stage of disease and occurs primarily from contact with the lesions of primary and secondary syphilis. Among sexual partners of patients with infectious syphilis, approximately one-third will acquire the disease. Transmission may also occur later in the course of the disease, notably when congenital syphilis occurs in infants born to women with latent disease.

CLINICAL PRESENTATION

Primary Syphilis

Primary skin lesions (chancres) typically begin as papules at the site of inoculation. They quickly erode to form a painless ulcer, which is usually indurated, with characteristic cartilaginous consistency on palpation of the margins and the base ([Fig. 186.1](#)). The chancre is found commonly on the penis, labia, fourchette, or cervix, and occasionally on extragenital sites such as the perianal area (especially in homosexual men), oropharynx, fingers, and nipples. The lesions are usually single, but may be multiple in up to one-third of cases. Untreated chancres usually heal within 3 to 6 weeks.

Figure 186.1. Syphilis: penile chancre.

Primary syphilis is associated with painless unilateral lymphadenopathy. Regional lymph nodes appear within 1 week of the onset of the lesion and are typically mobile, rubbery, and minimally tender.

Secondary Syphilis

The secondary stage of syphilis begins 4 to 10 weeks after the appearance of the chancre in virtually all cases of untreated primary syphilis. This stage is characterized by a broad spectrum of physical findings resulting from the immunologic response to the dissemination of *T. pallidum* in the bloodstream and lymphatics. Flulike symptoms, including myalgias, arthralgia, and low-grade fever, are common. Generalized lymphadenopathy with moderately enlarged, nontender lymph nodes is often present.

The most prominent feature of secondary syphilis is the rash, which is present in more than 75% of cases. It is typically nonpruritic. The initial lesions are symmetrically distributed pink macules, typically 5 to 10 mm in diameter, over the trunk and proximal extremities. The lesions may evolve with time into a maculopapular rash, although papular papulosquamous and pustular lesions may occur. The widespread distribution involves the soles and the palms ([Fig. 186.2](#) and [Fig. 186.3](#)). Skin findings may be subtle, and, in one-fourth of cases, patients fail to notice the rash.

Figure 186.2. Lesions of secondary syphilis on the soles.

Figure 186.3. Lesions of secondary syphilis on the palms.

Ten percent to 20% of patients with secondary syphilis develop large, pale, flat papules that coalesce to form broad-based, flat, or heaped-up fleshy lesions with a pearly gray appearance. These highly infectious lesions are termed *condylomata lata* and are located in the warm, moist intertriginous areas, notably the anogenital regions (Fig. 186.4). They are particularly common during relapses, when they tend to be asymmetrically distributed and more infiltrated. Examination of the oral and genital mucosa may reveal painless, superficial lesions covered with a silver-gray membrane (mucous patches). Hair loss may occur in a diffuse spotty distribution (alopecia areata) affecting the scalp, eyebrows, and beard. The lesions of secondary syphilis heal within 2 to 6 weeks, and the infection becomes latent.

Figure 186.4. Condylomata lata.

Gastrointestinal complaints are common in secondary syphilis and may be caused by hypertrophic gastritis, patchy proctitis, or an ulcerative lesion resembling a rectal neoplasm. Less common complications of secondary syphilis include hepatitis, nephropathy, arthritis, and periostitis. When symptomatic central nervous system (CNS) involvement occurs, ocular lesions (iritis, uveitis, retinitis, and optic neuritis) are the most common presentation. Patients with uveitis that has failed to respond to steroid therapy should thus be screened for syphilis.

Latent Syphilis

The latent period corresponds to the absence of clinical signs and symptoms but positive serologic test results (discussion follows). The World Health Organization arbitrarily divides latent syphilis into early latent (duration less than 1 year) and late (duration more than 1 year). However, because relapses of symptomatic syphilis can occur for up to 2 years and the risk of congenital syphilis continues to be high during this period, a 2-year cut-off (as used by the International Classification of Diseases) is more clinically accurate. Early latent syphilis is considered potentially infectious but requires a shorter course of treatment than late latent disease because *T. pallidum* is dividing more rapidly. Because the duration of infection cannot be established in many patients, however, it is safest to treat patients as if they had late latent syphilis but to manage their sexual contacts as if they had early latent disease.⁷

Tertiary Syphilis

Tertiary syphilis is rarely seen. It develops in only one-third of untreated patients, and, in the immunocompetent host, it occurs 4 to 30 years after the initial infection. Tertiary syphilis embraces a wide variety of manifestations: gummatous syphilis (approximately 15%), cardiovascular syphilis (10% to 26%), and neurosyphilis (8% to 10%).⁴

Gummas are circumscribed granulomas that develop on skin, mucous membranes, and subcutaneous tissue, predominantly at the site of trauma on the extremities, head, and neck. These lesions eventually become necrotic and develop central ulceration. Gummas also occur in the bone, most commonly the tibia.⁸ Mass effects lead to the principal clinical manifestations: bony pain, obstructive jaundice, and perforation of the nasal septum.

Cardiovascular syphilis has become rare in the penicillin era. On the basis of postmortem data, it occurs in 25% of untreated patients. The most common lesions are aortic aneurysms (40%), aortic regurgitation (29%), and coronary ostial stenosis (26%). Cardiac hypertrophy, myocarditis, pulmonary arteritis, cardiac gummas, and coronary artery disease at sites other than the coronary ostia occur less often.

CNS involvement occurs at all stages of syphilis. It presents as one of many clinical syndromes or may remain asymptomatic, the diagnosis being based on the serologic testing of the cerebrospinal fluid (CSF). Patients with neurosyphilis commonly present with seizures or ocular findings.⁵ Visual dysfunction, which may occur in both early and late syphilis, is often misdiagnosed in the active stages of the disease and underdiagnosed in the late stages.¹⁰

Syphilitic meningitis due to spirochetal spread tends to occur in the first 2 years after the initial infection. Patients with the disease may present with mild-to-moderate aseptic meningitis, with only a headache or with frank meningismus and associated cranial nerve abnormalities. Uveitis, retinitis, or optic neuritis may occur as isolated processes or in association with syphilitic meningitis.

In contrast, meningovascular syphilis occurs 5 to 10 years after infection and is due to involvement of small, medium, and large arteries. Patients present with a sudden cerebrovascular event occurring after months of a subacute encephalitic syndrome. For this reason, it is recommended that young patients presenting with stroke should have serologic testing to rule out syphilis.

The neurologic findings of tertiary syphilis are due to demyelination of the posterior columns, dorsal roots, dorsal root ganglia, and nerve trunks. Late neurosyphilis, once the most common form of CNS involvement, has also become very uncommon since the advent of penicillin. Tabes dorsalis and general paresis most often present from 10 to 20 years after infection. Tabes dorsalis is manifested by sudden episodes of pain predominantly in the lower extremities but occasionally in the larynx, rectum, vagina, and other organs. Physical findings include reflex changes, peripheral neuropathy, ataxia, urinary incontinence, and impotence. Ocular atrophy and an Argyll Robertson pupil (a poor reaction to direct light with a normal reaction to accommodation) are classically described. General paresis initially presents with mild personality changes; over time, memory loss, confusion, and, ultimately, organic psychosis develop.

DIFFERENTIAL DIAGNOSIS

Atypical lesions are common in primary syphilis, and, conversely, not all patients with “typical chancres” have syphilis. Other localized genital infections may occur in sexually active patients. Herpes simplex virus is a common cause of nonvesicular genital ulceration that can resemble a syphilitic chancre but is almost always painful.³ Multiple ulcerations are usually found and present as grouped vesicles with a yellow-white membranous coating on an erythematous base. The associated lymphadenopathy is usually painful.

Chancroid, caused by infection with *Haemophilus ducreyi*, produces a painful soft ulcer with a necrotic base and undermined edges. Granuloma inguinale produces a painless, shallow, sharply demarcated ulcer with a beefy-red friable base. The characteristic Donovan bodies are found in scrapings from the ulcer base. In lymphogranuloma venereum, when ulceration occurs, the lesions often go unnoticed by the patient because they are small and painless. The associated lymph nodes are firm and painful, with overly dusky skin. Streptococcal, staphylococcal, and candidal infections may result in painful genital ulceration. Trauma, hypersensitivity to drugs, and neoplasm may present as a genital ulceration.

The diffuse symmetrical rash of secondary syphilis needs to be differentiated from other papulosquamous rashes, such as exanthems, drug eruptions, and pityriasis rosea. If the palms and soles are involved, the differential diagnosis may be limited to a few disorders, such as hand-foot-and-mouth disease and Rocky Mountain spotted fever. Clinically differentiating secondary syphilis from the acquired immunodeficiency syndrome (AIDS) may be extremely difficult, because both diseases share common risk factors and may coexist. AIDS may present as a diffuse macular, maculopapular, or pustular rash, and only laboratory studies will distinguish the eruption from syphilis.

Condylomata acuminata may be confused with genital warts in which the initial lesions may consolidate to form a large perianal cauliflower-like mass. However, genital warts are smaller and more sharply raised. Visceral involvement in secondary syphilis may suggest other causes of gastritis, hepatitis, or nephropathy.

Gastric syphilis may present as gastritis, peptic ulcer disease, or malignancy. Prolonged duration of symptoms and lack of improvement with H₂ blockers suggest the diagnosis. Findings at endoscopy are typically limited to the antral and pyloric regions, with the appearance of multiple erosions or shallow ulcers, nodularity, and hypertrophy of the rugae.⁹

Neurosyphilis should be differentiated from degenerative neurologic disorders, from granulomatous disease and other causes of aseptic meningitis, and from disorders involving the vasculature of the CNS. General paresis should be differentiated from other causes of organic brain syndrome.

EMERGENCY DEPARTMENT EVALUATION

A careful history and physical examination should suggest the possibility of syphilis in patients presenting with genital lesions or with a rash consistent with secondary syphilis. Laboratory testing is generally required to confirm the diagnosis.

Although *T. pallidum* cannot be cultured, dark-field microscopy can visualize spirochetes in exudates from chancres and condylomata lata, as well in lymph node aspirates in secondary syphilis. A concentration of treponemes of at least 10⁴ is required to visualize the organism. The surface of the suspected lesion should be cleaned with saline solution and gauze without producing bleeding. Squeezing of the lesion may help produce serous fluid. Local cleansing with soap or application of topical antibiotics should be avoided before examinations.

Three negative examinations are required before a suspicious lesion is considered to be nonsyphilitic. When dark-field microscopy is unavailable, immunofluorescence may be utilized. Refinements in monoclonal antibody techniques have been shown to be just as accurate. Nonpathogenic treponemes are found in the mouth and gastrointestinal tract. Diagnosis of oral lesions should be made on the basis of clinical appearance, history, and serologic testing. Immunofluorescent microscopy is generally needed for biopsies of oral or rectal lesions.

The diagnosis of primary and secondary syphilis should be confirmed by serologic testing. The most common screening test, the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR) tests are nontreponemal antibody tests. These are easier and less expensive but less specific than treponemal antibody tests such as the fluorescent treponemal antibody absorption (FTA-ABS) test or the microhemagglutination assay for antibody to *T. pallidum* [MHA-TP]. There are many causes of false-positive nontreponemal tests and a few for false-positive treponemal tests ([Table 186.1](#)).

VDRL
<ul style="list-style-type: none"> • Pneumococcal pneumonia • Bacterial endocarditis • Tuberculosis • Chancroid • Lymphogranuloma venereum • Malaria • Rheumatoid arthritis • Mycoplasma pneumoniae • C. Fungus-like • Human immunodeficiency virus infection • Malaria • Infectious mononucleosis • Mumps • Viral hepatitis • Pregnancy • Connective tissue disease • Intravenous drug use • Multiple blood transfusions • Chronic liver disease • Multiple myeloma • Adenocarcinoma • Adenocarcinoma • Adenocarcinoma
TREPONEMAL TESTS
<ul style="list-style-type: none"> • Lyme disease • Malaria • Infectious mononucleosis • Systemic lupus erythematosus

TABLE 186.1. Common Causes of False-Positive Serologic Test Results for Syphilis

The VDRL is positive in 60% to 80% of patients with primary syphilis. Serologic testing has the most utility shortly after the initial infection, but the highest titers are found during secondary syphilis and the early phase of latent syphilis. The VDRL is positive in 99% of patients with secondary syphilis. False-negatives occur in patients with such high titers of antibody that they are in antibody excess (prozone phenomenon). Dilution of the serum paradoxically results in conversion to a positive test in these cases.

Because standard antibiotic therapy does not achieve treponemicidal levels in the CSF, a diagnosis of neurosyphilis implies the need for more intensive treatment. The diagnosis is based on a positive VDRL on the CSF and a reactive serum FTA-ABS test. It is generally agreed that a lumbar puncture should be done in all patients who demonstrate neurologic or neuropsychiatric findings and in certain high-risk individuals. These include those with syphilis of unknown duration, more than 1 year of untreated disease, or suspected treatment failure and all individuals who are positive for human immunodeficiency virus (HIV). Syphilis may progress more rapidly and present atypically in patients with HIV infection, and these individuals typically develop early neurosyphilis. False-negative serologic tests occur more commonly in these patients; a VDRL test should be performed on the CSF as well as the blood.

Although CSF findings suggestive of infection are rare in primary syphilis, CSF pleocytosis and elevated protein levels occur in more than 40% of patients with secondary or latent syphilis. Lumbar puncture is not useful in early syphilis in the absence of HIV infection. However, asymptomatic neurosyphilis occurs in later stages of the disease. Lumbar puncture should be performed if there is more than 1 year's duration of disease, when treatment failure has occurred, or when nonpenicillin therapy is planned. Lumbar puncture is mandatory in patients with cardiovascular syphilis, as 10% to 25% of these individuals have coexistent neurosyphilis.

EMERGENCY DEPARTMENT MANAGEMENT

Parenteral penicillin is the drug of choice for the treatment of all stages of syphilis. Primary, secondary, and early latent syphilis should be treated with a single intramuscular dose of 2.4 million U of benzathine penicillin. In penicillin-allergic patients, doxycycline (100 mg PO twice daily for 14 days) or erythromycin (500 mg four times a day for 14 days) may be used as an alternative. All sexual contacts within the previous 90 days should be identified and receive treatment for early syphilis. Importantly, the currently used treatment regimens for gonorrhea that include a b-lactam antibiotic appear to be effective against incubating syphilis.

Patients with late latent syphilis or cardiovascular syphilis should receive a similar dose of benzathine penicillin weekly for 3 weeks, or of oral doxycycline for 4 weeks.

Parenteral penicillin G is the only therapy with documented efficacy for neurosyphilis or for syphilis during pregnancy. Patients who report a penicillin allergy, including pregnant women with syphilis in any stage and patients with neurosyphilis, should be desensitized and treated with penicillin. Patients with neurosyphilis should be treated with either 2 million to 4 million U of penicillin G intravenously every 4 hours for 14 days, or with 2.4 million U of procaine penicillin G intramuscularly daily (with 500 mg of oral probenecid four times a day) for 14 days. Congenital syphilis is treated with penicillin G, 50,000 U/kg intravenously or intramuscularly every 8 hours for 14 days.

The Jarisch-Herxheimer reaction occurs in 50% of patients treated for primary syphilis, in 90% of patients with secondary syphilis, and in 25% of patients with early latent syphilis. The reaction, consisting of fever, myalgias, and headache, occurs within 2 hours of treatment and peaks within 7 hours of treatment. Vasodilatation, tachycardia, and mild hypotension may also be seen, and the lesions of secondary syphilis become more erythematous and edematous. These symptoms can almost always be managed with bedrest and aspirin, although rare cases of irreversible organ damage have occurred in some individuals with neurosyphilis or cardiovascular syphilis.

About 95% of patients with primary syphilis and about three-fourths of those with secondary or early latent syphilis revert to having a negative VDRL or RPR test within 2 years of appropriate treatment. These tests are thus used to monitor the effectiveness of treatment. Treponemal antibody titers are likely to remain positive indefinitely. They correlate poorly with disease activity and should not be used to assess treatment response.

DISPOSITION

All cases of syphilis must be reported to the state health department. Admission is indicated only for patients with neurosyphilis or congenital syphilis who require parenteral antibiotics. Some authorities have recommended that patients who are several months pregnant also be admitted to the hospital for treatment, basing their recommendation on the concern that a Jarisch-Herxheimer reaction may develop and that tocolytic therapy may be required. Patients should be warned that sexual partners require treatment, and all patients should be referred for follow-up to evaluate response to therapy.

COMMON PITFALLS

- Cleansing or applying topical antibiotics to chancres or other lesions, thereby possibly altering their appearance and reducing accuracy of dark-field examination of diagnostic specimens
- Failure to perform a lumbar puncture in high-risk patients, resulting in inadequate therapy
- Failure to order serologic testing for syphilis in the CSF of HIV-positive patients who undergo lumbar puncture
- Mistaking a febrile reaction 2 hours after the administration of penicillin for allergy to penicillin rather than a Jarisch-Herxheimer reaction

Lyme disease (LD), a tick-borne illness caused by the spirochete *Borrelia burgdorferi*, is the most common vector-borne disease in the United States.⁸ *Ixodes scapularis* (the deer tick, formerly named *I. dammini*) and related tick species are the primary vectors in the transmission of the disease to humans. LD occurs worldwide and has been reported on every continent except Antarctica. The three major epidemiologic foci in the United States are the northeastern coastal states, from Massachusetts to Maryland; Wisconsin and Minnesota; and Northern California and Oregon.⁵ Most human infections with *B. burgdorferi* occur during the months of May through August, when *I. scapularis* nymphal-stage activity and human outdoor activity are both at their peak. Early diagnosis and treatment are important to prevent morbidity (and, rarely, mortality) associated with later stages of the illness.

CLINICAL PRESENTATION

LD is a complex multisystem disorder with three clinical stages, each having a range of clinical manifestations and often overlapping with other stages ([Table 187.1](#)). Virtually any clinical feature may occur alone or recur at intervals, and late symptoms may occur without any preceding early symptoms.

Stage	Time	Manifestations
Early localized infection	7-14 days; range, 3-30 days	Erythema migrans With or without nonspecific constitutional symptoms (fever, malaise, fatigue, headache, myalgia, and arthralgia)
Early disseminated infection	Days to weeks	Asymptomatic Multiple or secondary erythema migrans lesions Nervous system Musculoskeletal system
Late disseminated disease	Weeks to months	Heart Arthritis Chronic neurologic manifestations

TABLE 187.1. Clinical Stages of Lyme Disease

The most recently recognized of the seven human spirochetel diseases, LD shares many features with them: (1) the skin or mucous membrane as a portal of entry; (2) spirochetemia early in the course of the disease, with wide dissemination; and (3) periods of latency followed by multisystemic involvement.

LD usually begins with localized infection of the skin, manifested by a lesion termed *erythema migrans* (EM), and its associated nonspecific constitutional symptoms. The lesion is followed by dissemination of the spirochete to other organs. Neurologic or cardiac symptoms may occur days to weeks later, and chronic arthritic and neurologic abnormalities may occur weeks to months later.

Early Localized Infection (Stage I)

LD begins with the inoculation of *B. burgdorferi* by the nymphal form of the tick vector during feeding, generally about 2 days after attachment.¹⁵ The onset of symptoms is usually about 1 week (range, 3 to 32 days) after the tick bite.

EM, the most characteristic clinical manifestation of LD, is nevertheless absent in about 20% of patients. It usually (but not always) occurs at the site of a tick bite, beginning as red macules that expand centrifugally. There are two general forms: (1) an expanding red patch with varying intensities of redness within the patch ([Fig. 187.1A](#)) and (2) a central red patch surrounded by normal-appearing skin, that is, in turn, surrounded by an expanding red band, resembling a target or a ring-within-a-ring configuration (see [Fig. 187.1B](#)).

Figure 187.1. Two general forms of erythema migrans. **(A)** Expanding red patch. **(B)** Target configuration. (Courtesy of the Centers for Disease Control and Prevention.)

Most lesions are smooth, although scaling may be present, and the involved area is warmer than the surrounding normal-appearing skin. The centers of some lesions may become red and indurated, crusted, or vesicular and necrotic; partial or complete central clearing may occur. Most EM lesions are annular, but triangular and elongated patches may occur. Most demonstrate gradual enlargement, but others expand rapidly, forming a large patch in a relatively short period. Although a rash diameter of at least 5 cm is necessary to satisfy the Centers for Disease Control surveillance criteria, individual patients with LD may not have lesions this size. In

patients seen 1 to 7 days after the appearance of lesions, the average size is 8 × 10 cm (ranges from 2 × 3 cm to 25 × 25 cm). Although most lesions are asymptomatic, some patients describe burning, itching, or, rarely, a painful sensation.¹²

The EM rash usually fades within several days of antibiotic therapy. Without treatment, primary and secondary lesions generally persist for about 28 days (range, 1 week to 14 months). Recurrent lesions may develop in patients who do not receive antibiotics. Untreated, the rash resolves over several weeks.

Minor constitutional symptoms commonly occur in stage I LD.^{11,14} Malaise, fatigue, and lethargy are most common (approximately 80% of patients). Fever is typically low grade and intermittent. Regional lymphadenopathy in the distribution of the rash often accompanies EM. General lymphadenopathy and splenomegaly may occur. Musculoskeletal symptoms such as arthralgias and myalgias are common and characterized by a migratory, asymmetric, and evanescent pattern. Often, symptoms last only hours in one location and reappear later in another location. Frank arthritis with joint effusion may occur at this stage, but it is rare.

Upper respiratory symptoms such as sore throat occur less commonly. Signs and symptoms of hepatitis, including anorexia, nausea, vomiting, and abdominal pain, may be noted. Headache is a common complaint and may be accompanied by photophobia, nausea, vomiting, and stiff neck, but Kernig and Brudzinski signs are usually absent. At this stage, the neurologic examination and cerebrospinal fluid (CSF) both yield normal findings.

In the absence of the characteristic rash or a history of a tick bite, the nonspecific nature of the early signs and symptoms can easily result in misdiagnosis of stage I LD as a viral illness or collagen vascular disorder. Stage I symptoms usually last for several weeks in untreated patients but may persist for months.

Early Disseminated Infection (Stage II)

After a variable latent period, early disseminated symptoms usually occur from days to weeks after the initial infection, but there can be an overlap with other manifestations. The skin, nervous system, heart, and eyes are the main targets in early disseminated disease.

Within several days to several weeks, 20% to 50% of patients develop multiple annular secondary skin lesions, which are smaller than the initial ones. Usually asymptomatic, they typically spare the palms, soles, and mucous membranes.

Neurologic involvement occurs in approximately 15% of untreated patients. The most common neurologic manifestation is a fluctuating meningoencephalitis. Symptoms of cranial neuropathy, peripheral neuropathy, or radiculopathy may be superimposed, or may each occur alone.⁹ Headache is usually present, and there may be nausea, vomiting, lethargy, or irritability. As in stage I, Kernig and Brudzinski signs are absent, and results of computed tomography are normal.^{15,16} By contrast with stage I findings, however, CSF examination in stage II may reveal a lymphocytic pleocytosis and elevated protein level; glucose levels are normal.

Cranial neuropathy is seen in about 50% of patients with Lyme meningitis, most commonly, a unilateral peripheral seventh-nerve palsy (it may be bilateral in about a third of patients). Peripheral nervous system manifestations may include mononeuritis and motor or sensory radicular involvement or brachial plexitis.

Estimates of the incidence of cardiac involvement in untreated patients with LD range from 4% to 8%. Lyme carditis usually presents as transient myocarditis associated with varying degrees of atrioventricular block.⁷ The average time from the initial illness to the development of carditis is about 5 weeks (range, 4 days to 7 months).¹¹ Common presenting symptoms of Lyme carditis are nonspecific, but include syncope, light-headedness, dyspnea, palpitations, and chest pain. Atrioventricular block of some degree occurs in almost 90% of patients.¹¹ More than half of them have either high-grade or complete block, yet almost all are symptomatic. Left ventricular dysfunction has been documented by two-dimensional echocardiography and radionuclide studies; in most reported cases, it has been mild and transient. Pericarditis is uncommon, and the heart valves are spared.

A variety of ocular manifestations of LD have also been reported. They include conjunctivitis, keratitis, choroiditis, retinal detachment, optic neuritis, and blindness. Papilledema, with or without increased CSF pressure, is associated with Lyme encephalitis.

Late Disseminated Infection (Stage III)

The chronic phase of LD typically occurs months to years after the initial infection and is characterized by arthritic and, less commonly, neurologic symptoms. As is the case with syphilis, chronic manifestations follow a variable latent period.

Before antibiotic therapy for LD became standard, approximately 50% of untreated patients developed arthritis characterized by intermittent attacks of joint swelling and pain developing several weeks to several years after the onset of the illness.¹⁶ The typical pattern of joint involvement is a monoarticular or asymmetric oligoarticular arthritis of the large joints. The knee is most often affected, with large, sometimes relatively asymptomatic joint effusions. The shoulder, elbow, temporomandibular joint, ankle, wrist, hip, and small joints of the hands and feet are involved less commonly. Episodes of arthritis are typically brief (weeks to months), separated by variable periods of complete remission.

Exacerbations and remissions often occur over a period of several years, with a gradual tendency toward less frequent and less severe occurrences. In untreated patients, there is a spontaneous long-term remission rate of 10% to 20% per year, but 10% of untreated patients develop chronic synovitis. An autoimmune response that persists after the pathogen has been eradicated may explain the unresponsiveness of some patients with chronic arthritis to antibiotic therapy. Chronic arthritis is much less common now, because most patients with early Lyme symptoms are recognized and treated.

Neurologic manifestations of late disease include a wide variety of abnormalities of the central and peripheral nervous systems, as well as fatigue syndromes.⁹ The diagnosis is difficult because the symptoms may mimic those of a number of other neurologic conditions and because late neurologic symptoms may be the first symptoms of the disease.¹⁴ Subtle encephalopathy with disturbances in mood, memory, or sleep may occur. Cases of cognitive dysfunction ranging from a mild "confusional" state to slowly progressive dementia have also been reported.^{2,9} Incapacitating fatigue is a widely described late feature.

Late disease may also involve the cranial nerves, spinal roots, plexuses, or peripheral nerves. The neurologic symptoms of late disease commonly manifest as a subtle polyneuropathy, with spinal or radical pain or numbness and tingling in the hands and feet. A demyelinating condition with multiple sclerosis–like exacerbations and remissions has been described.¹⁴

Acrodermatitis chronica atrophicans is a late cutaneous manifestation of LD that occurs in approximately 10% of European patients but has rarely been reported in North America. It is characterized initially by an edematous infiltration that progresses to an atrophic lesion resembling that of localized scleroderma.

DIFFERENTIAL DIAGNOSIS

Although LD presents in many ways, each stage has characteristic clinical findings that are helpful in narrowing a differential diagnosis that may, at first, seem rather broad.

Stage I disease may easily be confused with a variety of other diseases, especially if the rash is absent. Even in endemic areas, most patients who present with "flu-like" symptoms during the summer months do not have LD. The principal diagnostic distinction to be made is between LD and the enteroviral diseases and other causes of aseptic meningitis. The enteroviral diseases are frequently accompanied by diarrhea, which is not a feature of LD. Abdominal pain, anorexia, and nausea may suggest hepatitis. Sore throat, adenopathy, and fatigue, as seen in mononucleosis, may occur. When myalgias and arthralgias are the predominant symptoms, connective tissue disease may be considered. A distinctive feature of early LD, however, is that musculoskeletal pain is typically migratory and evanescent, and often occurs in brief attacks in one or a few locations at a time.

The characteristic initial skin lesion, EM, in its classic form is virtually pathognomonic for LD. Secondary skin lesions may, however, be confused with the target lesions of erythema multiforme. The lesions of erythema multiforme are generally smaller and nonexpanding and also involve the mucous membranes and palms and soles; EM does not. Hypersensitivity reactions to insect bites or spider bites may mimic EM, but these reactions usually occur within several hours of exposure, rather than 3 or more days after the exposure. Erythema nodosum has a predilection for the extensor surfaces of the legs and generally causes more painful induration than

does EM.

Erythema marginatum secondary to acute rheumatic fever may mimic EM, but the lesions of EM are generally fewer, larger, and less evanescent, and they migrate more slowly. Other common cutaneous entities to be considered in the differential diagnosis of EM include cellulitis and fixed drug-related eruptions. A useful rule is that LD must be considered in a patient with an atypical rash that is accompanied by a flulike or meningitis-like illness during the months of peak incidence.

The cardiac manifestations of LD may suggest coronary artery disease, viral myocarditis, or acute rheumatic fever. As noted previously, varying degrees of heart block are characteristic. As with rheumatic fever, carditis in LD may follow pharyngitis and migratory polyarthritis. Although the clinical aspects of the Jones criteria may be satisfied by some patients with LD, several features serve to distinguish the two illnesses:

1. EM usually precedes the carditis in LD, whereas, in rheumatic fever, skin lesions usually occur with the onset of arthritis.
2. Evidence of a preceding streptococcal infection (elevated antistreptolysin-O titer) is lacking in patients with LD.
3. Valvular involvement is not a feature of Lyme carditis.

The differential diagnosis of the neurologic manifestations of LD is wide and includes aseptic meningitis, herpes simplex encephalitis, Bell's palsy, multiple sclerosis, Guillain-Barré syndrome, dementia, primary psychosis, cerebral vasculitis, and brain tumor. Lyme encephalopathy is usually associated with CSF abnormalities such as lymphocytosis, elevated protein, and the presence of antibody to the spirochete. Chronic fatigue syndrome and fibromyalgia are frequently misdiagnosed as LD. ¹⁸

In contrast to patients with rheumatoid arthritis, those with Lyme arthritis rarely have symmetric polyarthritis, morning stiffness, positive rheumatoid factor, or subcutaneous nodules. LD is commonly mistaken for seronegative rheumatoid arthritis, but it is most similar to the rheumatoid variants, particularly Reiter syndrome. The absence of the extraarticular features of Reiter syndrome (conjunctivitis, urethritis or cervicitis, balanitis, keratoderma blennorrhagica) at the time of the arthritis helps distinguish LD from Reiter syndrome. In children, LD may mimic juvenile rheumatoid arthritis.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of LD is primarily clinical, based on the presence of EM and other specific manifestations, as well as a history of exposure in an endemic area. Diagnosis is difficult, however, especially in the early stages. A history of tick bite is present in only about one-third of cases. EM is present in most patients, but isolated late symptoms may appear months after the initial infection, and the patient might not recall having had a rash.

Routine laboratory studies are nonspecific and generally are not helpful in diagnosing LD. Culture of blood, tissue, and bodily fluids for *B. burgdorferi* are generally not clinically useful. Specialized laboratory studies must be cautiously interpreted within the clinical context and should be regarded as only adjuncts in the diagnosis.

Serologic testing for *B. burgdorferi* infection is the most practical and useful means of confirming clinical diagnosis of LD, but problems with the performance and interpretation of the tests often result in diagnostic confusion. The assays have not been standardized, and there is a significant interlaboratory and even intralaboratory variability. False-negative and especially false-positive results are common.

The antibody response to *B. burgdorferi* develops slowly. The peak of immunoglobulin M (IgM) titers appears between 3 and 6 weeks after the onset of illness, so assays for IgM are often negative during the first several weeks of infection. Moreover, IgM returns to nondiagnostic levels 4 to 6 weeks after peak. IgG antibody may be detectable 2 months after exposure and peaks approximately 12 months into the illness. Early antibiotic therapy may blunt or even abolish the antibody response. Patients with late disease usually have positive IgG antibody titer results. Nevertheless, a true-positive serologic result merely indicates previous exposure; the symptoms under evaluation need not be related to active LD. Long-term seropositivity may also result from previously treated LD.

Serologic cross-reactivity between *B. burgdorferi* and other spirochetes, most notably *Treponema pallidum*, can cause false-positive test results. Other illnesses known to be associated with false-positive serologic results include infectious mononucleosis, rheumatoid arthritis, and systemic lupus erythematosus.

Testing with the enzyme-linked immunosorbent assay (ELISA) is the cornerstone of the laboratory diagnosis of LD. Although ELISA alone has a sensitivity of 89% and a specificity of 72%, a positive result in patients with a pretest probability of LD of less than 0.20 is more likely to be a false positive than a true positive. ² In patients with a positive or equivocal ELISA, a confirmatory Western blot should be ordered. ⁴ Polymerase chain reaction (PCR) has been used to amplify the genomic DNA of *B. burgdorferi* in skin, blood, CSF, and synovial fluid, but PCR has not been standardized for routine diagnostic use. ³

In cases of suspected neurologic involvement, CSF should be examined for evidence of meningitis. ⁹ CSF serologic testing is generally not necessary, because almost all patients with neuroborreliosis have positive results on serum serologic testing. ²

EMERGENCY DEPARTMENT MANAGEMENT

The emergency management of patients with suspected LD should be focused on recognizing the illness, obtaining appropriate diagnostic studies, delivering supportive care when necessary, and arranging appropriate follow-up.

Active *B. burgdorferi* infection is usually amenable to antibiotic therapy, and treatment can be begun in the emergency department. In making treatment decisions, however, the clinical findings and the meaning and the reliability of laboratory results must be closely analyzed on an individual basis. For this reason, decisions regarding antibiotic therapy (which are almost invariably nonurgent) are often made in consultation with the patient's primary physician. [Table 187.2](#) is a summary of recommended antibiotic regimens. Treatment recommendations have been developed on the basis of disease stage and clinical manifestations.

TABLE 187.2. Recommended Antibiotic Regimens

Prompt treatment of early disease shortens the duration of symptoms and, more important, prevents progression to later stages in most patients. The decision of whom to treat is often difficult. As noted, early LD is diagnosed by clinical presentation alone, without the luxury of serologic confirmation. Patients are often seronegative at presentation, and curative antibiotic therapy may abort the development of a mature immune response and prevent seroconversion after treatment. Treatment is clearly indicated for a patient who has the characteristic skin lesion and a history of tick bite; there is no reason to wait for a positive antibody assay before beginning therapy. Patients in endemic areas who have a rash that is consistent with EM should be treated for LD without serologic testing.

Oral therapy with doxycycline is recommended for early LD (see [Table 187.2](#)).¹ Amoxicillin is an alternative for pregnant or lactating women and for children younger than 8 years old.¹¹ Jarisch-Herxheimer-like reactions (fever, chills, myalgias, headache, tachycardia, increased respiratory rate, and leukocytosis) may occur in the first 24 hours of treatment. Cefuroxime axetil appears to be as effective as doxycycline,¹ but cephalexin is ineffective in LD. Erythromycin is less effective than first-line

antibiotics. Azithromycin was less effective than amoxicillin in one controlled trial. ¹⁰

The duration of antibiotic therapy should be individualized according to the severity of illness and the rapidity of clinical response. EM and associated constitutional symptoms generally respond within days. Treatment failures or relapses despite recommended courses of antibiotics have been reported.

Neurologic Disease

Facial nerve palsy may occur within the first month of illness (mean time from the onset of EM is 20 days). For patients with Bell's palsy alone, oral therapy with doxycycline or amoxicillin can be used in the same dosage as for early disease (see [Table 187.2](#)), but the duration of therapy should be extended to 30 days. Corticosteroids have no identified role.

The decision to treat a patient who presents with facial palsy should be based on epidemiologic factors. Some authorities recommend lumbar puncture for all patients with LD-related Bell's palsy, and treatment with intravenous antibiotics if a pleocytosis is present. The implication of asymptomatic CSF pleocytosis is unknown, however.

For patients with more serious complications, such as meningitis, other cranial or peripheral neuropathies, cognitive deficits, or encephalitis, parenteral antibiotic therapy is required.

Cardiac Disease

Recommended antibiotic therapy for patients with cardiac involvement depends on the degree of heart block noted (see [Table 187.2](#)). Patients with minor cardiac involvement (first-degree atrioventricular block but a PR interval less than 0.30 second) can usually be treated orally, whereas those with more severe cardiac involvement (high-degree atrioventricular block) require intravenous antibiotics. Temporary cardiac pacing may be necessary in the latter group. Heart block generally resolves completely with antibiotic therapy.

Arthritis

Lyme arthritis usually responds to a 1-month course of oral doxycycline or amoxicillin (see [Table 187.2](#)). The response may be delayed for several weeks or months, however, regardless of antibiotic choice or route of administration. Oral regimens appear to be as effective as parenteral penicillin or ceftriaxone.

The diagnosis of LD should be confirmed by serologic testing of synovial fluid when possible. Chronic arthritis may not be responsive to antibiotic therapy (either oral or intravenous) in certain genetically susceptible individuals. Antiinflammatory agents may be useful in the treatment of this presumably immune-mediated syndrome.

Prophylaxis

Antibiotic treatment of asymptomatic patients who have been bitten by a tick is usually not recommended, ⁴ because the likelihood of acquiring LD is low, even in endemic areas. Infection is very unlikely unless the tick has remained attached beyond 72 hours. ¹² The approximate duration of attachment can be assessed by inspecting the tick for degree of engorgement. Early tick detection and removal limits the risk of disease transmission. Patients should still be counseled about the symptoms of early LD, however, and selective administration of antibiotics on an individualized basis (e.g., to pregnant women or those with engorged ticks) may be appropriate.

Vaccination

A LD vaccine (LYMERix) directed against the outer-surface protein A of *B. burgdorferi* is available. LYMERix is administered by injection of 0.5 mL (30 µg) into the deltoid muscle. Three doses are required for optimal protection. The first dose is followed by a second dose 1 month later, and a third dose administered 12 months after the first dose. In a randomized, controlled clinical trial involving over 10,000 subjects, the vaccine's efficacy in protecting against "definite" LD was 76% (95% CI = 58% to 86%).¹⁷

Vaccination will cause a positive ELISA result but a negative Western blot. LD vaccination should be considered for persons who reside, work, or enjoy recreation in areas of high or moderate risk and who engage in activities that result in frequent or prolonged tick exposure. ⁶

DISPOSITION

Decisions regarding the disposition of patients with documented or suspected LD are made on the basis of disease stage and severity of clinical manifestations.

Almost all patients with early disease can be appropriately managed as outpatients. Many patients with the chronic neurologic and arthritic manifestations of late disease remain fully ambulatory and can be treated on an outpatient basis, although admission may be necessary for selected patients requiring intravenous antibiotics. Follow-up care by a primary care physician, rheumatologist, or infectious disease specialist should be arranged for patients who are discharged from the emergency department.

Hospital admission for cardiac monitoring is required for patients with Lyme carditis and any manifestation more severe than mild PR prolongation. Patients with prominent neurologic symptoms usually must be treated with intravenous antibiotics and often require a degree of supportive care that warrants hospital admission.

COMMON PITFALLS

- Late symptoms of LD may occur without any preceding early symptoms. Because late symptoms usually occur months after the initial tick exposure, there is no constant seasonal incidence suggestive of a tick-borne illness. The diagnosis of LD might therefore not be considered, for example, in a patient who presents during February with an isolated knee effusion.
- Disorders such as chronic fatigue syndrome and fibromyalgia are commonly misdiagnosed as LD, resulting in inappropriate treatment with antibiotics. Despite LD's variable presentations and the limitations that remain in serologic testing, in most cases, it is possible to distinguish between *B. burgdorferi* infection and these disorders.
- Antibiotic treatment for patients with a tick bite who have signs or symptoms of LD is usually not recommended, even in endemic areas.
- Specific diagnostic laboratory tests should not be used in screening, but rather to confirm the clinical diagnosis of LD. Even in endemic areas, most patients with "summer flu" do not have LD. Indiscriminate serologic testing of these patients results in a high rate of false-positive tests.

CHAPTER 188 Rocky Mountain Spotted Fever

Michael A. Gibbs

[Epidemiology](#)
[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)

[Prevention](#)

[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Rocky Mountain spotted fever (RMSF) is the most common tick-borne illness in the United States, and one of the most serious systemic infections seen in clinical practice. Emergency physicians must maintain a high index of suspicion for RMSF and consider early empiric therapy in the patient at risk.

Despite significant advances in diagnosis and therapy, the case-fatality rate of RMSF remains between 5% and 10%. The disease continues to confound physicians because of its sporadic occurrence and nonspecific clinical presentation. Difficulties in making the diagnosis are especially relevant, because the prognosis is directly related to the timeliness of appropriate treatment.

In one study, 90% of patients were seen by a physician within 5 days of the onset of symptoms, yet less than half received treatment before day 6. Patients who received antirickettsial therapy within 5 days were significantly less likely to die than were those who received treatment later (6.5% vs. 22.9%). Three independent predictors of a failure to initiate therapy on first presentation to a physician were absence of a rash, presentation between August 1 and April 30, and presentation within the first 3 days of illness.³

EPIDEMIOLOGY

RMSF is caused by *Rickettsia rickettsii*, an obligate intracellular bacterium. It is transmitted by several species of ticks that also serve as the reservoir or natural host. In the Eastern states, the wood tick, *Dermacentor andersoni*, is the major vector; the dog tick, *Dermacentor variabilis*, is the predominant vector in Western states. More than 95% of cases occur between April 1 and August 31, the incidence corresponding to the seasonal life cycle of the tick.

RMSF has been reported throughout the continental United States, Canada, and Mexico. The disease tends to be focally endemic, with clustering of cases within larger endemic areas. Although first described in Idaho and Montana, the disease is now infrequent in the Western states. There has been a steady increase in the number of cases in the Southeastern states, particularly North Carolina, Tennessee, and South Carolina.

Centers for Disease Control (CDC) surveillance data from 1981 to 1990 indicate that RMSF is most common among children 5 to 9 years of age and least common among people 10 to 29 years of age. The case fatality rate is highest for people 40 years of age or older (8.2%), compared with 2.3% for those less than 40 years old. The case-fatality rate is also higher for people whose treatment is begun more than 3 days after the onset of symptoms (6.2%) than for those treated within the first 3 days (1.3%). RMSF is more common in men than in women, reflecting a greater potential exposure to the tick vector. Despite the fact that RMSF is more common in Whites than in African Americans, the case-fatality rate is significantly higher in the latter group (16% vs. 3%),⁵ a fact most likely related to the difficulty of detecting the characteristic rash on dark skin.

CLINICAL PRESENTATION

RMSF is a systemic vasculitis that may affect any organ system. For this reason, signs and symptoms are varied and nonspecific. A history of tick bite or presence of a tick is elicited in just over half of patients. The onset of illness is usually acute, with fever, headache, nausea, vomiting, abdominal pain, and myalgia, a presentation that is easily confused with a clinically benign viral illness. The clinical findings and their prevalence are summarized in [Table 188.1](#).

	Approximate Prevalence (%)	Approximate Prevalence (%)

TABLE 188.1. Clinical Manifestations of Rocky Mountain Spotted Fever

A rash of one type or another is seen in the majority of patients with RMSF, but “Rocky Mountain spotless fever” has been reported in 5% to 15% of cases.⁶ When patients present at symptom onset, the rash is typically absent, which is one reason that diagnosis is difficult. Likewise, the rash may be unappreciated in patients with dark skin. This group is at especially high risk for delays in diagnosis and therapy, and thus increased morbidity.⁵

The rash usually appears on the third day of illness and is first seen on the palms, soles, wrists, and ankles and progresses centripetally, but the rash may begin on the trunk (approximately 10%) or have a diffuse onset (approximately 10%). Lesions are initially macular and later evolve to become petechial and maculopapular in 50% of cases. Application of a tourniquet or blood pressure cuff causes the appearance of additional lesions distally (Rumpel-Leede sign). In severe case, there may be extensive purpura, skin sloughing, ulceration, and gangrene. Rarely, an eschar may be seen at the site of the tick bite.⁷

The *central nervous system* is perhaps the most crucial target “organ” of RMSF. Varying degrees of meningeal inflammation and cerebral vasculitis cause a wide range of neurologic signs and symptoms. Rickettsial encephalitis, which is manifested by severe headache, confusion, stupor, coma, and seizures, carries a particularly grave prognosis.⁸ Focal neurologic deficits, deafness, sensory neuropathy, tardive dyskinesia, and Guillain-Barré syndrome have all been described in patients with RMSF.^{9,10}

Neuroimaging with computed tomography (CT) or magnetic resonance imaging (MRI) may reveal a variety of subtle nonspecific abnormalities, including infarcts, cerebral edema, meningeal enhancement, and increased signal of the perivascular spaces.¹¹ There is some evidence that the presence of these radiographic findings may be associated with a less favorable clinical outcome. In patients with central nervous system involvement, the cerebrospinal fluid is almost always abnormal (discussion follows).

The *cardiovascular* effects of RMSF are the result of myocarditis and myocardial vasculitis.¹² Clinical manifestations include varying degrees of atrioventricular (AV) block, dysrhythmias (atrial and ventricular tachycardia, atrial fibrillation), and left ventricular dysfunction. It has been hypothesized that cardiac involvement may play

an important role in the cases of fatal RMSF.

Rickettsial *pneumonitis* results from microvascular injury and leakage of fluid into the interstitial tissues and alveolar airspaces. This potentially life-threatening complication occurs in 2% to 17% of patients. Signs and symptoms include cough, dyspnea, pleuritic chest pain, and hypoxemia. Chest radiography typically reveals diffuse patchy infiltrates.

Up to 80% of patients with RMSF have prominent *gastrointestinal* complaints early in the course of disease, including abdominal pain, nausea, vomiting, and diarrhea. This symptom complex may lead the clinician to incorrectly diagnose acute gastroenteritis, or even an acute surgical abdomen. Not surprisingly, patients with RMSF have undergone exploratory laparotomy for suspected appendicitis, cholecystitis, and perforated diverticulitis.¹³ Acute hepatitis and clinical jaundice have been described in severe cases.¹⁴

Approximately 10% to 15% of patients with RMSF develop significant *renal* dysfunction, the result of systemic hypovolemia and prerenal azotemia, as well as direct injury to the glomerulus. Renal biopsy in these patients demonstrates acute glomerulonephritis with subendothelial immune deposits. *Ocular* abnormalities are not uncommon in patients with RMSF. Conjunctivitis occurs in 15% to 60% of patients. Less common findings include anterior uveitis, retinal vasculitis and hemorrhage, papilledema, arterial occlusion, and iris nodules.

DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of RMSF can be difficult despite a careful history and physical examination and appropriate screening laboratory studies. Depending on the constellation of signs and symptoms present, the individual patient with RMSF may be misdiagnosed as having a viral illness (e.g., measles, infectious mononucleosis, or nonspecific viral syndrome), meningococemia, gastroenteritis, acute surgical abdomen, pneumonia, toxic shock syndrome, ehrlichiosis, or encephalitis. RMSF may also mimic noninfectious entities, including idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, drug reaction, and immune-complex vasculitis.

As with RMSF, diagnosis must be made quickly and accurately in acute meningococemia. Both diseases may present with headache, fever, nausea, vomiting, and upper respiratory symptoms. Meningococemia is typically more abrupt in onset. In contrast to RMSF, the meningococemic rash appears within 24 hours of symptom onset, is petechial at onset, and lacks a characteristic pattern. Gram stain of cerebrospinal fluid is diagnostic, and the causative organism can also be detected using latex agglutination and counterimmunoelectrophoresis. If either diagnosis is in question, immediate therapy for both RMSF and meningococemia is mandatory.

Toxic shock syndrome is an acute febrile illness characterized by the appearance of a diffuse desquamating erythroderma. Mucous membrane involvement and conjunctivitis are typical. Headache, myalgias, nausea, vomiting, and diarrhea are often present. Criteria for toxic shock syndrome include (1) fever greater than 38.9°C, (2) the typical rash, (3) hypotension, and (4) involvement of at least three organ systems.

Distinguishing RMSF from an enteroviral infection can also be quite difficult. Fever, headache, aseptic meningitis, and a maculopapular rash are common to both presentations. The rash of enteroviral infections usually starts centrally, but may also involve the palms and soles. Petechial lesions are not uncommon.

Measles (rubeola) occurs most often in unimmunized children during the winter and early spring. A prominent respiratory prodrome (cough, coryza, conjunctivitis), and the presence of Koplik's spots are important distinguishing features. The rash of measles typically begins on the face and upper trunk and spreads to the extremities and downward.

Infectious mononucleosis is characterized by fever, fatigue, malaise, sore throat, and prominent lymphadenopathy. A maculopapular rash involving the trunk and extremities is often present, and it may become more prominent if the patient is inadvertently treated with ampicillin. The diagnosis is confirmed by a positive Monospot test, or by detection of antibodies against the Epstein-Barr virus.

EMERGENCY DEPARTMENT EVALUATION

Laboratory studies typically available in the emergency department offer little help in the diagnosis of RMSF. While routine studies may provide subtle clues, these are inconsistent and nonspecific. It must be emphasized that treatment must be based on clinical findings alone, and should never be withheld while waiting for specific serologic confirmation of the disease.

Hematologic findings seen in RMSF include a normal or decreased white blood cell count, anemia, thrombocytopenia, and a high peripheral band count. It has been suggested that the observation of an increased percentage of immature white cells in the absence of leukocytosis can help distinguish RMSF from meningococemia. Anemia and thrombocytopenia are seen in 30% and in 30% to 50% of patients, respectively. Hyponatremia is seen in roughly one-fourth of cases. Elevation of serum transaminases and bilirubin may be noted in patients with hepatic involvement.

A lumbar puncture is mandatory in all patients with severe headache, fever, or signs of meningeal irritation. Elevated cerebrospinal fluid protein and pleocytosis are the typical finding in RMSF. Differential cell counts may reveal either lymphocytic or polymorphonuclear cell predominance. Of note, a cerebrospinal fluid white blood cell count more than 100 cells/μL is uncommon, occurring in only 11% of cases.¹⁵

Serologic tests are of value in the retrospective confirmation of RMSF, but are not helpful in the acute setting, as results are not reliably positive for 6 to 10 days after the onset of clinical illness. Currently, the most widely used tests, all of which rely on the presence of antibodies to *R. rickettsii* antigens, are the indirect immunofluorescent antibody assay (IFA), indirect hemagglutination assay (IHA), latex agglutination, and polymerase chain reaction (PCR).¹⁶ These serologic tests may not be routinely available in all hospital settings, but they can usually be obtained through state health department laboratories. The Weil-Felix test, once a widely used assay for RMSF, lacks sensitivity and specificity and has fallen out of favor.

Identification of *R. rickettsii* in skin biopsy specimens is the best diagnostic test for RMSF in the acute setting. This technique can be used only when the rash is present. A punch biopsy should be obtained at the center of a well-defined lesion. Immunofluorescent staining of frozen-section samples demonstrates the organism in about 70% of cases.

EMERGENCY DEPARTMENT MANAGEMENT

For the majority of the conditions seen in emergency medicine, a diligent search for the cause is undertaken, and specific therapy is initiated based on the findings. This management paradigm is not realistic or acceptable in RMSF for several important reasons: (1) Clinical signs and symptoms are typically nonspecific; (2) the results of specific diagnostic tests are unavailable in a timely fashion; and (3) outcome is directly affected by delays in initiating therapy.

The most important factor contributing to the persistent case-fatality rate of 5% is delayed administration of specific therapy.³ In one series, all patients treated within 5 days of symptom onset survived, whereas the mortality of those treated after the sixth day was 60%. It is not only appropriate, but essential for the clinician practicing in an endemic area to initiate antibiotic therapy in the patient with clinical findings suggestive of, but not necessarily diagnostic of, RMSF without the aid of serologic testing.

The tetracyclines and chloramphenicol are both effective in the treatment of RMSF and are considered the drugs of choice for therapy.¹⁷ There are no randomized, controlled trials comparing the efficacy of these two agents. The fluoroquinolones have also been demonstrated to possess antirickettsial activity.¹⁸ The penicillins, cephalosporins, erythromycin, sulfonamides, clindamycin, and aminoglycosides are ineffective against RMSF. Both the tetracyclines and chloramphenicol have significant adverse side effects; therefore, agent selection should be guided by the characteristics of the individual patient.

Because of a significant risk of thrombophlebitis and hepatotoxicity with the use of intravenous tetracycline, intravenous chloramphenicol is the preferred agent in the severely ill patient who cannot tolerate oral therapy. Chloramphenicol has also been advocated for treatment of RMSF during pregnancy. The recommended dosage is 50 to 100 mg/kg/d. Side effects associated with chloramphenicol include bone marrow depression, hemolytic anemia in patients with the Mediterranean form of glucose-6-phosphate dehydrogenase deficiency, "gray baby" syndrome in premature infants and neonates, and (rarely) aplastic anemia. Because chloramphenicol is

metabolized by the liver, drug interactions may occur in patients taking either inhibitors or inducers of hepatic enzymes.

The tetracyclines are considered the drugs of choice for oral therapy in adults. The recommended dosages for tetracycline hydrochloride and doxycycline are 500 mg four times a day, and 100 mg twice a day, respectively. Doxycycline is the most favorable agent for the treatment of RMSF in children less than 9 years of age because of its documented effectiveness, broader margin of safety, and convenient dosing schedule. The recommended dosage is 4.4 mg/kg in divided doses every 12 hours for the first day of therapy, followed by a daily dose of 2.2 mg/kg.

Prior recommendations discouraged administration of doxycycline to children because of concerns about staining of the teeth. More recent evidence suggests that up to five short courses of doxycycline may be administered with minimal risk of dental staining.¹⁹ Adverse effects associated with the use of tetracyclines include hepatitis, diarrhea, rash, thrombophlebitis, and impaired fetal bone formation.

Regardless of the agent selected, patients should be treated for at least 7 to 10 days, and therapy should be continued as necessary until the patient is afebrile and clinically improved for 24 to 48 hours.²⁰

Successful treatment of the critically ill patient with RMSF requires meticulous attention to fluid and electrolyte balance. Widespread systemic vasculitis and resultant fluid shifts may cause hypotension, oliguric renal failure, disseminated intravascular coagulation, adult respiratory distress syndrome, and shock. In the treatment of these complications, the clinician must maintain a delicate balance between adequate restoration of intravascular volume and overresuscitation with precipitation of pulmonary edema. Isotonic saline should be given in small serial boluses. Vasopressors may be required in patients with impaired tissue perfusion that is unresponsive to fluid therapy. Hemodynamic monitoring with a pulmonary artery catheter may provide the treating physician with an extra margin of safety, and is recommended in the unstable patient.

Prevention

Emergency physicians play an important role in educating the public about disease prevention. People who reside or work in tick-infested areas should be informed about tick-borne diseases and their prevention. The optimal method for preventing RMSF is avoidance of tick-infested areas. People entering these areas should wear protective clothing and use tick repellent. Exposed areas of the body should be examined for tick attachment. Remove ticks by grasping them with fine tweezers at the point of attachment and pulling slowly and steadily.

DISPOSITION

When an otherwise healthy, clinically stable patient presents with one or several clinical findings suggestive of RMSF, it is appropriate to initiate empiric therapy without confirmatory diagnostic testing and discharge the patient with appropriate follow-up. In endemic areas, patients presenting with a flulike illness during the spring or summer months are frequently discharged home on doxycycline. In this situation, contact with a primary care provider, or a return visit to the emergency department in 24 to 72 hours, is a sensible part of the discharge plan.

Patients presenting with more severe disease should be admitted to the hospital. This group includes those with significantly abnormal vital signs, dehydration, or end-organ dysfunction. Patients with severe organ dysfunction (e.g., cerebritis, pneumonitis, myocarditis) or hemodynamic instability should be admitted to an intensive care unit. Prompt administration of antibiotics and early consultation with an intensivist and an infectious disease specialist are also appropriate.

COMMON PITFALLS

- Failure to consider the diagnosis of RMSF in the patient with fever and a “viral syndrome” during the peak season (April 1 to September 30) in an endemic area
- Failure to recognize that roughly 15% patients with RMSF present without a rash (“Rocky Mountain spotless fever”). Among ultimately fatal cases, a rash is absent at the time of first presentation to a physician in more than 80%.
- Failure to appreciate the often prominent gastrointestinal features of RMSF, resulting in an incorrect diagnosis of gastroenteritis
- Failure to initiate appropriate antirickettsial therapy in a timely fashion
- Overreliance on laboratory testing, which offers little in the acute phase of RMSF, or withholding of indicated therapy while waiting for definitive serologic confirmation of the disease

Tuberculosis (TB) causes more deaths worldwide than any other single infectious disease.⁵ An estimated 30% to 60% of adults in developing countries are infected with *Mycobacterium tuberculosis*. Approximately 8 million new cases of active disease develop annually, resulting in as many as 3 million deaths worldwide. An estimated 10 to 15 million persons in the United States (4% to 6% of the population) are infected with *M. tuberculosis*.

The incidence of TB in the United States had been decreasing since the 1950s due to the introduction of better public health measures and effective anti-TB drugs. In the mid-1980s, however, that trend reversed itself and an increase in TB cases was noted. The resurgence of TB has disproportionately affected the poor, ethnic minorities, and immigrants, as well as prison and homeless populations. Multidrug-resistant strains of *M. tuberculosis* have also been found in increasing numbers, especially among immigrants and patients with the acquired immunodeficiency syndrome (AIDS). Increased efforts to control the disease in the United States have led to a decrease in TB cases in recent years.

M. tuberculosis is a slow-growing bacterium transmitted between persons by droplet nuclei produced from coughing and sneezing. The small size of the droplets allows them to remain suspended in the air for long periods of time. Infection may occur if contaminated droplets are inhaled and reach the alveoli. The risk of infection is a function of the level of contamination of the air and the length of time the air is breathed. Small, enclosed areas with poor ventilation are more likely to promote the spread of TB.

The small size of airborne droplet nuclei containing infectious organisms allows them to enter the alveoli of the lung. *M. tuberculosis* infection usually begins in the alveoli, where bacilli are able to multiply. Infection may spread through the lymphatics to regional lymph nodes, and subsequently to the bloodstream. In most persons, cell-mediated immunity will develop over 2 to 10 weeks and is adequate to contain the infection. The TB skin test usually becomes positive during this period. In this situation, in which the immune system prevents further spread, the person is said to have *M. tuberculosis* infection without disease. These people have no clinical symptoms of TB and cannot infect others.

M. tuberculosis survives within macrophages as a facultative intracellular parasite, and thus may remain dormant in the body for many years. Active TB develops within 2 years in about 5% of patients, and another 5% will develop reactivation disease at some later point over the course of a lifetime. Reactivation is more likely to occur in people with impaired cell-mediated immunity, such as those with diabetes, renal failure, immunosuppressive therapy, and malnutrition.

AIDS patients lack the ability to mount an effective cell-mediated immune response and are thus much more likely to progress to active disease. The incidence of TB in AIDS patients is almost 500 times that in the general population. The risk of developing active TB in human immunodeficiency virus (HIV)-infected persons with a positive tuberculin skin test is estimated to be 5% to 10% per year, compared with the 5% to 10% lifetime risk for people not infected with HIV.

Multidrug-resistant TB (MDR-TB) is defined as that due to an organism with resistance to two or more primary anti-TB drugs (currently, isoniazid [INH], rifampin, pyrazinamide [PZA], ethambutol, and streptomycin). Factors associated with the presence of MDR-TB include previous treatment (especially patients who were given an inadequate regimen or were not fully compliant), exposure to a known case of MDR-TB, birth or residence in an area of high MDR-TB incidence (e.g., Asia, South and Central America, and Africa), and living in environments such as homeless shelters and prisons, where there may be a high risk of MDR-TB transmission. HIV-infected patients who are exposed to MDR-TB are at especially high risk of developing disease.

Several factors contribute to the development and spread of MDR-TB. One of the most important is incomplete compliance with medications. Failure to take medication as prescribed may allow drug-resistant organisms to develop. The prescribed regimen must contain at least two drugs to which the organism is susceptible. Because susceptibility testing takes several weeks to complete, some patients receive inadequate treatment regimens while susceptibility results are pending. With ineffective therapy, the patient remains infectious and can spread the resistant organism to others.

Because patients on inadequate therapy are infectious for longer periods of time, MDR-TB may have a selective advantage over susceptible strains, which may lead to an increasing frequency of MDR-TB. Until more effective therapies or vaccines are available, the best weapon against TB is an aggressive infection control program focusing on early diagnosis, isolation, and directly observed therapy for TB patients.

CLINICAL PRESENTATION

The symptoms of TB vary dramatically, depending on the site and stage of infection as well as the overall health and immune status of the host. Some patients have mild symptoms that go unnoticed; some may be truly asymptomatic. Such patients may be identified only through exposure history, an abnormal chest radiograph, a positive TB skin test, or a positive TB culture.

Early pulmonary TB often causes no symptoms. As the disease progresses, patients may develop insidious constitutional symptoms such as fatigue, anorexia, weight loss, fevers, and night sweats. Cough may progress slowly over weeks to months, becoming productive of mucopurulent sputum. TB must be considered in any patient at risk who has a cough of more than 2 to 3 weeks' duration. Hemoptysis due to endobronchial erosion may be present, usually indicating more advanced disease. Some patients present with a more acute onset of fever, chills, cough, and myalgias, similar to an episode of acute bronchitis or pneumonia. Chest findings of rales or consolidation may be present. Patients may have a dull ache or tightness in the chest, or they may have pleuritic pain related to tuberculous pleuritis. Signs of pleural effusion may indicate a tuberculous empyema.

Most cases of disseminated TB have a subacute presentation with systemic symptoms. However, some patients with hematogenous dissemination of TB may present with an acute illness of fever, dyspnea, and cyanosis, mimicking bacterial sepsis. Physical findings may include hepatosplenomegaly, lymphadenopathy, erythema nodosum, and tuberculous lesions visible on examination of the optic fundi. Elderly patients are particularly prone to presenting with unexplained fever and hematologic abnormalities such as pancytopenia or leukemoid reaction.

TB may involve virtually any structure in the body and produce symptoms and signs related to the affected organs as well as systemic symptoms. In about 15% of TB cases, major involvement is seen at an extrapulmonary site. Granulomatous lymphadenitis is usually caused by *M. tuberculosis* in adults, but nontuberculous mycobacteria are a more common cause in children. The cervical and supraclavicular nodes are the most common sites of infection, but any nodes may be involved. Genitourinary TB may present as recurrent urinary tract infections without the growth of the usual bacterial pathogens, pyuria without bacteriuria, or simply recurrent fever. Skeletal tuberculosis is most common in the spine (Pott disease) and weight-bearing joints and usually presents as fever and localized pain.

Tuberculous meningitis is more common in small children as a complication of initial infection, but it can occur in any age group. TB meningitis typically has a subacute onset and may present as headache, altered mental status, or seizures. Cranial nerve signs attributable to involvement of the basilar meninges may be present. Some patients may have new psychiatric symptoms. The cerebrospinal fluid characteristically shows a moderate lymphocytic pleocytosis (usually 100 to 500

cells/mm²), elevated protein, and low glucose.

HIV-infected patients are especially prone to having atypical presentations of TB. TB usually causes disease at an earlier stage of HIV infection than opportunistic pathogens such as *Pneumocystis carinii*, presumably because TB is more virulent than these other pathogens. Extrapulmonary involvement is much more common in HIV-infected patients with TB, occurring in 40% to 75% of cases, usually with concomitant pulmonary disease. In patients with advanced HIV infection, cavitary lung disease and localized extrapulmonary disease are relatively less common; diffuse interstitial pneumonia (mimicking *P. carinii* pneumonia) and disseminated infection are more typical.

DIFFERENTIAL DIAGNOSIS

Pulmonary TB can potentially mimic many other diseases, including pneumoconiosis, bacterial pneumonia, bronchiectasis, sarcoidosis, lung abscess, neoplasm, and fungal infections such as coccidioidomycosis or histoplasmosis or *P. carinii*. Factors that may be helpful in identifying TB as a cause of illness include history of exposure to TB; characteristic radiographic findings, such as cavitation or apical infiltrates; presence of acid-fast bacilli (AFB) on sputum smear; and results of skin testing. The diagnosis of TB ultimately rests on the culture of *M. tuberculosis*, but culture may take several weeks.

Difficulty may arise in distinguishing disease due to *M. tuberculosis* from disease due to other mycobacterial species. A number of mycobacterial species other than *M. tuberculosis* have been identified. Many are ubiquitous in the environment and are usually contaminants when isolated, but some have been found to be human pathogens. *Mycobacterium avium* complex (MAC, also known as *Mycobacterium avium-intracellulare* [MAI]), *M. kansasii*, and other mycobacteria are rare causes of pulmonary disease; most other mycobacterial species are associated with skin, soft-tissue, and lymph node infections. AFB identified in sputum smears may represent colonization by nonpathogenic mycobacteria, but until they can be definitively identified as such by culture they should be considered to represent *M. tuberculosis* in a patient with a clinical picture consistent with TB.

MAC is the most common mycobacterial species isolated from persons with AIDS in the United States. Infection typically occurs as a systemic febrile illness in end-stage AIDS patients, rather than as a pulmonary infection in earlier stage AIDS patients, as with *M. tuberculosis*.¹⁶ A chest radiograph usually does not suggest mycobacterial disease, and pleuritis is uncommon. Acid-fast smears of stool are commonly positive, but acid-fast smears of sputum are often negative, suggesting that the gastrointestinal tract, rather than the lungs, is the portal of entry.

MAC infections in AIDS patients are often difficult to treat effectively, but they may respond to regimens containing clarithromycin or azithromycin, ethambutol, rifabutin, clofazimine, or ciprofloxacin.⁹ HIV-infected patients with suspected pulmonary mycobacterial disease should generally be given empiric therapy against *M. tuberculosis* initially. Therapy can be adjusted later if MAC or other nontuberculous mycobacteria are cultured.

EMERGENCY DEPARTMENT EVALUATION

The most important test in the initial evaluation of patients with suspected pulmonary TB is the chest radiograph. Findings strongly suggestive of pulmonary TB include nodular densities, with or without cavities, that are commonly seen in the apical and posterior segments of the upper lobes or in the superior segments of the lower lobes (Fig. 189.1).

Figure 189.1. Chest radiograph demonstrating apical infiltrate with cavitation, typical of pulmonary tuberculosis.

In disseminated TB, the chest radiograph often reveals a miliary pattern, but it may be normal in the early stages. TB may have many different radiographic appearances, ranging from lobar consolidation to a diffuse interstitial pattern. Patients with AIDS are especially likely to have TB without the typical radiographic pattern, and they are more likely to have lymphadenopathy on a chest x-ray.¹⁵ A diffuse interstitial pattern that is easily misdiagnosed as *P. carinii* pneumonia may be seen in patients with AIDS (Fig. 189.2).

Figure 189.2. Chest radiograph of HIV-infected patient with tuberculosis, demonstrating hilar adenopathy and scattered interstitial infiltrates. This patient was initially misdiagnosed with *Pneumocystis carinii* pneumonia.

If pulmonary TB is suspected, sputum samples should be obtained for AFB smear and culture. Collection of sputum can put health-care workers and other patients at risk for exposure to TB, and should be performed only in an isolation room adequately equipped with outside ventilation and filters or ultraviolet light. Emergency departments may consider having the patient step outside to provide a specimen if these facilities are not available. Ideally, three successive early-morning sputum samples should be obtained. In certain cases, they can be obtained on an outpatient basis.

A positive AFB smear supports a presumptive diagnosis of TB. A positive smear does not necessarily indicate infection with *M. tuberculosis*, however, because other mycobacteria (e.g., MAC) are also acid-fast. Patients with positive smears are potentially the most infectious, because they are usually coughing up large numbers of organisms. Because culture is more sensitive than AFB smear for the diagnosis of TB, the sample should be sent for culture even if the smear is negative.

AFB smear results are usually not available within the time frame of an emergency department visit. If there is a high likelihood of TB, the patient may be started on empiric therapy, with further AFB specimens obtained over the next couple of days. Empiric therapy will not significantly affect the diagnostic yield of specimens obtained over the next 1 to 2 days. Delays in diagnosis are a problem with current techniques, because culture usually takes 3 to 6 weeks, and susceptibility tests may take 8 weeks. Newer radiometric methods can provide results in as little as 10 to 15 days, but may not be available in many facilities. Nucleic acid amplification

tests, such as polymerase chain reaction (PCR), can be used to rapidly verify *M. tuberculosis* in AFB smear–positive specimens.¹²

Intradermal tuberculin skin testing is the standard method for identifying persons infected with *M. tuberculosis*. The Mantoux test is performed by injecting 5 U (0.1 mL) of purified protein derivative (PPD) intradermally. The arm is then examined for 48 to 72 hours for induration at the site. Persons for whom TB skin testing is recommended are listed in [Table 189.1](#), and interpretation of the test is summarized in [Table 189.2](#).

People with signs, symptoms, or chest x-ray suggestive of active TB Recent contacts of people known to have, or suspected of having, active TB People with HIV infection People with an abnormal chest x-ray compatible with past TB People with other medical conditions that increase the risk of TB (e.g., intravenous drug use, diabetes, immunosuppressive therapy, renal failure, rapid weight loss) Groups at high risk of recent infection with TB, such as immigrants from Asia, Africa, Latin America, and Oceania; medically underserved populations (e.g., homeless); personnel and residents in long-term care facilities and correctional institutions

TABLE 189.1. People in Whom PPD Skin Testing Is Indicated

INDURATION ≥ 5 MM
Close contact with someone with active TB Abnormal chest radiograph HIV infection
INDURATION ≥ 10 MM
Immigrants from an area with a high incidence of TB At risk because of low socioeconomic status—e.g., homeless, inner-city minority Intravenous drug users Residents or employees of long-term care facilities Demographic groups identified locally as being at risk for TB
INDURATION ≥ 15 MM
All others

TABLE 189.2. Criteria for Interpretation of PPD Skin Tests as Positive

A negative TB skin test does not rule out TB, because 60% of AIDS patients and up to 30% of those without HIV infection have a reaction of less than 5 mm even when they are infected. A skin test should nonetheless be performed in patients with AIDS, however, because it produces a positive reaction in up to 40% of those infected. False-positive reactions may be caused by cross-reaction with other mycobacteria, such as MAC.

A history of bacille Calmette-Guérin (BCG) vaccination generally does not alter the guidelines for interpretation of the skin test. BCG vaccination usually does not cause a reaction of more than 10 mm, and the extent of the reaction decreases with time. Because the vaccine is generally given only in areas with a high incidence of TB, a reaction greater than or equal to 10 mm should still be considered positive in these patients.²

The Centers for Disease Control and Prevention (CDC) recommend that facilities serving persons at high risk for HIV infection, TB infection, or both should provide screening for TB and encourage HIV testing. Facilities such as drug treatment centers, sexually transmitted disease clinics, correctional facilities, and homeless shelters have been suggested as important places for TB screening, and it has been recommended that TB case finding should be part of the regular health care provided to all homeless people.⁸ Many persons at risk for TB and HIV come into contact with the health-care system only for episodic care in emergency departments.

Emergency department–based screening for TB could potentially identify many patients who require treatment.¹⁶ However, the cost and time commitment necessary for an effective TB screening program may preclude the development of such a program in many emergency departments. If a TB screening program cannot be established in the emergency department, then patients at risk for TB should at least be referred to local public health clinics for testing. It is essential that all persons with suspected active TB be reported to local public health authorities.¹

EMERGENCY DEPARTMENT MANAGEMENT

Treatment of Active Tuberculosis

Rapid initiation of an effective drug regimen is important to prevent the spread of TB. Presumptive therapy can begin in the emergency department on the basis of clinical grounds alone if the patient is at risk for TB and has signs, symptoms, and radiographic findings suggestive of TB. Specimens should still be sent for AFB smear, culture, and sensitivity for subsequent management. If cultures are negative or yield only nontuberculous mycobacteria, treatment can be stopped or adjusted accordingly. It is crucial that patients can be followed up adequately, to ensure that treatment is appropriate and is being tolerated.

Active TB should always be treated with at least two drugs to which the organism is susceptible. Administration of a single drug can lead to the development of a bacterial population resistant to that drug. When two or more drugs are used simultaneously, each helps to prevent the emergence of TB resistant to the other. Because of concern about MDR-TB, the CDC recommends that initial therapy for TB include four drugs. The preferred initial regimen consists of daily INH, rifampin, PZA, and ethambutol or streptomycin.⁶ Doses of these drugs can be found in [Table 189.3](#). If four drugs are used in the initial regimen, it is very likely that the organism will not be sensitive to at least two of these drugs. The initial regimen is continued for 2 months, at which time the number of drugs and frequency of dosing can be reduced, depending in part on the results of susceptibility testing.

Drugs	Children ≤ 12	Adults
Isoniazid	10–20 mg/kg Maximum 300 mg	5 mg/kg Maximum 300 mg
Rifampin	10–20 mg/kg Maximum 600 mg	10 mg/kg Maximum 600 mg
Pyrazinamide	15–30 mg/kg Maximum 2 g	15–30 mg/kg Maximum 2 g
Ethambutol	15–25 mg/kg Maximum 2.5 g	5–25 mg/kg Maximum 2.5 g
Streptomycin	20–30 mg/kg Maximum 1 g	15 mg/kg Maximum 1 g

Adapted from Center for Disease Control. Initial therapy for tuberculosis in the era of multidrug resistance. Recommendations of the Advisory Council for the Elimination of Tuberculosis. MMWR 1993;42(RR7):3.

TABLE 189.3. Dosage Recommendation for the Initial Treatment of Tuberculosis

Immunocompetent patients usually cease to be infectious within 2 to 4 weeks of starting therapy, assuming the infecting organism is susceptible to the drugs being used and the patient is compliant. Expert advice should be sought if a patient is suspected of having MDR-TB. Alternative regimens may be recommended for these patients, including drugs such as cycloserine, ethionamide, amikacin, or quinolones.

Because rifampin interacts with protease inhibitors and nonnucleoside reverse transcriptase inhibitors, HIV-infected patients on these medications are treated with regimens that do not contain rifampin.¹³ Rifabutin may be substituted in some cases, but is also contraindicated with some antiretroviral drugs. Expert consultation should be sought before initiating TB treatment for individuals taking antiretroviral drugs.

Certain low-risk patients in areas with a very low incidence of drug-resistant TB may be started initially on a three-drug regimen of INH, rifampin, and PZA. All others should be started on a four-drug regimen until sensitivity results are known. Those who are at especially high risk for MDR-TB include anyone with HIV infection, those with known exposure to MDR-TB, and persons from a geographic area or demographic group with a high incidence of MDR-TB. A five-drug regimen may be recommended for some very high risk patients. Treatment should be continued for at least 6 months in immunocompetent persons. HIV-infected patients who are unable to take rifampin or rifabutin may require 9 months of treatment.

Recommendations for treatment of extrapulmonary TB are generally the same as for pulmonary TB. However, children with miliary TB, bone or joint TB, or TB meningitis should receive a minimum of 12 months' treatment.⁴

Common side effects of these medications include hepatitis (INH, rifampin), peripheral neuropathy (INH), optic neuritis (ethambutol), and, rarely, purpura (rifampin). Adults should have baseline measurements of hepatic enzymes, bilirubin, serum creatinine or blood urea nitrogen, complete blood count, and platelet count. Serum uric acid should be measured if PZA is used, and a baseline examination of visual acuity should be obtained for patients to be treated with ethambutol. For this reason, unless resistance to other drugs is strongly suspected, ethambutol is not generally used for children younger than 6 years of age, in whom visual acuity cannot be assessed well.

Patients should be instructed to report any symptoms suggestive of hepatitis or thrombocytopenia. Pyridoxine (10 to 50 mg/d) may be given with INH to persons with conditions in which neuropathy is common, such as diabetes, alcoholism, or malnutrition. The rate of adverse reactions to antituberculous agents increases with age, and also appears to be higher in HIV-infected patients.

Management of Tuberculosis Exposure

Management of persons exposed to others with active TB involves several considerations: (1) the likelihood that the exposed person has been newly infected with *M. tuberculosis*; (2) the likelihood that the infecting strain is drug-resistant; and (3) the estimated likelihood that the newly infected contact will develop active TB. Contacts who are not immunosuppressed and do not have a history of a positive PPD skin test should receive a tuberculin skin test and, if indicated by symptoms, a chest radiograph and sputum examination. Those who have a PPD skin test reaction equal to 5 mm should be considered newly infected and should be considered for preventive therapy once active TB has been ruled out.

Persons with a high-risk exposure and a negative PPD should have a follow-up skin test 12 weeks after the exposure has ended; if the PPD test is still negative at that time, no further evaluation is necessary. Because the risk of developing TB is higher for young children, preventive therapy may be considered for all children younger than 5 years of age who are close contacts of TB cases until repeat skin testing is done at 12 weeks after exposure.

Persons who are known to be HIV-infected or otherwise immunosuppressed and who are close contacts of patients with infectious TB should be carefully evaluated for evidence of TB. If there are no findings suggestive of active TB, preventive therapy with INH may be recommended, even if PPD skin testing is negative.⁴

Management of Positive Tuberculosis Skin Tests

Persons with a positive TB skin test need to be evaluated for the presence of active TB with a chest radiograph. If the chest radiograph is abnormal or if symptoms suggest TB, an examination of sputum for AFB smear and culture is indicated. Those with no evidence of clinical disease should be referred for consideration of preventive therapy for TB. It is not necessary to initiate therapy urgently in this situation, but it is important that patients understand the importance of follow-up to obtain preventive therapy. It has been shown in numerous studies that preventive therapy substantially reduces the risk of latent infection's progressing to clinical disease. Immunocompetent persons who are not at risk for MDR-TB are generally treated with INH for 6 months.⁴ HIV-infected persons who are not at risk for MDR-TB should receive preventive therapy with INH for a minimum of 9 months.¹³ Alternatively, they may receive rifampin plus PZA daily for 2 months.

The effectiveness of preventive therapy for people exposed to MDR-TB strains has not been prospectively studied, and guidelines for management of such patients are less clear. If the infecting strain of TB is known to be less than 100% resistant to INH, then INH should be included in the preventive regimen; rifampin should be included for those with less than 100% resistance to rifampin. Those with exposure to strains resistant to both INH and rifampin who are at increased risk for developing active disease may be treated with regimens of PZA plus ethambutol or PZA plus a fluoroquinolone.⁷

Consultation with local infectious disease experts familiar with local patterns of resistance and current recommendations may be helpful in the management of such patients. Because the efficacy of drugs other than INH and rifampin for preventive therapy is unknown, persons on alternative therapies should have regular follow-up.

Recommendations for TB therapy are likely to continue to change because of shifting patterns of infection and drug resistance. The most current recommendations can be found in *Morbidity and Mortality Weekly Report* and the publications of the American Thoracic Society.

Preventing the Spread of Tuberculosis

The basic principles for preventing the transmission of TB include early identification of persons with active TB, early initiation of AFB isolation precautions in persons with suspected TB, and initiation of effective therapy to render the patient noninfectious. Lapses in infection control measures have led to nosocomial transmission of MDR-TB between patients and from patients to healthcare workers.¹⁸

The emergency department is potentially a high-risk area for the transmission of TB, because patients may be undiagnosed with TB when they present initially, and patients sometimes are crowded together for long periods of time, especially in busy inner-city emergency departments, which are likely to have a larger number of TB patients. There may be long delays in recognition and initiation of infection control measures for infectious TB patients in the emergency department, and HIV-infected patients appear to be even more likely to have delays in recognition, because they often have atypical presentations.¹⁷

Emergency departments should consider triage protocols to identify possible TB patients early. Those with possible TB should have an expedited chest radiograph, and can have a mask placed or wait outside while they are being evaluated for possible infectious TB.

Once a patient is suspected of having active TB, infection control measures should be initiated.^{3,10} These measures are aimed at isolating the source from other patients and reducing the microbial contamination of indoor air. Recommendations include the use of a private room for the source patient, with negative pressure in relation to surrounding areas and a minimum of six air exchanges per hour. Air from the room should be exhausted directly to the outside. Use of ultraviolet lamps and/or high-efficiency particulate air filters to supplement ventilation may be considered.

Many emergency departments do not have the facilities to comply with these recommendations, and the costs associated with fitting a department with such facilities are substantial. If facilities that meet these standards are not available, it is important to at least designate an area for persons with possible TB that will keep them isolated from other patients and will minimize air exchange with other patient areas. Ordinary surgical masks may help reduce the amount of airborne droplets produced by patients who are coughing, but they are not truly effective for preventing the transmission of TB when worn either by TB patients or by those at risk for exposure. Masks used in the conventional manner are not designed to filter out particulates in the 1- to 5- μ range and can leak large amounts of air around the edges. The CDC recommends that health-care workers use masks capable of filtering out at least 95% of particles in the 1- μ range (commonly designated as N-95) for protection against TB. Individually fit-testing these masks may help ensure that they will provide adequate protection.¹¹

DISPOSITION

Criteria for admission of patients with TB are similar to those for patients with other types of pneumonia. Patients who are not seriously ill and are not immunocompromised may safely be sent home with close follow-up, but precautions must be taken to avoid the spread of TB to others. Any patient who is discharged home with possible TB must be reported to local public health authorities. It may be assumed that household contacts have already been exposed, and will need to be tested.

Patients should be instructed to avoid crowded, enclosed, public areas and to wear a mask for at least the first 2 weeks of therapy to reduce the amount of airborne droplets produced by coughing. Other factors, such as homelessness, degree of compliance with medications, follow-up, and compliance with infection control measures should be considered when making decisions regarding admission. In the United States, laws vary among the states in regard to forced treatment and quarantine of patients who will not cooperate with therapy and are believed to be a public health hazard. ¹⁴

COMMON PITFALLS

- Failure to consider the possibility of TB in a patient presenting with nonspecific systemic complaints
- Failure to rapidly initiate infection control measures for patients suspected of TB
- Risking the spread of TB in the emergency department by performing high-risk procedures such as sputum induction in infectious TB patients without proper isolation procedures
- Misdiagnosis of TB in AIDS patients as *P. carini* or other infections
- Failure to refer patients at risk of TB for skin testing
- Failure to recognize and follow up patients whose cultures may become positive several weeks after an emergency department visit
- Failure to report persons with suspected TB to local public health authorities

CHAPTER 190

Infectious Mononucleosis

David Anthony Jerrard

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Infectious mononucleosis is clinically defined by the triad of fever, lymphadenopathy, and pharyngitis, combined with the development of heterophil antibodies and atypical lymphocytosis. It is caused by the Epstein-Barr virus (EBV), which is also strongly implicated in the etiology of nasopharyngeal cancer and Burkitt's lymphoma. The most characteristic feature of the disease is its predilection for the young adult population, especially the 15- to 30-year age group. Early fall and spring are the two peak times of occurrence.⁵

Seroepidemiologic studies have shown that the presence of antibody to EBV (indicating exposure) correlates strongly with immunity and that its absence is highly indicative of susceptibility.¹² The age at which individuals develop the infection depends on socioeconomic factors as well as hygiene. Most children in developing countries have been exposed by the age of 3, whereas only 50% of those in economically advanced countries have antibodies by adolescence. Primary EBV infection during childhood is usually subclinical.¹² By adulthood, most individuals are seropositive.

Epidemiologic and laboratory evidence indicates that transmission occurs through the oropharyngeal route. EBV may be found in throat washings many months after clinical symptoms have abated, and may even be cultured from 10% to 20% of completely asymptomatic individuals. It is likely to be found in nearly 100% of patients with acquired immunodeficiency syndrome (AIDS).¹² Most transmission occurs from asymptomatic individuals to previously uninfected members of the population.

When EBV is transmitted by saliva, the initial site of replication is in the oropharynx. Both B lymphocytes and oropharyngeal epithelial cells have specific surface receptors for EBV, and replication takes place within these cells. Both humoral and cellular components are important in the immune response to EBV infection. The cellular response, consisting of the elaboration of T lymphocytes having very similar characteristics to suppressor-cytotoxic T lymphocytes,¹² is responsible for controlling B-cell proliferation.

CLINICAL PRESENTATION

The incubation period is 4 to 8 weeks. Nonspecific symptoms such as malaise, anorexia, fatigue, and chills often herald the illness and are followed by the development of fever, pharyngitis, and lymphadenopathy. Most patients seek medical care because of sore throat, but headache and myalgia are often complaints as well. Abdominal pain is rare in the absence of splenic rupture.

A pharyngeal exudate is present about one-third of the time,¹² and palatal petechiae may be observed. Anterior or posterior cervical lymphadenopathy is reported in about 90% of patients¹² and tends to be particularly impressive in these areas. Generalized adenopathy is often present; the nodes may be moderately tender or painless. Lymphadenopathy tends to be less prominent in patients older than the age of 40.⁴

Splenomegaly is noted in about 50% of patients, mostly in the second or third week of illness, and is usually not associated with pain. The presence of pain should alert the clinician to the possibility of impending or actual splenic rupture, an uncommon but well-documented complication of the disease that may be life-threatening if not identified and treated promptly.¹² Splenectomy is the most common treatment of choice. Splenic abscess has also been reported as a complication of infectious mononucleosis.⁸

Tonsillitis may occur during any stage of the illness, although it is usually most pronounced during the first 2 weeks of the postprodromal period. Tonsils hypertrophied to the point of "kissing" in the midline are not at all unusual and do not, in themselves, mandate hospital admission. The distinction between severe pharyngitis and airway compromise is necessary for obvious reasons, but tonsillar hypertrophy only rarely causes airway compromise.

Complications of infectious mononucleosis are rare, but the clinician must be alert for them. Autoimmune hemolytic anemia may appear within 1 to 2 months of initial symptoms; mild thrombocytopenia develops in about half of all cases. Both appear to be antibody mediated and are usually self-limited, lasting approximately 6 weeks. Glucocorticoids have been recommended for the treatment of both the thrombocytopenia and the hemolytic anemia, but there is little evidence to support their use.¹²

A number of neurologic complications of infectious mononucleosis have been described. Cranial nerve palsies (especially Bell's palsy) and various forms of encephalitis are the most common. Cerebellar dysfunction and episodes of Guillain-Barré syndrome have also been associated with infectious mononucleosis. Roughly 90% of patients with EBV-associated neurologic findings recover without sequelae.¹²

About 90% of patients with infectious mononucleosis have transient elevation of hepatic enzymes, although significant hepatic dysfunction is exceedingly unusual. Roughly half of these patients have mild hepatic tenderness, but hepatomegaly is infrequent. Clinical jaundice may develop early in the illness, but resolution usually occurs within a few weeks. Subclinical illness that mimics mild viral hepatitis may in fact be due to infectious mononucleosis.

Although rare, airway obstruction secondary to extreme lymphoid hyperplasia is a potential complication. Airway compromise, as evidenced, for example, by stridor, requires active airway management.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of sore throat is lengthy ([Table 190.1](#)). Because several of the entities (e.g., foreign body, retropharyngeal abscess and hematoma, and, although less likely, adult epiglottitis) may be associated with airway compromise, it is vital to rule them out as possibilities. Compared with other causes of sore throat, infectious mononucleosis is likely to feature more prominent systemic complaints.

Retropharyngeal abscess
Epiglottitis
Esophageal candidiasis
Peritonsillar abscess
Foreign body
Uvulitis
Pharyngitis (bacterial or viral)*
Laryngitis
Cervical adenopathy

*Includes infectious mononucleosis.

TABLE 190.1. Differential Diagnosis of Sore Throat

Generalized lymphadenopathy prompts consideration of other viral illness, AIDS, leukemia, lymphoma, or tuberculosis.

The differential diagnosis of splenomegaly is broad as well. Infectious endocarditis, abscess, and disseminated tuberculosis are all possible infectious etiologies of splenic enlargement. Infiltrative processes such as lymphoma and leukemia must also be included for consideration.

EMERGENCY DEPARTMENT EVALUATION

If there is suspicion of adult epiglottitis or retropharyngeal abscess or hematoma, a soft-tissue lateral radiograph of the neck should be performed. In any patient presenting with the complaint of sore throat, indications of airway compromise should be sought.

The diagnosis of infectious mononucleosis is based on clinical, hematologic, and serologic criteria. In a patient strongly suspected of having infectious mononucleosis, certain laboratory features may aid in making a firm diagnosis.

A relative and absolute *lymphocytosis* is seen in 39% to 75% of patients with infectious mononucleosis.⁷ The lymphocytosis is characterized by the presence of cells, roughly 10% of the total, that have atypical morphology. They are larger than mature lymphocytes and have large lobulated or indented nuclei and vacuolated or bluish cytoplasm. Lymphocytosis usually peaks in the second or third week of illness.

A significant number of patients with acute EBV infection, particularly those older than the age of 40,^{4,7,11} do not fulfill the classic hematologic criteria for infectious mononucleosis, that is, lymphocytosis of at least 50%, with at least 10% atypical lymphocytes. Conversely, atypical lymphocytosis may be seen in other infections, such as toxoplasmosis, rubella, mumps, and hepatitis.¹³ Complicating matters further, mononucleosis-like syndromes may be associated with cytomegalovirus infection, toxoplasmosis, and hepatitis A and B, and sometimes cannot be distinguished clinically from infectious mononucleosis due to EBV.

Because so many of the symptoms of infectious mononucleosis are nonspecific, serologic evidence may be required to make the diagnosis. *Heterophil antibodies* (defined as antibodies that react with antigens not responsible for their production) are characteristically produced in infectious mononucleosis.³ The Monospot test is based on this tube dilution principle.

Heterophil agglutination is apparently almost never positive in persons of Japanese ancestry, for unknown reasons.¹³ False-positive results have been known to occur in leukemia, lymphoma, malaria, rubella, hepatitis, pancreatic cancer, systemic lupus erythematosus, and hepatic abscess.^{8,9,13} In addition, children younger than 4 years of age often fail to demonstrate heterophil antibody; likewise, the incidence of heterophil-negative infectious mononucleosis due to EBV increases with age.⁴ The false-positive rate for heterophil antibody in adults is roughly 2%, and the false-negative rate is 5% to 7%. Only 70% of patients tested in the first week of the illness have a positive test, but 85% to 90% are positive by the third week. One study reported that positive titers were associated with four physical findings: palatal petechiae, posterior auricular adenopathy, axillary adenopathy, and inguinal adenopathy.³

More recently, latex agglutination tests have been developed for the detection of infectious mononucleosis-associated heterophil antibody.⁶

Because many individuals are heterophil antibody negative during the first week of illness, it seems reasonable to omit this test in patients with an illness of recent onset, unless the physical examination raises a high suspicion for mononucleosis. Patients should be instructed to return for testing if symptoms persist beyond 7 days.

Individuals with infectious mononucleosis also produce specific antibody directed against EBV antigens. Even though the development of detectable heterophil antibodies may be delayed, EBV antibody tests are rarely necessary, because 90% of cases are heterophil positive, and false-positive heterophil results are rare; more practically, illness is usually mild and self-limited.⁶ Nevertheless, it should be noted that, as with heterophil antibodies, antibodies specific to EBV may sometimes not be detectable until several weeks after the onset of illness.

EMERGENCY DEPARTMENT MANAGEMENT

The treatment of infectious mononucleosis usually consists only of supportive care. Fever and pharyngeal pain may be ameliorated by acetaminophen. Aspirin should probably be avoided because of the risk of increasing any bleeding tendency due to thrombocytopenia. Adequate rest should be advised, although this does not seem to expedite recovery. Ampicillin, via an unknown mechanism, causes a rash in roughly 90% of those with infectious mononucleosis. When treating presumed streptococcal tonsillitis in patients with infectious mononucleosis, therefore, erythromycin or penicillin should be prescribed instead. Because of the small but real risk of splenic rupture, contact sports should be avoided for 6 to 8 weeks after the onset of illness. Some authors recommend that college and intramural athletics be avoided for 6 months.¹⁵ Patients should be advised that feelings of malaise may linger, sometimes for months.

Severe pharyngitis may be treated with corticosteroids (prednisone, 40 to 60 mg/d, and tapered over 7 to 10 days). Impending airway obstruction or an inability to take oral medications may necessitate the use of dexamethasone. Symptoms of dysphagia and difficulty breathing are usually improved within 1 to 2 hours of administration of parenteral corticosteroids. As noted previously, active airway management is rarely necessary. Although corticosteroids do not decrease spleen size or reduce the likelihood of splenic rupture, some benefit may be obtained in decreasing neurologic, hematologic, and cardiac complications. Corticosteroid therapy is not generally recommended for uncomplicated infectious mononucleosis, however.

In patients presenting with abdominal pain, a computed tomography scan should be performed. Infectious mononucleosis may be the most common reason for splenic rupture.¹ Splenic rupture is unlikely to occur in the first 2 weeks of the illness, however; the capsular and trabecular changes that are necessary to permit rupture to occur do not develop for 2 to 4 weeks.

DISPOSITION

The vast majority of patients with infectious mononucleosis do quite well without any intervention whatsoever and can be discharged from the emergency department with instructions to return should abdominal pain develop and breathing or swallowing become difficult.

Consultation with appropriate specialists is indicated for neurologic or hematologic complications.

Patients who are unable to maintain oral intake because of difficulty in swallowing should be admitted and begun on parenteral corticosteroids. This also holds true if airway compromise becomes a concern.

In the unlikely event of splenic rupture, a surgical consult is imperative. Should either computed tomographic scanning or surgical backup not be available, immediate transfer to a center that does have these resources is crucial.

COMMON PITFALLS

- The differential diagnosis of sore throat includes more than simple viral or bacterial pharyngitis. Other infections localized to the throat can have disastrous consequences if they go undetected. These include retropharyngeal abscess and epiglottitis.
- Errors in management are usually the result of a failure to examine the patient thoroughly. This may result, for example, in a failure to diagnose splenic rupture (either spontaneous or posttraumatic), an uncommon but potentially dangerous complication. Patients should be strongly encouraged to refrain from contact sports for at least 6 months after their illness.
- Patients should be advised to seek medical attention promptly if they develop difficulty breathing or abdominal pain.
- Ampicillin should be avoided because of the high likelihood that a rash will develop.

CHAPTER 191

Influenza

Jonathan S. Olshaker

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Prevention/Vaccination](#)
[Common Pitfalls](#)
[Chapter References](#)

More people died in the 1918 influenza pandemic than in all of World War I. ¹⁸ Today, influenza remains a major killer and causes more morbidity and mortality than the acquired immunodeficiency syndrome (AIDS). In nonpandemic years, 20,000 to 40,000 persons die of influenza-related illness in the United States alone; in pandemic years, deaths can exceed 100,000. ⁸ Influenza infections account for several billion dollars in health-care expenditures each year. ¹³

Influenza is caused by large RNA viruses belonging to the myxovirus groups. Of the three immunologically distinct groups (A, B, and C), influenza A and B are encountered most frequently. Group A is responsible for the majority of the mortality and significant morbidity. It appears to cause more severe disease than type B, making secondary bacterial infection more likely, and is more common in older populations. ¹⁹ Not surprisingly, the vast majority of deaths occur in elderly individuals and in those with chronic medical conditions, particularly chronic obstructive pulmonary disease. ¹

CLINICAL PRESENTATION

Influenza is an extremely common respiratory illness, characterized by the abrupt onset of fever, sore throat, headache, myalgias, and nonproductive cough. The malaise is often much more extreme than that seen with most other common respiratory illnesses. ⁴ Symptoms last from a few days to a week in most patients. More severe illness can result if there is pulmonary involvement due to primary viral or secondary bacterial pneumonia, which is the most common cause of death. This occurs almost exclusively in the elderly, in the immunosuppressed, and in patients with chronic cardiovascular or pulmonary disease.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of influenza includes the myriad respiratory and infectious diseases seen in the emergency department. The clinician's major task should be to recognize serious illness that requires specific antibiotic treatment or other aggressive interventions.

Prominent severe headache, meningeal signs, or changes in mental status make it mandatory to rule out meningitis. Sore throat, often seen with influenza, may be due to peritonsillar abscess, epiglottitis, or streptococcal pharyngitis. Myalgia may be due to bacteremia or sepsis, particularly in the elderly. A finding of hypotension or marked orthostasis mandates evaluation for sepsis or toxic shock syndrome, particularly if there is evidence of multiple organ system involvement. Cough or difficulty breathing may be due to bacterial or viral pneumonia, acute bronchospasm, or cardiac processes such as congestive heart failure or myocardial ischemia.

Unfortunately, the differentiation of viral from bacterial pneumonia in the patient with influenza is difficult. Antibiotics should be instituted early if there is any suspicion of a bacterial process.

EMERGENCY DEPARTMENT EVALUATION

Initial management should focus on assessment of the airway, breathing, and circulation. Pulse oximetry is a simple, noninvasive test that may provide a quick indication of respiratory compromise. Physical examination should focus on the heart and lungs. A thorough examination of the skin should include a search for any cutaneous manifestations of infectious disease, such as purpura or petechiae.

Patients with significant cough, respiratory symptoms, or abnormalities on lung examination should have a chest radiograph. Lumbar puncture and urinalysis may be indicated if suggested by appropriate symptoms. A complete blood cell count, though nonspecific, may lend support to a diagnosis of superimposed bacterial infection. Tests to determine levels of electrolytes, blood urea nitrogen, creatinine, and blood glucose should be ordered in those patients with severe derangements of fluid balance or in those who have chronic medical problems or take medications, such as diuretics, that can affect electrolyte balance. Arterial blood gas analysis is appropriate when hypoxia or sepsis is suspected. Blood cultures should also be obtained if sepsis is a possibility.

Specific serologic testing for influenza cannot be carried out quickly enough to provide any benefit while the patient is in the emergency department.

EMERGENCY DEPARTMENT MANAGEMENT

Initial treatment for patients with suspected influenza is directed at ensuring adequate oxygenation and hemodynamic stability. Patients with viral or bacterial pneumonia, particularly the elderly or those with chronic obstructive pulmonary disease, can present *in extremis* with an immediate need for endotracheal intubation and mechanical ventilation. Supplemental oxygen should be given to patients with significant respiratory symptoms or low pulse oximeter readings.

Patients who are tachycardic, hypotensive, or orthostatic should have a large-bore intravenous line in place and receive initial fluid resuscitation with normal saline. Care should be taken to avoid overhydration, particularly in the elderly or in those with a history of congestive heart failure. Standard bronchodilator therapy is indicated for any accompanying reactive airway disease.

If the patient has a coexisting pneumonia, antibiotics should be instituted in the emergency department, because it is, as a rule, difficult to differentiate viral pneumonia from bacterial pneumonia. Antibiotics should provide adequate coverage against *Haemophilus influenzae* and group B *Streptococcus*, as well as *Staphylococcus aureus*, which is a relatively common bacterial pathogen associated with influenza outbreaks. ¹²

The antiviral drugs rimantadine and amantadine are both effective in reducing the severity and duration of illness in high-risk individuals who have not been vaccinated or who have not received adequate protection by vaccination. ^{3,20} In addition, they can significantly reduce subsequent illness when given to nursing home residents exposed to an influenza outbreak. The most common adverse effects of these drugs relate to the central nervous system and the gastrointestinal tract. Rimantadine appears to cause fewer central nervous system side effects than amantadine and requires less dosage adjustment in patients with mild-to-moderate renal impairment. The normal adult dosage is 200 mg/d. Patients older than 65 should probably receive 100 mg/d because of the potential for side effects and renal toxicity.

Some evidence suggests that oral or aerosolized riboflavin can be of benefit in controlling influenza infections in high-risk individuals. ² Also, zanamivir and other neuraminidase inhibitors are promising investigational antiviral agents that are just reaching clinical trials. ¹⁰ Remaining unresolved issues on these agents include prophylactic efficacy, cost efficiency, administration, and the emergence of resistance.

DISPOSITION

The majority of patients with influenza can be treated as outpatients. Close follow-up should be ensured, and the patient should be given specific instructions to return immediately if symptoms progress.

There should be a low threshold for admission for elderly patients, the immunocompromised, and those with chronic pulmonary or cardiac disease. These patients

should be admitted if there is any evidence of pneumonia, which can often progress rapidly in these individuals. Admission to an intensive care unit should be considered for patients who are hypoxic or show any signs of significant respiratory difficulty.

PREVENTION/VACCINATION

Influenza vaccines have been shown in a number of studies to be effective in preventing clinical disease.^{4,11} Each year, a different vaccine preparation is developed, using virus strains believed likely to appear in North America the following winter. As many as 90% of influenza cases can be prevented when there is a good match between vaccine and epidemic strains of the virus.⁵ Influenza vaccine has also been extremely effective in reducing morbidity and mortality (by up to 80%) in vaccinated individuals who nevertheless develop clinical disease, particularly the elderly and the immunocompromised.⁹ A number of studies have shown that vaccination reduces influenza-related hospitalizations and deaths in nursing home populations during epidemics.^{6,7,9} Adverse effects of the vaccine itself have been minimal and should not deter its use in the high-risk patient.¹⁵

Despite the overwhelming evidence supporting the benefits and efficacy of influenza vaccines, many high-risk individuals go unvaccinated. Studies have shown poor vaccination rates in both the elderly and younger persons with high-risk medical conditions such as asthma.²⁰ One study also showed that only 60% of pediatric emergency physicians received an influenza vaccine with the past year.¹⁴

Emergency physicians can play a major role in educating patients and the general public about the need for vaccinations in high-risk groups. This should occur before the peak influenza season begins.^{6,11} Target groups for vaccination programs are listed in [Table 191.1](#). Vaccinations should be offered between late September and early November, depending on when regional influenza activity is expected to begin. Many emergency departments offer the vaccine on-site. This approach has been shown to be both needed and feasible,¹⁷ even for most patients presenting with acute attacks of asthma requiring prednisone treatment.¹⁶

GROUPS AT RISK FOR INFLUENZA COMPLICATIONS
Adults and children with chronic respiratory or cardiovascular disorders
Healthy persons 65 years of age or older
Immunocompromised persons
GROUPS CAPABLE OF INFLUENZA TRANSMISSION
Residents of nursing homes and chronic care facilities
Physicians
Nurses
Hospital personnel who have close contact with high-risk patients
Home health-care or nursing home care providers

TABLE 191.1. Influenza Vaccination Target Groups

Emergency physicians are often in a position to recognize the outbreak of influenza in closed environments such as nursing homes. Rimantadine, 100 mg/d, should be administered prophylactically to residents of such an institution, whether or not they received influenza vaccine the previous fall.¹⁹

COMMON PITFALLS

- Failure to realize that the elderly, the immunosuppressed, and those with chronic cardiac or pulmonary disease are at high risk for complications from influenza or acute worsening of their baseline chronic disease
- Failure to realize that *Staphylococcus aureus* has a significant role as a pneumonia pathogen during influenza outbreaks
- Failure to use rimantadine in the high-risk patient with influenza. Dosage should be reduced to 100 mg/d in those older than 65.
- Failure to be on the alert for nursing home patients with influenza and to notify appropriate officials about potential outbreaks
- Failure to implement vaccination programs from late September through November

Reports of Kaposi's sarcoma (KS) and *Pneumocystis carini* pneumonia (PCP) in previously healthy homosexual males appeared in the literature beginning in 1981. These are now recognized to represent the earliest cases of the disease known as the acquired immunodeficiency syndrome (AIDS), which has since escalated to become a global public health issue. The medical, social, and economic impact of this disease is enormous and continues to grow.

As of June 1998, there have been more than 688,000 reported cases of AIDS in the United States.⁴ Although true population-based seroprevalence surveys are difficult to conduct, current estimates indicate that well over 1.1 million persons are infected with the human immunodeficiency virus (HIV) (approximately one in every 250 Americans). New laws requiring mandatory reporting of HIV in over 20 states have resulted in the identification of a shift in the regional distribution of HIV and AIDS. While more than 50% of cases occurred in five large urban settings (New York, Newark, Miami, San Francisco, and Los Angeles) up until 1987, the majority of new HIV cases now occur outside of these centers, principally in smaller metropolitan areas.

EPIDEMIOLOGY

HIV infection results in a broad spectrum of clinical conditions, ranging from an asymptomatic seropositive state to severe immunocompromise. The most recent Centers for Disease Control and Prevention (CDC) definition of AIDS, published in 1993, is summarized in [Table 192.1](#). The diagnosis of AIDS is usually made by laboratory evidence of HIV infection and the presence of one of more "indicator" conditions or laboratory evidence of severe immunosuppression (CD4 T-lymphocyte count of less than 200 cells/ μ L).

Esophageal candidiasis
Cryptococcosis
Cryptosporidiosis
Cytomegalovirus retinitis
Herpes simplex virus
Kaposi's sarcoma
Brain lymphoma
Mycobacterium avium complex
<i>P. carini</i> pneumonia
Progressive multifocal leukoencephalopathy
Brain toxoplasmosis
HIV encephalopathy
HIV wasting syndrome
Disseminated histoplasmosis
Isosporiasis
Disseminated <i>M. tuberculosis</i> disease
Recurrent <i>Salmonella</i> septicemia
ADDED IN 1993
CD4 cell count <200 cells/ μ L
Pulmonary tuberculosis
Recurrent bacterial pneumonia
Invasive cervical cancer

TABLE 192.1. Indicator Conditions for Case Definition of AIDS

The majority of AIDS cases in the United States have occurred in men; 16% of cases are in women and less than 2% are in children. Approximately 87% of cases have occurred in individuals 20 to 49 years of age.⁴ Risk factors associated with an increased likelihood of acquiring HIV infection include homosexuality or bisexuality, intravenous drug use, heterosexual exposure to a partner at risk, history of having received blood products before 1985, and horizontal maternal-to-neonatal transmission. Sexual partners of high-risk individuals and children of mothers engaging in high-risk behaviors are also at increased risk. A greater number of risk factors are associated with a greater likelihood of infection.⁹

The pattern of infection among high-risk individuals is changing. Worldwide, heterosexual transmission is the most common route of transmission of HIV infection, and heterosexual transmission accounts for the largest proportionate increase in HIV infection. In the United States, new infections among the homosexual population have significantly decreased in many areas, and in some regions are now rare. Meanwhile, the proportion of AIDS cases in women has increased rapidly, with the male-to-female ratio in certain populations approaching 1:1. During the past several years, the greatest increase in reported AIDS cases has occurred among women, minority populations, and children. Seroprevalence in one inner-city emergency department (ED) demonstrates these trends, with rates of HIV rising from 6% to 11% over a 4-year period.¹³

PATHOPHYSIOLOGY AND TRANSMISSION

HIV is a cytopathic retrovirus that kills infected cells. In humans, HIV appears to selectively attack cells within the immune system (primarily CD4 T-lymphocytes), a characteristic that accounts for much of the immunodeficiency it produces in affected individuals. Following infection of host cells, the viral genes, which are encoded by a single-stranded RNA molecule, are reverse-transcribed into DNA (using the enzyme reverse transcriptase), and then permanently integrated into the host's genome. Once integrated, retroviral DNA may lie dormant, or be actively transcribed and translated to produce virally encoded proteins and new HIV virions.

HIV protease converts viral protein precursors into functional enzymes required for virion infectivity. Antiretroviral therapy is directed at reducing levels of HIV RNA by interfering with the enzymes reverse transcriptase (nucleoside and nonnucleoside reverse transcriptase inhibitors) and HIV protease (protease inhibitors). Although the introduction of these agents has had a significant impact on disease progression, the emergence of mutant drug-resistant strains of HIV and the occurrence of drug toxicity have limited the ability to attain long-term and lasting inhibition of viral replication.

Proven modes of HIV transmission include via semen, vaginal secretions, blood or blood products, transplacental transmission *in utero*, and breast milk. There have been no documented cases of transmission by casual contact, although one report exists of possible transmission, by deep kissing, from an HIV-infected male with bleeding gums to a female partner.⁷

DISEASE PROGRESSION

The spectrum of HIV-induced disease ranges from asymptomatic to acute retroviral infection, to a wide variety of opportunistic infections, malignancies, and other symptoms directly attributable to HIV infection. Several weeks after exposure to the virus, an acute “flulike” illness is reported to occur in 50% to 90% of patients. During this stage of infection, high-level HIV RNA viremia occurs, along with a precipitous decline in CD4 cell counts. Symptoms, including fever, sore throat, fatigue, and myalgias, typically last for 2 weeks, after which there is a significant reduction in HIV RNA levels and moderate increases in CD4 counts.

Infectious disease experts suggest that it may be helpful to identify patients at this early stage, because it may be the optimal time to begin antiretroviral therapy. The best way to establish diagnosis during this acute stage is by quantitative plasma HIV RNA, because HIV antibody serology is usually negative until at least 4 weeks after infection. Median time from exposure to antibody detection has been estimated at 2.1 months, although delayed seroconversion of up to 11 months has been reported.

Disease progression varies among infected individuals. The average incubation time from initial infection to clinical AIDS has been estimated to be 8.23 years for adults, and 1.97 years for children under age 5. In the clinical setting, the laboratory variables that are most predictive of the stage of disease are CD4 cell counts and viral burden.

As the CD4 cell count drops below 500 cells/ μ L, patients present with a variety of conditions that may occur in the immunocompetent host, but are more common and more severe in the presence of HIV infection. Characteristic conditions that occur during “early symptomatic infection” include thrush, recurrent herpes zoster, persistent vulvovaginal candidiasis, and idiopathic thrombocytopenic purpura (ITP).

AIDS is defined by the appearance of any “indicator” condition (see [Table 192.1](#)) or a CD4 count of less than 200 cells/ μ L.² During this stage, a variety of opportunistic infections and malignancies are common. The average survival time after a diagnosis of AIDS has been estimated to be between 16 and 24 months.²⁵ Patients in this group should receive prophylaxis for opportunistic infections as well as antiretroviral therapy, as this has been shown to delay the time of onset of complications and death.²⁶ In patients with CD4 cell counts less than 50 cells/ μ L, median survival is 12 to 18 months, with common life-threatening complications, including disseminated *Mycobacterium avium* complex (MAC) and disseminated cytomegalovirus (CMV).

DIAGNOSIS OF HIV INFECTION

Diagnosing or testing for HIV directly in the ED as part of patient evaluation is rarely indicated, owing to difficulty in obtaining informed consent, appropriate counseling (particularly the time involved), maintaining confidentiality, and ensuring appropriate follow-up. Testing is appropriate in the ED for a few limited indications, such as when health-care providers are exposed to patients' blood.^{8,9} For those patients with identified risk factors, or significant exposure to those with risk factors, emergency physicians play a critical role in referral for voluntary outpatient testing and counseling.^{9,14}

The standard procedure for diagnosing HIV in the United States is viral antibody detection by the enzyme-linked immunoassay technique (EIA), followed by a confirming Western blot on EIA-positive specimens. EIA was initially developed to screen blood and blood products. There are several commercially available tests, each with a sensitivity and specificity greater than 98%. False-negative EIA tests can occur during acute disease before seroconversion or as a result of other factors, such as malignancy or long-term immunosuppressive therapy.

False-positive tests can also occur (among patients with severe liver disease, renal transplants, hematologic malignancies, and other disorders) and are most frequent in populations with a low seroprevalence for the disease. In children younger than 6 months of age, a positive test may be due to transplacentally acquired maternal antibodies and does not necessarily imply the presence of disease. Other false-positive results are due to cross-reacting antibodies, including anti-hepatitis A IgM, anti-hepatitis B core IgM, and antinuclear, anti-smooth muscle, antiparietal cell, and antimitochondrial antibodies.

When the EIA test indicates the presence of HIV antibodies, a second, more specific test, such as the Western blot test, is required before the diagnosis is established. The Western blot technique detects electrophoretically separated viral antigens in the patient's serum and is nearly 100% sensitive. In those cases in which the Western blot test is indeterminate (if bands are present that do not meet criteria for a truly positive test), it should be repeated; if it remains indeterminate, the entire testing sequence should be repeated in 3 to 6 months. An indeterminate test among those with risk factors usually indicates infection; however, among those without risk factors, true infection is rare.

Other less commonly used techniques for HIV testing include viral culture, p24 antigen assays, indirect immunofluorescence, monoclonal antibody detection, the production of reagent antigens by recombinant DNA techniques, and DNA amplification or polymerase chain reaction (PCR).

Measurement of the CD4 lymphocyte count is valuable in evaluating the clinical immunologic status of HIV-infected patients. When this test is available, and in cases in which stage of disease is unknown, the total lymphocyte count (TLC) can be used to approximate the CD4 count. A TLC of less than 1,000 cells/ μ L is highly predictive of a CD4 count of less than 200 cells/ μ L.

EMERGENCY DEPARTMENT MANAGEMENT

It is reasonable to inquire about risk factors as part of the routine evaluation of all adult ED patients, especially in endemic areas, and particularly when patients present with atypical diseases or atypical presentations of common diseases. The infection rate may be surprisingly high, even in patients with presenting complaints not usually associated with HIV infection.⁹ Furthermore, inquiries about risk factors help in the medical evaluation, remind physicians of the potential for occupational exposure to blood-borne infections, and afford the opportunity to offer counseling and referral for testing to those who engage in high-risk behaviors.

Patients with HIV infection may present with any number of symptoms and diseases, ranging from complaints unrelated to HIV infection to life-threatening complications. Virtually any organ system may be involved. The following focuses on some of the more common presentations that may be encountered in the ED.

Constitutional Symptoms and Fever

Systemic symptoms such as fever, malaise, and weight loss are common among patients with HIV infection.¹¹ For patients with newly acquired HIV, fever may occur in the course of primary infection, 8 to 12 weeks after exposure. When due to HIV infection alone, fever tends to occur in the afternoon or evening and is generally responsive to aspirin or acetaminophen. In patients with known HIV infection presenting with an acute febrile illness or a change in the patient's usual fever pattern, systemic infection and malignancy must be excluded. A thorough history and physical examination should be performed in an attempt to identify a site of infection and stage of disease.

Laboratory evaluation of fever may include blood cultures (aerobic, anaerobic, and fungal), blood tests for cryptococcal antigen and *Toxoplasma* and *Coccidioides* serologies, and chest radiography. Syphilis serology; viral hepatitis evaluation, purified protein derivative (PPD) with anergy panel; stool culture; stool examination for ova and parasites; urine culture for bacteria, fungus, and mycobacteria; and sputum smear and culture for fungus and mycobacteria may also be appropriate. If no other source of fever is identified and there are no contraindications, lumbar puncture should be performed, especially if there are neurologic signs or symptoms. Admission should be considered for patients with unexplained fever, particularly when oral intake and the patient's level of functioning have deteriorated.

Two of the more common infectious etiologies of fever to consider in patients with advanced disease are disseminated MAC and CMV infection. MAC is the most common opportunistic bacterial infection in AIDS patients, causing disseminated disease in up to 50% of patients at some time during their illness. It is usually associated with severe weight loss, diarrhea, and constitutional symptoms such as fever, malaise, and anorexia. Infection occurs most often in patients with CD4 counts of less than 100 cells/ μ L. The diagnosis may be made in one of several ways: A Ziehl-Neelsen (acid-fast) stain of stool or other body fluids is frequently positive, or the organism can also be cultured from blood.

Clarithromycin combined with ethambutol and rifabutin reduces bacteremia and improves symptoms, but is not curative. CMV is the most common cause of opportunistic viral infection in HIV-positive patients. Disseminated disease usually involves the pulmonary or gastrointestinal system, with definitive diagnosis often requiring biopsy, demonstrating intranuclear inclusion bodies. CMV retinitis (discussion follows) is the most important manifestation to recognize in the ED. Treatment

is with foscarnet or ganciclovir.

A malignancy that frequently presents with fever is non-Hodgkin's lymphoma. New central nervous system (CNS) symptoms, particularly a change in mental status in the presence of fever, should be evaluated with neuroimaging. Definitive diagnosis requires biopsy. Effective treatment regimens include combined radiotherapy and chemotherapy.

Intravenous drug users (IDUs) who present with fever have been shown to be at increased risk for infective endocarditis (IE). The current standard of care is to admit all febrile IDUs, because there are no reliable clinical or laboratory predictors of this disease.¹⁷ Inpatient evaluation for IE includes following blood culture results and findings on echocardiography. Recent studies suggest that a short ED-based evaluation for IE may be feasible, using echocardiography, culture, and new PCR-based technology as an alternative to blood culture.^{21,22} Currently, however, inpatient hospitalization is advised due to the significant morbidity and mortality of missed IE and the difficulties associated with outpatient follow-up in this population.

Disposition of patients with fever depends on the patient's level of functioning and ability to maintain sufficient oral intake to prevent volume depletion, the availability of timely medical follow-up, and the physician's confidence that fever is due to a benign etiology that may be successfully managed on an outpatient basis.

Pulmonary Involvement

Pulmonary presentations are among the most frequent reasons for ED visits among patients with known HIV infection.^{9,11} More than 80% of AIDS patients develop pulmonary disease. Presenting complaints may include cough, hemoptysis, shortness of breath, and chest pain. The differential diagnosis includes viral, bacterial, mycobacterial, fungal, and protozoal pneumonias, as well as malignancies. The more common etiologies are shown in Table 192.2. Although differentiation of these entities in the ED may be difficult, appreciation of the epidemiology and the common findings associated with various pathogens can assist the emergency physician in arriving at a working diagnosis and instituting appropriate treatment and disposition decisions.

INFECTION	
Viral	Protozoa
Cytomegalovirus	<i>Pneumocystis carinii</i>
Herpes simplex virus	<i>Toxoplasma gondii</i>
Adenovirus	Bacteria
Mycobacteria	<i>Streptococcus</i>
<i>M. tuberculosis</i>	<i>Staphylococcus aureus</i>
<i>M. avium</i>	<i>Haemophilus influenzae</i>
<i>M. kansasii</i>	<i>Legionella</i>
Fungi	<i>Nocardia</i>
<i>Histoplasma</i>	MALIGNANCY
<i>Cryptococcus</i>	Lymphoma
<i>Coccidioides</i>	Kaposi's sarcoma
<i>Candida</i>	PNEUMONITIS
	Lymphoid interstitial pneumonitis

TABLE 192.2. Common Causes of Pulmonary Involvement in AIDS

The physical examination itself is not likely to aid in establishing a diagnosis. Patients with fever and productive cough are likely to have a bacterial pneumonia, whereas a nonproductive cough is more likely to accompany PCP, CMV pneumonia, fungal infection, or neoplasm. Hemoptysis is most often associated with pneumococcal pneumonia and tuberculosis (TB). Fulminant respiratory failure is most likely to be caused by PCP or CMV.

Evaluation of HIV-infected patients who present with pulmonary complaints should generally include pulse oximetry and chest radiograph; additional testing that may be helpful includes a complete blood cell count, electrolyte determination, arterial blood gas analysis, serum lactate dehydrogenase, sputum culture, Gram stain, and special stains (Gomori, Giemsa, acid-fast). Obtaining blood cultures may avoid delays in initiating antimicrobial therapy.

Findings of leukocytosis and focal infiltrates on plain chest radiography suggest bacterial pneumonia. A diffuse infiltrative process on chest radiography, especially in the absence of leukocytosis, is associated with PCP or CMV. PCP is suggested by an increased serum lactate dehydrogenase level and hypoxia more severe than expected from radiographic findings. Hilar adenopathy with diffuse pulmonary infiltrates suggests cryptococcosis, histoplasmosis, mycobacterial infection, or neoplasm. KS can present with cough, fever, and dyspnea; the chest radiograph may mimic that seen with PCP. PCP can be demonstrated by histologic techniques (Gomori, methenamine silver, or Giemsa stain) but cannot be cultured.

PCP is the most common opportunistic infection among AIDS patients. More than 70% of AIDS patients will acquire PCP at some time during their illness, and it is the initial opportunistic infection in 60% of cases. Although typically seen in HIV-infected adults with CD4 lymphocyte counts below 200/ μ L, pediatric cases may be seen with higher CD4 counts.

Classic presenting symptoms of PCP are an insidious cough (typically nonproductive), dyspnea, and fatigue. A determined investigation of new or subtle symptoms may lead to an early diagnosis, which, in turn, may lead to a better outcome. Typical chest radiographic findings are diffuse interstitial infiltrates. Atypical x-ray findings are more common in patients with CD4 counts less than 100 cells/ μ L, and negative chest x-rays have been reported in up to 20% of patients with PCP.⁶ Up to 10% of patients with PCP have been found to have pneumothoraces. In patients with PCP, arterial blood gas analysis may show hypoxemia and an increased alveolar-arterial oxygen gradient.

In the ED, a presumptive diagnosis of PCP is often made if there is hypoxia without any other explanation. Although bronchoscopy (bronchoalveolar lavage, brush biopsy, transbronchial biopsy) has been the mainstay of establishing the diagnosis, examination of induced sputum by indirect immunofluorescent staining using monoclonal antibodies has been shown to be a relatively easy and effective method of diagnosing PCP.

When PCP is suspected, treatment should be initiated without waiting to obtain a definitive diagnosis. Initial treatment is with 15 mg/kg/d of trimethoprim (TMP) and 75 mg/kg/d of sulfamethoxazole (SMZ), given either orally or intravenously in two to three daily divided doses for a total of 3 weeks. Intravenous pentamidine isethionate (4 mg/kg/d) is an alternative and equally efficacious initial choice for patients with adverse reactions (typically rash, fever, or neutropenia) to TMP/SMZ. Systemic corticosteroid treatment is recommended for patients with a PaO₂ less than 70 mm Hg, or an alveolar-arterial gradient of more than 35 mm Hg. Prednisone may be administered in a dose of 80 mg for 5 days, followed by 40 mg for 5 days, followed by 20 mg for an additional 11 days. Prophylactic therapy for PCP (with TMP/SMZ 1 DS PO qd) is recommended to prevent reinfection, and in all patients with CD4 cell counts less than 200 cells/ μ L.

The incidence of *M. tuberculosis* in HIV-infected patients is increasing, particularly in socioeconomically disadvantaged groups, including the homeless, immigrant, and intravenous drug-using populations. The incidence of TB in the AIDS population is estimated to be 200 to 500 times that of the general population.¹⁹ Disease may occur from reactivation of prior infection or direct progression of disease from recently acquired infection. Because less immunosuppression is required to reactivate infection of this organism than that required to permit other opportunistic infections to become established, pulmonary TB may be the initial finding in HIV-infected patients, frequently occurring in patients with CD4 counts of 200 to 500 cells/ μ L.

Classic presenting symptoms of TB include cough (with hemoptysis), fever, nightsweats, and weight loss. In patients with severe immunosuppression, clinical manifestations are increasingly atypical, and extrapulmonary findings may occur. Frequent sites of dissemination include peripheral lymph nodes, bone marrow, and the genitourinary system. Typical pulmonary upper lobe lesions are less common in those with CD4 counts less than 200 cells/ μ L, and the chest radiograph may be indistinguishable from those due to a variety of other opportunistic infections.⁵

In the ED, physicians should maintain a high index of suspicion for TB among HIV-infected patients with pulmonary symptoms. For any patient in whom the diagnosis is being considered, immediate isolation should be instituted because of the high rate of person-to-person transmission.²⁰ Decisions for ongoing isolation and admission should be based on the results of chest x-ray and detailed historic and clinical information. Negative PPD tests are frequent among those infected. Attempts to diagnose TB by stain and culture of sputum may not be fruitful; bronchoscopy or biopsy of affected organs (e.g., lymph nodes, liver, brain) may be

required. Patients with AIDS with TB should receive four-drug initial empiric therapy with isoniazid, rifampin, pyrazinamide, and streptomycin. All HIV-infected patients with a positive PPD should receive isoniazid or rifampin prophylaxis.

In HIV-infected patients, the most common pulmonary infections are nonopportunistic bacterial pneumonias, such as *Streptococcus pneumoniae*, *Mycobacterium pneumoniae*, and *Haemophilus influenzae*. In patients with severe immunosuppression, other pulmonary infections to consider include CMV infection, cryptococcosis, histoplasmosis, aspergillosis, and coccidioidomycosis. Malignancies, particularly KS and lymphoma, may also cause pulmonary involvement.

In patients with pulmonary symptoms who fall into high-risk groups but who do not carry a diagnosis of HIV infection, careful evaluation is nonetheless warranted. If initial ED tests (chest radiography, sputum examination, arterial blood gas analysis) are not helpful, the patient should be referred (or admitted, if warranted) for voluntary HIV testing, counseling, and follow-up. Disposition decisions for patients with pulmonary complaints are primarily dependent on respiratory status, oxygenation, and evidence of systemic toxicity.

Neurologic Involvement

CNS disease occurs in 90% of patients with AIDS, and 10% to 20% of AIDS patients initially present with CNS symptoms.^{11,15} A wide variety of symptomatology may be seen, including altered mental status, coma, seizures, headache, and focal neurologic symptoms. Infection accounts for the vast majority of neurologic presentations and is often accompanied by fever. Noninfectious complications include HIV encephalopathy (AIDS dementia complex), lymphoma (primary and secondary), KS, intracerebral hemorrhage, subarachnoid hemorrhage, cerebral infarction, and cerebral edema.

A specific diagnosis may often be established with the aid of computed tomographic (CT) scanning, cerebrospinal fluid (CSF) studies, and, in some cases (e.g., lymphoma), biopsy. Patients with known HIV infection and those in high-risk groups who have a change in mental status, headache (new or different from previous pattern), seizure, or new neurologic finding should have a head CT performed on an emergent basis.²³ Lumbar puncture is also indicated unless there is a clinical contraindication. Specific CSF studies should include measurement of opening and closing pressures; cell count; glucose; protein; Gram stain; India ink stain; bacterial, viral, and fungal culture; and toxoplasmosis, cryptococcus, and coccidioidomycosis titers.

Toxoplasma gondii is the most common cause of focal encephalitis in patients with HIV infection. Typical manifestations include headache, confusion, lethargy, seizures, or other focal neurologic symptoms. Serologic testing is not useful because antibody to *T. gondii* is prevalent in the general population; the presence of *T. gondii* in the CSF is helpful, although there is a high rate of false negatives. Diagnosis is usually made by a contrast-enhanced head CT scan showing one or more ring-enhancing lesions associated with edema (Fig. 192.1).

Figure 192.1. Contrast-enhanced CT scan with typical ring-enhancing lesions of cerebral toxoplasmosis.

A noncontrast CT scan can be used as an initial imaging study in the ED, because the addition of contrast has been shown to be of marginal value in patients with completely normal noncontrast CT scans. The typical appearance of toxoplasmosis on a noncontrast scan is multiple subcortical lesions, with a predilection for the basal ganglia. In cases in which the clinical suspicion for CNS pathology is high but the CT scan is equivocal or negative, contrast CT should be performed in the ED. The finding of multiple ring-enhancing lesions with surrounding edema is highly suggestive of toxoplasmosis.

Magnetic resonance imaging is slightly more sensitive than contrast CT but is usually not indicated in the ED. Patients with suspected toxoplasmosis should be admitted and treated with sulfadiazine (4 to 8 g/d) and pyrimethamine (100 to 200 mg load, then 50 to 100 mg/d). Folinic acid may be added to blunt hematologic megaloblastic toxicity. Short courses of high-dose corticosteroids may also be used, particularly in cases in which significant edema or mass effect is noted. Presumptive treatment may be initiated before a definitive diagnosis is made. In cases in which the patient does not respond to therapy, alternative diagnoses should be considered.

Other focal lesions on CT that may be confused with toxoplasmosis include lymphoma, progressive multifocal leukoencephalopathy, and *Candida*. Definitive diagnosis may require biopsy. For those patients who respond to therapy, chronic suppressive treatment for toxoplasmosis is usually indicated because of the high likelihood of relapse.

Cryptococcus neoformans occurs in up to 10% of AIDS patients and may cause either focal cerebral lesions or diffuse meningoencephalitis. Presenting symptoms may be subtle (e.g., mild depression, headache, or dizziness without meningismus) but are often dramatic (e.g., cranial nerve palsies and seizures). The diagnosis depends on identifying organisms in the CSF by India ink preparation (60% to 80% sensitive), fungal culture (95% to 100% sensitive), or cryptococcal antigen (nearly 100% sensitive and specific). Serum cryptococcal antigen is also useful, but has a lower sensitivity (approximately 95%) than CSF cryptococcal antigen.²⁸

Treatment of cryptococcal meningitis usually begins with intravenous amphotericin B (0.5 to 0.6 mg/kg/d), with or without 5-flucytosine, for 14 days. Fluconazole, 400 mg/d orally, or itraconazole may be considered as alternative therapies. The initial course of therapy should be followed by 8 to 10 weeks of oral fluconazole. Because of the high relapse rate (about 50%), chronic suppressive therapy is often continued after successful treatment. The major adverse effect of treatment for cryptococcal meningitis is marrow suppression.

Other infections, such as bacterial meningitis, TB meningitis, aseptic meningitis, brain abscess, CMV encephalitis, herpes simplex virus (HSV) encephalitis, aspergillosis, nocardial encephalitis, and neurosyphilis, may also be considered as possible causes of neurologic symptoms. Noninfectious CNS processes include CNS lymphoma, cerebrovascular accidents, metabolic encephalopathy, and AIDS dementia complex (HIV encephalopathy).

AIDS dementia is a common, progressive disorder characterized by impaired memory, lethargy, concentration difficulties, and other cognitive impairment. After other organic causes of neurologic symptoms are ruled out, the diagnosis of HIV encephalopathy may be made on the basis of neuropsychologic testing. CT scan typically shows atrophy and ventricular enlargement. HIV encephalopathy often responds to zidovudine therapy.

HIV-infected patients with new or changed CNS symptoms or signs should be considered for hospital admission, particularly if the ED evaluation is unrevealing. CT scan and lumbar puncture should usually be performed as part of the ED evaluation, although CSF culture and serologic results will not be available immediately. When CT and all CSF studies are unrevealing, magnetic resonance imaging may be helpful in identifying early CNS lesions.

Peripheral neuropathies are common in the HIV-infected population and may be caused by HSV, mononeuritis multiplex (possibly related to multifocal CMV), idiopathic sensory neuropathy, or drug reactions (specifically to dideoxyinosine and dideoxycytidine). In certain patients, symptomatic relief with pain-modifying agents such as amitriptyline or phenytoin may be helpful, although these agents should be used judiciously because of their potential for causing delirium in patients with concurrent HIV dementia. Narcotic analgesia may be indicated in severe cases.

Gastrointestinal Involvement

About one-half of all AIDS patients have symptoms due to infection of the gastrointestinal tract at some time during the course of their illness. The most common symptoms are abdominal pain, bleeding, and diarrhea. [Table 192.3](#) contains a partial list of common etiologies of gastrointestinal infections.

BACTERIA	PARASITES
Salmonella	Cryptosporidium
Shigella	Isospora belli
Campylobacter	Entamoeba histolytica
Neisseria gonorrhoeae	Giardia
	Strongyloides
VIRUSES	FUNGI
Cytomegalovirus	Candida
Herpes simplex virus	
Adenovirus	

TABLE 192.3. Common Gastrointestinal Infections in AIDS

Oropharynx

Oral candidiasis is the most common oral manifestation of HIV infection and affects more than 80% of AIDS patients. *Candida albicans* typically involves the tongue and buccal mucosa. It can be distinguished from hairy leukoplakia by its characteristic whitish, lacy plaques, which are easily scraped away from an erythematous base. Microscopic examination of the material on potassium hydroxide smear can confirm the diagnosis in the ED. Oral and esophageal involvement with *Candida* is considered predictive of a progressive course of HIV infection. Most oral lesions can be managed symptomatically on an outpatient basis, with topical treatment such as clotrimazole troches, 10 mg five times daily. Oral ketoconazole or fluconazole may be considered for refractory cases.

Painful oral and perioral ulcerations may be caused by HSV, which can be recognized by typical vesicular lesions and diagnosed in the ED by the identification of multinucleated giant cells in scrapings of the lesions. Oral HSV may be treated with acyclovir, 200 to 800 mg five times daily. Topical acyclovir is not effective.

Oral KS may appear as nontender, well-circumscribed, slightly raised, violaceous lesions anywhere in the oropharynx. Definitive diagnosis and therapy should be carried out by a consultant.

Hairy leukoplakia, thought to be caused by the Epstein-Barr virus, causes a benign epithelial thickening and typically involves the lateral borders of the tongue. The tongue may appear to have hairlike projections. Because it is usually asymptomatic and benign, no specific therapy is necessary.

Esophagus

Complaints of dysphagia or odynophagia are indicative of esophageal involvement. Candidal infection, HSV infection, and CMV infection may all cause painful esophagitis. Treatment of esophagitis in the ED is usually presumptive for *Candida*, which accounts for up to 70% of cases. Oral ketoconazole (100 to 200 mg/d) or fluconazole (200 to 400 mg/d) is equally efficacious. An air-contrast barium swallow may be obtained as part of the ED evaluation. An ulcerative pattern with plaques is characteristic of candidal esophagitis. HSV esophagitis typically produces easily seen punched-out ulcerations without associated heaped-up plaques. Endoscopy, fungal stains, viral cultures, and, occasionally, biopsy may be required to establish the definitive etiology.

Liver and Biliary Tract

Viral hepatitis occurs commonly among HIV-infected patients, and standard serologic testing and supportive care are indicated. Several opportunistic organisms, including CMV, *M. avium*, *M. tuberculosis*, and *Histoplasma*, can produce a hepatitis-like picture in patients with HIV infection. Most commonly, the patient presents with an elevation in the alkaline phosphatase level that is disproportionate to the levels of other liver enzymes.

Acalculous cholecystitis may be seen as a result of infection with CMV or *Cryptosporidium*.

Rectum

Anorectal disease is common in AIDS patients. Proctitis is characterized by painful defecation, rectal discharge, and tenesmus. Common causative organisms include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, syphilis, and HSV. Proctocolitis presents with the same symptoms but is accompanied by diarrhea. Typical causative organisms include those just listed, plus bacterial agents such as *Shigella*, *Salmonella*, *Campylobacter*, and *Entamoeba histolytica*. Diagnostic evaluation in the ED should include anoscopy with evaluation of stool or pus (or both) by Gram stain, culture, and testing for ova and parasites. A Thayer-Martin culture and chlamydial culture or immunoassay should be ordered. The diagnosis of rectal gonorrhea can be confirmed on a Gram stain of stool by the presence of leukocytes and intracellular organisms. HSV can be diagnosed by viral culture or by the identification of multinucleated giant cells on scrapings of anal lesions.

Diarrhea

Diarrhea is extremely common among AIDS patients, and may vary in severity from a few loose stools per day to massive fluid loss with prostration, fever, chills, and weight loss. ED evaluation should be directed toward stabilization, hydration, and laboratory studies, including cultures.

The differential diagnosis of diarrhea in the HIV-positive population is broad. Common identified etiologies include bacterial infections caused by *Salmonella*, *Shigella*, and *Campylobacter* species; viral infections, such as those from CMV, rotavirus, and Norwalk agent; fungal infections, such as histoplasmosis and candidiasis; and parasitic infections, such as *Giardia*, *Cryptosporidium*, and *Isospora belli*. Although a definitive diagnosis is usually not made in the ED, certain patterns may provide clues regarding the most likely etiology. Bacterial pathogens tend to follow an acute and fulminant course, while parasitic infections are more often indolent. Significant gastrointestinal bleeding has been associated with many pathogens, particularly CMV. *Cryptosporidium* and *Isospora* are associated with profuse, watery diarrhea. The most common agents in end-stage disease are CMV and *M. avium-intracellulare*.

The stool should be examined for leukocytosis, ova and parasites, and bacterial culture. When ordering stool cultures, it is important to specify which organisms are suspected, because not all are routinely cultured. The diagnosis of infection with mycobacteria, *Cryptosporidium*, and *Isospora* is made by acid-fast stain. Because of intermittent shedding, repeated examination of the stool for trophozoites, cysts, and larvae is often necessary to diagnose *Cryptosporidium* and *Isospora*, as well as amebiasis, giardiasis, and strongyloidiasis.

In general, patients who can tolerate oral intake and are not orthostatic may be discharged from the ED, with outpatient follow-up of test results. If bacterial infection is strongly suspected, empiric treatment with an antibiotic such as ciprofloxacin can be initiated. Patients who present with severe diarrhea may benefit from symptomatic therapy with agents such as attapulgite (Kaopectate), psyllium (Metamucil), and, if necessary, diphenoxylate hydrochloride with atropine (Lomotil).

Dermatologic Involvement

Skin disease may affect up to 90% of HIV-infected patients. Several cutaneous manifestations of AIDS are likely to be seen in the ED; cutaneous infection, dermatitis,

and neoplasms are the most common. Viral infections may include HSV, herpes zoster, papillomavirus infection, and molluscum contagiosum.

HSVs are common in AIDS patients and can present as either a localized infection or systemic disease. Localized infections respond well to standard therapy with oral acyclovir (200 mg five times daily for 10 days). Intravenous therapy (15 to 30 mg/kg/d) may be required in cases of extensive disease. Reactivation of varicella zoster virus occurs more frequently in patients with HIV compared with the general population. The clinical course is prolonged, and complications are more common. In patients with single dermatomal involvement who are not significantly immunosuppressed, outpatient treatment with acyclovir (800 mg PO five times a day) or famciclovir (500 mg PO three times a day) for 7 days is usually sufficient. Patients with disseminated disease or ophthalmic zoster should be admitted to isolation beds for intravenous acyclovir.

Papillomavirus infection is manifested as warts, which may appear in various areas. Treatment may be initiated with topical salicylic acid, and referral to a dermatologist is generally indicated.

Molluscum contagiosum lesions are typically clusters of white umbilicated papules. Unless of cosmetic significance, molluscum lesions are considered benign, and treatment is not mandatory. If desired, referral to a dermatologist may be made for consideration of such therapy as cryosurgery or curettage.

Bacterial infections, such as staphylococcal infections (e.g., folliculitis, impetigo, cellulitis), are seen with increased frequency. Therapy involves standard antibiotic treatment, although the duration of treatment may need to be increased.

Several fungal infections are commonly seen. Dermatophyte infections, such as tinea corporis, tinea pedis, and tinea cruris, should be treated with topical antifungal agents such as miconazole or clotrimazole. Tinea versicolor should be treated with topical selenium sulfide. *C. albicans* infection may involve the oral, esophageal, nail, inguinal, and perianal areas with increased frequency. Treatment for mucosal infection is discussed in the section on gastrointestinal involvement; treatment for cutaneous infection may consist of topical antifungal agents such as clotrimazole or, in severe cases, oral ketoconazole, fluconazole, or intravenous amphotericin B.

Other types of dermatitis are also commonly seen. Seborrheic dermatitis manifests as erythematous scaly eruptions typically involving the nasolabial folds, cheeks, and chest, and is treated with a topical corticosteroid preparation. Diffuse xerosis (dry skin) and pruritus are common among HIV-infected patients. Treatment with topical emollients, oatmeal baths, and oral antihistamines such as diphenhydramine or hydroxyzine may be of benefit.

The most common cutaneous neoplasm is KS, which has involved approximately 25% of known AIDS cases, occurring most often in homosexual men. KS typically presents as raised, irregular, nonblanching, brown-black or purple macules or nodules. Cutaneous KS is generally not associated with significant morbidity or mortality; palliative therapy is indicated only for extensive, painful, or cosmetically disfiguring lesions. In addition to cutaneous involvement, KS may also involve the gastrointestinal tract, lungs, liver, spleen, and heart. Treatment may include antiretroviral therapy, radiation therapy, and chemotherapeutic agents.

Psychiatric Issues

HIV-infected patients may present with a variety of social and emotional issues, complicated by neuropsychiatric and cognitive components. Some of the common psychiatric conditions include depression, bipolar disease, suicidal ideation, anxiety, and adjustment disorder. Patients with depression tend to have lower CD4 counts, and they report more AIDS-related symptoms. All psychiatric symptoms should be evaluated with the goal of identifying treatable, reversible conditions, such as neurologic lesions or drug reactions.¹⁶ Many patients will benefit from initiation of pharmacologic therapy in conjunction with social intervention and support. Suicidal potential should be taken seriously, particularly in patients who have limited social support; management at an inpatient facility is often required.

Ophthalmologic Manifestations

Eye complaints are common among patients with AIDS. Although a wide range of ophthalmic disease can occur, recognition of two is critical for the emergency physician.

CMV retinitis is the most serious ocular opportunistic infection and the leading cause of blindness in patients with AIDS, occurring in up to 40% of patients at some time during their illness. Presenting complaints are variable and may include changes in visual acuity, photophobia, scotoma, visual field cuts, eye redness, or pain. Funduscopic examination typically shows fluffy white perivascular lesions with areas of hemorrhage. These findings may be easily confused with retinal cotton wool spots, a benign lesion with no prognostic significance seen in patients with AIDS (indicative of retinal microvasculopathy). Because of the risk of blindness associated with CMV retinitis, any patient in whom there is suspicion of CMV retinitis requires immediate ophthalmologic consultation. Patients with CMV require immediate treatment to prevent progression of disease. The treatment regimen consists of induction therapy with intravenous ganciclovir (5 mg/kg every 8 hours for 14 to 21 days), followed by 6 mg/kg/d, oral or intravenous.

Herpes zoster ophthalmicus is another common cause of ocular damage in patients with HIV. The typical presentation is pain or paresthesia in the distribution of cranial nerve V₁, followed by the emergence of the vesicular zoster skin rash. Complications include conjunctivitis, episcleritis, iritis, kera-titis, secondary glaucoma, and, rarely, retinitis. As with CMV, early recognition and treatment can prevent morbidity. Immunocompetent patients can be treated with acyclovir on an outpatient basis in consultation with ophthalmology; immunocompromised patients require admission for intravenous antibiotics.

Other Organ Systems

Several sexually transmitted diseases (STDs) are epidemiologically associated with HIV infection. Diseases causing genital ulcers are believed to provide vascular portals of entry for HIV. Increased STD surveillance in the ED has been recommended as a potential means to help control HIV transmission.^{5,27}

Patients presenting with any symptoms suggestive of a possible STD should be evaluated for gonorrhea, chlamydia, and herpes. Serologic testing for syphilis with rapid plasma reagin (RPR) or Venereal Disease Research Laboratories (VDRL) tests should also be performed. Careful consideration should be given to identify patients with serologic false-negative results due to a lack of normal antibody response. In such cases, in which syphilis is clinically suspected, dark-field microscopy and direct fluorescent antibody staining from suspicious lesions may be undertaken. Empiric therapy may be instituted even without laboratory evidence of infection.

Primary (chancre) and secondary (rash, mucocutaneous lesions, adenopathy) syphilis should be treated with a single intramuscular dose of benzathine penicillin, 2.4 million U; latent syphilis, or secondary syphilis of unknown duration, requires three weekly injections. Patients with known or suspected syphilis should be evaluated for the presence of neurosyphilis, which has had a recent increase in incidence among HIV-infected individuals.

Renal complications of HIV include HIV-associated nephropathy, prerenal azotemia, vasculitis, drug reactions, and systemic infections. Renal involvement is often discovered incidentally on laboratory analysis, but initial ED presentations may include general malaise, edema, or oliguria. Because of the complexity of these disorders, management in consultation with a nephrologist or primary care provider is generally indicated.

Clinically significant cardiac involvement with HIV-related conditions is uncommon. Cardiac findings at autopsy in AIDS patients include cardiomyopathy, myocarditis, endocarditis, and pericardial effusion.

Antiretroviral Therapy

In 1996, the CDC reported a decline in the number of new AIDS cases and AIDS-related deaths for the first time since the beginning of the epidemic, attributed in large part to the use of antiretroviral therapy. Although not commonly instituted in the ED, antiretroviral therapy is an important aspect of management of HIV-infected patients.

Zidovudine (AZT) is a thymidine analog that inhibits the replication of HIV by interfering with the action of viral RNA-dependent DNA polymerase (reverse transcriptase). It is the first antiviral agent to have demonstrated clinical benefit, delaying progression to AIDS and decreasing mortality in patients with AIDS. Oral absorption is good, serum concentrations that inhibit viral replication are easily obtainable, and the drug is able to cross the blood-brain barrier to attack virus in the CNS. In several controlled trials, zidovudine has been shown to decrease the number and severity of opportunistic infections, as well as to improve general health and survival. Recent studies have shown that combination therapy, with two nucleoside reverse transcriptase inhibitors and a protease inhibitor, results in maximal

clinical efficacy.²⁴ A large number of antiretroviral medications and combination regimens are currently prescribed.

Antiretroviral therapy is generally considered in patients with CD4 cell counts of less than 500 cells/ μ L, because the goal is to reduce viremia, bolster the CD4 cell count, and delay the onset of opportunistic infections. Treatment strategies are tailored to the individual patient, however, with attention to a variety of issues, including suppression of viral replication, preservation of immune function, drug side effects, drug interactions, and patient preference. Any decision regarding initiation and change in antiretroviral medications should be made in consultation with the patient's primary care provider or an infectious disease consultant.

Adverse Drug Reactions

Adverse drug reactions occur commonly among HIV-infected patients. These patients tend to be on multidrug therapy and, in addition, appear to have an increased risk of adverse effects. It is useful to be familiar with several of the most common adverse drug reactions in HIV-positive patients. TMP/SMZ reactions occur in up to 65% of AIDS patients, significantly more commonly than in the general population. Adverse effects generally become apparent after 7 to 14 days of therapy; the most common are nausea, vomiting, rash, fever, neutropenia, thrombocytopenia, hyponatremia, and hepatitis. Pentamidine can cause nausea, vomiting, diarrhea, neutropenia, hypoglycemia, hyperglycemia, renal impairment, hepatic toxicity, and orthostatic hypotension; about 50% of patients experience at least one adverse effect. AZT has been associated with several severe reactions, including anemia, neutropenia, headache, nausea, cardiomyopathy, and myopathy. Common etiologies of neurologic and psychiatric effects include therapy with acyclovir, amphotericin, corticosteroids, ganciclovir, pentamidine, TMP/SMZ, and zidovudine.

Drug reactions should be considered in the evaluation of all patients, and decisions to alter pharmacologic management should be made on an individual basis and in conjunction with the primary care provider. Review of current references and consultation with a hospital pharmacologist are indicated when drug reactions are suspected.

DISPOSITION

Disposition decisions for HIV-infected patients are based, as for any patient, on clinical condition, the availability of outpatient resources, and the ability to arrange adequate follow-up.

Patients who are known to be seropositive for HIV but who are not admitted to the hospital should be referred for follow-up, or for medical consultation and counseling if they do not have an established source of care. It has been found useful for each institution to have arranged appropriate mechanisms for these referrals. Patients who have symptoms or signs suggestive of HIV infection (e.g., weight loss, generalized adenopathy, chronic diarrhea, oral thrush) but who do not require admission should also receive similar referral.

Although the AIDS epidemic has raised grave concerns regarding the economic impact of the disease, financial considerations should not be a factor in determining management or disposition. General considerations related to discharge and admission decisions are listed in [Table 192.4](#). When there is doubt about diagnostic or management options, consultation with an infectious disease specialist, neurologist, psychiatrist, AIDS specialist, or others is appropriate.

Conditions Suggesting Admission	Conditions for Considering Discharge
New presentation of fever of unknown origin	Normal or baseline vital signs
Hypoxemia (worse than baseline) (PaO ₂ <60)	Stable medical condition
Suspected PCP	Able to take PO/not orthostatic
Suspected tuberculosis	Follow-up and referral arranged
New CNS symptoms	Patient or caregiver understands instructions
Intractable diarrhea	Patient, caregiver, or hospice able to care for patient
Suicidality	
Suspected CMV retinitis	
Zoster ophthalmicus	
Cachexia/weakness	
Unable to care for self or receive adequate care	
Unable to assure appropriate follow-up	

TABLE 192.4. Considerations for Disposition Decisions for HIV-Infected Patients

ETHICAL CONSIDERATIONS

Some experts contend that in the advanced stages of AIDS, major resuscitative measures are not appropriate because of the uniformly poor prognosis. Many patients may agree as they approach the terminal stages of their disease. However, decisions regarding the withholding of extraordinary resuscitation efforts are difficult to make in the ED, because the emergency physician is rarely in possession of sufficient information about individual patients, their wishes, the state of their disease, and the judgment and intentions of their physicians. In general, when confronted with a patient with AIDS, it is best to take the same actions that would otherwise be taken with any other patient, unless an advance directive is available, indicating that resuscitative efforts should be withheld.

Confidentiality is paramount in the care of patients with HIV-related diagnosis. Extra attention must be paid to this issue in the ED, where busy and crowded conditions make this aspect of patient care more challenging.

The management of patients with nonoccupational exposure to HIV (e.g., through sexual contact or injection drug use) may become a problem that will increasingly confront emergency physicians. Although clear guidelines exist regarding postexposure prophylaxis (PEP) following occupational exposure (discussion follows), the CDC has withheld making definite statements regarding PEP for nonoccupational exposure, owing to the lack of available data in this setting. PEP must, therefore, be considered on a case-by-case basis, and should generally be restricted to situations in which the risk of infection is high, the intervention can be initiated promptly (less than 36 hours), adherence to the regimen is likely, and the individual is most likely to maintain risk-reduction behavior over time. If the emergency physician is confronted with a case in which PEP is being considered, consultation should be sought with the patient's primary care provider (when available), an infectious disease specialist, or the CDC (via a 24-hour physician hotline: PEP Hotline, 1-888-448-4911).

PREVENTION/PRECAUTIONS

Health-care workers are often exposed to the blood and body secretions of AIDS patients or of other individuals who are at high risk of harboring the AIDS virus. Because there is no cure for AIDS at this time, the best strategy is to take proper precautions in handling potentially infectious body fluids. It should be noted, however, that the risk of acquiring HIV through occupational exposure appears to be very low. The rate of HIV infection after parenteral exposure has been calculated to be 0.32% (representing six infections in more than 2008 needlesticks involving HIV-infected blood).¹⁸

Several studies have shown that a substantial number of patients in the ED have unsuspected HIV infection and that HIV seroreactivity cannot be accurately predicted, even with the aid of risk factor assessment.²¹ Because asymptomatic individuals who are HIV-antibody-positive can transmit the disease, *all* contacts with patients' blood or body secretions must be considered potentially infectious by ED personnel. Even if HIV is not suspected in a particular patient, the possibility of other blood-borne infections mandates the use of universal precautions with all patients when contact with body fluids is likely.^{10,12}

HIV is a very labile virus. It is easily neutralized by heat and common disinfecting agents, such as 50% ethanol, 35% isopropyl alcohol, 0.3% hydrogen peroxide, Lysol, and a 1:10 solution of household bleach. Routine disinfection of surfaces that have come in contact with body fluids should be effective.

Although there is one unusual instance of HIV transmission from a dentist's practice to patients, evidence indicates that the risk of transmission of HIV infection to patients by health-care workers is extremely low, if present at all. Although still controversial, the debate concerning HIV-infected health-care workers, their ability to continue to work, and notification of patients possibly at risk has diminished, owing to the lack of further documented transmissions. Thus, routine screening of health-care personnel for HIV infection is not indicated. However, because HIV can potentially be transmitted to patients through contact with infected blood, body

fluids, or secretions, the infected health-care worker should protect against exposing the patient to these sources of virus.

Guidelines for PEP of health-care workers following an occupational exposure have recently changed. The new policies are based on a recent case-control study of needlestick injuries from an HIV-infected source, which found that AZT prophylaxis was associated with a 70% reduction in transmission.¹ PEP recommendations are based on exposure category, with the highest risk injuries associated with deep punctures and injuries caused by large-bore hollow needles.

Treatment regimens vary by type of exposure; all include AZT and 3TC.³ Decisions should generally be made in consultation with an infectious disease specialist. Treatment should be initiated as quickly as possible, however, preferably within 1 to 2 hours. Antiretroviral therapy is not indicated in patients presenting more than 36 hours after exposure. Care of the exposed individual should include baseline testing, with follow-up testing at 6 weeks, 3 months, 6 months, and 1 year after the exposure. The exposed person should also be referred for counseling, which should include advice to practice safe sex. Documentation of the risk factors and HIV status of the source is also helpful.

Each hospital should have policies in place regarding testing of a source patient in cases of occupational exposure. When policies on HIV testing are developed, certain principles should be considered. There should be a mechanism for obtaining permission from the source patient. Special policies may be necessary for patients who are unable to give consent (e.g., unconscious patients). Provisions should be made for informing source patients of test results, and counseling should be made available. Confidentiality should be rigorously protected while still ensuring that the appropriate information is provided to the exposed individuals. Finally, the identification of a seropositive patient should not affect the delivery of appropriate health care.

COMMON PITFALLS

- Failure to recognize undiagnosed infection. Because patients often may not volunteer information regarding HIV risk factors, this information must be actively sought whenever a patient with possible opportunistic infection or other symptoms suggestive of HIV infection (e.g., weight loss, fever) is being treated.
- Failure to fully evaluate complaints of fever, headache, and shortness of breath in HIV-positive patients who appear well. Fever may indicate systemic infection; blood cultures should be obtained, even in patients who appear nontoxic. Chronic low-grade headache or headache different from a patient's usual pattern of headache may be suggestive of CNS infection or malignancy; a head CT and lumbar puncture are indicated in such patients. Subjective shortness of breath may be the only early sign of PCP.

CHAPTER 193

Spinal Infections

Ellen H. Taliaferro and Allan B. Wolfson

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Vertebral osteomyelitis and epidural abscess are uncommon but devastating conditions that are easily overlooked in a busy emergency department. If undetected and untreated, they can result in vertebral collapse, cord compression, and paralysis.

The vertebral column is the most common site of hematogenous osteomyelitis in the adult, and most cases of vertebral osteomyelitis are blood-borne. Identifiable sites of antecedent infection include the genitourinary tract, soft tissues, the respiratory tract, infected vascular prostheses, and heart valves.¹² No source can be identified in approximately one-third of cases. Vertebral osteomyelitis can also occur by direct extension (e.g., from a retropharyngeal abscess) or by direct contamination (e.g., from trauma or after vertebral disc surgery).

Most patients with vertebral osteomyelitis fall into one of the following high-risk groups: patients older than the age of 50, intravenous drug users, and other immunocompromised individuals, including diabetics and alcoholics. Vertebral osteomyelitis is also reported occasionally in patients with sickle cell disease.⁶ The incidence of spinal infection appears to be increasing in association with increases in intravenous drug use, iatrogenic immunosuppression, and the use of indwelling vascular and urinary catheters.

Pyogenic vertebral osteomyelitis in adults is most commonly caused by *Staphylococcus aureus* and *Escherichia coli*.^{24,7,10,12} In intravenous drug users, the most common organisms are *Pseudomonas aeruginosa*, other gram-negative bacilli, *S. aureus*, and *Candida* species.⁴ In the past, tuberculosis was a common cause of vertebral osteomyelitis (Pott disease), but the advent of effective antituberculous drugs has greatly reduced its role as a cause of this infection.

When osteomyelitis occurs by hematogenous spread, the richly vascularized flat bone adjacent to the disc cartilage is probably the first area involved (discitis).^{4,8} Extension can occur longitudinally to other vertebrae or anteriorly to form a paraspinal abscess. When a disc and adjacent vertebral body have been destroyed, there may be vertebral collapse and kyphosis. Posterior extension can lead to meningitis or to epidural abscess and neurologic deficits such as paraplegia.

The introduction of antibiotics has changed the natural history of osteomyelitis. Early, aggressive treatment results in a high cure rate. With delayed or unsuccessful treatment, vertebral osteomyelitis may result in complications such as vertebral collapse, epidural abscess, cord compression, or vascular thrombosis.

CLINICAL PRESENTATION

Patients with vertebral osteomyelitis classically present with neck or back pain,^{5,12,14} but early manifestations are often more subtle. Fever is commonly absent.^{2,4,10,12} The onset of pain is often insidious; many patients have had back symptoms for months before seeking medical attention. Occasional patients present with an abrupt onset of the disease, however, and run an acute toxic course. Patients with Pott disease often present with nonspecific symptoms, such as fever, weight loss, nightsweats, and neck or back pain and stiffness.¹⁵ Tuberculous osteomyelitis often runs a more indolent course than does pyogenic bacterial vertebral osteomyelitis.

Osteomyelitis most commonly affects the lumbar vertebrae (50% of cases); involvement of the thoracic spine is somewhat less frequent (35%).¹² Localized tenderness over the affected area of the spine is a major warning sign, and neck or back pain not relieved by rest is especially suggestive. Spasm of the paravertebral muscles is common but nonspecific. Some patients have limitation of back motion or a positive straight-leg raising sign.

Cord compression associated with osteomyelitis, reported in up to 40% of patients in some series, can result in irreversible deficits, especially when the compression is not treated surgically.¹⁴ Abnormalities of bladder or bowel function or motor or sensory deficits of the lower extremities are clearly suggestive of spinal cord involvement.

The majority of patients with bacterial spinal epidural abscess also present with neck or back pain, which may have been present from 1 day to 2 months. Other symptoms include radicular pain, weakness of an extremity, sensory deficit, and cord symptoms.

DIFFERENTIAL DIAGNOSIS

Because back pain due to minor trauma or musculoskeletal strain is extremely common, back symptoms in emergency department patients are often attributed to these causes, especially when the symptoms are of relatively short duration. Spinal infection is suggested, however, by persistent pain and tenderness that localizes to one area of the midline, particularly in members of high-risk groups.

A sudden onset of neck or back pain, especially with neurologic signs, suggests a vascular event, such as spontaneous epidural hemorrhage. In sickle cell anemia, the difficulty of diagnosis may be compounded by the simultaneous presence of vasoocclusive complications.⁶

In the early stages, infection can be virtually indistinguishable from other septic conditions or may mimic malignancy. Moreover, it may be difficult to differentiate vertebral osteomyelitis from metastatic disease, severe degenerative changes, or postoperative changes on the basis of either plain films or radionuclide studies alone.

EMERGENCY DEPARTMENT EVALUATION

The emergency department evaluation begins, as always, with a careful history and thorough physical examination; a careful neurologic examination is critical. As noted earlier, localized vertebral tenderness, deformity, or neurologic signs are highly suggestive, particularly if they occur in a patient who is at risk.

Laboratory studies are of limited value. The white blood cell count is often elevated, but this finding is quite nonspecific. The erythrocyte sedimentation rate is nearly always elevated with vertebral osteomyelitis and epidural abscess, often above 100 mm/h. Blood cultures are positive in less than half of patients with vertebral osteomyelitis.^{12,14}

Diagnostic imaging can often provide evidence for the diagnosis but tends to be less revealing in early cases. Plain radiography, often combined with tomography, is usually the initial imaging study ordered. The classic radiographic findings of osteomyelitis are lytic lesions, periosteal elevation, cortical irregularity, and demineralization. As the disease progresses, segments of devascularized and necrotic bone can separate and form sequestra; periosteal reaction and pathologic fracture may occur. In blood-borne vertebral osteomyelitis, the well-vascularized flat bone adjacent to the disc space tends to be involved earliest, and infection of the disc space (discitis) and the adjacent vertebral body follow. Radiographic findings usually do not appear, however, until at least 7 to 14 days after the onset of symptoms, and extensive destruction can occur before radiographic changes become evident.^{9,11}

Computed tomographic scanning or radionuclide studies often reveal evidence of infection when plain radiographs are negative.^{9,10,11} and ¹² Technetium radionuclide scanning is sensitive but nonspecific; gallium scanning is more specific but less sensitive.¹²

Magnetic resonance imaging has superior sensitivity and specificity in detecting osteomyelitis.^{10,11} It has the additional advantage of allowing direct visualization of the intervertebral discs, spinal cord, and soft tissues, making it extremely useful in detecting epidural pathology. Finally, it can differentiate infection from degenerative and neoplastic disease. When enhanced with gadolinium, magnetic resonance imaging readily detects actively inflamed tissues and appears to be the most useful diagnostic test for epidural abscess.^{10,13}

The definitive diagnosis of osteomyelitis rests on the isolation of a pathogen from blood cultures or a bone lesion. Bone biopsy or aspiration is thus necessary for diagnosis if blood cultures are negative.^{12,14} Sinus tracts, when present, should not be cultured, because the organisms that are identified from these sites bear little relation to the results of cultures obtained at surgery.¹⁴

EMERGENCY DEPARTMENT MANAGEMENT

Several factors have helped improve the outcome of vertebral osteomyelitis. They include greater awareness of the disease on the part of clinicians; the increasing availability of radionuclide imaging and magnetic resonance imaging; improved orthopedic techniques; and prophylactic antibiotic regimens for trauma, surgery, and invasive procedures.¹⁴ The use of the newer antibiotics has improved outcomes in established infection as well. In most cases, osteomyelitis can be cured without surgical intervention.¹²

Treatment for osteomyelitis consists of 4 to 6 weeks of parenteral antibiotic therapy, sometimes followed by a prolonged course of oral antibiotics. Immobilization is also an accepted principle of treatment, at least during the initial phases.¹

In view of the prolonged course of treatment that is generally required and the importance of eradicating the causative organism, the initiation of empiric antibiotic therapy in the emergency department is almost never appropriate. Definitive antibiotic therapy must be guided by culture results. In those few instances in which antibiotics might be started empirically before culture results are available, a combination of penicillinase-resistant penicillin and either a third-generation cephalosporin or an aminoglycoside would be a reasonable choice.

The more rapid the onset of symptoms and the more serious the manifestations, the more aggressive the clinician must be both in establishing the diagnosis and in obtaining specimens for culture. When cord compression or other neurologic complications occur, immediate surgical intervention is necessary to decompress the cord and stabilize the spine. Surgery is also indicated for abscess or significant bone necrosis.

DISPOSITION

Patients with suspected spinal infection require admission to the hospital for diagnostic evaluation and initiation of intravenous antibiotic therapy. Orthopedic or neurosurgical consultation is almost always mandatory. Patients with neurologic compromise should be transferred promptly to a tertiary care facility if rapid surgical intervention is not otherwise available.

COMMON PITFALLS

- An indolent spinal infection may be overlooked because of the paucity and nonspecific character of the patient's signs and symptoms. Although uncommon, the diagnosis must be considered in elderly or immunosuppressed individuals with persistent localized pain or tenderness in the neck or back, whether or not neurologic signs are present.
- Delays in treatment lead to a worse outcome.

STAPHYLOCOCCAL TOXIC SHOCK SYNDROME

Toxic shock syndrome (TSS) associated with *Staphylococcus aureus* was originally described in 1978 and was found to be associated with tampon use in young women. The peak reported incidence, in 1980, has been followed by a marked and persistent decline.⁴ Mortality from TSS has also declined—from 10% before 1980 to less than 5% in the early 1980s and to less than 1% in 1989.

Initial studies showed that this illness was associated with the use of new super-absorbent tampons during menses, and that vaginal colonization and infection by *S. aureus* played a major etiologic role. However, nonmenstrual cases of staphylococcal TSS were found in both sexes and in all age groups¹¹ and were associated with surgical procedures such as rhinoplasty, augmentation mammoplasty, liposuction, and burns. Nonmenstrual TSS has also been associated with influenza, sinusitis, tracheitis, intravenous drug use, human immunodeficiency virus (HIV) infection, cellulitis, burn wounds, gynecologic infections, and the postpartum period. The proportion of reported nonmenstrual cases has increased from 7% in 1980 to approximately 50% in recent years.²

A bacterial toxin, toxic shock syndrome toxin-1 (TSST-1), has been isolated in over 90% of menstruation-associated cases.⁸ In contrast, TSST-1 has been detected in only half of the strains isolated in nonmenstrual TSS. Other toxins, such as staphylococcal enterotoxin B (SEB) and enterotoxins A (SEA) and C (SEC), are found in the remaining cases. The exotoxins are thought to be absorbed into the blood through inflamed or injured mucous membranes, leading to the production of cytokines, which produce widespread multisystem clinical effects such as fever, rash, emesis, hypotension, and shock.⁸

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Staphylococcal TSS often presents with flulike symptoms of malaise, myalgias, and chills, which progress over 2 to 3 days to a systemic shock-like syndrome. Some patients present with signs of hypovolemia due to diarrhea, generalized vasodilatation, or capillary leak. Others present with an abrupt onset of fever, tachycardia, tachypnea, and hypotension. A major feature of TSS is the erythematous rash, resembling a sunburn, which may be diffuse or patchy in distribution. The rash can be very subtle and may be misdiagnosed as a "fever flush." Desquamation of the skin occurs in 7 to 14 days at the sites of the previous rash, with full-thickness peeling of the skin involving the palms, soles, and fingers.

Criteria for the diagnosis of staphylococcal TSS are provided in [Table 194.1](#).¹⁰ TSS can involve every organ system and can produce a wide constellation of symptoms. Patients often complain of severe myalgias or edema of the face and eyelids, with hyperemia of the pharynx, tongue, and vaginal mucosa. Headache is common. There may be confusion, somnolence, lethargy, agitation, or combativeness, without focal neurologic signs. Gastrointestinal manifestations may include vomiting, diarrhea, abdominal pain, and hepatomegaly.

1. Fever of 38.3°C (101°F)
2. Presence of diffuse macular erythroderma ("sunburn" appearance)
3. Desquamation 5 to 2 wk after onset of illness, particularly of the palms and soles
4. Hypotension, defined as a systolic blood pressure of 90 mm Hg for adults and less than the fifth percentile for children younger than 16 years, an orthostatic decrease in diastolic blood pressure of 12 mm Hg with a positive change from lying to sitting, orthostatic syncope, or orthostatic dizziness
5. Involvement of three or more of the following organ systems: Classical history of vomiting or diarrhea at the onset of illness Muscular elevated creatine phosphokinase level or severe myalgia Mucosal membranes: conjunctivae, conjunctivae, oropharyngeal hyperemia, or vaginal hyperemia or discharge Renal: abnormal results of renal function tests or azotemia Hepatic: elevated serum transaminase and bilirubin levels Hematologic: thrombocytopenia Central nervous system: disorientation or alteration in consciousness without focal neurologic signs and in the absence of hypotension or fever
In addition, normal results of the following tests, if performed: Blood, throat, cerebrospinal fluid cultures (blood culture may be positive for <i>Staphylococcus aureus</i>) Antibody tests for Rocky Mountain spotted fever, ehrlichiosis, leptospirosis, and rubella
Toxic shock syndrome is "probable" when at least four of the five criteria are fulfilled.
Reprinted from American Academy of Pediatrics. Staphylococcal toxic shock syndrome. In: <i>Pediatrics</i> , 6th ed. 1983; 72:1000-1004. Copyright of the Committee on Infectious Diseases, 34th and 35th Councils, American Academy of Pediatrics, 1983.

TABLE 194.1. Criteria for Staphylococcal Toxic Shock Syndrome

The differential diagnosis of TSS includes *streptococcal* toxic shock syndrome (discussion to follow), Kawasaki disease, staphylococcal scalded-skin syndrome, scarlet fever, Stevens-Johnson syndrome, Rocky Mountain spotted fever, ehrlichiosis, leptospirosis, meningococemia, atypical measles, viral illness, anaphylaxis, heat stroke, gram-negative sepsis, and drug reactions.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The diagnosis of TSS must often be made on clinical grounds. Because the disorder is caused by toxins, blood cultures may be negative. Laboratory examination may demonstrate a marked thrombocytopenia (platelets less than 100,000), an elevated blood urea nitrogen and creatinine, and elevated liver function tests. The diagnosis is most often suggested by the characteristic blanching macular erythematous rash.

Initial treatment consists of intravenous fluid replacement. Large volumes of crystalloid or albumin are often required to maintain normal perfusion, and hemodynamic monitoring and vasopressors are sometimes necessary as well. Tampons, nasal packs, or other foreign bodies, if present, must be removed. Surgical wounds or areas of infection need to be incised and drained.

Antibiotics may not affect the clinical course, because the syndrome is caused by bacterial toxins rather than the bacterial infection *per se*. However, antibiotics may be beneficial if the patient is bacteremic or if there is a site of on-going infection. The drug of choice is a penicillinase-resistant synthetic penicillin or a first-generation cephalosporin. Vancomycin or clindamycin may be used as alternatives in penicillin-allergic patients.

Adjunctive treatments for TSS have included intravenous immunoglobulin, steroids, plasmapheresis, and monoclonal antibodies. At present, these therapies have not demonstrated a clear benefit. Some European studies have found corticosteroids to be effective in cases of severe TSS that are unresponsive to antibiotic therapy.

COMMON PITFALLS

- Failure to recognize staphylococcal TSS in young healthy patients with fever and an erythematous rash
- Failure to administer adequate fluid volumes to maintain tissue perfusion

- Failure to seek an occult source of staphylococcal colonization or infection

STREPTOCOCCAL TOXIC SHOCK SYNDROME

In the late 1980s, a disease similar to staphylococcal TSS, but caused by a strain of group A streptococci, was recognized.¹³ This illness, characterized by hypotension and multiorgan failure, was termed *streptococcal toxic shock syndrome* (STSS). The Centers for Disease Control and Prevention case definition of this syndrome is shown in [Table 194.2](#).³

1. Isolation of group A streptococci
A. From a normally sterile site (e.g., blood, cerebrospinal fluid, peritoneal fluid, tissue biopsy, surgical wound)
B. From a nonsterile site (e.g., throat, superficial skin lesion)
2. Clinical signs of severity
A. Hypotension: systolic blood pressure 90 mm Hg in adults or less than 10th percentile for age in children, and
B. Two or more of the following signs:
Renal impairment: creatinine 2 mg/dL for adults or at least twice the upper limit of normal for age
Congulopathy: platelets less than 100,000/ μ L or disseminated intravascular coagulopathy
Liver involvement: serum alanine aminotransferase (SGOT), aspartate aminotransferase (SGPT), or total bilirubin concentrations at least twice the upper limit of normal for age
Adult respiratory distress syndrome
A generalized erythematous macular rash that may desquamate
Soft tissue necrosis, including necrotizing fasciitis or myositis, or gangrene
An illness fulfilling criteria 1A and 2 (A and B) can be defined as a definite case.
An illness fulfilling criteria 1B and 2 (A and B) can be defined as a probable case if no other etiology for the illness is identified.
Adapted from the Centers for Disease Control and Prevention, the Working Group on Severe Streptococcal Infection. Defining the group A streptococcal toxic shock syndrome: rationale and consensus definition. <i>JAMA</i> 1993;269:391.

TABLE 194.2. Case Definition for the Streptococcal Toxic Shock Syndrome

Cases of STSS are often associated with minor nonpenetrating trauma or soft-tissue infection.^{1,7} Viral infections, such as varicella⁵ and influenza, are thought to provide a portal of entry in other cases, but, in many patients, no source of the organism can be identified. Bacterial toxins produced by group A streptococci (GAS), particularly streptococcal pyrogenic exotoxins (SPE), as well as host factors, are thought to play an important role in determining disease severity.¹⁴ Blood cultures are generally positive. The young, the elderly, and the immunosuppressed are at greatest risk, but, significantly, a large proportion of patients with STSS are young, healthy adults.⁶

CLINICAL PRESENTATION AND EMERGENCY DEPARTMENT EVALUATION

STSS often presents with a flulike syndrome of fever, malaise, myalgia, nausea, vomiting, and diarrhea. Hypotension is an essential part of the case definition of STSS. Half of patients have a normal blood pressure on admission but develop hypotension within a few hours of presentation. Hypotension may require aggressive fluid and vasopressor therapy. Organ system involvement also becomes evident. Renal dysfunction may be severe enough to require hemodialysis. Acute respiratory distress syndrome may require endotracheal intubation.

In distinction to staphylococcal TSS, a diffuse scarlatina-like rash is uncommon in STSS (less than 10%). A majority of patients have signs of a soft-tissue infection, such as localized swelling and erythema; of these, many progress to necrotizing fasciitis or myositis. Pain, out of proportion to physical findings, is usually severe and abrupt in onset, and occurs initially without associated tenderness. It may involve an extremity, the abdomen, the pelvis, or the chest. An ominous sign is the appearance of vesicles, which develop into violaceous or bluish bullae. These are an indication for emergent surgical exploration, both to establish the diagnosis of GAS infection and to debride nonviable tissue.

Despite prompt, aggressive medical and surgical management, the mortality rate of STSS is high, usually about 30%.

EMERGENCY DEPARTMENT MANAGEMENT

Early treatment with antibiotics is critical. Although *Streptococcus pyogenes* continues to be susceptible to beta-lactam antibiotics, including penicillin, several studies recommend treatment with both penicillin and clindamycin. However, because the differential diagnosis includes other infectious etiologies, initial broad-spectrum coverage is required. Prompt and aggressive surgical exploration and debridement of suspected deep-seated *S. pyogenes* infections are mandatory, however.

Massive quantities of intravenous fluids (up to 20 L/d) may be necessary. Vasopressors such as dopamine are frequently used, but outcome trials have not demonstrated their benefit. Cases of symmetrical gangrene of the digits have resulted with the use of vasopressors; however, it is difficult to determine whether this is due to pressors, infection, or both.

Case reports have described the successful use of intravenous gamma globulin infusions in a small number of patients with STSS.⁹ Anecdotal reports of hyperbaric oxygen have been used in a handful of patients,¹² but it is unclear whether this treatment is useful.

COMMON PITFALLS

- Failure to consider the diagnosis of STSS early and to institute antibiotics promptly.
- Failure to debride soft-tissue infections aggressively. Areas of apparently minor, painful, erythematous swelling may represent the first sign of a serious GAS infection.

CHAPTER 195 Bacteremia and Septic Shock

J. Stephan Stapczynski

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Bacteremia is the presence of viable bacteria within the liquid component of blood.³ Although bacteremia can be confirmed only by bacteriologic or immunologic tests, its potentially explosive course and high mortality rate mandate the institution of antibiotic therapy when its presence is suspected on clinical grounds, before the results of these tests are known.

Bacteremia can be *transient*, as is commonly seen after injury to mucosal surfaces (e.g., from tooth brushing, urethral catheterization, sigmoidoscopy, angiography), but intact host defenses usually neutralize the bacteria and their harmful products and prevent clinical infection. Bacteremia can be *primary* (without an identifiable focus of infection) or *secondary* to an extravascular or intravascular focal infection. Most bacteremias are secondary to an extravascular focus of infection.

A consensus conference of the American College of Chest Physicians and the Society of Critical Care Medicine, in August 1991, developed definitions for sepsis, severe sepsis, and septic shock to clarify the terminology and usage concerning these concepts³ (Table 195.1). The conference first noted that physiologic alterations and organ dysfunction similar to those seen with bacterial infections can follow a wide variety of clinical insults. This clinical state was termed the *systemic inflammatory response* (SIRS) and was defined by changes in body temperature, heart rate, respiratory function, and peripheral leukocyte count. *Sepsis* was defined as the systemic host response to *infection*, the condition characterized by the presence of microorganisms or the invasion of normally sterile host tissue by those organisms. It should be noted that sepsis is defined by the host's reaction to infection and not only by the presence of microorganisms. The use of these recommendations is encouraged to avoid the confusion that has developed from the variety of bacteriologic, physiologic, and clinical meanings for the term *sepsis* and for the even less precise term *septicemia*.

<p>Systemic Inflammatory Response Syndrome (SIRS): the physiologic response to a variety of severe clinical insults manifested by two or more of the following:</p> <ul style="list-style-type: none">A. Temperature $\geq 38^{\circ}\text{C}$ or $\leq 36^{\circ}\text{C}$B. Heart rate ≥ 90 beats/minC. Respiratory rate ≥ 20 breaths/min or a $\text{PaCO}_2 < 32$ mm HgD. White cell count (WBC) $> 12,000$ cells/μL, $< 4,000$ cells/μL, or $> 10\%$ immature (band) forms <p>Sepsis: the systemic response to infection manifested by the presence of SIRS</p> <p>Severe sepsis: sepsis associated with organ dysfunction, hypoperfusion, or hypotension (systolic BP < 90 mm Hg or a reduction of > 40 mm Hg from baseline). Definitions of sepsis and organ failure and guidelines for the use of innovative therapies in sepsis. Crit Care Med 1992;20:864-874.</small></p>

TABLE 195.1. Definitions

Septic shock was defined as sepsis with hypotension and evidence of inadequate tissue perfusion despite fluid resuscitation. In the case of bacterial infections leading to septic shock, circulatory insufficiency occurs when bacterial products interact with host cells and serum proteins to initiate a series of reactions leading to cell injury and death.⁴ Not only are the bacterial products harmful, but the widespread and unregulated host response to these bacterial products also results in the elaboration of an extensive array of chemical mediators that lead to further cell damage.²² The following systems and mediators are stimulated in septic shock: arachidonic acid metabolites (leukotrienes, prostaglandins, and thromboxanes), the complement system, coagulation cascade, the fibrinolytic system, catecholamines, glucocorticoids, prekallikrein, bradykinin, histamine, beta-endorphins, enkephalins, adrenocorticotrophic hormone, circulating myocardial depressant factor(s), cachectin (tumor necrosis factor [TNF]), and interleukin-1 (IL-1).

Septic shock develops in fewer than half of patients with bacteremia; it occurs in about 40% of those with gram-negative aerobes such as *Escherichia coli*, *Klebsiella* species, *Pseudomonas aeruginosa*, and *Proteus* species, and in about 20% of those with gram-positive bacteremia with organisms such as *Staphylococcus aureus*. Multicenter studies of patients with septic shock have found that approximately 50% of patients have bacteremia, and another 30% have a documented bacterial infection without bacteremia.^{4,6,14,18,19}

Septic shock is present in about a fourth of patients at the onset of sepsis syndrome.¹⁸ While sepsis and septic shock are common events in hospitals, there are limited studies on the incidence or frequency of these syndromes. A multicenter study has identified a rate of approximately two cases per 100 hospital admissions for sepsis syndrome.¹⁵ Of these cases, approximately half were diagnosed in the intensive care unit (ICU), 12% in the emergency department, and one-third in a non-ICU patient care unit.

With the development of advanced monitoring and cardiorespiratory support of patients with life-threatening illnesses, it has become increasingly clear that the major threat to survival is not the underlying disease or a specific complication, but a process of progressive failure of multiple independent organs. This process has been termed *multiple organ failure syndrome* and is the major cause of death in patients with severe sepsis and septic shock.^{3,4} and ^{5,10}

CLINICAL PRESENTATION

Bacteremia is usually found in association with an acute illness and symptoms of fever, chills, and prostration—the so-called toxic state. Not all patients have such a classic presentation, particularly those at the extremes of age or in debilitated states. Bacteremia and septic shock are dynamic processes in which the observed clinical manifestations depend on when in the disease course the patient presents and on the ability of the patient's neurologic, cardiovascular, and pulmonary systems to respond to the various stimuli. For example, elderly patients may not manifest fever, but may present with hypothermia.

The mean age reported for SIRS and sepsis syndrome is 55 to 60 years old.^{6,14,18,19} This is most likely because older patients have conditions (e.g., diabetes, surgical procedures, and cancer) that predispose them to bacterial infections. While there is no reason to suspect that the occurrence of sepsis and septic shock would vary according to the patient's age, two large-scale perspective studies of SIRS and sepsis syndrome have found a slightly higher percentage of men than women (55% to 60%).^{18,19} This difference may reflect a higher rate of preceding surgical procedures in men as opposed to women.

The cardiovascular response in septic shock depends on the stage of disease. Initial hemodynamic measurements usually indicate the presence of vasodilation due to widespread arteriovenous shunting, a decrease in systemic vascular resistance, an increase in cardiac output, and an increase in oxygen consumption; this pattern is consistent with a distributive variety of shock.⁴ Initially, blood pressure may not be altered much, and the abnormal hemodynamic parameters respond to volume infusion alone. Despite an increased cardiac output, there is impairment of myocardial function, with a decreased left ventricular ejection fraction and left ventricular dilatation.¹² As septic shock progresses, uncontrolled vasodilation and capillary leakage of plasma lead to splanchnic pooling of circulating volume, decreased oxygen consumption, and a falling blood pressure. Typically, blood pressure falls 6 to 8 hours after the initial signs of bacteremia due to gram-negative organisms.

Cardiac function may also be diminished by two other factors: inadequate coronary perfusion and the presence of humoral myocardial depressant factors.

Hemodynamic measurements in human bacteremia and septic shock are influenced by the administration of volume, inotropic, and vasoconstrictor agents. Persistently low systemic vascular resistance, regardless of cardiac output, is the major hemodynamic derangement in patients who die of septic shock. In advanced septic shock, depressed cardiac output and severe hypotension produce a vicious cycle of multiorgan failure that is usually unresponsive to volume and inotropic or vasoconstrictor therapy.

The initial pulmonary response to bacteremia and septic shock is hyperventilation with dyspnea and tachypnea.⁴ The development of leaky pulmonary capillaries leads to noncardiogenic pulmonary edema, progressive hypoxemia, and ventilatory failure, termed the *adult respiratory distress syndrome* (ARDS). ARDS has been observed in 6% to 10% of patients with sepsis and in approximately 20% of those with septic shock.^{18,19} Other significant complications from sepsis and septic shock include central nervous system (CNS) dysfunction, liver failure, acute renal failure, and disseminated intravascular coagulation (DIC).^{4,8} The reported incidence of these complications from different studies for patients with sepsis is approximately 20% for CNS dysfunction, 12% for liver failure, 9% to 23% for acute renal failure, and 8% to 18% for DIC. In septic shock, DIC has been observed in approximately 40%, and acute renal failure in approximately 50%.

DIFFERENTIAL DIAGNOSIS

Acute infections due to viruses, rickettsiae, mycobacteria, fungi, and parasites may present as acute “sepsis,” but severe infection due to these organisms is less common than that due to bacteria. Early diagnosis of these infections requires an awareness of specific predisposing host factors. Most affected patients have underlying depressed immunity. Specific antimicrobial therapy is often delayed, because diagnostic tests for nonbacterial infection are generally less routinely available and are more complicated to perform.

Hyperthermia and heat stroke may mimic many of the cardiopulmonary and neurologic manifestations of sepsis. Chills, however, are not expected with heat stroke.

Shock from other causes may also mimic sepsis; hemodynamic measurements are often helpful in narrowing the diagnostic possibilities. Septic shock should be suspected when hemodynamic measurements showing decreased vascular resistance and increased cardiac output are found.

The ultimate prognosis of gram-negative bacteremia is determined primarily by the presence of underlying host disease. Patients with rapidly fatal disease (such as acute leukemia and neutropenia) have a poor prognosis despite appropriate therapy, whereas patients with ultimately fatal disease (likely death within 5 years) and nonfatal disease (unlikely death within 5 years) do not.

The overall mortality in sepsis varies according to the degree of pathophysiologic derangement in the presence of a documented infection.¹⁸ Mortality in SIRS has been reported to be about 8%, with mortality in sepsis syndrome of 16% to 20% and mortality from septic shock approximately 50%.^{6,14,18,19} While there is a statistically significant trend for decreased mortality over the last 40 years in published studies, such reduction should be reviewed with caution, understanding the heterogeneity of the patients in question.¹⁰

EMERGENCY DEPARTMENT EVALUATION

Because sepsis may progress rapidly, the emergency department evaluation must be expeditious. Appropriate stabilization measures are often carried out simultaneously with assessment.

Vital signs must be reviewed. Unexplained tachycardia or tachypnea may be early clues to infection. Oral temperatures do not accurately reflect core temperature; rectal temperature measurement is recommended in any patient with suspected hypothermia or fever.

The physical examination should concentrate on potential sources for sepsis: The oral cavity, lungs, abdomen, urinary system, and skin are the most common locations. Violation of a mucosal or cutaneous barrier carries the risk of sepsis; all indwelling catheters and lines should be suspected as possible sources.

A wide variety of laboratory and ancillary tests are potentially useful in assessing the septic patient, but the following basic tests usually yield the most information: chest radiograph; serum electrolytes, glucose, blood urea nitrogen, and creatinine determinations; complete blood cell count, including white blood cell count and differential; urinalysis; blood cultures; and cultures of overt foci of infection. Initial antibiotic management is guided by the history and physical examination, not by the results of specific laboratory tests.

Most patients who present to the emergency department with fever and possible sepsis have localizing symptoms or signs, which identify a focal infection. More difficult to assess are those patients without localizing symptoms or signs. Mellors and coworkers found that five factors were useful in predicting the likelihood of bacteremia or occult focal bacterial infection in adults presenting to the emergency department with unexplained fever.¹⁶ The risk of bacterial infection increased with the number of factors present (Table 195.2). Interestingly, the presence of high fever (greater than 103°F [39.4°C]) or a “toxic” appearance had no correlation with the presence of bacterial infection. These five factors have been further validated in hospitalized patients.

No. of Features Present	Bacteremia	Bacteremia and/or Focal Bacterial Infection
0	0/21 (0%)	1/21 (5%)
1	3/45 (7%)	15/45 (33%)
2	6/38 (16%)	15/38 (39%)
3-5	12/31 (39%)	17/31 (55%)

Features: age greater than 50; presence of diabetes mellitus; Wintrobe erythrocyte sedimentation rate greater than 30 mm/h; white blood cells greater than 15,000/ μ L; absolute neutrophil count greater than 1500/ μ L.

Adapted from Mellors JW, Horwitz RI, Harvey MR. A simple index to identify occult bacterial infection in adults with acute unexplained fever. *Arch Intern Med* 1987;147:666-670.

TABLE 195.2. Presence of Bacteremia or Focal Bacterial Infection in Adults Presenting to the Emergency Department with Unexplained Fever

Other conclusions have been derived from studies of adults with unexplained fever:

1. Initially inapparent infections were most often due to common bacteria in common locations.
2. The incidence of diagnostic abnormalities on routine urinalysis and chest radiography was 13% to 16% and 3% to 4%, respectively.
3. Empiric use of urinalysis and chest radiography would have detected about half of the clinically occult infections.
4. About two-thirds of patients with “clinically occult” infections present with general findings that lead to hospital admission based on physician judgment, but among the one-third that are sent home, the incidence of bacterial infection is 20%.

Other studies have sought to develop prediction rules for the presence of bacteremia in different patient populations. A study of hospitalized patients found that shaking chills, a history of intravenous drug use, presence of an acute abdomen, major comorbidity, and a fatal or ultimately fatal underlying disease were all associated with an increased risk of bacteremia. These factors could be combined into a prediction rule, yielding estimates of the prevalence of bacteremia ranging from 1% to 2% for patients at the lowest risk to 15% for those at the highest risk.

EMERGENCY DEPARTMENT MANAGEMENT

Stabilization often begins before assessment is complete. Adequate intravenous access should be ensured, supplemental oxygen should be administered, and cardiac monitoring instituted.

All patients with sepsis require supplemental fluids. The amount and rate of infusion are guided by an assessment of the patient's volume and cardiovascular status.^{4,17} Because of vasodilatation and capillary leakage, large quantities of fluid may be required to support the peripheral circulation. Measurements of central venous pressure or pulmonary artery wedge pressure may provide confusing information about the inadequacy of intravascular volume. Volume administration is best guided by observing the response of the central venous pressure or pulmonary artery wedge pressure to aliquots of fluid given over a short period of time. A rise of more than 5 cm H₂O or 5 mm Hg after a volume infusion of several hundred milliliters indicates that the compliance of the vascular system is decreasing as further fluid is being given and that the intravascular space is most likely "full." Colloids (albumin, hetastarch) have no proven benefit over crystalloids (normal saline or Ringer's lactate) in the resuscitation of sepsis.²⁰

Treatment beyond the supportive measures has four components: (1) parenteral antibiotics, often in combination; (2) removal or drainage of infected foci; (3) treatment of complications; and (4) pharmacologic interventions to prevent harmful host responses.^{4,15}

Initial antibiotics should be administered in the emergency department. Selection of particular agents is empiric, based on assessment of the patient's underlying host defenses, potential sources of infection, and most likely responsible organisms.⁴ Antibiotics must be "broad spectrum," covering both gram-positive and gram-negative bacteria, because both classes of organisms produce an identical clinical picture. Antibiotics must be given parenterally in doses adequate to achieve bactericidal serum levels; many studies have found that clinical improvement correlates with achievement of serum bactericidal levels rather than the number of antibiotics given.

Antistaphylococcal coverage is recommended for patients with a history of intravenous drug abuse or indwelling intravascular lines or devices. Coverage against anaerobes should be included for patients with intraabdominal or perineal infections. Antipseudomonal coverage is indicated in patients with neutropenia or burns. Immunocompetent patients can usually be treated with a single drug that has broad-spectrum coverage, for example, a third-generation cephalosporin such as cefotaxime, ceftriaxone, or cefuroxime. Monodrug therapy in the immunocompetent adult is also possible with either an antipseudomonal penicillin (ticarcillin or piperacillin) or a carbapenem (imipenem or meropenem). Alternatives would be ceftazidime plus either clindamycin or metronidazole; or a parenteral fluoroquinolone plus clindamycin.

Immunocompromised patients usually require coverage with two broad-spectrum antibiotics with overlapping coverage, such as an aminoglycoside plus either ticarcillin, piperacillin, or ceftazidime. Within these general guidelines, no one combination of antibiotics is clearly superior to another.

If the patient does not respond to several liters of isotonic crystalloid (usually 4 L or more) or there is evidence of volume overload, the depressed cardiovascular system can be stimulated by inotropic and vasoconstrictive agents.^{4,17} Dopamine is the agent most commonly used for this purpose. Infusion should begin at a rate of 5 to 10 µg/kg/min intravenously and then adjusted according to the blood pressure and other hemodynamic parameters. Occasionally, patients may require higher doses of dopamine, in the range of 20 µg/kg/min. A pure vasoconstrictor, such as norepinephrine, can increase blood pressure, but the deleterious side effects on cardiac output and regional perfusion are significant. However, there are cases of survival when norepinephrine has been used to treat septic shock refractory to dopamine. Assessing response to the potent inotropes and vasoconstrictors by bedside observation is difficult in these very ill patients. Most patients require intravenous hemodynamic monitoring with arterial lines and pulmonary artery catheters.

While there is theoretical and experimental support for the use of large doses of corticosteroids in severe sepsis and septic shock, all randomized human studies (with the exception of one from 1976) have found that large doses of corticosteroids do not prevent the development of shock, reverse the shock state, or improve the 14-day mortality.^{7,13} Thus, there is no support in the medical literature for the general use of high doses of corticosteroids in patients with sepsis or septic shock.

The insight that endotoxin, a lipid-polysaccharide compound found in the cell wall of gram-negative bacteria, plays a key role in initiating the cascades seen in septic shock has led to the hypothesis that neutralizing circulating endotoxin with intravenous administration of an antiendotoxin antibody might be beneficial. Several products have been developed and investigated in clinical trials. However, there has been no proven benefit with these agents to date.¹⁵ Highlighting the uncertain benefits of antiendotoxin antibody therapy is the high cost, estimated to be at least \$4,000 per course of treatment. Taurolidine, an antiendotoxin agent, has also not shown benefit in the treatment of sepsis syndrome.²¹

Serum levels of TNF and IL-1 are elevated in patients with septic shock.²² Both cytokines produce hemodynamic effects that duplicate that found in sepsis. Many studies indicate that both mediators play a key role in sepsis and septic shock, and it is thought by some that TNF may be the central mediator in sepsis. Similar to the hypothesis concerning antiendotoxin antibodies, it is hypothesized that antibodies to TNF or IL-1 might be useful in septic shock. However, anti-TNF or anti-IL-1 antibodies have not been shown to improve the outcome in sepsis or septic shock in human trials.^{1,2,9,15}

Agents such as naloxone, arachidonic acid inhibitors, prostaglandin E₂, antihistamines, thyroid-releasing hormone, glucagon, and calcium channel inhibitors that antagonize humoral mediators elaborated in severe sepsis and septic shock have not proven beneficial in limited studies.¹⁵

DISPOSITION

The disposition from the emergency department of patients with a fever and no localizing signs of infection presents a dilemma. Otherwise healthy individuals in a stable clinical state and at low risk for occult bacterial infection can generally be discharged with instructions for fever control and a warning to return if symptoms persist or worsen. A "toxic" appearance itself is of little diagnostic value.¹⁶

Patients with underlying immunodeficiency or with disorders that predispose them to bacterial infection and bacteremia pose an additional dilemma. Careful consideration should be given to the decision whether to admit these patients or to discharge them with close follow-up. It is common practice to admit those patients with a reasonable risk for bacteremia (above 2% to 5%), even if they appear well, because of the difficulties in excluding potentially serious infections and predicting the clinical course. For example, it has been found clinically impossible to determine which febrile intravenous drug users have serious infections and which do not when they present to the emergency department.

The value of blood cultures in adults being discharged from the emergency department is controversial. The incidence of bacteremia in febrile adults presenting to an emergency department is 1% to 2%, and more than three-fourths of these patients are admitted to the hospital because of their clinical presentation. The use of outpatient blood cultures requires a reliable patient and an efficient call-back mechanism, but discharging these patients does entail a small but real risk of delay in treating a potentially explosive infection.

COMMON PITFALLS

- Failure to consider bacterial infection as a possibility in the assessment of subtle or confusing symptoms and signs
- Restriction of fluid resuscitation for fear of inducing pulmonary edema, even though large quantities of fluid may be required because of capillary leakage
- Delaying the administration of antibiotics until after all of the cultures are collected, the consultant is contacted, or the patient is admitted. All patients with suspected serious infections should receive antibiotics in the emergency department.
- Patients with an internal focus of infection often require surgical drainage or excision. Because many of these have serious or coexistent medical problems, surgery is often delayed to "get the patient into better shape." Experience teaches that such delays are usually not in the patient's best interest.

[Chapter References](#)

The aging of the population, the increasing frequency of transplants, advances in cancer chemotherapy, and the longer life spans of patients with chronic conditions have contributed to the increasing number of immunocompromised patients seen in emergency departments (EDs). The presence of an immunocompromised state alters ED evaluation and management by rendering patients more susceptible to infection, by altering or modifying the presenting signs and symptoms of disease, and by affecting management and disposition.

THE IMMUNE SYSTEM

The components of the immune system—nonspecific host defenses, antibodies, complement, granulocytes, and cell-mediated immunity—work synergistically to prevent infection.

NONSPECIFIC HOST DEFENSES

The skin and mucous membranes provide a physical barrier against microbes. The respiratory tract is protected by an aerodynamic filtration system and mucociliary transport away from the lungs. The defenses of the gastrointestinal tract include the acidic pH of the stomach, pancreatic enzymes, bile and intestinal secretions, peristalsis, epithelial cell turnover, and competition with normal bowel flora. The urinary tract resists microbial infection by frequent flushing, urinary pH and other antimicrobial constituents of urine, the hyperosmolarity of the kidney, and the length of the male urethra. The acid environment of the vagina is unfavorable to the growth of most pathogenic bacteria.

Patients in whom any of these host defenses are disrupted are at risk for infection. Iatrogenic breaching of physical barriers (e.g., by an indwelling urinary, intravenous catheter, or endotracheal tube) and alteration of protective indigenous flora by broad-spectrum antibiotics are important causes of infection.

Humoral Immunity

Antibody deficiency results in increased susceptibility to infection with encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Mycoplasma*, *Staphylococcus aureus*, and *Neisseria meningitidis*. Sinopulmonary infections are most common. There is also an increased incidence of infections with gastrointestinal organisms such as *Salmonella*, *Shigella*, *Campylobacter*, and rotavirus.

There are several inherited disorders of humoral immunity, including X-linked common variable immunodeficiency and selective immunoglobulin A (IgA) deficiency. Acquired IgG deficiency is seen in malignancies such as multiple myeloma, Waldenström's macroglobulinemia, chronic lymphocytic leukemia, lymphoma, lymphosarcoma, and thymoma. In addition, immunoglobulins may be lost in protein-losing states such as severe burns, protein-losing enteropathies, and nephrotic syndrome. Immunoglobulin deficiency is also seen in human immunodeficiency virus (HIV) disease and after bone marrow transplantation.

Complement deficiency is usually inherited and results in susceptibility to infections such as pneumonia and meningitis with organisms such as *N. meningitidis*, *Neisseria gonorrhoeae*, *S. pneumoniae*, *H. influenzae*, and *S. aureus*. Acquired complement deficiency is most common in patients with autoimmune diseases, especially systemic lupus erythematosus (SLE) (5.9% of patients with SLE), discoid lupus, and glomerulonephritis.¹⁴ Meningococcal disease is the most common infection in complement deficiency. Special attention should be paid to the risk for infection with encapsulated organisms, and blood cultures should be obtained. When stable, these patients should be referred for immunizations.

Multiple myeloma is associated with both decreased immunoglobulin production and impaired complement function. The degree of immunocompromise increases as the disease progresses, and, in advanced disease, cell-mediated immunity and granulocyte function are impaired as well. Pneumonia, urinary tract infection (UTI), and sepsis caused by *S. pneumoniae*, *H. influenzae*, and *Escherichia coli* are the most common infections.^{6,13} The first 2 months of chemotherapy are a particularly high-risk period. With progressive disease and decreased granulocyte production, gram-negative and fungal bacteremia become more likely.

The spleen both produces antibody and clears bacteria from the blood. Splenectomized patients are at risk of infection from encapsulated organisms such as *S. pneumoniae*, *H. influenzae*, or *N. meningitidis*. Many patients have splenectomies during staging laparotomies for lymphoma or for treatment of leukemia or platelet dysfunction. Others are functionally asplenic because of sickle cell disease or other hemoglobinopathies, or are hyposplenic from a variety of systemic diseases. Patients who have splenectomy after trauma may have some residual splenic function because of seeding of the peritoneum by small splenic implants.

Overwhelming postsplenectomy infection (OPSI) occurs more commonly in children than in adults, but it must be considered in any postsplenectomy patient with a fever. Infections with *Babesia* (from tick bites) and *Capnocytophaga canimorsus* (from dog bites) are particularly severe and likely to result in sepsis. OPSI typically starts with a prodrome of fever, chills, sore throat, malaise, nausea, or vomiting in a relatively well-appearing patient. Rapid deterioration can occur, with hypotension, disseminated intravascular coagulation, respiratory failure, and coma developing over hours. Even with appropriate treatment, mortality is more than 50%.¹⁵ OPSI can be associated with pneumonia, meningitis, or endocarditis. Vaccines against encapsulated organisms such as pneumococcus, *H. influenzae*, and *N. meningitidis* reduce the likelihood of OPSI, but do not eliminate it. Asplenic children may be taking prophylactic penicillin, or patients may have been given a supply of antibiotics to take when symptoms of infection appear.

Patients with defects in humoral immunity who present with symptoms of infection must be evaluated thoroughly. A complete history must include information about infectious exposures, immunizations, and prophylactic medications, if any. A chest x-ray, urinalysis and culture, and two sets of blood cultures are mandatory. If the bacterial load is high, a Gram stain of the buffy coat may demonstrate organisms. Patients should be closely observed in the hospital or observation unit for at least 24 hours after blood cultures are obtained. Empiric antibiotics appropriate for both the presumed infection site and encapsulated organisms should be started, especially in the ill-appearing patient.

Granulocytes

Neutrophils and macrophages are the granulocytes primarily responsible for phagocytosis of microbes and enzymatic destruction of their cell walls. Neutropenia is caused by cancer chemotherapy, a variety of drugs, bone marrow disease, or inherited conditions. Functional abnormalities of granulocytes can be caused by steroids, cancer chemotherapy, or irradiation.

The neutropenic patient is significantly immunosuppressed, and 50% to 60% of those with fevers have an infection.⁷ Fever in this population is defined as a single

oral temperature of greater than 38.3°C, or 38.0°C over at least 1 hour.⁷ Neutropenia is defined as a neutrophil count less than 1,000/μL. The frequency and severity of infections is inversely proportional to the neutrophil count, so patients with neutrophil counts less than 500/μL are at even greater risk of infection. A rapid decline of the neutrophil count and a protracted duration further increase infection risk.⁷ As with other patients, neutropenic patients may be infected but afebrile.

Neutropenic patients may have a blunted inflammatory response, resulting in vague or nonspecific clinical symptoms that do not indicate the location of the infection or its serious nature. History taking and physical examination must be careful and comprehensive. In the neutropenic cancer patient, infection is most likely to be found in the periodontium, pharynx, lower esophagus, lung, perineum and anus, skin, instrumentation sites, the ocular fundus, and the periungual area.⁷ Patients with chronic hereditary neutropenia tend to have infections of the upper respiratory tract, periodontium, and skin. The most common bacterial causes of fever in neutropenic patients are *Staphylococcus (aureus, epidermidis, and other coagulase-negatives)*, *Streptococcus (pneumoniae, pyogenes, viridans)*, *Enterococcus faecalis/faecium*, *Corynebacterium spp.*, *E. coli*, *Klebsiella spp.*, and *Pseudomonas aeruginosa*.⁷ Gram-positive organisms cause about 60% to 70% of infections.⁷ Fungal infections are most common after courses of broad-spectrum antibiotics.

Neutropenic enterocolitis, also called typhlitis, is a fulminant necrotizing infection associated with severe neutropenia. Symptoms include nausea, vomiting, and abdominal pain. Bowel wall thickening or pneumatosis is a nonspecific but suspicious finding. Causative organisms are enteric and anaerobic bacteria, as well as *Candida* species. Both surgical and medical management have been successful, although mortality is more than 50%.

Laboratory evaluation must include a complete blood count (CBC); chest x-ray; and cultures of blood (peripheral and catheter), urine, lesions, and diarrheal stools. Liver function tests, electrolytes, creatinine, and blood urea nitrogen (BUN) are obtained to plan supportive care and to monitor for drug toxicity. Other tests are obtained as appropriate to the clinical presentation.

It is currently standard practice to administer high-dose intravenous antibiotics (Fig. 196.1) to all patients with neutrophil counts less than 500, and in those with counts below 1000 in whom a further decrease is anticipated. More recent studies suggest that “low-risk” patients may be treated with oral amoxicillin–clavulanate plus ciprofloxacin.⁴ High-risk factors include inpatient status when fever and neutropenia develop; a requirement for acute hospital care for problems in addition to the fever and neutropenia; uncontrolled cancer; allogenic bone marrow transplant; recent antibiotic use; renal failure; respiratory insufficiency; or evidence of specific infection.⁴ Vascular access devices may often be left in place, even if infected, unless the infection is in the catheter tunnel or is causing septic emboli. Empiric antiviral or antifungal treatment is not routinely indicated.

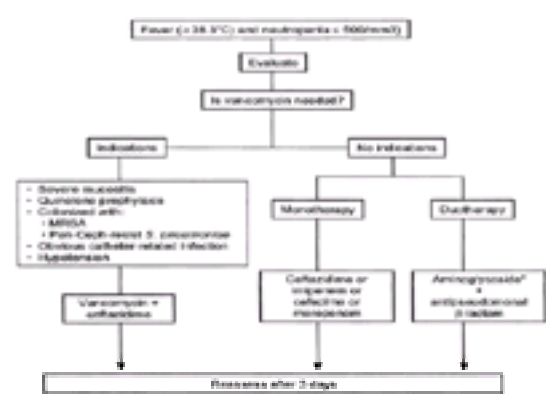

Figure 196.1. Guide to the initial management of the febrile neutropenic patient.

Cell-Mediated Immunity

Impairment of cell-mediated immunity (CMI) results in infection with a wide variety of intracellular pathogens. These include certain bacteria (*Mycobacterium spp.*, *Listeria monocytogenes*, *Legionella pneumophila*, *Salmonella spp.*, *Nocardia spp.*), all viruses (particularly herpes simplex, varicella-zoster, cytomegalovirus, Epstein-Barr), and some fungi (*Candida*, *Cryptococcus*, *Mucor*, *Aspergillus*, *Histoplasma capsulatum*, *Coccidioides immitis*) and protozoa (*Pneumocystis carinii*, *Toxoplasma gondii*, *Cryptosporidium*, *Strongyloides stercoralis*). Clinical infection with these organisms is rare in the normal host, except for tuberculosis, herpes, and varicella.

The classic example of a defect in CMI is the acquired immunodeficiency syndrome (AIDS) (see Chapter 192). Defects in CMI may be congenital and are often accompanied by defects in humoral immunity, because the systems are intertwined. In clinical practice, CMI usually results from drug or radiation therapy. Drugs used in organ transplants (cyclosporin and tacrolimus) and for autoimmune diseases, corticosteroids, antineoplastic agents, and total lymphoid irradiation (used for rejection in solid tumor transplants) are most commonly implicated. The likelihood of infection is related to the intensity and duration of immunosuppressive therapy. Defects of CMI also occur in malnutrition, aging, viral infections, lymphoma, lymphocytic leukemia, uremia, sarcoidosis, leprosy, trauma, and pregnancy.

Impairment of CMI may reduce the inflammatory response and mute the clinical presentation. The history and physical examination must be comprehensive and meticulous. Clues to infection must be aggressively pursued, and localizing signs must prompt attempts to identify a pathogen. The treatment threshold should be low.

Recommended antibiotic therapy for a number of common immunocompromised states is presented in Table 196.1.

Immunodeficiency	Antibiotic Choices	Antifungal Choices	Antiviral Choices
Acquired immunodeficiency syndrome (AIDS)	Trimethoprim-sulfamethoxazole	Fluconazole	Zidovudine
Chronic granulomatous disease	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Common variable immunodeficiency	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Cyclosporin	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Tacrolimus	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Corticosteroids	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Antineoplastic agents	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Total lymphoid irradiation	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Malnutrition	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Viral infections	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Lymphoma	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Lymphocytic leukemia	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Uremia	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Sarcoidosis	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Leprosy	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Trauma	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir
Pregnancy	Trimethoprim-sulfamethoxazole	Fluconazole	Acyclovir

TABLE 196.1. Antibiotic Choices in Immunodeficiency

SPECIFIC CLINICAL SITUATIONS

Transplantation

A host of factors predispose the transplant patient to infection. Chief among these are the immunosuppressive agents that are necessary to prevent transplant rejection. Cyclosporine and tacrolimus both affect T-lymphocyte function. Corticosteroids affect all aspects of immunity. Azathioprine is a cytotoxic agent that can lead to bone marrow suppression. Antilymphocyte and antithymocyte globulins decrease CMI.

Most transplant recipients are able to mount fevers in response to infection, despite their immunosuppressive therapy. Information about the type and amount of both immunosuppressive and antimicrobial prophylactic drugs should be obtained. A careful history and physical examination may demonstrate the source of the fever.

Symptoms suggestive of a localized infection should be evaluated, even in the absence of a fever. Both the transplant and infectious disease services should be consulted early. If a parenchymal infection is located, efforts should be made to obtain samples for culture and smear.

These patients are hospitalized and started on antibiotics. Patients unable to go about their normal activities should also be hospitalized unless special arrangements can be made. A patient with a persistent fever greater than 38.5°C and an unknown source should be hospitalized for more intensive evaluation. The stable, well-appearing patient without an identified source may be observed without antibiotics. Noninfectious causes of fever, such as drug reaction or transplant rejection, should also be considered.

Diabetes Mellitus

Many mechanisms are responsible for immunosuppression for the diabetic patient. Chemotaxis, phagocytosis, bacterial killing, and T-lymphocyte response are impaired.^{2,12} High tissue glucose levels enhance bacterial growth. Diabetic peripheral vascular disease results in ischemic tissue, which is more susceptible to infection. Autonomic and peripheral neuropathy predispose patients to repetitive injury of the lower extremities. Diabetic patients have a higher incidence of complications, such as septic shock, renal failure, and late superinfections.² A good rule of thumb is that a diabetic with any parenteral infection should be admitted for intravenous antibiotics, close follow-up for complications, and control of metabolic derangements (see [Chapter 168](#)).

The Elderly

Both cell-mediated and humoral immunity decrease with age. Increased skin fragility and decreased subcutaneous tissue also contribute to increased risk for skin infections and slower healing. A less vigorous cough and decreased mucociliary clearance may predispose to pneumonia. Impaired circulation, the presence of comorbid conditions, the use of immunosuppressive drugs, and the presence of foreign bodies (indwelling catheters and prostheses) all may predispose the elderly to infection.

The relative mortality of infections in the elderly is increased from three- to 15-fold over that of younger adults.¹⁷ Respiratory, urinary tract, and soft-tissue infections (mnemonic: PUS, for pneumonia, UTI, and soft tissue) are the predominant infections of the elderly and should be sought in every febrile older patient. Forty percent of all cases of bacteremia and sepsis occur in the elderly, and the elderly account for 60% of deaths from these conditions. More than 85% of elderly individuals have a medically supervised chronic disease⁵ that may predispose to certain infections and increase morbidity. Those with chronic obstructive pulmonary disease (COPD) may get respiratory infections; those with an indwelling urinary catheter or prostatic hypertrophy may have UTIs; and those with degenerative or rheumatic heart disease, valvular prostheses, or pacemaker/defibrillators may develop endocarditis.

Nonspecific complaints—malaise, anorexia, nausea, vomiting, frequent falls, or a decline in functional or mental status—may be the only clue to the presence of a serious infection. Moreover, symptoms are often not referable to the infected area; for example, gastrointestinal symptoms are more common in urosepsis than are dysuria or urgency.

The physical examination can also be misleading. Fever is commonly absent in the elderly patient with an infection, although the presence of fever is significant. In one study of ambulatory patients, a bacterial infection was found 86.8% of the febrile elderly.⁹ A tachycardic response can be limited by cardiovascular pathology or medications. Cellulitis or decubitus ulcers may be easily overlooked. New mental status changes may be attributed to chronic dementia.

Although test selection is guided by the history and physical, almost all elderly patients with fever need a chest x-ray and urinalysis. A CBC, blood cultures, and serum creatinine determination should be seriously considered. Elderly patients with a parenchymal infection, or infection of a system in which chronic disease is present, should be admitted for intravenous antibiotics. Those treated as outpatients should have close follow-up arranged.

Alcoholism

Chronic alcohol abuse or binge drinking is associated with an increased risk of infection. The infections that have been most closely linked to alcohol abuse are bacterial pneumonia, tuberculosis, and spontaneous bacterial peritonitis (SBP). Alcohol abuse has also been linked to an increased risk of acquiring hepatitis B and HIV infections, independent of the high-risk behaviors associated with alcohol abuse.^{1,8,11}

The evaluation and disposition of these individuals is particularly challenging. The alcoholic presenting with an infectious disorder often has vague and nonspecific complaints of malaise, fever, tremulousness, or lethargy. Patients may be intoxicated or in withdrawal, often present without accompanying family or friends, and rarely have a close relationship with a single health-care provider from whom one can obtain a medical history. The clinician should perform a meticulous examination and have a low threshold for ordering diagnostic tests such as radiographs and cultures, in order to avoid missing potentially life-threatening conditions. Alcoholics often minimize their complaints, and the fact that they are in the ED may be an important clue to the severity of their illness.

Initial management should focus on ensuring airway patency in the lethargic individual, optimizing hydration, assessing the serum glucose level, and observing for signs of withdrawal (tachycardia, tremor, seizures, or fever). Cough, pleuritic chest pain, and dyspnea suggest pneumonia, which may be due to a wide range of bacterial and atypical organisms. Chest radiographs, sputum, and blood cultures are helpful in identifying the causative agent, and patients should be covered broadly for *S. pneumoniae*, *H. influenzae*, *Klebsiella pneumoniae*, *Mycoplasma*, and *Legionella*. Individuals with suspected tuberculosis should be admitted for respiratory isolation and workup. Patients with seizures and/or persistent lethargy should be carefully assessed for meningitis after intracranial pathology and acute intoxication have been excluded. Fever is not always a feature of meningitis in these individuals. The cirrhotic patient with fever, abdominal pain, increasing abdominal distention, or acute hepatic insufficiency should be presumed to have SBP. Paracentesis is usually diagnostic, the fluid having a cloudy appearance and greater than 250 white blood cells (WBC)/ μ L. Broad-spectrum antibiotic coverage should be instituted. *E. coli* is identified in over half of positive peritoneal cultures.¹⁰

Disposition decisions should take into account the fact that these individuals may have inadequate social support, may be likely to drink immediately upon discharge, and may be poorly compliant with outpatient regimens. Alcoholic individuals with a disorder that has the potential for significant early morbidity or that requires compliance with treatment should be admitted to the hospital. For patients who are stable enough to be discharged, access to housing, food, prescriptions, and follow-up should be assessed and plans made for careful follow-up.

Injection Drug Use

Infectious complications are the most frequent reason for hospitalization and death among injection drug users, but immunosuppression directly related to intravenous drug injection plays a relatively minor role.

Infections in the injection drug use (IDU) patient are usually the direct result of the injection of substances into the skin and bloodstream. Injected drugs are typically unsterile and may be cut with any one of a large number of adulterants. Preparation of the drug for injection requires that it be dissolved, and the diluent is usually unsterile water or even saliva. Injection needles are frequently shared and are unlikely to be cleaned between uses.

Skin and soft-tissue infections of the extremities are thus common, but as peripheral injection sites are exhausted, almost any accessible part of the body is at risk. Infection introduced by needle into the bloodstream places the individual at risk for infections involving the vessels and heart, in addition to those organs secondarily infected by septic emboli, most notably the axial skeleton, brain, lungs, and kidneys.^{3,16}

Smoking, promiscuous sexual behaviors, malnutrition, and concomitant alcohol and nonintravenous substance abuse are common in this group of patients, and place the individual at further risk for infection. HIV infection and its associated immune defects play an increasingly important role in determining the immunocompetence of the IDU patient and risk of infection, and must be taken into account when the HIV status of the individual is unknown.

The injection drug-using patient often presents to the ED with complaints that are vague and seemingly minor. They include localized skin infections, extremity pain, fatigue, malaise, fever, and back pain. Fever is often the only sign of serious illness. Up to 42% of intravenous drug users with fever have documented bacteremia, and 10% are eventually diagnosed with endocarditis. Moreover, it is difficult, if not impossible, in the ED for physicians to identify those individuals with fever who are bacteremic or have endocarditis. Furthermore, follow-up or compliance with outpatient treatment regimens is often unreliable. It is thus standard practice to admit

these individuals to the hospital pending the results of blood culture and other ancillary studies.

Infections involving the skin are common and can be as simple as a superficial cellulitis or subcutaneous abscess, or as life-threatening as necrotizing fasciitis or gas gangrene. IDU patients with a painful skin condition should be asked about routes of injection and substances injected. They should also be examined carefully for evidence of muscle and/or compartment involvement or subcutaneous air. Patients with fever or a toxic appearance should have cultures taken of blood and wound and be admitted for intravenous antibiotics and definitive wound care.

Endocarditis is a particularly difficult diagnosis to make in the ED. It should be suspected in any IDU patient presenting with fever, even when there is a clear alternative source of infection, such as cellulitis or pneumonia. Skin infections often lead to valvular infection; the lung, brain, axial skeleton, and kidney are common sites of infection secondary to endocarditis.^{3,16} Patients in whom the diagnosis of endocarditis is suspected should have at least three peripheral blood cultures obtained before antibiotics are started. There is little value to routine screening of these patients with echocardiography prior to the finding of a positive culture. An exception is in individuals who have a partially treated infection, a new murmur or conduction delay, or hemodynamic instability.

Back pain, particularly when accompanied by fever, should always be considered a sign of serious underlying pathology among IDU patients. Although a common complaint in the ED, and usually benign in etiology, in this population, this complaint may indicate vertebral osteomyelitis or epidural space infection. Plain radiographs may be normal in the early stages, and laboratory studies, such as peripheral white count and erythrocyte sedimentation rate, even when elevated, are nonspecific markers of inflammation. Thus, the evaluation should include a diagnostic imaging study such as magnetic resonance imaging or bone scan.

[Chapter References](#)

Diagnosing parasitic disease in the emergency department is difficult: The physician must be aware of the many potential manifestations of infestation by parasites, a large group of organisms. Parasitic disease, however, can usually be diagnosed through methods available to most emergency physicians, and effective treatments are available that are generally minimally toxic to the human host.^{3,9} A history of foreign travel or habitation in an endemic area, including certain regions of the United States, should alert the clinician to the possibility of parasitic infection.

Symptoms may not manifest themselves until well after the traveler has returned home. In addition, over the last two decades, the proportion of the United States population born abroad has increased steadily, with newer immigrants typically coming from Latin America and Asia.¹⁹ The proper treatment of immigrants in the United States requires a familiarity with diseases common in the developing world, such as malaria, amebiasis, and neurocysticercosis.

Four major groups of organisms infest humans. *Protozoans* cause malaria, amebiasis, giardiasis, and many other diseases. Helminths or worms, including *nematodes* (roundworms), *cestodes* (tapeworms), and *trematodes* (flukes), are also responsible for a wide variety of human illnesses. A comprehensive review of parasitic diseases would encompass infections due to literally scores of organisms, so this chapter is limited to the parasitic diseases most common in emergency departments in the United States. (Trichomoniasis is excluded.) This chapter is divided into four discussions: systemic illnesses, predominantly gastrointestinal (GI) disease, predominantly central nervous system (CNS) disease, and ectoparasitic diseases.

SYSTEMIC ILLNESS

CLINICAL PRESENTATION

Fever in a patient with a history of recent travel or habitation in the tropics should suggest the diagnosis of malaria. Caused by four species of the protozoan *Plasmodium* (*P. vivax*, *P. ovale*, *P. falciparum*, and *P. malariae*), malaria is the most common parasitic disease in the world, accounting for an estimated 300 million cases and 1.5 to 2.7 million deaths annually.¹² Although malaria is no longer endemic in the United States, the increase in immigration from and travel to countries where the disease is common has made malaria a not infrequent presenting complaint at emergency departments in this country.¹⁴ Patients with malaria are frequently misdiagnosed on their initial presentation to the emergency department, thus increasing their risk for serious morbidity and mortality.

Classic symptoms of malaria include fever, chills, and rigors. These symptoms last 4 to 10 hours, culminating in an episode of profuse diaphoresis followed by defervescence. This pattern may recur at 2- or 3-day intervals, depending on the species of *Plasmodium* involved. Other clinical signs and symptoms include general malaise, headache, and, occasionally, hypotension. Physical examination is not generally helpful. Splenomegaly and jaundice may be seen in established infections. Laboratory abnormalities include a mild anemia, neutropenia, thrombocytopenia, and increased prothrombin time. Clinical evidence of impaired hemostasis is rare, however.

The periodicity of the disease can be explained by examining the life cycle of the infecting organism. *Plasmodium* species may be injected into the human circulation following the bite of the *Anopheles* mosquito, after sharing needles or receiving a blood transfusion, and by congenital transmission. Immature sporozoites migrate to the liver, beginning the exoerythrocytic phase, the duration of which is species-dependent. Ultimately, mature parasites (merozoites) are released into the circulation and invade red blood cells, beginning the erythrocytic phase. Replication within red cells is followed 48 to 72 hours later by red cell lysis and release of further merozoites into the circulation, which again invade erythrocytes and repeat the cycle. The fever corresponds to episodes of red cell lysis.

The classic pattern of periodic fever is not always seen, however, particularly early in the course of the illness. The variability of the clinical course also depends on the infecting species and the host's immune status. People living in endemic areas often have partial "immunity" that results in much less severe manifestations and symptoms. It is presumed to be an acquired immunity caused by frequent exposure to the infecting organism. Months after leaving an endemic area, these persons may experience relapses that resemble the acute form of the disease, probably caused by a loss of immunity and the release of exoerythrocytic parasites from the liver. *P. vivax* and *P. ovale* can persist for long periods in the exoerythrocytic state. Even patients who have received adequate antimalarial therapy may experience relapses associated with the release of exoerythrocytic organisms.

P. falciparum causes the most severe type of malaria and is responsible for almost all complications and deaths related to malaria.¹⁴ Falciparum malaria has two important features that account for differences in its presentation and in the severity of the disease it produces. First, this species causes widespread capillary obstruction, resulting in end-organ hypoxia and dysfunction, with severe complications that can include CNS dysfunction, hemolytic anemia, hypoglycemia, pulmonary edema, septicemia, renal failure, or splenic rupture. A second distinguishing feature of *P. falciparum* is that, unlike other malarial species that infect only the most mature red cells, it infects red cells of all ages, resulting in a greater degree of hemolysis and anemia and the potential for acute tubular necrosis.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of malaria is a difficult one to make because of the disease's nonspecific clinical features—fever, chills, headache, and malaise. Because approximately 90% of travelers who contract malaria do not become ill until returning home, the diagnosis should be entertained for anyone presenting to the emergency department with a febrile illness and a history of travel or habitation in an endemic area.¹² A high degree of suspicion is necessary for physicians who rarely encounter this disease. The most common incorrect diagnosis is a viral syndrome, but a history of recurrent fever generally distinguishes malaria from these disorders. Other disorders that cause fever and are endemic in foreign countries, such as viral hepatitis, dengue fever, typhoid fever, and amebiasis, should also be considered.

The standard way to make the diagnosis of malaria is through demonstration of intracellular forms of the parasite on a thin Giemsa-stained peripheral blood smear. If malaria is strongly suspected, negative blood films should be repeated every 12 hours for 2 days. Sometimes, it is necessary to use the thick-smear technique, which usually requires the expertise of a trained technician. Serologic tests may be helpful when there are very low levels of parasitemia, as in infection with *P. malariae*.¹¹

EMERGENCY DEPARTMENT MANAGEMENT

Management of malaria in the emergency department is guided by the severity of the infection. Assessment of airway patency and respiratory, circulatory, and neurologic status should be performed in a timely fashion. The emergency physician should be prepared to treat potential complications such as anemia,

coagulopathies, pulmonary edema, azotemia, hypoglycemia, metabolic acidosis, and hypotensive shock.¹¹

Volume should be restored and fever controlled. Hypotension usually responds well to saline infusion. Fever usually responds to standard cooling measures; for temperatures less than 104°F, oral antipyretics are likely to be effective. Acetaminophen is recommended rather than aspirin because of the common occurrence of thrombocytopenia. For patients with high-density parasitemia, altered mental status, pulmonary edema, or renal failure, exchange transfusion may be helpful.⁵

Pharmacologic therapy of malaria is outlined in [Table 197.1](#). Chloroquine remains the oral drug of choice for acute treatment of all infections except those due to chloroquine-resistant *P. falciparum* and *P. vivax*. For chloroquine-resistant *P. falciparum* infection or for severely ill patients with an unidentified malarial infection, quinine plus doxycycline or pyrimethamine and sulfadoxine or clindamycin is recommended.

TABLE 197.1. Treatment of Malaria

In addition to acute therapy, patients infected with *P. vivax* or *P. ovale* require more prolonged treatment to prevent reactivation of exoerythrocyte forms. These patients should be treated with primaquine phosphate, 15 mg base/d for 14 days or 45 mg base/wk for 8 weeks. The pediatric dose is 0.3 mg base/kg/d for 14 days. Patients should be screened for G-6-PD deficiency before beginning primaquine therapy, and the drug is contraindicated during pregnancy.⁵

To prevent fatal outcomes in cases of falciparum malaria, the following are required: improved health information and preventive measures for travelers to malarious areas, improved recognition of infection by physicians, and prompt initiation of effective therapy.¹²

DISPOSITION

Hospital admission is indicated for patients with severe dehydration, significant underlying medical illness, inability to tolerate oral medications, or evidence of end-organ involvement such as stroke, renal failure, or pulmonary edema. Those whose ability to comply with an outpatient regimen is questionable should also be admitted. Suspected *P. falciparum* infection is commonly considered to require hospitalization because of the increasing prevalence of drug resistance and the potential for life-threatening complications. Severely ill patients or those with significant parasitemia (greater than 3% of red cells containing parasites) should be treated in an intensive care unit with intravenous medications.

Prophylaxis is the most important aspect of malaria control in the United States, given the frequency of foreign travel. Before going to an endemic area, travelers should consult an expert to determine whether chemical prophylaxis is indicated and whether chloroquine resistance has been reported in the area. Chloroquine is usually recommended for persons traveling to endemic areas but may not be necessary in all cases, particularly for a short trip to an urban area. The standard dose is 300 mg base (500 mg) orally once a week, beginning 1 week before and continuing for 4 weeks after exposure. Chloroquine is indicated even when traveling to chloroquine-resistant areas, because many strains are still sensitive in such areas. However, a second agent should be added if a febrile illness develops during travel. The particular medication chosen must depend on the pattern of resistance in the area. Mefloquine, 250 mg once a week, is the drug of choice for adults traveling to most chloroquine-resistant areas. Contraindications for the use of mefloquine include serious psychiatric illness, seizures, or serious cardiac arrhythmias.⁶ Because no drug regimen guarantees protection against malaria, if fever develops within the first year after travel to a malarious area, travelers should be encouraged to seek medical attention.⁵

GASTROINTESTINAL DISEASE

The GI tract is commonly affected by parasites, because exposure occurs readily through fecal contamination of food and water. Protozoans and helminths are common causes of GI symptoms such as abdominal pain, malabsorption, obstruction, diarrhea, rectal prolapse, and pruritus ani. The protozoans that cause GI diseases include *Giardia lamblia*, *Entamoeba histolytica*, and *Cryptosporidium*.

G. lamblia, a flagellated protozoan, affects the small intestine. This infection may be transmitted through the ingestion of contaminated food or water, by person-to-person contact, or through male homosexual activity.¹⁸ Most patients experience explosive, watery, foul-smelling diarrhea. Cramping epigastric pain is common; bloody diarrhea is unusual. Physical examination of the abdomen often reveals diffuse upper quadrant tenderness without evidence of peritoneal irritation. Malabsorption may be responsible for the substantial weight loss that may be associated with *Giardia* infestations.¹⁸ Microscopic stool examination may demonstrate active trophozoites, but cysts are more commonly found. In homosexual men who have oral–anal contact, giardiasis may be associated with other bowel infections, particularly amebiasis and shigellosis. Diarrhea and other bowel symptoms occurring in this population, often with evidence of infection by several organisms, has been termed *gay bowel syndrome*. Because *Giardia* is most often transmitted by contaminated water or by the fecal–oral route, efforts at prevention should focus on these routes of transmission.

E. histolytica, upon invasion of the colonic mucosa, can cause amebic dysentery with abdominal pain, tenesmus, and bloody stools.¹⁶ It may result in severe dehydration. The large bowel is typically most affected. Transmission of amebiasis is linked directly to hygiene and sanitation; risk factors for amebiasis include recent travel and institutionalization. The spectrum of clinical disease ranges from mild diarrhea to fulminant rectocolitis. Massive GI bleeding may occur when amebic trophozoites invade large areas of colonic mucosa and cause ulceration; toxic megacolon, perforation, and peritonitis are other severe complications of amebic dysentery. Extraintestinal infection, most commonly amebic liver abscess,¹⁹ may occur with invasion of the trophozoites through the colonic mucosa. The diagnosis of amebic dysentery is made by stool examination for cysts and trophozoites or in biopsy specimens obtained by sigmoidoscopy or colonoscopy.¹⁶

Cryptosporidium may affect any part of the GI tract. Immunocompetent patients frequently experience a clinical syndrome similar to that of giardiasis, whereas immunodeficient ones typically develop more serious disease and may die of dehydration and electrolyte abnormalities. In addition to water sources, such as drinking water, pools, lakes, and water parks, there have been three food-borne outbreaks of cryptosporidiosis in the United States since 1993.^{7,13} Diagnosis is based on the identification of fecal oocysts. The disease is typically self-limited.⁵ Paromomycin has been used to treat cryptosporidiosis in several cases, but there is currently no effective therapy.

Infection by the helminths *Ascaris lumbricoides* and *Strongyloides stercoralis* and the hookworms *Necator americanus* and *Ancylostoma duodenale* causes cramping upper abdominal pain when associated with large worm burdens. Patients presenting from tropical climates, particularly Central America, South America, and Southeast Asia, may be infested with more than one of these GI parasites. Hookworms are also endemic in the southeastern United States.

Infection with *A. lumbricoides* and *S. stercoralis* may present with nonspecific abdominal pain and diarrhea. *Ascaris*, a roundworm, can migrate into the biliary system through the ampulla of Vater and induce inflammation and fibrosis of the biliary ducts through chemical irritation. They may also cause partial or intermittent obstruction of the bile ducts.¹⁵ Midepigastric and right upper quadrant pain may also mimic peptic ulcer disease. *Ascaris* has also been reported to cause bowel obstruction, especially in children.²⁰ Upper respiratory symptoms can develop due to pulmonary migration of larvae (Loeffler syndrome). *S. stercoralis* larvae may mature within the GI tract, as the gravid adult female releases rhabditiform larvae that rapidly evolve into the invasive filariform larval form. The filariform larvae can

penetrate the GI tract or perianal skin, causing the hyperinfection syndrome characteristic of strongyloidiasis;⁹ this is particularly likely to appear in the immunocompromised patient. Both *Necator* and *Ancylostoma* penetrate the mucosa of the small bowel in heavy acute infestations and cause cramping epigastric pain. In addition, GI blood loss at worm attachment sites may result in a profound hypochromic microcytic anemia.

The physical examination of patients with worm infestation is often unremarkable. Minimal diffuse upper abdominal tenderness may be present, but peritoneal signs are unusual when the worms are intraluminal. Presentation as an acute abdomen does occur, however, when there is complete biliary obstruction or small bowel obstruction secondary to a massive worm burden, as may be the case with acute *Ascaris* infestation. A “whirlpool” pattern of intraluminal worms may be seen with plain abdominal x-rays.²⁰ In ascariasis and hookworm disease, microscopic examination of the stool often reveals typical ova. Rhabditiform and filariform larvae of strongyloidiasis may be seen in stool samples and Papanicolaou-stained gastric aspirate or sputum smears. The larval forms of *S. stercoralis* are more likely than ova to be visible in the stool samples from these patients. Eosinophilia is common with all helminthic infections and should alert the clinician to this possibility.

Trichuris trichiura and *Enterobius vermicularis* often present as an annoyance rather than the cause of serious illness. Rectal prolapse may occur with massive infestation by *T. trichiura*, the whipworm, particularly in children.³ Large worm burdens with *T. trichiura* may cause a clinical pancolitis and a mild chronic illness,¹⁰ which is referred to as “trichuris dysentery syndrome”: chronic diarrhea, anemia, and growth retardation.¹⁶ In patients with rectal prolapse from trichuriasis, the adult worms are normally visible on the exposed rectal mucosa. Microscopic examination of stool samples demonstrates the typical barrel-shaped ova of *T. trichiura*.

Infestation with the pinworm *E. vermicularis* is the most common helminthic infection of humans, with the prevalence highest among children ages 5 to 10.¹⁰ Pinworm infection causes severe perianal pruritus, especially at night, when female worms crawl out onto the perianal skin to lay eggs.⁹ This is typically the live worm seen by patients in the perianal region. Examination of the perineum may reveal secondary bacterial infection of perianal excoriated skin. On occasion, dead parasites or eggs deposited in ectopic sites may lead to the formation of granulomas or abscesses.¹ For diagnosis, clear cellulose tape may be placed against the perianal skin, lifted off, and then applied, adhesive side down, to a glass slide and viewed under a microscope to identify the characteristic eggs. Family members and other close contacts should be examined and, if necessary, treated. Pharmacologic therapy of GI parasitic disease is outlined in [Table 197.2](#).

Parasite	Drug	Adult Dosage	Paediatric Dosage
Ascariasis	Albendazole	400 mg po qd × 3 d	10 mg/kg po qd × 3 d (max 400 mg)
	Mebendazole	100 mg po tid × 3 d	10 mg/kg po tid × 3 d (max 100 mg)
Enterobiasis	Mebendazole	100 mg po tid × 3 d	10 mg/kg po tid × 3 d (max 100 mg)
	Albendazole	400 mg po qd × 3 d	10 mg/kg po qd × 3 d (max 400 mg)
Strongyloidiasis	Ivermectin	200 µg/kg po qd × 2 d	200 µg/kg po qd × 2 d
Trichuriasis	Mebendazole	100 mg po tid × 3 d	10 mg/kg po tid × 3 d (max 100 mg)
	Albendazole	400 mg po qd × 3 d	10 mg/kg po qd × 3 d (max 400 mg)
Pinworm	Mebendazole	100 mg po tid × 3 d	10 mg/kg po tid × 3 d (max 100 mg)
	Albendazole	400 mg po qd × 3 d	10 mg/kg po qd × 3 d (max 400 mg)
Hookworm	Albendazole	400 mg po qd × 3 d	10 mg/kg po qd × 3 d (max 400 mg)
	Mebendazole	100 mg po tid × 3 d	10 mg/kg po tid × 3 d (max 100 mg)
Hydatid	Albendazole	400 mg po bid × 30 d	10 mg/kg po bid × 30 d (max 400 mg)
	Mebendazole	100 mg po tid × 30 d	10 mg/kg po tid × 30 d (max 100 mg)
Tapeworm	Albendazole	400 mg po qd × 3 d	10 mg/kg po qd × 3 d (max 400 mg)
	Mebendazole	100 mg po tid × 3 d	10 mg/kg po tid × 3 d (max 100 mg)

TABLE 197.2. Treatment of Gastrointestinal Parasitic Infections

CENTRAL NERVOUS SYSTEM DISEASE

Several common parasitic diseases are responsible for CNS pathology. They require the emergency physician to have a basic understanding of the life cycle of the organisms involved.

Protozoal infestations such as malaria may present with neurologic manifestations. Falciparum malaria can cause sludging of parasitized red cells in brain capillaries, resulting in severe CNS dysfunction that can progress to coma and death. Early recognition and treatment are essential to prevent this outcome.

Helminthic CNS disease is caused primarily by two tapeworms: *Taenia solium* (pork tapeworm) and *Echinococcus granulosus*. *T. solium*, an intestinal parasite in humans, can invade other tissues in its larval form, causing cysticercosis. Although 60% of reported cases of cysticercosis involve the brain, it is believed that muscular and subcutaneous encystment is more common.²¹ Humans may acquire the infestation by eating cured or undercooked pork meat that has been infected with the larvae of *T. solium*.²¹ In addition, infection may be acquired through the fecal–oral route by consuming contaminated food, such as raw vegetables, or water.⁸ Cysts formed in the brain (i.e., neurocysticercosis) can cause seizures or produce symptoms through mass effect.⁹ Worldwide and in the United States, cysticercosis is the most common parasitic disease of the CNS.⁸ Immigrants from endemic areas, such as Mexico and Central America, account for the vast majority of cases in the United States. Cysticercosis is most prevalent in communities where there is close contact between humans and pigs, and where hygiene is poor.⁸ *E. granulosus* also forms cysts in the CNS that can mimic neoplastic disease by causing compression effects or seizures.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Although *T. solium* is the most common parasitosis of the human CNS, it is symptomatic in only 50% of patients.²¹ Patients with cysticercosis of the brain may present with focal neurologic findings or impaired sensorium. The clinical features depend primarily on the location of the cyst. The cyst may be located in the meninges, brain parenchyma, or ventricles. The common presenting features include seizures (most prevalent), focal neurologic deficits, increased intracranial pressure, obstructive hydrocephalus, and stroke.^{8,21} Neurocysticercosis should be considered when these features are noted in patients with a history of living in an endemic area. Status epilepticus and mechanical hydrocephalus are the most frequent causes of death.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The information obtained from laboratory examination is often limited. A mild peripheral leukocytosis and eosinophilia may be seen. Cerebrospinal fluid (CSF) findings suggestive of cysticercal arachnoiditis include an elevated protein level, eosinophilia, and a predominantly lymphocytic pleocytosis. Several immunologic tests of the serum and CSF have been developed to aid in the diagnosis of cysticercosis.⁸ Microscopic examination of stool preparations may reveal typical eggs, proglottids (gravid uterus segments), or scolices, which are the heads of the worm. Although the patient with neurocysticercosis may no longer have a tapeworm at the time the diagnosis is made, stools of both the patient and family members should be examined for several days.⁸ Serologic diagnosis is necessary to confirm *E. granulosus* infection.

Laboratory personnel should be consulted to determine the most appropriate procedures for collecting and handling specimens. The laboratory should be informed of the patient's clinical diagnosis to assist in sample analysis. Consultation with an infectious disease expert may be helpful if the clinician is unfamiliar with the potential manifestations of a particular disease.

Computed tomography (CT) scanning of the head may show both calcified and uncalcified cysts.^{8,15} Contrast-enhanced CT scanning may demonstrate ring-enhancing lesions in both cysticercosis and echinococcal cyst disease. Magnetic resonance imaging (MRI) has been shown to be more sensitive than CT scan for the detection of active neurocysticercosis, due to the superior ability of MRI to image cysts in the brainstem, subarachnoid space, and ventricles. CT, however, is a better modality for imaging inactive, calcified cysts.¹⁵

Treatment of parasitic CNS disease may involve medical or surgical interventions and depends on the clinical signs and symptoms, the presence of active noncalcified or inactive calcified cysts, and the occurrence of complications. In addition to symptomatic treatment, options for the treatment of neurocysticercosis include anticysticercal drugs, corticosteroids, CSF shunting, and surgical cyst removal.⁸ Most parasitic infections in the active phase with viable cysts are readily treated with safe and effective agents. Patients can commonly be treated as outpatients, with appropriate follow-up.

If active neurocysticercosis is suspected, praziquantel (50 mg/kg/d in three divided doses for 15 days) or albendazole (400 mg two times a day for 8 to 30 days) should be initiated.⁵ Corticosteroids should be given for 2 to 3 days before and during drug therapy.⁵ Albendazole (400 mg two times a day for 28 days) has been used to treat echinococcal cysts. Surgical removal of cysts remains the most effective treatment.⁵

Patients who present with inactive disease (e.g., seizures secondary to parasitic calcifications) are not candidates for treatment with antihelminthic agents. Seizures are treated no differently than seizures from other causes. Neurologic or neurosurgical consultation is appropriate for these patients.

ECTOPARASITES

Ectoparasites live on the surface of the body. Those commonly seen in the emergency department include scabies (*Sarcoptes scabiei*), chigger mites (*Eutrombicula alfreddugesi* and *E. splendens*), body lice (*Pediculus humanus*), head lice (*P. humanus capitis*), and pubic lice (*Phthirus pubis*). Except for the common cold, *P. humanus capitis* affects more school-age children than all other communicable diseases combined.¹⁷

CLINICAL PRESENTATION

Ectoparasites may cause a pruritic rash, with pruritus alone or as a visual nuisance. The location of the complaints aids in the differential diagnosis. *S. scabiei* burrows under the superficial layers of the epidermis, causing small vesicles to form. Scratching may result in spread of the parasite, bleeding, and secondary bacterial infection. The most common sites for infestation include the interdigital and popliteal folds and the groin. Chigger mites, in contrast, attach to the skin surface and feed on tissue fluids, causing an intense pruritus and dermatitis. These mites attach to areas where clothing may be tight, such as the ankles, waist, and armpits. The human body lice or head lice can be found wherever personal or general hygiene is at a low level. The pubic or crab louse is found most commonly on the hairs of the genital region, although it may be found in other areas, such as the axilla and eyebrows. Lice may cause considerable distress from itching, scalp irritation, and potential secondary infection.²

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

S. scabiei may be identified by looking at a potassium hydroxide (KOH) skin scraping preparation under low-power magnification. *P. humanus* eggs or nits appear glistening white when seen in the hair. Wood's light examination may aid in the diagnosis, because the nits fluoresce under ultraviolet light.

Ectoparasites are managed primarily with topical lotions, although oral ivermectin may also be used⁴ (Table 197.3). Because transmission of ectoparasites occurs by direct contact with infested persons or with their bedding or clothing, contacts should be treated as needed, and clothing should be washed in hot water. Children should remain home from school until the infestation has resolved.²

Infection	Adult and Pediatric Dosage
LICE (PEDICULUS HUMANUS, P. CAPITIS, PHTHIRUS PUBIS)	
Drugs of choice	1% Permethrin, topically or 0.5% Malathion, topically
Alternatives	Pyrethrins with piperonyl butoxide, topically ^a Ivermectin 200 mcg/kg oral × 1 dose (adult and pediatric) ^b
MITES (SEE SCABIES)	
SCABIES (SARCOPTES SCABIEI)	
Drug of choice	5% Permethrin, topically
Alternatives	Ivermectin 200 mcg/kg oral × 1 dose (adult and pediatric) ^b 10% Crotamiton, topically
^a A second application is recommended in 1 week to kill hatchlings.	
^b An approved drug, but is considered investigational for this specific condition by the U.S. Food and Drug Administration.	
Adapted from Drugs for parasitic infections. <i>Med Lett Drugs Ther</i> 1998;46:1.	

TABLE 197.3. Treatment of Ectoparasite Infections

COMMON PITFALLS

- Failure to consider parasitic disease as a potential etiology for a variety of systemic, GI, CNS, and skin complaints. Parasitic disease should be considered in any patient presenting from an endemic area or with a travel history to an endemic area.
- Failure to consult reference textbooks concerning the appropriate diagnosis and treatment for these diseases

CHAPTER 198 Blood and Body Fluid Exposures in the Health-Care Worker

Peter E. Sokolove

[Clinical Presentation](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Hepatitis B Virus Exposure](#)
[Hepatitis C Virus Exposure](#)
[Human Immunodeficiency Virus Exposure](#)
[Summary of Acute Management](#)
[Common Pitfalls](#)
[Chapter References](#)

Despite the introduction of a safe and effective vaccine in 1982, hepatitis B remains a major problem among health-care workers. Although only about 4% of the estimated 300,000 cases of hepatitis B virus (HBV) infections in the United States each year occur in workers in health-care-related fields, seroprevalence studies indicate that health-care workers who have frequent contact with blood have a threefold to sixfold increase in seropositivity over that of the general population (15% to 30% vs. 5%).^{4,16} It is also apparent that the more frequent the blood contact, the higher the rate of seroconversion. In studies of emergency medical personnel, emergency physicians exhibited a 12% to 16% seroprevalence rate,^{11,12} emergency medical services personnel a 16% to 25% rate,^{14,17,22} and emergency department nurses a 30% rate.⁹

Although the acquired immunodeficiency syndrome (AIDS) accounts for a much smaller number of cases than does hepatitis B, it often causes more concern among health-care workers. As of June 1997, there were only 52 confirmed occupational human immunodeficiency virus (HIV) infections among health-care workers in the United States,⁵ compared with a previous Centers for Disease Control and Prevention (CDC) estimate of 12,000 health-care worker infections and 250 deaths each year from HBV.³

Previously known as non-A non-B hepatitis, hepatitis C virus (HCV) is now the most common chronic blood-borne infection in the United States. About 3.9 million Americans are infected with this virus, with about 36,000 new infections each year. While the overall prevalence of HCV in health-care workers is similar to that of the general population (1% to 2%), emergency department personnel are at high risk of exposure.⁷ In one study from an inner-city emergency department, the prevalence of HCV infection among patients was 18%, compared with 5% for HBV and 6% for HIV.¹³

CLINICAL PRESENTATION

Health-care workers frequently present to the emergency department after exposure to material potentially infected with HBV, HCV, or HIV. First, the exposure must be assessed. Although blood is the single most important source of infection, other fluids may also transmit disease. Semen or vaginal secretions; cerebrospinal, synovial, pleural, peritoneal, pericardial, or amniotic fluids; and tissue are capable of transmitting HIV, HBV, and probably HCV. Unless blood is visible in them, feces, nasal secretions, sputum, sweat, and tears have not been identified as vehicles of transmission for HBV, HCV, or HIV infection. Transmission occurs most effectively through direct percutaneous exposure (e.g., needlestick); although far less likely, exposure through mucous membranes or open skin lesions can also result in HBV, HCV, and HIV transmission. Casual contact, airborne, and fecal-oral transmission have not been documented.^{5,7,10}

EMERGENCY DEPARTMENT EVALUATION

An initial evaluation should be made to assess the risk of disease transmission. Information about the injury should be gathered, including the infectious material, instrument, procedure performed, depth of penetration, and volume of blood transferred. The source person should be evaluated for HIV and hepatitis risk factors, clinical signs of disease, previous HIV therapy, and viral load or CD4 count, if known.

The health-care worker should be evaluated for his or her medical history and immunization status for hepatitis B and tetanus. The source blood should be tested for hepatitis B surface antigen (HBsAg), HCV, and HIV antibodies. If the source is found to be positive for HBsAg, the source should also then be tested for hepatitis B e antigen (HBeAg). The health-care worker should be tested for hepatitis B surface antibody (HBsAb), HCV, HIV, and pregnancy, as appropriate. Testing of sharp instruments is not recommended or reliable.⁵

EMERGENCY DEPARTMENT MANAGEMENT

Hepatitis B Virus Exposure

Two types of products are available for the management of the exposed health-care worker. Hepatitis B immune globulin (HBIG), derived from plasma containing high titers of antibody to HBsAg, confers passive immunity. Side effects are minimal, and there is no evidence of HBV or HIV transmission with this product. For postexposure prophylaxis, the dose is 0.06 mL/kg intramuscularly. It should be administered within 72 hours of exposure (preferably within 24 hours), and is probably not useful beyond 7 days.⁴ The average wholesale cost (in 1998) is \$652 per dose.¹⁸

Hepatitis B vaccine is available for active immunization. It is a recombinant vaccine that is very safe, even in pregnancy. For postexposure prophylaxis of nonvaccinated individuals, 1 mL of vaccine is administered intramuscularly in the deltoid within 7 days of exposure and repeated at 1 month and 6 months.⁴ Because about 10% of adults will not initially achieve the recommended antibody titer following this series, antibody levels should be checked 4 to 6 weeks after the series is completed. Health-care workers who are smokers, obese, over the age of 50, or immunocompromised are less likely to respond to the initial vaccination series.^{20,23} Nonresponders may require a fourth dose of vaccine or intradermal administration. For health-care workers who achieve a level of at least 10 mIU/mL, the vaccine is essentially 100% effective in preventing subsequent HBV infection. The average wholesale price of HBV immunization is \$165 per course.¹⁸

Whether to administer HBIG, HBV vaccine, both, or neither is based on the HBsAg status of the source person and the vaccination status of the exposed health-care worker (Fig. 198.1).^{3a} A source person can transmit HBV if HBsAg is present, but the degree of infectivity is best correlated with HBeAg positivity. The risk of seroconversion after a percutaneous exposure to HBsAg-positive blood ranges from 2% (HBeAg negative) to 40% (HBeAg positive).¹⁰ Of those infected with HBV, about 25% develop acute hepatitis, and 6% to 10% develop chronic infection.³ These patients are at increased risk of cirrhosis and hepatocellular carcinoma.

Figure 198.1. Hepatitis B exposure algorithm. (1) Adequate antibody greater than or equal to 10 mIU/mL. (2) Preferred for those who have failed to respond to at least four doses of vaccine. (Adapted from Centers for Disease Control. Immunization of health-care workers; recommendations of the Immunization Practices

Hepatitis C Virus Exposure

There are currently no agents available for managing exposure of the health-care worker to HCV.⁷ Immune globulin is not useful for postexposure prophylaxis of HCV¹⁹ for a number of reasons. In contrast to HBsAb, HCV antibody is only a marker antibody, not a neutralizing antibody. Even if a neutralizing antibody did exist among the donor population, immune globulin is derived from plasma donors that are excluded from donation if they test positive for HCV. Finally, HCV mutates rapidly, and new variants may be unaffected by neutralizing antibodies.

There is currently no vaccine against HCV, as this virus demonstrates great genetic heterogeneity and a high mutation rate.¹ Alpha-interferon, sometimes in combination with ribavirin, has been used successfully to treat patients with chronic hepatitis due to HCV.¹⁵ Unfortunately, there is currently no evidence to support a role for such agents in postexposure prophylaxis.

The average risk of acquiring HCV infection after percutaneous exposure is 1.8%, and ranges from 0% to 7%.⁷ Of those who acquire HCV infection, approximately 75% to 85% develop chronic infection, of whom 60% to 70% have liver enzyme elevations.⁶ Of patients with chronic HCV infection, about 10% to 20% develop cirrhosis, and about 1% to 5% develop hepatocellular carcinoma.⁷

Human Immunodeficiency Virus Exposure

Emergency department management of potential exposure to HIV materials consists of serologic testing of the exposed health-care worker and exposure source, counseling the health-care worker on the risk for infection, and consideration of postexposure prophylaxis. While previously the use of antiviral agents to prevent HIV seroconversion in exposed health-care workers was considered highly controversial, new evidence supports the use of certain drugs in many cases. The theoretical basis for postexposure prophylaxis is that there is a window of opportunity before HIV infection is established in the host. Antiviral agents may prevent or limit the replication of HIV in dendritic cells or regional lymph nodes, which appear to be the initial targets and route of spread of HIV.⁵

Many animal studies have demonstrated that the use of postexposure antiviral agents can prevent or delay HIV infection.²¹ In human studies, when HIV-infected mothers were administered zidovudine (AZT) during pregnancy, perinatal transmission of HIV was decreased by 67%.⁸ While transmission during pregnancy is different from percutaneous exposure, these data clearly demonstrate that antiviral agents can be used to prevent blood-borne infection in an HIV-negative individual. The most compelling evidence of postexposure prophylaxis efficacy, however, was a multinational case-control study, performed by the CDC.² In this study of health-care workers who had HIV exposures, mostly as a result of hollow-bore needlesticks, the risk for HIV infection was reduced by 81% if AZT was given following exposure. These new data prompted the Public Health Service to recommend postexposure prophylaxis for health-care workers exposed to HIV.⁵

AZT is a nucleoside reverse transcriptase inhibitor, and is administered in divided doses totaling 600 mg per day. Treatment should be continued for 4 weeks, but about one-third of health-care workers will discontinue therapy because of adverse symptoms. Short-term toxicity of AZT mostly consists of gastrointestinal (GI) discomfort and fatigue. Bone marrow suppression can be seen, but it is reversible and very rare in healthy individuals.

While AZT is the only drug shown to be beneficial for HIV postexposure prophylaxis in humans, multidrug regimens are often employed because of concerns about AZT-resistant strains of HIV, as well as a demonstrated synergistic effect of certain antiviral agents in the treatment of patients for AIDS. AZT resistance should be suspected if the source person is an HIV-positive patient who is not responding to AZT therapy. However, AZT-resistant strains can be found in HIV-positive patients who have never taken AZT.

Lamivudine (3TC) is another nucleoside reverse transcriptase inhibitor, and has been demonstrated to have synergistic antiviral activity when added to AZT to treat patients who have AIDS. The primary toxicity of 3TC is adverse GI symptoms, and pancreatitis is rare. 3TC is administered at a dose of 150 mg twice a day for 4 weeks. Because of the potential for increased efficacy without an increase in side effects, 3TC is usually added to the postexposure prophylaxis regimen whenever AZT is given.⁵

Protease inhibitors should be considered for use as a third agent in the postexposure prophylaxis regimen for certain high-risk exposures. These agents inhibit HIV aspartyl protease and are very potent antiviral agents. Unlike the nucleoside agents, protease inhibitors do not require phosphorylation to become active, providing the theoretical benefit of having an active agent present in the bloodstream very rapidly following exposure.

Indinavir or nelfinavir are generally the preferred agents for postexposure prophylaxis because of their rapid bioavailability and the fact that patients are able to start treatment at full dose. Indinavir is administered at a dose of 800 mg three times a day for 4 weeks. Its major side effects are GI discomfort, hyperbilirubinemia (10%), and renal stones (4%). Patients should be instructed to drink at least 1.5 L of fluid each day to help prevent stones. Nelfinavir is administered at a dose of 750 mg three times a day for 4 weeks.⁵ This agent commonly results in diarrhea, so antimotility agents (e.g., loperamide) should be prescribed. All protease inhibitors may result in hyperglycemia. In rare cases, these agents may precipitate diabetic ketoacidosis, even in nondiabetic patients.

When determining whether to initiate postexposure prophylaxis, as well as which agents to choose, the physician must consider a number of factors. The type of exposure helps determine the risk of seroconversion, and thus the potential benefit of postexposure prophylaxis. As of this writing, there have been no reported cases of HIV seroconversion when blood has come in contact with intact skin. If the skin integrity is compromised, or if mucous membranes are exposed, transmission is unlikely but can occur.

The risk of transmission following a mucous membrane exposure to blood is about 0.1% (one in 1,000). The risk of transmission can be higher if a large volume of blood is involved or if prolonged contact occurs. The average risk for HIV transmission following percutaneous blood exposure is about 0.3% (one in 300) but depends on the severity of the exposure.⁵ Table 198.1 lists the risk factors for HIV transmission after percutaneous blood exposure, as reported in the previously described CDC case-control study.²

Risk Factor	Odds Ratio	95% CI
Deep injury	15	6-41
Blood visible on device	6.2	2.2-21.0
Procedure with needle placed directly into artery or vein	4.3	1.7-12.0
Terminal AIDS in source patient	5.6	2-16
Postexposure zidovudine (AZT)	0.19	0.06-0.52

Adapted from Cardo DM, Culver DH, Ciesielki CA, et al. A case-control study of HIV seroconversion in health care workers after percutaneous exposure. *N Engl J Med* 1997;337:1487.

TABLE 198.1. Risk Factors for HIV Transmission after Percutaneous Blood Exposure

The HIV status of the source person is also important when assessing the risk of transmission and choice of antiviral agents. If the source person is currently HIV-negative and has not had a recent retroviral-like illness (symptoms similar to those of acute mononucleosis), postexposure prophylaxis is not indicated. For HIV-positive source persons, the degree of infectivity is related to the patient's viral load. High viral loads are seen in patients with advanced AIDS or primary HIV

infection. In 1998, the Public Health Service published a three-step algorithm for determining the need for and choice of HIV postexposure prophylaxis ([Fig. 198.2](#)).⁵

Figure 198.2. Determining the need for HIV postexposure prophylaxis. (Adapted from Centers for Disease Control. Public Health Service guidelines for the management of health-care worker exposures to HIV and recommendations for postexposure prophylaxis. *MMWR* 1998;47(RR-7):14–15.)

The timing of the initiation of postexposure prophylaxis is very important, as animal models have demonstrated an increased risk of infection with delays in AZT administration. It is best to initiate therapy promptly, preferably within 1 hour of exposure. It is unclear how long following exposure treatment can be initiated and still be effective, but animal data suggest that some benefit may persist up to 36 hours.²¹

Summary of Acute Management

Acute management includes thorough washing of the exposed area with soap and warm water or flushing of mucous membranes. As with all wounds, the need for tetanus toxoid administration should be considered. HBIG or hepatitis B vaccine or both should be administered as indicated (see [Fig. 198.1](#)). HIV postexposure prophylaxis should be recommended based on the exposure type and the source HIV status (see [Fig. 198.2](#)). The health-care worker should be counseled regarding the risks of HBV, HCV, and HIV infection, as well as modifications of behavior (e.g., abstinence or condom use) to prevent secondary infection of others.

COMMON PITFALLS

A common error in the management of health-care worker exposures is to provide either unnecessary or inadequate treatment. Unnecessary treatment usually results from an overestimation of the infectious potential of an exposure, such as providing three-drug antiretroviral therapy for a blood splash onto intact skin. Undertreatment can occur if the treating physician is unaware of the benefit of postexposure prophylaxis, or if treatment for HIV exposure is delayed. These pitfalls can be avoided by applying a standardized protocol, such as the algorithms presented here. In uncertain or complex cases, consultation with an employee health service or an infectious disease specialist is advised.

CHAPTER 199

Altered Mental Status and Coma

Gregory L. Henry

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation and Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Coma is the most dramatic of the disorders of consciousness, but it is only the end point in a continuum of disease. Any disease process that can cause coma may initially present with mild alterations of mental status. It is often difficult or impossible to determine the direction and final outcome of a change in mental status until the most important test—the test of time—has been applied.

In severe nervous system disease, a change in mental status is often the first sign of a serious pathologic process.¹⁴ It is generally recognized that the functional change is always greater and always precedes structural change in the brain and spinal cord. Of all the central nervous system functions, mental status is the most delicate and the most sensitive early indicator of advancing involvement of the nervous system.

Sophisticated evaluation of altered mental status always comes after the standard emergency medicine approach of initial stabilization, control of airway and breathing, and cardiovascular support.^{19,20} When this has been achieved, the emergency physician should divide patients with severely altered mental status into two distinct groups: (1) those with diffuse metabolic or toxic causes of altered mental status and (2) those with focal disease that may require immediate surgical therapy. Although the differential diagnosis is exhaustive, the major job of the emergency physician is to differentiate between these two major groups. The management of toxic and metabolic disease is principally medical, and the management of focal disease is often surgical. To delay diagnosis may mean considerable harm to the patient.

When recording the patient's status, it is often better to describe in detail exactly which mental functions are present and which are not, rather than using potentially misleading nonspecific terms.⁶ Such terms convey little information about the patient's neurologic functioning. The charting in the record of objective findings, such as the patient's ability to handle three-object retention and mathematic calculations, is much more effective than the use of terms such as *stuporous* or *lethargic*. *Consciousness* may be defined as an awareness of self and the environment. Disorders of consciousness can be divided according to levels of patient responsiveness.

CLINICAL PRESENTATION

Patients with altered mental status may present in multiple ways.¹⁹ Sleep, a state of nonpathologic decreased mental status from which the patient can be easily aroused to full consciousness, may be a frequent finding in emergency departments. Although the sleepy patient experiences a transitory deterioration of mental status, the ability to return to normal function on arousal should separate sleep from pathologic conditions.

The term *lethargy* is, unfortunately, still part of medical jargon. *Lethargy* may best be defined as depressed mental status in which the patient may appear wakeful but has depressed awareness of self and environment globally and cannot be aroused to full function. However, the term is extremely vague and often causes as much confusion as enlightenment.

Stupor refers to an unresponsive condition from which the patient can be aroused with vigorous stimuli to purposeful activity. The stuporous patient, however, does not return to normal baseline awareness of self or environment.

Coma is the extreme end of the continuum of mental status change. A comatose patient is unresponsive and is not arousable by either verbal or physical stimuli to a level at which any purposeful or meaningful response can be made.

Like all aspects of emergency medicine, psychological factors are ever present. Psychogenic coma is a state of unresponsiveness, either voluntary or involuntary, from which the patient cannot be brought to reasonable cortical response by noxious, verbal, or physical stimuli, yet in which physiologic test results and electroencephalographic responses are normal.

Another major group of patients may appear awake but does not respond to stimuli. One group exhibits the abulic state, often referred to as akinetic mutism.^{9,19} These patients are awake, with their eyes open, but are extremely slow in all mental processes and find it difficult to respond to questioning. Frontal lobe function is so depressed, from any number of processes, that they cannot respond meaningfully within a normal time frame. These patients often can process information, but because of the huge time delays in their ability to respond and answer, they are often misdiagnosed in the emergency department. They may take several minutes to respond to any problem or question posed.

A most unusual and dramatic form of seemingly awake but altered mental status is the locked-in syndrome. A patient with such a syndrome appears motionless, with eyes open. The lesion in the locked-in syndrome is the destruction of the ventral pontine motor tracts. The only function these patients maintain is vertical eye movement. Unresponsive patients who appear awake should be asked to look up. If a patient can look up but cannot move the eyes side to side in a horizontal plane, the diagnosis of locked-in syndrome is confirmed.^{7,8 and 9}

Some patients appear awake but have psychogenic unresponsiveness (previously called the catatonic state). The level of unresponsiveness may vary; the patient may maintain normal motor posturing and neurologic testing but, for voluntary or involuntary reasons, cannot communicate with the examiner. Common psychiatric practice in the past was to use psychotropic medication to disinhibit such patients and to allow communication.

Patients may have altered mental status without actual depression of mentation. Acute confusional states exist in which the patient is alert and active but misinterprets external stimuli. The hallmark of such confusional states is global disorientation with an inability to appropriately process stimuli or an inability to make meaningful responses. Such findings are characteristic of toxic ingestions and metabolic encephalopathy and occasionally accompany central nervous system infections.

It is often a challenge to distinguish mental status changes caused by structural or chemical disease from those that are the result of psychological processes. The terms *encephalopathy* and *delirium* should be reserved for the former. In general, these organically based changes in mental status can be differentiated from psychological problems by certain characteristics.

An important difference has to do with *orientation*. In organic disease, orientation is virtually always lost in a predictable manner: Orientation to time is almost always lost before orientation to specific place, generic place, or person. When there is a loss of orientation that does not follow the expected order (i.e., time, specific place, generic place, and person), a psychological component should be suspected.

In contrast, abnormal *vital signs* should always raise suspicion of an organic process. Vital signs should be reassessed frequently as a usual part of patient evaluation. Be aware of the patient with altered vital signs who is diagnosed as having a "psychiatric condition."

Speech is perhaps the most sensitive indicator in differentiating between organic and psychiatric disease. Patients with an organic alteration of mental status generally have globally slowed speech patterns. There are often problems with articulation, particularly in toxic–metabolic encephalopathies. Speech that is rapid, well articulated, and well enunciated indicates that the vast majority of the nervous system is functioning normally. Even patients with severe psychiatric disorders often speak rapidly, clearly, and without any obvious hesitation.⁶

Thought content, as well as the way in which it is articulated, can also be extremely helpful. Patients with organic lesions rarely display bizarre or unusual ideation or associations and rarely have complex delusional systems. Patients with organic depression generally display a paucity of ideas or thought but no depressive content, morbid fears, or ideation.

Finally, the pattern of any *changes* in mental status provides important information. A progressive decline of alertness and slowing of mental activity are characteristic of organic neurologic disease. Similarly, many organic toxic–metabolic conditions (e.g., alcohol or drug intoxication) tend to improve progressively with time. Clouding of consciousness and a waxing and waning of alertness are also characteristic of delirium, however. In contrast, psychiatric patients often display moment-to-moment alterations in behavior that tend in different directions at different times. The psychiatrically unstable patient may be extremely active one minute and essentially catatonic the next. Thus, psychiatric disease must be a consideration if there are rapid up-and-down changes in alertness or behavior.

DIFFERENTIAL DIAGNOSIS

There is a vast array of chemical agents and disease entities that can alter mental status. The emergency physician must have a basic framework in which to place all of these before considering the individual causes. From an operational standpoint, the neurologic examination and laboratory studies divide the causes of altered mental status into toxic–metabolic diseases and infratentorial lesions that affect the reticular activating formation ([Table 199.1](#) and [Table 199.2](#)).

Metabolic Disorder	Significant Differential Elements
Hypoglycemia/hyperglycemia	Diabetes at high risk, both insulin-dependent and users of oral hypoglycemics; also more prone to infectious disease and renal failure. Hypoglycemia may be seen in patients with certain tumors, chronic alcoholism.
Hepatic failure	More common in long-standing alcohol abuse and/or hepatitis. May lead to rapid rise in serum ammonia. May be associated with hypoglycemia due to decreased glycogen storage.
Uremia	Affects intracranial cerebral water content.
Oxygen deprivation	All aspects of cardiopulmonary system may be involved. Severe anemia, decreased cardiac output due to poor myocardial contractility, and arrhythmias. Central hypoglycemia secondary to medications. Rapid increase in CO ₂ despite adequate O ₂ will alter mental status.
Indirect bilirubin	Rapid changes in serum values affect osmolality and cerebral water content. Hyperbilirubinemia gradual elevation of mental status. Hyperbilirubinemia generally associated with renal disease; not seen until the patient is in advanced stages of disease.
Carcinoma	Remote effect of carcinoma and alteration of osmolality (i.e., syndrome of inappropriate secretion of antidiuretic hormone). Metabolic alkalosis with Cushing syndrome. Hypo- and hypernatremia states may alter consciousness, but progressive metabolic leukoencephalopathy seen with hyponatremia may present as depression of consciousness.
Poisons and toxins	Alcohol still most widely used and commonly seen metabolic poison, relatively characteristic. Barbiturates (often may be of several weeks' duration). Heavy metals (lead, iron, selenium, and fungal infections acquired immunodeficiency syndrome, encephalopathy, methanol/poison) underused.

TABLE 199.1. Toxic–Metabolic Disorders

Structural Disease	Significant Differential Elements
Subdural hematoma	Severe neurologic signs, particularly involving motor functions, may be associated with focal neurologic signs but usually become localized when symptoms begin. Progressive mental deterioration. Common in elderly patients, alcoholics, and patients on anticoagulants. Most of the time, the patient is found in a supine position. The patient may be found in a supine position or in a position of prolonged unconsciousness. The patient may be found in a supine position or in a position of prolonged unconsciousness.
Epidural hematoma	Altered consciousness, focal neurologic signs, and pupillary changes. Common in young patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Chronic subdural hematoma (SDH)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Intracranial hemorrhage	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Cerebral neoplasms	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Intracranial neoplasms (meningiomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms (gliomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms (ependymomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms (astrocytomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms (oligodendrogliomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms (schwannomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms (meningiomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms (gliomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms (ependymomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms (astrocytomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms (oligodendrogliomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.
Brain stem neoplasms (schwannomas)	Altered consciousness, focal neurologic signs, and pupillary changes. Common in elderly patients who sustain head trauma. The patient is usually found in a supine position or in a position of prolonged unconsciousness.

TABLE 199.2. Structural Disease

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Emergency department evaluation of the patient with severely depressed mental status or coma requires a systematic approach. The principles of management are to support the patient's airway, breathing, and circulation; treat most obvious causes first; perform a detailed examination; produce the specific diagnosis; and begin specific therapy. [Table 199.3](#) lists initial management steps, both supportive and diagnostic measures, that should be performed on such patients. ^{10,11}

TABLE 199.3. Initial Evaluation and Management for Patients with Altered Mental Status

After initial supportive measures and examination, decisions on further examination must be made ([Fig. 199.1](#)).¹⁷ The first step is to separate patients who have intact brainstem function from those who do not. As the algorithm of [Fig. 199.1](#) shows, patients with acute brainstem failure can then be divided into those with obvious herniation syndromes or signs of transtentorial herniation and those without such findings. Patients without evidence of herniation require toxic–metabolic screens and a computed tomographic (CT) scan. Normothermic patients who have not received neurologically active drugs and have no brainstem reflexes are considered to have unsalvageable brain tissue.² Patients with evidence of focal herniation require immediate neurosurgical consultation; mannitol may be given if recommended by the neurosurgeon. In the patient who has developed the complete tentorial herniation syndrome, if an operating room is not immediately available, burr hole decompression on the side of the dilated pupil should be considered.

Figure 199.1. Diagnostic and treatment approach to coma.

Similar decisions must be made about patients whose brainstem reflexes are intact. If CT scan results are normal, a lumbar puncture may be done. Bloody cerebrospinal fluid and a CT scan without a focal finding indicate subarachnoid hemorrhage. If the patient's condition is stable, angiography can be done; if a focal aneurysm or arterial venous malformation is found, surgery should be a serious consideration.

For patients with intact brainstem reflexes and initially positive CT scans, the neurosurgeon should decide whether the offending lesion is operable or inoperable.

In those patients who, after testing, are found to have toxic–metabolic conditions, appropriate medical therapy should be instituted without delay.

DISPOSITION

Consultation is immediately required on any potentially operable focal lesions, and immediate contact with a neurosurgeon is essential if the brain is to be saved. In patients in whom there is no surgically treatable disease, consultation with either a neurologist or internist for intensive care unit admission is indicated.

All patients with significantly altered mental status require admission after definitive diagnosis for continued evaluation and treatment.

When transferring comatose patients, it is important to provide basic support. Such patients generally require definitive airway control before transfer. Rapid transfer to a center with neurologic and neurosurgical diagnostic and treatment capabilities is essential in patients with potentially surgically treatable disease.

COMMON PITFALLS

- A major mistake is to wait for laboratory results when physical examination findings clearly point to a focal process requiring immediate surgical intervention. Many things in the evaluation of the comatose patient must be done simultaneously, and to wait for the sequential return of tests may doom the patient to permanent neurologic damage or death.
- Another common pitfall is failure to treat common causes first. Proper establishment of an airway, cardiovascular support, and provision of adequate oxygen and glucose are critical to proper care of the patient with severely altered mental status.^{12,13}
- The most critical common pitfall in the evaluation of altered mental status is failure to reexamine the patient at intervals. Close attention to changes in level of consciousness, vital signs, speech patterns, and thought content is often helpful in separating organic from psychiatric conditions.

CHAPTER 200

Organic Brain Syndrome

Sandra M. Schneider

- [Clinical Presentation](#)
- [Differential Diagnosis](#)
- [Emergency Department Evaluation](#)
- [Emergency Department Management](#)
- [Disposition](#)
- [Common Pitfalls](#)
- [Chapter References](#)

Organic brain syndrome is a disorder of orientation, memory, intellect, judgment, and affect resulting from diffuse impairment of brain tissue.⁵ This impairment leads to an altered mental status (either lethargy or excitement), confused thinking, and/or abnormal behavior. Organic brain syndrome may occur at any age. Although every intoxicated patient seen in the emergency department could be said to have “organic brain syndrome,” the term is more commonly applied to older or debilitated patients in whom the etiology is less obvious.

CLINICAL PRESENTATION

Of the several types of organic brain syndrome, the two most important to emergency physicians are dementia and delirium. [Table 200.1](#) and [Table 200.2](#) illustrate the important differences between dementia and delirium. The distinction is extremely important for diagnosis, prognosis, and determination of the need for hospitalization and treatment. [Table 200.3](#) summarizes the clinical characteristics of delirium, dementia, and psychosis.

- A. Disturbance of consciousness (i.e., reduced clarity of awareness of environment) with reduced ability to focus, sustain, or shift attention.
- B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.
- C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.

From Diagnostic and statistical manual of mental disorders, 4th ed. Washington, DC: American Psychiatric Association, 1994.

TABLE 200.1. Diagnostic Criteria for Delirium (as defined by DSM-IV)

- A. The development of multiple cognitive deficits manifested by both:
 1. memory impairment (impaired ability to learn new information or to recall previously learned information)
 2. one (or more) of the following cognitive disturbances:
 - a. aphasia (language disturbance)
 - b. apraxia (impaired ability to carry out motor activities despite intact motor function)
 - c. agnosia (failure to recognize or identify objects despite intact sensory function)
 - d. disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
- B. The cognitive deficits in Criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
- C. The deficits do not occur exclusively during the course of a delirium.

From Diagnostic and statistical manual of mental disorders, 4th ed. Washington, DC: American Psychiatric Association, 1994.

TABLE 200.2. Diagnostic Criteria for Dementia (as defined by DSM-IV)

Delirium	Dementia	Psychosis
ONSET		
Rapid	Slow	Rapid
PATTERN		
Fluctuating	Fluctuating or stable	Stable
ORIENTED		
No	Yes	No
ATTENTION		
Disordered	Normal	Delusional
COGNITION		
Disordered (impaired)	Impaired	Selectively
SPEECH		
Incoherent	Perseveration	Rapid, pressured

TABLE 200.3. Clinical Characteristics of Delirium, Dementia, and Psychosis

Dementia is the chronic insidious loss of intellectual function. Common causes are listed in [Table 200.4](#). Correctable causes of dementia include thyroid dysfunction, vitamin deficiencies, and normal pressure hydrocephalus. Memory is impaired, along with other higher cerebral functions, such as abstract thinking, judgment, and personality. Although dementia is slow in onset and there may be fluctuations in mental function, complete return of normal function is rare. Patients are generally oriented and aware of their environment until quite late in the disease.¹¹ Some patients experience depression as they try to make sense of their impaired mental function and become fearful of their future dependence. This depression may then lead to additional alterations in affect.

ALTERED STATE	Fluctuating, disoriented, nondescript, waxing/waning, hyperactive
PRE-EXISTING	Usually none; personality change when in Alzheimer's disease; usually none; personality change when in Alzheimer's disease
ETIOLOGICAL SYNDROMES WITH SUBCORTICAL DEFICITS	Includes Parkinson disease, Wilson disease, and Huntington disease
ADULT-ONSET INFANTILE DEMENTIA	Highly variable presentation, often with aggressive deterioration and fluctuating course; may have history of previous normal intelligence or childhood intellectual disability; focal neurologic deficits or generalized tonic-clonic seizures may occur
VERBAL AND OTHER SPERMATOPHYTES	Includes progressive degenerative neurodegenerative disorders associated with frontal lobe dysfunction; usually, but not always, associated with personality, judgment, and executive dysfunction
TOXIC AGENTS AND DRUGS	Includes heavy metals, chronic drug abuse, industrial agents
METABOLIC DISORDERS	Includes thyroid disease, hypothyroidism, hyperthyroidism, uremia, hepatic failure, and hypoxia
VITAMIN DEFICIENCIES	Vitamin B ₁₂ , folate, and other deficiencies
CEREBRAL VASCULAR DISEASES, SUBARACHNOID HEMORRHAGE	Thrombotic infarction and subarachnoid hemorrhage; focal lesions; subarachnoid hemorrhage; cerebral aneurysm, and multiple sclerosis
PROLIFERATIVE DISORDERS	Depression, mania, schizophrenia, and bipolar disorder

EMERGENCY DEPARTMENT EVALUATION

A careful history should be obtained from the patient, family members, friends, neighbors, medical records, primary care physicians, or emergency medical services personnel. The goal of the history is to (1) establish the preexisting mental status; (2) establish the time pattern of the onset of the altered mental status; (3) establish rapport with the patient and with the family to avoid unnecessary restraints or sedating medications; and (4) identify current medical problems, medications (particularly over-the-counter medications), and stresses in the patient's life that may have predisposed to the alteration in mental status. Some families may engage in denial about preexisting dementia symptoms or try to hide suspected drug or alcohol use. Access to alcohol, over-the-counter drugs, and prescription drugs, including narcotics, is an important clue to the diagnosis.

The physical examination should be directed at two items: establishing the existence and severity of delirium or dementia and identifying potential causes. Hypothermia or hyperthermia suggests sepsis or environmentally based disease. Some infections may be inapparent, and evidence for them should be sought (e.g., decubiti, dental caries, and perirectal disease). Even benign-looking decubiti should be examined thoroughly for underlying purulence. Fecal impaction may contribute to acute delirium, particularly in patients with underlying dementia. Rectal examination with disimpaction is appropriate in all patients.

The best way to assess the presence of an altered mental status is to use the Mini-Mental Status examination ([Table 200.6](#)).⁷ This test has a high sensitivity (87%) and specificity (82%) when compared with a psychiatrist's opinion of the presence of delirium.¹ One of the earliest signs of acute delirium is the inability to recall three items after 3 minutes. Acute delirium can fluctuate rapidly; the patient who is currently lucid may be quite different 1 or 2 hours later.

	Maximum Points
ORIENTATION	
What is the year, date, day, month?	5
Where are you: state, country, town, hospital, floor?	5
REGISTRATION	
Recalling 3 objects immediately	3
ATTENTION	
Serial 7's or spell "world" backward	5
RECALL	
Renaming the above 3 objects after another exercise	3
LANGUAGE	
Name a pencil and a wristwatch	2
Repeat "no ifs, ands, or buts"	1
Follow 3 state commands (e.g., take a paper in your right hand, hold it in ball, and put it on the floor)	3
Read and copy "close your eyes"	1
Write a sentence (from dictation)	1
Copy a design	1

TABLE 200.6. Mini-Mental Status Examination

The laboratory evaluation of patients with acute delirium should be directed at uncovering the cause or causes of the delirium. A tiered approach to laboratory ordering is perhaps best. The initial evaluation should include a complete blood cell count and differential; determination of levels of electrolytes and glucose; renal and liver function tests; and urinalysis (with culture when pyuria is present). When indicated, a chest radiograph, an electrocardiogram, and an arterial blood gas analysis should be performed. Patients with headache or a history of head trauma should have an urgent computed tomographic scan of the head. In debilitated, chronically ill, or malnourished individuals, knowledge of magnesium, calcium, and phosphorus levels may be helpful. Patients with no obvious cause of their mental status change should have computed tomography of the head, sedimentation rate determination, a serum and urine osmolality study (to screen for toxins such as methanol and ethylene glycol), and a toxicology screen, including levels of prescription drugs normally taken. Febrile patients warrant a more aggressive workup, often including a lumbar puncture if no other source of fever has been discovered or if there are signs of CNS infection or immunosuppression. HIV-positive individuals should have an early computed tomographic scan of the head and lumbar puncture. Finally, patients still without an obvious cause may require thyroid function tests, vitamin B₁₂ and folate levels, and, if indicated, heavy-metal screens. The results of some of these tests will not be immediately available and are often best ordered in consultation with the primary physician. Electroencephalographic evaluation may be beneficial in selected patients to distinguish between fast activity (seen in drug-withdrawal states) and slow activity (seen with either toxic or other physiologic causes of acute delirium) and to detect the occasional patient with nonconvulsive status epilepticus.

EMERGENCY DEPARTMENT MANAGEMENT

Management should be directed toward three basic goals. As always, the first is to search for and correct potentially life-threatening causes (e.g., hypoxemia, temperature abnormalities, hypotension). The second goal is to discover and treat the underlying cause of delirium. All patients should have a bedside test to determine the serum glucose concentration or receive 50% dextrose. Naloxone should be given to any patient with a seriously depressed level of consciousness and possible narcotic exposure and to comatose patients for diagnostic purposes. In patients in whom the cause is obvious (e.g., infection, fluid or electrolyte imbalance), definitive treatment should eventually return the patient to a baseline state. Patients in whom the cause is less obvious may require a different approach. In these cases, it may be necessary to discontinue, or at least decrease, the dose of all medications with the potential to cause delirium. Patients identified as suffering from anticholinergic-induced delirium should be placed in a safe environment while the drug clears the body. Reversal of anticholinergic effects with physostigmine should be reserved for life-threatening arrhythmias and should not be used as a test for anticholinergic toxicity nor to reverse delirium. Administration of physostigmine can cause seizures and sudden death.

The final goal of management is to protect the patient while diagnostic evaluation and therapy proceed. Patients should be oriented to their new surroundings (the emergency department) to reduce anxiety. Patients should be kept in a well-lit room with as little extraneous noise as possible. Those who use hearing devices or glasses should be encouraged to wear them. Caregivers should be careful to introduce themselves and to explain their role and any planned procedures. Family and friends should be allowed to remain with the patient or to visit frequently.

Restraints may be necessary to control potentially dangerous behavior (e.g., wandering) and to prevent falls from bed. There are two types of restraints, physical and chemical, and the use of either should be reserved for patients who present a danger to themselves or whose behavior is extraordinarily disruptive. When physical restraints are used, there should be clear documentation on the chart stating their necessity. Explanation should be given to family members and visitors, as well as to other patients and visitors in close proximity to the patient. Mildly confused individuals can be reminded by soft restraints to stay in bed. More aggressive devices involving a netlike blanket or leather restraints can be used to control and protect more aggressive patients.

Chemical sedation is often preferable to physical restraints but may further add to the patient's confusion, and certainly will not aid in establishing the diagnosis. The ideal sedating drug would be one that calms the patient without worsening delirium, and it would have no anticholinergic or extrapyramidal side effects. The ideal drug could be given parenterally with no effect on blood pressure, the heart, or the respiratory system. Unfortunately, such ideal therapy does not exist. Haloperidol (5 to 10 mg intramuscularly) and droperidol (5 mg intramuscularly) are the agents most commonly used for acute sedation. Peak effect occurs at 30 minutes, and the dose can be repeated at that time. Major side effects include orthostatic hypotension, a decrease in seizure threshold, and, rarely, neuroleptic malignant syndrome. Other side effects of haloperidol or droperidol include dystonic reactions and akathisia. As an alternative, a benzodiazepine such as lorazepam (0.5 to 1.0 mg intramuscularly) can be given initially and repeated every hour. It can be used alone or as an adjunct to haloperidol. Several other psychotropic drugs, including chlorpromazine and thioridazine, have also been used for acute sedation.

DISPOSITION

Disposition is determined by the presence or suspicion of a serious underlying disease, the abruptness with which the organic brain syndrome has developed, and the ability of family and caretakers to provide a safe environment for the patient.

The following patients are likely to require admission:

Patients with identified infection, fluid or electrolyte imbalance, or CNS structural disease

Patients with acute confusion and no obvious underlying etiology, provided the confusion is significant or appropriate close follow-up is not available

Patients with a preexisting normal mental status who experience acute delirium, unless the delirium can be cleared while in the emergency department (e.g., as with hypoglycemia)

The chronically demented person who has not experienced an acute deterioration, but is often brought to the emergency department by exhausted caretakers looking for relief. The patient or family may have previously refused or been denied assistance through social services or long-term care placement.

In some hospitals, there are on-call teams to assist with the disposition of these individuals. However, without proper backup, many emergency physicians are forced to hospitalize such patients when caretakers are unable or unwilling to provide a safe environment for them.

COMMON PITFALLS

- Failure to appreciate the patient's true baseline mental status. It is often necessary to call neighbors and friends, rather than to rely on visiting, distant relatives.
- Failure to obtain a complete medication history, including the use of over-the-counter medications
- Failure to suspect substance abuse. Narcotics given for chronic pain relief may be abused or overused. Illicit drugs or alcohol may be used surreptitiously, often as self-treatment for depression.
- Failure to use appropriate restraints, leading to further injury of the patient within the emergency department. Soft restraints should be used on any confused patient who is not under direct observation by either staff or family at all times. More aggressive physical restraints, or chemical restraints, should be used as necessary to protect patients and others.
- Refusing admission to a patient in need
- Failure to recognize that patients with acute delirium are often able to return to baseline functional status
- Allowing admission decisions to become emotionally charged
- Failure to diagnose head trauma. Remote, seemingly minor injuries may lead to chronic subdural hematoma, leading to slow deterioration over a period of weeks to months, particularly in the elderly.

[Chapter References](#)

Head pain accounts for nearly 1 million emergency department (ED) visits annually in the United States. Fortunately, the vast majority of headaches presenting to the ED do not represent serious underlying disease. The goal in managing the patient with headache in the ED is to distinguish the small fraction of patients with serious illness who require immediate diagnosis and hospitalization from the great majority in whom the clinical focus is directed toward headache-specific, short-term pain management; prophylaxis against recurrence, as indicated; explanation; reassurance; and careful follow-up.

CLASSIFICATION OF HEAD PAIN

There are multiple axes along which headaches can be classified. The International Headache Society classifies head pain into 13 categories, which are further subdivided into a total of 129 diagnostic subcategories.⁸ Although this classification offers a standardized and comprehensive taxonomy of headache, it is of limited clinical value to the emergency physician. It is presented for reference in an abbreviated form in [Table 201.1](#).

TABLE 201.1. International Headache Society Classification of Headache (Abridged)

Another means of categorizing headaches is to dichotomize them into primary headaches (e.g., migraine) versus secondary (or “organic”) headaches that can be attributed to some underlying cause (e.g., subarachnoid hemorrhage [SAH]).

The pain-sensitive structures of the head include the blood vessels and all extracranial structures of the head and neck. The only intracranial structures sensitive to pain are the arteries at the base of the brain, their major branches, the periarterial dura mater, and the venous sinuses. The parenchyma of the brain itself and most of its meningeal coverings are not pain-sensitive.

For many years, traditional teaching held that there were three major mechanisms of head pain: vasodilatation within the cranial vasculature, causing a “vascular” headache; spasm of the neck and scalp muscles, causing a “muscle contraction” headache; and traction on blood vessels or inflammation around or within these and other pain-sensitive structures, causing a “traction-inflammatory” headache.

In light of more recent evidence, traditional concepts of the etiology of headache in general—and migraine in particular—have given way to more evidence-based explanations in which neuropeptides, most notably serotonin, and their many central nervous system (CNS) receptors play an important, though ill-defined, role. Experimental observations of the relationship between these neural transmitters and alterations in CNS vascular tone suggest that an exclusively neurogenic or vasogenic etiology is unlikely to provide a unifying theory of head pain.⁷

Perhaps the most useful categorization scheme for the emergency physician is to classify headache into one of four groups based on the temporal profile of the pain pattern: acute single headache; acute recurrent headache; subacute headache; and chronic headache ([Table 201.2](#)).¹⁶

Acute Single Headache (presenting within hours of onset)	Non-Recurrent Headache (presenting within days to weeks of onset)	Subacute Headache (presenting within weeks to months of onset)	Chronic Headache (presenting within months to years of onset)
Bacterial meningitis	Migraine	Chronic subdural hematoma	Chronic tension-type headache
Subarachnoid hemorrhage	Cluster	Brain tumor	Trigeminal neuralgia
Cerebral ischemia	Spontaneous intracranial hemorrhage	Brain abscess	Androgen deprivation
Hypertension	Trigeminal neuralgia	Subarachnoid aneurysm	Depression
Narrow-angle glaucoma	Idiopathic intracranial hypertension	Temporal arteritis	
Optic or retrobulbar neuritis	Cerebral artery disease	Headache associated with low CSF pressure	
Acute sinusitis	Spontaneous dissection of cranial arteries	Idiopathic intracranial hypertension	
Spontaneous dissection of cranial arteries	Acute posttraumatic headache	Temporal arteritis	
Acute posttraumatic headache	Acute headache associated with metabolic disorder	Headache in HIV-positive patients	
Acute headache associated with metabolic disorder	Acute headache associated with substance or withdrawal		

TABLE 201.2. Differential Diagnosis of Headache

Ten worrisome headache patterns are listed in [Table 201.3](#). Only about 1% to 5% of headaches seen in the ED will fit any of these patterns, but they are among the most important headaches to diagnose.

1. Single acute headache, characterized as “first or worst” of the patient’s life
2. Single acute or subacute headache with fever unexplained by other systemic illness
3. Single acute or subacute headache with vomiting unexplained by other systemic illness
4. Any headache associated with focal findings, unless focality known to be chronic and unchanged from baseline
5. Any headache associated with abnormal mental status, unless cognitive changes are known to be chronic and unaltered from baseline
6. Any headache associated with papilledema (specific, not sensitive for increased ICP)
7. Single acute headache with pain on neck flexion, but absent on rotation
8. Subacute headache, unremitting or progressively worsening
9. Acute or subacute headache in the elderly
10. Any headache in the immunocompromised host, especially if HIV-positive or with risk factors for HIV

TABLE 201.3. Ten Headaches to Worry About

DIFFERENTIAL DIAGNOSIS

Acute Single Headache

Bacterial Meningitis

Diffuse headache is a characteristic but not invariable feature of meningitis. Although only about two-thirds of community-acquired cases of bacterial meningitis have the triad of fever, nuchal rigidity, and altered mental status, all patients appear to demonstrate at least one of these features. Among these, fever (greater than or equal to 37.7°C or 100°F) is present in 95%, neck stiffness in nearly 90%, and altered mental status in about 80%.⁵

Subarachnoid Hemorrhage

Headache of SAH is the prototypic “first or worst” headache of the patient's life, presenting as a “thunderclap headache” of sudden onset, often associated with nausea, vomiting, neck stiffness, and a transient or prolonged alteration of consciousness. In patients with focal findings or sustained abnormalities of consciousness, the need for a neuroimaging study is apparent. However, in the many patients without neurologic findings, this entity may be clinically indistinguishable from a first attack of migraine, particularly in the case of SAH due to bleeding from an arteriovenous malformation, which may be considerably less dramatic than that of an aneurysm.

An especially difficult challenge for the emergency physician is identification of the “sentinel leak” that precedes major hemorrhage in more than one-third of patients. Detection of this premonitory bleed presents an opportunity to prevent a neurologic catastrophe.

Cerebral Ischemia

Although about 35% of stroke patients and about 25% of patients with transient ischemic attacks experience headache, the diagnosis is usually evident because the clinical picture is dominated by focal findings. It is difficult to distinguish hemorrhagic, thrombotic, and embolic causes of headache on clinical grounds alone.

Hypertension

Most headaches in hypertensive patients are either migrainous or tension-type, and only rarely are due to elevated blood pressure. In general, hypertensive headache requires an acute elevation of diastolic pressure by about 25% above baseline or sustained elevations in excess of 130 mm Hg.

Narrow-Angle Glaucoma

Ocular or periorbital pain distinguishes headache caused by narrow-angle glaucoma, along with diminished visual acuity, a pupil that is typically fixed in midposition, an edematous (“steamy”) cornea, perilimbal injection, and increased intraocular pressure. Vomiting may be the dominant feature, especially in the elderly, who may also present with altered mentation.

Optic or Retrobulbar Neuritis

In optic or retrobulbar neuritis, the characteristic feature of this ocular–periorbital headache is the “deafferented” pupil, which paradoxically dilates when a bright light is moved from the contralateral to the involved eye. In optic neuritis, there is evidence of inflammation of the disc, but in retrobulbar neuritis, the fundus may appear normal. In contrast to acute papilledema, visual acuity is usually diminished in both optic and retrobulbar neuritis.

Acute Sinusitis

Although acute sinusitis can be a difficult clinical diagnosis, sinus inflammation that presents with local pain and tenderness over the involved sinuses is usually apparent.

Spontaneous Dissection of the Cranial Arteries

Spontaneous dissection of the cranial arteries is an uncommon syndrome, often associated with surprisingly minor trauma. It is marked by sudden onset of headache associated with neck pain and focal ischemic symptoms. The pain and its location are determined by the location of the dissection in the carotid or vertebrobasilar system. In the carotid system, the pain is anterior and often accompanied by monocular symptoms, Horner syndrome, and other focal findings. With dissection in the

posterior circulation, the pain is occipital and brainstem findings predominate.

Acute Headache Associated with Metabolic Disorders

Most metabolic disorders produce acute single or acute recurrent headache. Of all patients presenting to the ED with headache, just over one-third have a systemic illness, usually associated with fever, causing their head pain. Other metabolic causes of headache include hypoglycemia, hypoxia, and hypercarbia.

Acute Headache Associated with Substances or Their Withdrawal

Among substance-related headaches, the single most important entity is carbon monoxide poisoning, which is the leading toxicologic cause of accidental death in the United States. Because the temporal profile of the headache associated with chemicals, drugs, and toxins depends on the pattern of exposure and withdrawal, substance-related head pain can fit any of the four categories of headache in [Table 201.2](#).

Acute Recurrent Headache

The differential diagnosis of acute recurrent headache includes some of the serious entities discussed previously under “Acute Single Headache”: SAH presenting as recurrent sentinel bleeds; repeated transient ischemic attacks; substance-related headache, varying as a function of exposure to toxins; and, rarely, severe hypertension, if the elevations are marked and episodic. Tumors, brain abscesses, subdural hematomas, and idiopathic intracranial hypertension (pseudotumor cerebri) can present as acute recurrent headache, but these are more commonly subacute or chronic.

The differential diagnosis of acute recurrent headache centers around the two most common primary (“nonorganic”) headache syndromes seen in emergency practice: migraine and episodic tension-type headache. However, this differential may represent a distinction without a meaningful clinical difference, because there is increasing evidence that tension-type headache may represent a migraine variant.³

Migraine

The definition of *migraine* has been broadened in recent years. Although migraine is classically defined as a throbbing, unilateral headache, neither the quality of the pain nor its location offers as much clinical discrimination between migraine and other causes of headache as do the associated symptoms and signs.⁶ During the headache, most patients complain of photophobia, phonophobia, or gastrointestinal symptoms such as nausea (90%), anorexia (75%), vomiting (60%), and diarrhea (15%). *Constitutional symptoms* occur primarily during the prodrome (which precedes the aura) and the “postdrome.” These include mood changes, fatigue, myalgias, food cravings, and irritability. *Neurologic symptoms* occur mainly during the migrainous aura (which occurs in a minority of patients), and include visual phenomena such as bright sparkling lights (scintillating scotomata), jagged lines (fortification spectra), and geometric figures. A unique characteristic of migrainous visual auras is their propensity to move across the visual field and to vary in color or intensity, sometimes shifting from positive to negative phenomena (scotomata). Less common migrainous auras include motor abnormalities (hemiparesis, ophthalmoplegia, aphasia), sensory dysesthesias, and brainstem disturbances (vertigo, ataxia).

Cluster Headache

In contrast to migraine, cluster headache is uncommon, affecting about 0.1% of the population, predominantly middle-aged men. Characteristic features are listed in [Table 201.4](#). The first episode of cluster headache may be indistinguishable from SAH or from acute orbital, periorbital, or ocular disease. Usually, however, the short-lived, self-limited nature of the headache, accompanied by the findings in [Table 201.4](#), clarify the diagnosis before further workup is necessary.

Feature	Cluster	Migraine
Location of pain	Always unilateral, periorbital	Unilateral (60%) or bilateral (40%)
Age at onset	20-50 yr	10-40 yr
Sex incidence	90% male	70% female
Occurrence of attacks	Daily for several weeks to several months with headache-free intervals	Intermittent
Time of day	Often nocturnal, same time each night	Anytime
Seasonal occurrence	Above common in spring and fall	No variation
Duration of pain	10 min to 3 h	4-48 h
Aura	Absent	30% of cases
Nausea or vomiting	2%	90%
Lacrimation	Frequent, unilateral	Infrequent
Nasal congestion	70%, unilateral	Uncommon
Pupils	30%	1% to 2%
Polyuria	2%	40%
Family history of vascular headaches	7%	90%
Miosis	50%	Absent
General appearance	Irritation, pacing	Lying immobile

Adapted from Diamond & Sjaahda (1991): The practicing physician's approach to headache, 5th ed. Baltimore: Williams & Wilkins, 1993.

TABLE 201.4. Principal Distinguishing Features of Cluster and Migraine Headache

Episodic Tension-type Headache

Formerly known as muscle contraction headache, episodic tension-type headache may represent a migraine variant.^{3,13} It is usually bilateral and dull, often bandlike, and occurs without nausea or vomiting. Tenderness of the pericranial musculature may be a feature of one form of this headache, although electromyographic studies have shown more muscle contraction with typical migraines than with tension-type headaches.¹²

Trigeminal Neuralgia

Trigeminal neuralgia is prototypic facial neuralgia characterized by repetitive, unilateral, lancinating pain in the distribution of one or more branches of the trigeminal nerve. Attacks may be triggered by some minor stimulus, such as a light touch on the face.

Postherpetic Neuralgia

The syndrome of postherpetic neuralgia results from a prior attack of herpes zoster. It is characterized by dermatomal hyperesthesia and pain that is often severe.

Coital Headache

Headache that occurs immediately before, during, or shortly after orgasm is termed *coital* or *orgasmic headache*. The pain is often severe and may persist for several hours. SAH must be excluded.¹⁰

Subacute Headache

A new and unremitting headache that is present for weeks warrants a complete neurologic investigation, particularly in patients who do not usually suffer from headache. There are only a few entities that conform to the temporal profile of subacute headache, but most of them are worrisome.

Chronic Subdural Hematoma

Chronic subdurals may be produced by minor trauma, especially in the elderly. As many as half the patients have no recollection of head trauma. Focal findings are often minimal and therefore go undetected about half the time. Alterations in mental status are often subtle and may require a knowledge of the patient's baseline level of cognition to be appreciated. In elderly patients with subdurals, a gradual deterioration in mental status may be misdiagnosed as dementia.

Brain Tumor

Headache is the presenting symptom of brain tumor in about 40% of cases. Like that of other space-occupying lesions, the headache is usually mild to moderate, diffuse, and often relieved by over-the-counter analgesics, at least initially. In about 90% of patients who can adequately describe their symptoms, the headache is intermittent, dull, rarely throbbing, and sometimes worse in the morning. Nausea and vomiting occur in about half the patients. In about 25%, the headache is worsened by Valsalva maneuvers (e.g., coughing or straining).

Brain Abscess

The headache of brain abscess is similar to that of brain tumor, but it is typically accompanied by fever and other evidence of infection. Often, it is associated with a chronic focus of infection in the ears or sinuses, a cerebrospinal fluid (CSF) leak from a basilar skull fracture, or an embolic cardiac or pulmonary source.

Subacute and Chronic Sinusitis

Subacute and chronic sinusitis may not present with headache or facial pain. Consequently, it can be extremely difficult to diagnose. Pain, if present, is usually dull and pressure-like, and may be associated with nasal congestion or rhinorrhea.

Temporomandibular Joint Syndrome

Temporomandibular joint syndrome is a poorly defined syndrome that may be caused by malocclusion, which produces masseter spasm. Features of tension-type headache and depression have also been reported.

Posttraumatic Headache

Although it may present acutely, posttraumatic headache is more commonly subacute. It is no longer classified as postconcussion syndrome because loss of consciousness is not a prerequisite for its development. Symptoms are usually present within the first 24 to 48 hours postinjury and are marked by a postural component to the head pain and associated postural dizziness. Typically, symptoms are improved by lying down. Transient neurocognitive impairment, depression, irritability, and emotional lability are common. The syndrome persists for more than 2 months in 60% of patients.

Headache Associated with Low Cerebrospinal Fluid Pressure

Headache after a lumbar puncture (LP) is thought to be due to low CSF pressure resulting from a post-LP CSF leak. It has some of the orthostatic features of the posttraumatic headache: worsening of pain, dizziness, and nausea when upright, and improvement on lying down. Usually, the history is diagnostic. If a repeat LP is performed to exclude arachnoiditis or infection, an opening CSF pressure of less than 30 mm H₂O strongly suggests this diagnosis.

Idiopathic Intracranial Hypertension (Pseudotumor Cerebri)

Headache in idiopathic intracranial hypertension is associated with high CSF pressures in the absence of intracranial structural disease. Pain is often postural and associated with pulsatile tinnitus, nausea, vomiting, and progressive visual loss. Papilledema is present in about 90% of patients. The diagnosis is confirmed by CSF pressures greater than 250 mm H₂O and no mass on computed tomography (CT).

Temporal (Cranial) Arteritis

Headache is the dominant complaint in this progressive, systemic, inflammatory disorder. It may occur anywhere in the scalp, and is localized to the temporal area in only half the cases. The syndrome tends to occur in patients over 50 years of age and is accompanied by constitutional symptoms such as anorexia and weight loss. The onset is gradual, with polymyalgia, proximal weakness, masseter claudication, and periocular discomfort developing over months to years. The diagnosis is suggested by a firm, tender, nonpulsatile cranial artery and an elevated erythrocyte sedimentation rate (greater than 50 mm/h), although about 25% of cases have only mild elevations of the sedimentation rate. Major complications include monocular blindness and stroke.

Headache in HIV-Positive and AIDS Patients

Headache in this group of patients is usually subacute, and is often associated with positive clinical findings. The list of possible opportunistic CNS infections includes mycobacteria (*Mycobacterium tuberculosis* and *Mycobacterium avium-intracellulare*), spirochetes (*Treponema pallidum*), viruses (herpes simplex, herpes zoster, cytomegalovirus, and HIV-1), fungi (*Cryptococcus*), protozoa (*Toxoplasma*), and actinomycetes (*Nocardia*). Noninfectious causes of headache include CNS lymphoma (primary and secondary) and Kaposi's sarcoma.

Chronic Headache

Patients presenting to the ED with chronic headache (i.e., headache that has been present for months to years) are part of what has been called the "last straw" syndrome.⁶ Most of the serious entities included in this category have been discussed previously under subacute headache, and they usually conform to a similar temporal profile.

Chronic headaches can be divided clinically into several different groups, each requiring a different diagnostic and therapeutic strategy. These include patients with features of chronic tension-type headache, so-called transformational migraine (transformed from an episodic pattern to a chronic daily pattern), analgesic abuse, depression, and, rarely, tumor, subdural hematoma, idiopathic intracranial hypertension, and posttraumatic headache.

Most patients with chronic tension-type headache have mild-to-moderate pain, rarely see a doctor, and only occasionally come to the ED; fewer still see neurologists. Consequently, little is known about these patients other than the fact that, on the basis of anonymous prevalence surveys, they seem to exist in large numbers. One plausible speculation is that their headaches represent symptoms of depression.

The existence of transformational migraine supports the theory that migraine and many of the more severe tension-type headaches are related. Among a large cohort of migraineurs, 80% of whom had their first headache before the age of 26, 90% had developed chronic daily headache by age 45.¹⁵ Many of these patients also suffered from superimposed periodic episodes of typical migraine.

Some patients with severe tension-type headache or frequent migraines overuse nonnarcotic analgesics or ergotamines, resulting in worsening of their headache. Gradual withdrawal provides relief, but it may require hospitalization for supervised detoxification.¹

As noted previously, depression is a frequent concomitant of chronic headache of all varieties. This relationship may simply represent a response to living with constant pain, or it may reflect the central role of serotonin in both headache and depression.

Although chronic headache is rarely a presentation of a space-occupying lesion or increased intracranial pressure (ICP), most of these patients warrant a CT at some point in their management, especially if they do not respond to medical intervention.

EMERGENCY DEPARTMENT EVALUATION

A meticulous history is the key to headache diagnosis. Only in unusual circumstances does the neurologic examination, laboratory testing, or neuroimaging procedure reveal an abnormality that was completely unsuspected following a careful history.

Headache History

Temporal Profile

Because this is the primary axis along which headaches can be classified in the ED, this information should be obtained first in order to place the patient into one of the four groups shown in [Table 201.2](#).

1. Single acute: Is this a “first and worst” headache of sudden onset?
2. Recurrent acute: What is the frequency, pattern, and duration of individual headache episodes?
3. Subacute: Is the headache progressively worsening?
4. Chronic: Has there been a pattern break or is this a “last straw” visit to the ED?

Associated Symptoms

In particular, look for transient loss of consciousness or imbalance at onset, nausea, vomiting, neck stiffness, unilateral lacrimation or rhinorrhea, photophobia, and phonophobia.

Circumstances of Onset

For single acute headaches, determine exactly what the patient was doing when the headache began. For recurrent headache, identify any usual precipitants.

Prodromes and Aura

Prodromes such as a shift in appetite or mood suggest migraine, and characteristic visual aura essentially define a subtype of migraine.

Location of Pain

Hemicranial, hemifacial, and unilateral ocular and periorbital pain have greater discriminating value than holocranial or bilateral pain.

Quality and Severity of Pain

This has limited value in identifying the type of headache, and correlates poorly with the seriousness of underlying disease.

Age at Onset

New-onset headache in the elderly is worrisome.

Recent Trauma

This is relevant to chronic subdural hematomas and posttraumatic headaches, although trauma may also precipitate a migraine or cluster headache.

Relief Measures

Headaches that are substantially relieved by lying down are usually posttraumatic or low CSF pressure (post-LP) headaches.

Family History

Migraine, depression, and, to a lesser extent, a predisposition to SAH are inherited.

Medical History

Ask about concurrent illnesses, medications (including oral contraceptives), hospitalizations, allergies, smoking, alcohol and drug use, and risk factors for HIV.

Occupational History

Note exposure to carbon monoxide, fumes, solvents, and other toxins.

Psychosocial History

Search especially for signs and symptoms of depression, anxiety, and marital or job-related stress.

Multiplicity

Many patients suffer from different kinds of headaches. To minimize confusion, it is important to determine this early and to obtain parallel but distinct histories of each headache type.

Physical Examination

General Examination

After obtaining vital signs, the remainder of the nonneurologic examination should be goal-directed, including the eyes, neck, face, and scalp. Visual acuity should be checked with a pinhole and the eye examined for ptosis, conjunctival injection (perilimbal vs. diffuse), corneal clouding, and pupillary size, reactivity, and equality. Any suggestion of acute glaucoma mandates measurement of intraocular pressure. The swinging flashlight test should be performed as described earlier to detect optic or retrobulbar neuritis.

A funduscopic examination is essential, looking specifically for signs of increased ICP, severe hypertension, optic neuritis, or subhyaloid hemorrhage (preretinal hemorrhages obscuring retinal vessels due to overlying blood in the subarachnoid space). Spontaneous venous pulsations (SVPs) are lost when the ICP exceeds about 200 mm H₂O. However, monitoring has shown enormous pressure fluctuations in patients with increased ICP, ranging from 50 to 500 mm over a 24-hour period. Thus, a patient with increased ICP might have SVPs if examined during a transient trough in intracranial pressure. In addition to the problem of false negatives (presence of SVPs in patients with increased ICP), there is the problem of false positives (absence of SVPs in patients with normal ICP), which is seen in about 20% of the normal population. Bilateral papilledema is a highly specific indicator of increased ICP, but, because it may lag behind acute elevations of ICP by several hours, this finding lacks sensitivity.

The neck should be examined for pain with flexion, which indicates meningeal irritation secondary to chemical or infectious meningitis. Tension-type headache also characteristically produces tightness in the paracervical muscles with discomfort on flexion. Unlike the nuchal rigidity of meningitis, tension-type headache causes pain with chin to shoulder rotation of the head. Because it may take several hours for subarachnoid blood to reach the cervical area of the meninges, and several

more hours for it to produce a chemical meningitis, absence of nuchal rigidity early in the course of an SAH does not reliably exclude this entity.

The sinuses, temporomandibular joints, and scalp should be palpated for tenderness, paying special attention to the temporal arteries in older patients. In posttraumatic headache, hemotympanum, CSF otorrhea, infraorbital ecchymoses, posterior auricular ecchymoses, and CSF rhinorrhea indicate basilar skull fracture.

Neurologic Examination

Mental status assessment is a critically important feature of the neurologic examination that is commonly overlooked. Focality is detected most readily by pronator drift, asymmetry of cranial nerves II to VIII, and abnormalities of gait and station. In general, sensory examination (other than cranial nerve V), assessment of reflexes, and motor testing of individual muscle groups are not efficient use of the emergency physician's time in the evaluation of the patient with headache.

Laboratory Testing

As with the physical examination, laboratory tests are usually normal. In patients with a history strongly suggestive of a particular kind of headache (e.g., migraine), no laboratory tests are necessary. The erythrocyte sedimentation rate in patients suspected of having cranial arteritis is an exception to this rule. Other tests of occasional value include hemoglobin, leukocyte count, glucose, pulse oximetry, arterial blood gas, and carboxyhemoglobin level.

Imaging

When a diagnosis can be made on the basis of the history and clinical picture, no imaging is needed. Other patients with acute single or recurrent headache should probably have a CT or magnetic resonance imaging (MRI) at the time of their ED visit. Those with subacute and chronic headache may have an imaging procedure scheduled electively.

CT is preferred for the detection of acute intracranial bleeding, idiopathic intracranial hypertension, and hydrocephalus. Noncontrast CT, followed by a contrast CT, is useful in HIV-positive patients, in whom a ring-enhancing lesion suggests toxoplasmosis. Patients with suspected spontaneous SAH constitute a special case. State-of-the-art CT scans obtained within 12 hours of the onset of headache in suspected SAH have a sensitivity of 98% (95% CI, 94% to 100%), a specificity of 100% (95% CI, 94% to 100%), a negative likelihood ratio of 0.02 (95% CI, 0.005 to 0.06), and a positive likelihood ratio of at least 33 (95% CI, 11 to 316).¹⁷

Because a negative CT cannot completely exclude the diagnosis of SAH, the LP remains the criterion standard for this diagnosis. As shown by the likelihood ratios, a negative CT markedly reduces the probability of this entity by decreasing the odds of SAH by about 50-fold from the clinician's pretest estimates. Thus, the pretest probability of SAH would have to exceed 33% in order for the posttest probability of SAH to remain above 1% following a negative CT. The sensitivity of CT drops off as the time from headache onset increases. The sensitivity of MRI is inferior to that of CT during the first 24 hours, becomes slightly superior between 24 and 72 hours, and exceeds that of CT thereafter.¹¹

The choice of CT versus MRI depends on the clinical picture, cost, and availability. In addition to late identification of SAH, MRI is preferred for imaging the posterior fossa (cerebellum and brainstem), detecting nonhemorrhagic strokes less than 2 days old, and visualizing transient ischemic attack, tumor, localized infection, or chronic subdural hematoma.

Finally, magnetic resonance angiography (MRA) promises to replace traditional angiography as the imaging modality of choice for aneurysms, arteriovenous malformations, and dissection of the cranial arteries.

Lumbar Puncture

There are two primary indications for an emergency LP in a patient with headache: suspicion of CNS infection (e.g., meningitis) or a substantial suspicion of SAH despite a normal CT. The other two circumstances in which an LP is the diagnostic standard is in headache due either to high (idiopathic intracranial hypertension) or low (post-LP) CSF pressure. In the first instance, the LP is clearly indicated and often therapeutic. In the case of a post-LP headache, another LP should be done only if the diagnosis is in serious doubt.

The risk of herniation after LP in patients with increased ICP or a mass lesion is low but unknown. Proponents of LP without prior CT argue that an association between herniation and LP has not been causally established. Proponents of CT prior to LP cite a small number of instances in which herniation has been temporally associated with LP. The difficulties inherent in studying this question suggest that the controversy will not soon be resolved. Because CT scanning is so widely and readily available, in the absence of definitive information supporting either position, many clinicians perform a CT prior to LP, provided that appropriate time-dependent emergency care (e.g., institution of antibiotics in suspected bacterial meningitis) is not delayed.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Treatment of the following causes of headache is discussed in the corresponding chapters elsewhere in this text: bacterial meningitis, SAH, stroke, cranial artery dissection, hypertensive encephalopathy, acute glaucoma, optic neuritis, retrobulbar neuritis, sinusitis, temporomandibular joint syndrome, toxic–metabolic disorders, chronic subdural hematoma, brain tumor, and brain abscess.

Migraine

Table 201.5 lists some of the many therapies for management of acute migraine in the ED. Direct comparison of migraine abortive agents is confounded by a failure of clinical trials to target uniform end points, inconsistent documentation of adverse effects and recurrence rates, and variability in methods of pain measurement. Dihydroergotamine (DHE-45) is an effective abortive agent for the treatment of moderate-to-severe migraine. DHE and a dopamine antagonist provide the benefit of two effective abortive agents plus an antiemetic effect. Results of two randomized, placebo-controlled trials favor intravenous prochlorperazine over metoclopramide.^{4,9}

TABLE 201.5. Emergency Management of Migraine and Related Headache

Proposed doses of prochlorperazine range from 3.5 to 10 mg. When used in combination therapy with intravenous DHE, 3.5 mg may be nearly as effective as higher doses, but with fewer adverse effects, such as sedation and akathisia.¹⁴ Intravenous diphenhydramine has recently been shown to be effective in preventing the akathisia associated with the use of prochlorperazine.¹⁸ Sumatriptan is highly effective (70% of patients experience improvement within 1 hour of subcutaneous administration) and provides a more rapid onset of action than DHE. However, the drug is expensive, and a high proportion of patients (in one clinical trial, a majority,²

and in another, 2.5 times that of DHE²⁰) experience a recurrence of headache within 24 hours.

New triptans may be found to provide a longer duration of action and reduction in headache recurrence. At present, the oral, rectal, and nasal forms of sumatriptan have a limited role in the ED management of migraine. Prochlorperazine suppositories have been shown to be effective in the ED setting, but, like the alternative routes of administration for sumatriptan, do not work as rapidly as parenteral treatment. At the present time, for treatment of migraine, we recommend 10 mg of prochlorperazine (10 mg of metoclopramide may be nearly equivalent),^{4,9} 50 mg of diphenhydramine,¹⁸ and 1 mg of DHE, all administered intravenously.^{2,13,20}

Neurologic consultation is indicated in the ED if the diagnosis is in doubt, if the attack does not conform to the patient's typical migraine, or if intractable vomiting or unrelenting pain is encountered. Following successful treatment, patients should be referred to a neurologist or headache specialist. Indications for admission are summarized in [Table 201.6](#).

1. Persistent underlying disease
a. CNS infection
1) Bacterial meningitis
2) Brain abscess
3) Any evidence of infection in CSF-positive fluid
b. CNS vascular disease
1) Subarachnoid hemorrhage
2) Cerebral ischemia
3) Cerebral arteritis
4) Spontaneous aneurysm
5) Spontaneous dissection of cerebral arteries
c. Spontaneous aneurysm
1) Brain tumor
2) Subdural hematoma
3) Toxic-metabolic encephalopathy
4. Acute sinusitis with evidence of spread or an ill-appearing patient
5. Intracranial hypertension
1) Idiopathic intracranial hypertension, not responding to usual measures to reduce
2) Headache associated with serious medical or surgical illness
3. Severe, unrelenting frontal or facial pain
a. Status migrainosus
1) Persistent cluster, unresponsive to usual measures
2) Unrelenting trigeminal or postherpetic neuralgia
c. Continuous vomiting, absolute intolerance, or inability to take PO (usually migraine or severe posttraumatic headache)
4. Acute or chronic medication headache, requiring immediate detoxification
5. Complex drug interactions and careful drug level monitoring required for headache management
6. Social situation associated with unrelenting headache or serious depression
7. Social situation not conducive to outpatient management
8. Repeated ED visits

TABLE 201.6. Criteria for Hospitalization of Patients with Headache

Cluster

High-flow 100% oxygen should be administered as soon as the patient enters the ED. Because many patients with cluster are smokers, they should be observed for carbon dioxide retention while on oxygen. As indicated in [Table 201.5](#), DHE and sumatriptan are effective in the ED management of cluster (sumatriptan has been shown to provide relief in about 10 minutes). However, concerns about coronary vasospasm limit the use of these drugs in patients with any cardiovascular risk factors. On discharge, patients with an exacerbation of cluster should receive a trial of prophylactic verapamil, starting at 80 mg t.i.d., if there are no contraindications. A tapering course of steroids should also be given until the verapamil can be increased to therapeutic levels (about 120 mg t.i.d.). Indications for admission are summarized in [Table 201.6](#).

Episodic Tension-type Headache

In only a minority of cases do these patients require acute ED management. Those with severe symptoms may respond to a migraine regimen,³ as indicated in [Table 201.5](#). Most patients with mild episodic tension-type headaches can be managed with NSAIDs. Unless they have developed the syndrome of medication overuse, which requires inpatient detoxification,¹ these patients can usually be discharged with referral.

Trigeminal Neuralgia

This syndrome usually responds to carbamazepine, phenytoin, valproate, clonazepam, or baclofen. Superiority of one agent over another has not been established, and neurologic consultation may be helpful in choosing a drug. Some elderly patients with this syndrome become suicidal and require in-patient management, often beginning with intravenous or intramuscular fosphenytoin or intravenous phenytoin in the ED. Opioids may be necessary until other medications take effect. ED management of most patients is limited to referral for diagnostic confirmation and long-term care.

Postherpetic Neuralgia

Treatment with famciclovir prevents postherpetic neuralgia if given during an attack of zoster. Proposed treatments for postherpetic neuralgia include topical capsaicin cream (derived from hot peppers), amitriptyline, valproate, carbamazepine, and phenytoin. As with trigeminal neuralgia, neurologic consultation is helpful in choosing an appropriate regimen. Unless patients have unremitting pain, most can be discharged from the ED and referred for further management.

Coital Headache

Once an SAH has been excluded, these patients require explanation, reassurance, and referral. It is reasonable to offer the patient a therapeutic trial of indomethacin 50 mg PO, taken 1 to 2 hours before intercourse, if there is no contraindication.

Posttraumatic Headache (Acute and Chronic)

Once the diagnosis has been confirmed by a normal CT or MRI, these patients should be educated, reassured, and encouraged to spend as much time recumbent as possible. Confirmation that this is indeed "real," and that it will improve with time, is an important therapeutic intervention. Patients should be referred to a neurologist.

Headache Associated with Low Cerebrospinal Fluid Pressure

Traditional management of post-LP headache includes fluid replacement and bedrest. If the syndrome persists, 1 g of intravenous caffeine sodium benzoate, 500 mg over 15 minutes, followed by an additional 500 mg over 3 hours, may be administered. This increases CSF pressure by causing cerebral vasoconstriction, and should be considered only in young patients without cardiovascular risk factors or a history of arrhythmias. Continual monitoring is necessary. If caffeine is inadvisable or ineffective, an epidural blood patch may help. In most institutions, this requires anesthesia consultation. Unless individuals are incapacitated by the headache, they can be managed as outpatients.

Idiopathic Intracranial Hypertension

ED management requires neurologic consultation, ophthalmologic consultation, and administration of acetazolamide, often combined with furosemide. Repeated LP may be necessary to maintain reduced pressure. Steroids are used if these interventions fail. If this regimen does not reduce ICP, the headache can be treated with analgesics and migraine medications. However, control of pain does not treat the underlying threat to the patient's vision. If acuity worsens in spite of maximal medical management, an optic sheath decompression or ventricular shunt will be needed.

Temporal Arteritis

ED management requires ophthalmologic consultation for arterial biopsy and rheumatologic consultation for steroid management. Because 50% of untreated patients develop blindness, all patients with the working diagnosis of temporal arteritis should immediately receive steroids and then be admitted to the hospital for monitoring of symptoms and the sedimentation rate.

Headache in HIV-Positive and AIDS Patients

HIV-positive patients presenting with headache should be discharged only if they are afebrile, have an unaltered or baseline mental status (confirmed by a family member or caretaker), a negative contrast and noncontrast CT, and a negative LP. They should be followed by infectious disease or primary care physicians specializing in the management of AIDS.

Chronic Headache

Individuals with chronic headache are among the most challenging to manage in a busy ED. Within this heterogeneous group, one must try to identify treatable subsets and make the appropriate referrals. The only subgroup of chronic headache patients that may benefit from hospital admission are those with analgesic abuse. Individuals in this group require an inpatient washout and withdrawal protocol, utilizing DHE and a dopamine antagonist. ¹

In general, patients with chronic daily headache, including chronic tension-type headache, transformational migraine, analgesic abuse, and chronic headache as a depressive equivalent, are among those who can benefit most from the expertise of a headache specialist.

COMMON PITFALLS

- Failing to diagnose the sentinel leak of SAH until a major bleed occurs subsequently ¹⁹
- Mistaking headache and other constitutional symptoms of carbon monoxide toxicity for a clustered outbreak of afebrile winter flu
- Misdiagnosing a chronic subdural hematoma in the elderly as progressive dementia because there is no history of head trauma
- Mistakenly attributing headache to hypertension, which is rarely the cause
- Failing to diagnose and treat migraine appropriately either because a large tension-type component is present or because the headache is not hemicranial. Nonthrobbing and bilateral pain occur in about 50% and 40%, respectively, of migraine patients during some episodes. ¹³
- Presuming that response to certain medications necessarily defines the etiology of a headache. The headache of brain tumors, aneurysms, and SAH may respond to a migraine regimen.
- Missing a significant treatable component of depression associated with many headache disorders

[Epidemiology and Pathophysiology](#)
[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Spontaneous subarachnoid hemorrhage (SAH) is a relatively common yet devastating entity. Despite advances in resuscitation, critical care, cerebral pharmacotherapy, and microneurosurgical techniques, the overall mortality rate from SAH is 30% to 50%.^{1,13} Of surviving patients, only half eventually have a good outcome, and less than one-third ever return to their premorbid functional status.^{7,10,21}

SAH frequently affects healthy individuals in the most productive years of adult life and is responsible for half of all fatal strokes in patients younger than 45 years of age. The diagnosis of SAH is frequently delayed or missed entirely.¹ Because most patients with SAH initially seek medical attention in the emergency department, the emergency physician may be able to prevent death and limit disability from this potentially catastrophic disorder.

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

In the United States, SAH accounts for approximately 10% of all acute cerebrovascular accidents and affects nearly 30,000 people each year, with an estimated annual incidence of five to ten cases per 100,000 persons.^{13,21} Rupture of an intracranial aneurysm is responsible for most cases. The prevalence of asymptomatic intracranial aneurysms has been estimated from autopsy and neuroradiology studies at 0.5% or higher.¹⁹

The risk of rupture from these aneurysms is estimated to be 1% to 2% per year, and the risk of rupture increases with aneurysm size.¹⁸ While few aneurysms less than 3 mm in diameter rupture, surgical clipping has been suggested for unruptured aneurysms of more than 5 to 7 mm in diameter.¹⁵ Aneurysms are rare in children, but the incidence increases sharply in people after age 25 years and peaks at nearly 12% by age 60 years. Young and middle-aged Blacks have a substantially greater risk of aneurysmal SAH than do Whites of similar age.⁶

In contrast to most other cerebrovascular diseases, aneurysmal SAH is more common in women than in men. Factors leading to a state of relative estrogen deficiency, such as menopause and cigarette smoking, are associated with an increased risk. Among premenopausal women, the risk of hemorrhage appears greatest in the perimenstrual period and during pregnancy.¹⁴ Smoking, hypertension, and a moderate-to-heavy alcohol consumption are risk factors for both men and women.²³

Disorders that produce vascular wall defects, as well as certain connective tissue diseases, are associated with an increased likelihood of aneurysm formation. These include polycystic kidney disease, coarctation of the aorta, Marfan syndrome, Ehlers-Danlos syndrome, and fibromuscular hyperplasia. Consistent with and including these associations, genetic predisposition represents a nonmodifiable risk factor for SAH.⁵

Aneurysmal rupture typically is associated with sudden blood pressure surges, such as occur during strenuous physical activity, emotional stress, sexual intercourse, or during the Valsalva maneuver.⁸ Other factors associated with increased risk of rupture include heavy alcohol consumption, cocaine or phencyclidine abuse, heavy cigarette smoking, and long-term use of aspirin or analgesics. Aneurysmal rupture may, however, be independent of any physical or environmental stress; SAH may occur during nonexertional, normal daily activity, or even during sleep.^{1,8}

Nontraumatic SAH also may result from bleeding secondary to arteriovenous malformation (AVM), mycotic aneurysm, extension from parenchymatous hemorrhage, anticoagulant therapy, hemorrhagic encephalitis, or cerebral vasculitis. In approximately 20% of cases, an underlying cause cannot be determined.

CLINICAL PRESENTATION

Sudden, excruciating headache is the hallmark of SAH. The headache is typically severe, begins abruptly, peaks rapidly (within seconds to minutes), and differs from other headaches the patient has experienced. It may be described as “exploding,” “bursting,” or “the worst headache of my life,” and is typically accompanied by nausea and vomiting. The pain is usually diffuse and poorly localized, but may be unilateral or confined to the frontal or occipital region. Headache is frequently accompanied by neck pain, and, on occasion, pain may radiate down the spine and to the legs.

Although the presentation of SAH is often dramatic, some patients present atypically, and the classic signs and symptoms may be absent or subtle. A sudden headache occurring days to weeks before the onset of SAH occurs in 30% to 50% of patients.²⁴ This “sentinel headache” has characteristics similar to those already discussed and may be accompanied by neurologic symptoms, vomiting, nuchal pain, dizziness, or drowsiness; it generally resolves in 2 to 3 days. The headache may be relatively mild and unimpressive, and its severity may be minimized by the patient. Such warning symptoms represent a premonitory “warning leak” that may reflect a minor initial hemorrhage (sentinel headache), enlargement or thrombosis of the aneurysm, isolated hemorrhage into the aneurysm wall, pressure exerted by an unruptured aneurysm, or local ischemia.

Syncope or coma is common, and most patients experience an alteration of consciousness of some degree at the onset of SAH.^{12,15} Loss of consciousness may result from a sudden decrease in cerebral perfusion pressure as intracranial pressure (ICP) transiently approaches mean arterial pressure at the moment of aneurysmal rupture.

Seizures occur in as many as 25% of patients after SAH.²² They are more common in younger patients and are not related to overall prognosis. Seizures occurring within 12 hours of SAH are thought to result primarily from increased ICP rather than from an irritative cerebral focus.

An alteration in mental status is common in patients with SAH, but focal neurologic findings are typically absent unless hemorrhage involves the brain substance or a large clot has produced a mass effect. Focal signs may also be caused by compression of cranial nerves or brain parenchyma by an unruptured but expanding intracranial aneurysm.⁷ Nonfocal neurologic signs such as impaired memory, speech disorders, personality changes, and bilateral extensor plantar responses may be overlooked unless specifically sought or elicited. Patients may also complain of photophobia, dizziness, diplopia, or blurred vision.

Other physical findings may be present in the acute phase of SAH. Careful funduscopic examination may reveal preretinal or subhyaloid hemorrhages—small, smooth, round hemorrhages that usually occur near the optic nerve head. Although these hemorrhages are seen in only 10% to 20% of patients, they are pathognomonic for SAH when they occur with acute headache. Nuchal rigidity is common with SAH, but it may not develop for several hours after SAH and may be absent in patients with deep coma.

Systolic hypertension (greater than 200 mm Hg) occurs in up to 35% of patients with SAH. Acute blood pressure elevation may be due to increasing ICP (Cushing response) or may result from acute catecholamine release. Significant hypertension following SAH is associated with an increased incidence of cerebral vasospasm, an increased likelihood of hydrocephalus, and poor outcome. Hypotension is unusual immediately following SAH but is an ominous finding when present. Low-grade temperature elevation occurs in approximately 20% of patients with SAH and is thought to result from meningeal inflammation.

Cardiac dysrhythmias and ST-T wave abnormalities occur in most patients with SAH. Premature ventricular complexes, supraventricular tachycardia, and bradycardias are most common, but potentially life-threatening dysrhythmias (e.g., ventricular tachycardia, idioventricular rhythm, and complete heart block) have

been documented in up to 40% of patients; they occur most frequently during the first 24 hours after SAH.³ Acute ST-T wave changes similar to those associated with cardiac ischemia may also be noted.

Other characteristic electrocardiographic (ECG) changes associated with intracranial hemorrhage include peaked (deep, broad, symmetrically inverted) T waves, QRS complex prolongation, an increased QT interval, and large U waves. It is undetermined whether these ECG abnormalities are due to structural subendocardial myocardial damage associated with SAH or whether they result from alterations in autonomic input to the heart or increased levels of circulating catecholamines.⁴

Several clinical grading scales are used for patients with SAH (Table 202.1). These classification systems are useful for describing neurologic status and for timing surgical intervention.¹² In general, the poorer the clinical grade, the worse the prognosis. Thus, patients with severe neurologic impairment on presentation tend to have greater morbidity and mortality and usually require more intensive support.

Grade	Description
HUNT-HESS SCALE	
I	Asymptomatic or mild headache
II	Moderate-to-severe headache, nuchal rigidity
III	Coma, drowsiness, or mild focal signs
IV	Stupor or coma
V	Coma, moribund, and/or posturing
COOPERATIVE ANEURYSM SCALE	
I	Free of symptoms
II	Mildly ill—alert and responsive, headache
III	Moderately ill—lethargic, headache, no focal signs or alert, focal signs present
IV	Severely ill—stuporous, no focal signs or drowsy, focal signs
WORLD FEDERATION OF NEUROLOGICAL SURGEONS	
I	No headache or focal signs (GCS 15)
II	Headache, nuchal rigidity, no focal signs (GCS 15)
III	Headache, nuchal rigidity, no focal signs (GCS 13-14)
IV	Headache, nuchal rigidity or focal signs (GCS 13-14 or 9-12)
V	Headache, nuchal rigidity or focal signs (GCS 8 or less)

TABLE 202.1. Clinical Grading Scales for Subarachnoid Hemorrhage

Patients who are neurologically intact on admission require constant surveillance and prompt intervention to avoid the complications that can lead to neurologic deterioration. Major central nervous system (CNS) complications are common in patients who survive an initial SAH. They include rebleeding, vasospasm, and acute hydrocephalus.

Rebleeding is the most devastating CNS complication and is associated with mortality rates of greater than 50%.^{4,25} The peak risk of rebleeding is during the first 48 hours after the initial SAH. Risk of rebleeding is about 4% of untreated patients during the first 24 hours, and 1% to 2% per day thereafter for the subsequent 4 weeks.¹¹

Cerebral vasospasm, another major cause of delayed morbidity, accounts for 14% to 36% of poor outcomes in patients with SAH.²⁵ Vasospasm occurs in 20% to 30% of patients following SAH, with an onset 3 to 5 days after the initial bleed and maximal severity 5 to 10 days afterward.¹⁵ Vasospasm can result in cerebral infarction or death. Cerebral vasospasm appears to be most common in patients in whom a large amount of blood is seen within the subarachnoid cisterns on initial computed tomography (CT) scan.

Hydrocephalus, which is also relatively frequent, is usually due to obstruction of the flow of cerebrospinal fluid (CSF) secondary to a clot blocking the basal cisterns and the foramen of the fourth ventricle. Depending on the location of the bleeding and the amount of blood in the subarachnoid space, acute hydrocephalus may develop as rapidly as a few hours after aneurysmal rupture; more typically, it occurs within the first few days. In the Cooperative Aneurysm Study, evidence of hydrocephalus was noted on the initial CT scan in approximately 16% of patients and was more common in patients who had severe neurologic impairment at the time of initial presentation.²

Patients with SAH are also subject to nonneurologic complications. Pulmonary complications, including aspiration pneumonia, hypoventilation due to decreased level of consciousness, and neurogenic pulmonary edema, may occur within the first hours or the first several days after SAH. Hyponatremia develops in up to 30% of patients after SAH; it may be due to inappropriate secretion of antidiuretic hormone or release of natriuretic peptides, and it contributes to cerebral edema, altered consciousness, and seizures.⁴ Diabetes insipidus (with progressive hypernatremia) is most common in comatose patients with extensive SAH and elevated ICP. Late complications of SAH include systemic infections (e.g., sepsis), postoperative complications (e.g., meningitis), and venous thromboembolic disorders (e.g., pulmonary embolism).

DIFFERENTIAL DIAGNOSIS

The diagnosis of SAH is readily considered in the patient with an acute onset of severe headache accompanied by vomiting and loss of consciousness. SAH should be considered in the differential diagnosis of every patient with a clinical presentation that involves sudden-onset headache, with or without an altered level of consciousness (Table 202.2). Many patients, however, present in a more benign fashion. The occurrence of an unusual headache, acute neck pain, a headache of sudden onset, or new unexplained headache should prompt consideration of SAH. Likewise, change in a chronic headache pattern, new-onset “migraine” headaches, or unexplained neurologic symptoms or signs should be strongly suspected as potential symptoms of SAH or cerebral aneurysm.

ACUTE HEADACHE
Migraine headache
Cluster headache
Neck muscle contraction headache
Meningitis
Encephalitis
Scoliosis
Temporoparietal arthritis
Viral syndromes
Acute glaucoma
Carbon monoxide poisoning
Polyarteritis nodosa
ALtered Consciousness, Unexplained
INTRACRANIAL HEMORRHAGE
Intracerebral hemorrhage
Subarachnoid hemorrhage
Cerebral infarction
Cerebral contusion
Cerebral metastasis
Epilepsy
Delirium
Head injury
Diabetic oculomotor nerve palsy
Adrenergic intoxication
Syncope
OTHER DISORDERS
Heart attack
Acute myocardial infarction
Stroke
Cervical arthritis
Acute myelitis

TABLE 202.2. Differential Diagnosis of Subarachnoid Hemorrhage

The differential diagnosis for acute headache in an awake patient includes new-onset migraine, muscle contraction headache, viral illness, encephalitis, meningitis, and musculoskeletal cervical pain. In patients with an altered level of consciousness, intracranial processes such as cerebral infarction may be confused with SAH. Because hypertension is common in the acute phase of SAH, hypertensive crisis may be an erroneous diagnostic consideration. Likewise, the ECG changes that frequently accompany SAH may be misinterpreted as representing acute cardiac ischemia.

Cranial CT scanning and, if necessary, lumbar puncture (LP) are performed to distinguish SAH from the more common causes of acute cephalgia. Although these tests exclude SAH in the vast majority of cases, the devastating consequences of failing to diagnose SAH in patients with unruptured aneurysms or warning leaks justifies the costs and risks of these procedures.

EMERGENCY DEPARTMENT EVALUATION

The goals of the emergency department evaluation are to establish the diagnosis of SAH, to identify associated complications, and to assist the neurosurgeon in determining the patient's fitness for angiography and surgery. In many cases, the clinical features are suggestive of the diagnosis, which can be confirmed simply and safely by cranial CT scanning and LP.

Unenhanced cranial CT scanning is the procedure of choice for diagnosing acute SAH, with a sensitivity estimated at between 80% and 90%, depending on the elapsed time between the onset of SAH and performance of the scan. Within 24 hours of SAH, CT demonstrates blood in the subarachnoid space or basal cisterns in 90% to 95% of cases of aneurysmal SAH (Fig. 202.1).^{4,13} The sensitivity of CT declines with time after the initial hemorrhage and is lower in patients with relatively minor symptoms and normal neurologic examinations.

Figure 202.1. Cranial computed tomographic scan showing diffuse subarachnoid hemorrhage.

In the Cooperative Aneurysm Study, 8.2% of patients with SAH had normal CT scans; normal scans were significantly more frequent when obtained 3 or more days after SAH.² Even with later generation CT scanners, the overall sensitivity of CT scan alone for detecting SAH is greatest within 12 hours of symptom onset, and about 90% to 95% overall.^{16,20} Thus, further testing is required after a normal CT scan in order to completely exclude SAH.

Besides establishing the diagnosis, CT provides important additional information. It reveals nonaneurysmal bleeding sources (e.g., hypertensive hemorrhages and AVMs), demonstrates acute complications that may require urgent intervention (particularly acute hydrocephalus or significant intraparenchymal hematoma), helps localize the probable site of aneurysmal rupture, helps determine the timing of surgical intervention, establishes a baseline for the diagnosis of complications (e.g., rebleeding, ischemia, or hydrocephalus), and serves as an important prognostic indicator for predicting ultimate neurologic outcome.

Magnetic resonance imaging (MRI) is less sensitive than CT scan for detecting SAH. Compared with CT scanning, MRI requires more time to perform, is often tolerated poorly by the patient, provides only limited emergency accessibility to the patient, and is available less frequently in some centers. Moreover, a positive MRI is usually no more likely than a positive CT to obviate the need for cerebral arteriography.¹⁷ Although magnetic resonance angiography (MRA) can visualize some aneurysmal sources of SAH, the absence of rapid blood flow in the lumens of some aneurysms may render them less visible by MRA than by conventional angiography.

Although other diagnostic studies seldom aid directly in emergency management, they provide a baseline against which to assess subsequent complications. An ECG should be obtained, and continuous cardiac monitoring should be instituted. Chest radiographs, hematologic studies, and blood chemistry tests should also be ordered in the emergency department.

An LP is indicated in the symptomatic patient with suspected SAH if the CT scan is equivocal or negative. LP can identify subarachnoid blood missed on CT because of poor study quality, motion artifact, mixture of blood and CSF, severe anemia, or localized or subtle subarachnoid bleeding. However, it is generally recommended that CT be performed before the LP so that intracranial hematoma, mass effect, intracranial hypertension, and obstructive hydrocephalus may be ruled out. The risk of untoward neurologic events directly attributable to the performance of an LP in this situation is unknown.

The CSF is grossly bloody in acute SAH, usually containing from 100,000 to more than 1 million red blood cells (RBC)/ μ L. In rare cases, fewer than 100,000 RBC/ μ L are present, and greater than 1,000 RBC/ μ L has been used as a criterion for SAH in some studies.¹⁸ Xanthochromia, the pink or yellow discoloration of the CSF supernatant caused by heme pigments released from the degradation of hemoglobin in CSF, is pathognomonic of SAH. Xanthochromia typically appears 4 to 6 hours after the initial hemorrhage, is present in virtually all patients 12 hours after aneurysmal SAH, and persists for up to 3 weeks in 70% of patients.

LP findings can be the cause of diagnostic confusion. Clinicians may have difficulty distinguishing blood in the CSF due to SAH from local bleeding into the CSF caused by the LP (traumatic tap). In SAH, comparable numbers of RBCs are present in the first and last (usually the fourth) specimen collection tube, whereas CSF samples taken after a traumatic tap usually yield decreasing number of RBCs in consecutively collected tubes. Patients whose presentation for care for SAH has been delayed may demonstrate decreasing numbers of RBCs in serially collected CSF specimen tubes, however, and the same number of RBCs may be seen in all specimens collected from some patients with traumatic taps.

The most accurate method for distinguishing subarachnoid bleeding from a traumatic tap is spectrophotometric examination of the CSF supernatant for the presence of xanthochromia. Xanthochromia is present in virtually all cases of SAH and is absent in most traumatic taps. Bedside visual inspection is insufficiently sensitive to rule out xanthochromia, however, so spectrophotometric analysis is required. Furthermore, because RBCs from a traumatic tap may lyse and discolor the supernatant if centrifugation and examination are delayed, analysis should be carried out on a freshly obtained specimen as soon as possible after collection.

Four-vessel cerebral angiography provides the definitive diagnostic information in patients with SAH or a sentinel headache. Angiography precisely defines the location of bleeding, delineates the cerebral anatomy, determines the degree of cerebral vasospasm, defines the extent and number of aneurysms, differentiates between aneurysm and AVMs, identifies unusual causes of SAH (e.g., tumors), and aids in decision making regarding surgical intervention. Angiography is not a routine part of the emergency department diagnostic evaluation in most centers, however. The admitting neurosurgeon generally determines the optimal timing of angiography in relation to plans for surgical intervention.

Although other diagnostic studies seldom aid directly in emergency management, they provide a baseline against which to assess subsequent complications. An ECG should be obtained, and continuous cardiac monitoring should be instituted. Chest radiographs, hematologic studies, and blood chemistry tests should also be ordered in the emergency department.

EMERGENCY DEPARTMENT MANAGEMENT

Emergency management of SAH involves the immediate stabilization of acute life-threatening conditions and the institution of appropriate supportive therapy. Once SAH is diagnosed, therapy is aimed at preventing complications such as seizures, rebleeding, and vasospasm, and preparations are made for angiography and possible surgical intervention.

The necessary supportive therapy depends on the patient's clinical status. Vital signs, cardiac rhythm, and oxygen saturation should be monitored, and an intravenous line should be established. A urinary catheter should be inserted in confused or obtunded patients. The head of the bed should be elevated 30 degrees from the horizontal to facilitate venous drainage and help reduce ICP. If possible, the patient should be kept in a quiet area, and visits by family or friends should be minimized.

Patients with respiratory compromise secondary to hypoventilation, obtundation, hypoxia, hypercarbia, loss of airway protective reflexes, or pulmonary edema require endotracheal intubation and assisted ventilation, as do those who require hyperventilation to reduce increased ICP. Controlled hyperventilation with target P_{CO_2} levels

of 25 to 30 mm Hg is effective for acutely reducing elevated ICP. Adjunctive pharmacologic agents (e.g., lidocaine, sedatives, and neuromuscular blocking agents) may be necessary to ensure rapid, smooth, airway control and to minimize increases in ICP.

Adequate cerebral perfusion pressure must be maintained, and excessive increases or surges in mean arterial pressure must be avoided. Although hypertension at time of admission is associated with poor prognosis,¹² studies have failed to demonstrate a consistent benefit of antihypertensive treatment.¹⁵ Thus, administration of antihypertensive agents should be performed in consultation with a neurosurgeon for most patients unless there is significant and sustained blood pressure elevation (diastolic greater than 120 to 130 mm Hg). For these patients, a titratable, short-acting agent, such as intravenous nitroprusside, should be employed. The drug should be titrated to reduce the diastolic pressure below 100 to 110 mm Hg diastolic over 20 to 30 minutes. Other agents, such as nifedipine or hydralazine, should be avoided, because they cannot be titrated and may cause excessive hypotension.

The administration of prophylactic anticonvulsant agents is a widespread practice. Anticonvulsants may prevent the seizures that can occur in as many as 25% of ruptured aneurysms.²² Preventing seizures and the concomitant increases in ICP can reduce the risk of rebleeding. Phenytoin is typically used as a prophylactic anticonvulsant. Although studies have not demonstrated a consistent benefit from prophylactic anticonvulsant use, their short-term use in the interval after rupture and surgery has been recommended as a reasonable precaution.¹⁵ Seizures should be aggressively managed if they occur. Diazepam or lorazepam may be used as first-line agents when seizures occur and should be followed by phenytoin loading. Phenobarbital loading is an effective alternative, but its sedating effects may interfere with subsequent neurologic assessment.

Antiemetics such as prochlorperazine or promethazine are indicated to control nausea and vomiting. Alert patients with significant headache or neck pain may require narcotic analgesics for pain control. Despite the lack of proven benefit of corticosteroids in decreasing cerebral edema associated with SAH, some neurosurgeons advocate their use to help reduce the irritative effects of blood in the subarachnoid space.

Treatment with a calcium channel blocker such as nimodipine (orally or via nasogastric tube) or nicardipine (intravenously) appears to be effective in reducing the risk and severity of cerebral vasospasm; patients who have a relatively good neurologic status after SAH derive the most benefit.^{9,18}

Antifibrinolytic therapy (e.g., with aminocaproic acid) decreases the rate of rebleeding after SAH, but is associated with an increased risk of ischemic complications, including cerebral infarction, as well as hydrocephalus, pulmonary embolism, and deep venous thrombosis. Consequently, the use of antifibrinolytic agents has decreased with the trend toward earlier surgical intervention.

DISPOSITION

All patients with SAH require admission to the hospital for monitoring of neurologic status and evaluation for surgical intervention. A neurosurgeon should be consulted immediately once the diagnosis of SAH is established, and admission to a neurosurgical unit or critical care setting should be considered. The neurosurgeon evaluates the need to evacuate an acute intracerebral hematoma or to perform an intraventricular drainage procedure, and determines the pace of further evaluation, including angiography. The timing of definitive surgery for SAH secondary to ruptured cerebral aneurysm is somewhat controversial.

Early surgical intervention (i.e., within 24 to 48 hours after initial bleeding) appears to decrease the incidence of rebleeding and vasospasm and results in improved neurologic outcome, particularly for patients with good neurologic status after SAH. Prompt neurosurgical consultation is also indicated when there is evidence of increased ICP or progressive or lateralizing neurologic signs.

In hospitals without CT scanning or available neurosurgical expertise, the patient should be stabilized rapidly and transferred to a facility that has the necessary capabilities for treating patients with SAH.

COMMON PITFALLS

- Failure to consider the diagnosis and order the appropriate diagnostic studies. Although some patients with SAH may present with catastrophic hemorrhage, a significant proportion experiences less severe and relatively less impressive warning symptoms, most commonly consisting only of an unusual headache.
- Failure to perform an LP in a patient with suspected SAH in whom the head CT is negative. Conversely, performing an LP before obtaining a CT scan may result in substantial neurologic morbidity in the occasional patient who has a significant mass lesion or obstructive hydrocephalus.

The term *stroke* refers to the sudden onset of a neurologic deficit of varying duration, caused by an acute vascular lesion of the brain that is either hemorrhagic, embolic, thrombotic, or aneurysmal in nature. *Cerebrovascular disease* is a broader term, encompassing stroke and other vascular causes of central nervous system dysfunction.

Stroke is the third leading cause of death in the United States, after heart disease and cancer. In 1995, there were over 700,000 new cases of stroke in the United States, with approximately 150,000 deaths and a cumulative total of 3 million stroke survivors, many requiring chronic care. The estimated annual cost of cerebrovascular disease in the United States exceeds \$30 billion.

DIAGNOSTIC PROCEDURES IN CEREBROVASCULAR DISEASE

A knowledge of the common diagnostic procedures used to evaluate suspected cerebrovascular disease is essential for the emergency physician.

COMPUTED TOMOGRAPHY OF THE HEAD

Computed tomography (CT) has become the most commonly ordered examination in patients with symptoms of cerebrovascular disease. Image resolution can be optimized by the use of intravenous contrast material, which enhances the density of vascular structures and areas where the blood-brain barrier is breached.

Current scanners are capable of identifying hematomas of less than 1 cm in diameter and infarcts as small as 1.0 to 1.5 cm, provided the lesion is transected by a given slice and not lost in volume averaging. CT is less reliable in identifying lesions at the base of the brain and in the posterior fossa because of artifact from surrounding bony structures. In ischemic stroke, the infarct area becomes hypodense 6 to 72 hours after onset and by 10 days becomes isodense with the surrounding tissue. In hemorrhagic infarcts, the initially hyperdense area becomes isodense with surrounding tissue at 3 to 4 weeks. CT imaging identifies 95% of patients with subarachnoid hemorrhage (SAH) due to aneurysmal leak or rupture; lumbar puncture should be performed to rule out SAH in patients with a high index of suspicion and a normal CT scan.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) has several important advantages over CT in emergency care. First, MRI is superior in identifying lesions of the posterior fossa, brainstem, and skull base. Second, MRI accurately localizes gray and white matter pathology and is more sensitive than CT in the early detection of infarction. Third, major intracranial blood vessels can be visualized by MRI without the use of iodinated contrast media. This improved visualization makes MRI the preferred diagnostic study for suspected venous sinus thrombosis. Fourth, coronal and sagittal views are easily obtained with MRI, whereas reconstruction is required with CT. Finally, patients are not exposed to ionizing radiation with MRI.

Major limitations to the emergent use of MRI include its lack of availability, increased scanning time, and increased cost compared with CT. In addition, its sensitivity to motion artifact requires a high degree of patient cooperation in a tight, enclosed environment. There is limited access to the critically ill patient, and no ferromagnetic materials or monitors may be used while the patient is in the magnetic field.

DUPLEX SCANNING

Vascular duplex scanning combines high-resolution, brightness-modulated (B-mode) imaging of the vessel wall with pulsed-wave spectral analysis of the intravascular flow velocity. This combination of modalities improves the reliability of noninvasive carotid studies to greater than 90% for identifying significant carotid artery disease.

Indications for emergent duplex scanning of the carotid system include transient ischemic attacks (TIAs) and completed ischemic strokes in which vascular dissection is suspected. Duplex scanning is also useful in evaluating asymptomatic bruits and in identifying nonstenotic vascular lesions. It is a safe, noninvasive test to screen patients for extracranial carotid disease before angiography.

Duplex scanning has several limitations. It is unreliable for imaging high in the internal carotid and intracranial arterial systems, and its ability to evaluate the vertebrobasilar system is unproved. The accuracy of duplex scanning in distinguishing severe carotid stenosis from complete occlusion is controversial.

CEREBRAL ANGIOGRAPHY

There are several potential indications for emergent cerebral angiography: (1) evaluation of stenotic lesions seen on carotid duplex scanning in patients being considered for emergent endarterectomy; (2) detection of vertebrobasilar or carotid artery dissection in young adults presenting with a new ischemic stroke; and (3) localization of bleeding in patients presenting with acute SAH. Other indications for scheduled angiography include definitive evaluation of extracranial and intracranial arterial stenosis, arteriovenous malformations, aneurysms, and vasculitis.

Limitations of cerebral angiography include its lack of universal availability and its associated morbidity. There is a 0.1% to 1.0% risk of stroke from the procedure that is angiographer-dependent. There is also the possibility of hemorrhage from the femoral puncture site and the risk of anaphylactoid reactions and renal failure from the contrast media employed.

ISCHEMIC CEREBROVASCULAR DISEASE

Ischemic neurologic deficits are commonly categorized by their time course. Deficits persisting less than 24 hours are referred to as *transient ischemic attacks*; those persisting up to 6 weeks are termed *reversible ischemic neurologic deficits*; those with progressive symptoms are *strokes in evolution*; and stable deficits are classified as *completed strokes*. In the Dutch TIA study trial, a relevant infarct corresponding to a clinical deficit was found on CT scanning in 13% of patients with TIAs, 35% of patients with reversible ischemic neurologic deficits, and 49% of patients with "minor" strokes.¹⁴ This suggests that these temporal classifications should be thought of as a continuum rather than as separate entities with specific causes, prognoses, and treatments. Nevertheless, this classification is useful for the emergency physician evaluating the patient at a single point early in the disease process. Other classification systems define stroke syndromes by probable cause or anatomic location.

RISK FACTORS

Not surprisingly, risk factors for ischemic cerebrovascular disease parallel those for atherosclerotic heart disease. Hypertension is the major risk factor for stroke and accounts for a fourfold increase in the incidence of atherothrombotic brain infarction as compared with normotensive subjects. The degree of risk corresponds to the level of elevation of either the systolic or diastolic pressure and may be reduced by appropriate antihypertensive therapy. The presence of coronary heart disease triples the risk of stroke. Left ventricular hypertrophy, atrial fibrillation, and acute myocardial infarction (AMI) are all independent risk factors for ischemic stroke. Patients with diabetes have a prevalence of stroke 2.5 to four times higher than persons with normal glucose levels.

There are significant associations of ischemic cerebrovascular disease with age, sex, and race. The incidence of all strokes increases with age, doubling with each decade of life. In 1990, 13% of the population in the United States was over 65 years of age, and this group accounted for more than 75% of all strokes. There is a slightly higher risk in men compared with women, and Black men and women have age-adjusted stroke incidence rates that are 1.5 to 2.3 times higher, respectively, than those in Whites.⁹ The Japanese population shares this higher incidence of stroke relative to the White population of the United States. Cerebrovascular disease in both Blacks and Japanese is typically intracranial, rather than the extracranial disease more common in White males.

Other medical conditions predisposing to stroke include a history of migraine headaches, elevated fibrinogen levels or hematocrit (causing increased blood viscosity), and advanced age with elevated total serum cholesterol levels.

Environmental risk factors for ischemic cerebrovascular disease include smoking and heavy alcohol consumption. Women taking oral contraceptives, particularly high-estrogen formulations, are also at increased risk for stroke. This risk is more pronounced in women smokers older than 35 years of age and in those with other cardiovascular risk factors.

Finally, patients with a history of ischemic stroke represent a high-risk population, with 1- and 5-year recurrence rates among survivors of 10% and 20%, respectively.¹⁶

Transient Ischemic Attacks

Although TIA is arbitrarily defined as a deficit that resolves within 24 hours, the typical carotid TIA lasts less than 15 minutes. TIAs serve as a warning sign, though the exact number progressing to completed stroke is the subject of numerous studies and much debate. If untreated, TIAs carry a cumulative risk of 5% to 6% per year for completed stroke (30% to 35% over 5 years), but the risk may be as high as 20% in the first month. Other studies, however, indicate that 3% to 9% of patients with TIAs experience a stroke within 1 week and approximately 15% have additional TIAs over this period.

Classically, the majority of TIAs were believed to result from plaque ulceration or embolism of platelet aggregates from extracranial or intracranial atherosclerosis. After impeding local blood flow, these emboli break up, accounting for the transient nature of the episode. Other sources of emboli include prosthetic heart valves and infective or marantic vegetations on valve leaflets. However, one report indicates that small-vessel disease in penetrating cerebral arteries may actually be the most common cause of TIAs and that these "lacunar" TIAs may represent a subgroup with a better prognosis than TIAs with cortical symptoms.¹² Hypotension and mechanical kinking of the extracranial vessels are less common causes of TIAs. Cardiac dysrhythmias are also an important potential etiology.

CLINICAL PRESENTATION

Carotid artery syndrome results from transient disruption of the anterior circulation of one cerebral hemisphere or of the retina. Hemispheric ischemia results in an abrupt onset of contralateral monoparesis or hemiparesis, numbness, tingling, aphasia, or hemianopia. Occlusion of the ophthalmic branch of the internal carotid artery results in retinal ischemia, causing temporary monocular blindness (amaurosis fugax). The patient complains of a "fog," "mist," "cloud," or "shade being drawn" over the visual field of one eye. Funduscopic examination of the involved eye may reveal cholesterol crystals (Hollenhorst plaques) in the retinal vessels.

Transient ischemia involving the posterior circulation (the brainstem or occipital lobes) is termed *vertebrobasilar artery syndrome*. Interruption of brainstem circulation may result in symptoms of vertigo, dizziness, ataxia, nausea, and vomiting secondary to involvement of the vestibular nuclei. Dysarthria, dysphagia, and perioral numbness may also occur. Occipital lobe ischemia results in blurred or dim vision or total cortical blindness. Diplopia may result from loss of conjugate gaze.

Basilar artery TIAs may cause *drop attacks*, which are brief paretic spells resulting in the patient dropping to his or her knees. There is no loss of consciousness, distinguishing it from true syncope, and the patient attempts to rise immediately after falling.

Transient global amnesia is thought to be caused by ischemia of the temporal lobes or thalamic area supplied by the posterior cerebral arteries. These episodes affect men more frequently than women and are characterized by a rapid development of retrograde memory loss and confusion, with preservation of self-identity. The length of retrograde amnesia gradually shortens until only the period during the attack remains lost.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of TIAs includes (1) transient deficits secondary to mass lesions from either tumor or hemorrhage (these patients often have a residual neurologic deficit detectable on examination); (2) infection (as with focal abscess, septic emboli, meningitis, or encephalitis); (3) seizure with a subsequent Todd's

paralysis; (4) complicated migraine; (5) exacerbation of multiple sclerosis; (6) hypoglycemia; and (7) syncope from any cause, particularly cardiac dysrhythmias.

EMERGENCY DEPARTMENT EVALUATION

Clinical investigation of TIA is directed toward identifying whether the deficit involves the anterior or posterior circulation, establishing the source of the TIA, and ruling out other causes of focal deficits. A detailed history often provides the most significant information. The patient may not be aware of any deficits, and the family should be questioned, if possible, along with the patient.

The onset and course of symptoms should be carefully elicited. Were there any prior episodes and, if so, how many; and were the events in the same or differing vascular distributions? “Crescendo” TIAs are defined as more than three events occurring in a 72-hour period, and these patients represent a high-risk group. A history of multiple events in differing territories points to a cardiac or other proximal source of emboli. Is there a history of intravenous drug use? Are there any medications predisposing the patient to decreases in blood pressure? Are there risk factors for cerebrovascular disease, or is there evidence of peripheral vascular disease?

Is there a history of claudication in an exercised arm occurring simultaneously with symptoms of vertebrobasilar insufficiency? With significant occlusion of the brachiocephalic or left subclavian artery, exercise of the ipsilateral extremity results in a reversal of blood flow through the vertebral arteries, shunting blood to the involved limb and causing posterior circulation symptoms (subclavian steal syndrome). Is there a history of significant arthritis predisposing the patient to formation of cervical osteophytes that could mechanically compress the extracranial vessels? This would indicate a need for radiologic evaluation of the cervical spine.

The neurologic examination in patients with TIAs is often unremarkable, but a complete assessment is essential. Orthostatic blood pressures should be measured in patients with vertebrobasilar TIAs, because symptoms are often related to postural changes. Auscultation for cervical and subclavian bruits should be performed, as well as evaluation for cardiac dysrhythmias, murmurs, and left ventricular dysfunction.

Laboratory evaluation of patients with suspected TIA include a complete blood cell count to assess hemoglobin and hematocrit (anemia or polycythemia), coagulation studies (prothrombin time and partial thromboplastin time), and a glucose determination. An erythrocyte sedimentation rate is useful for suspected vasculitis, and a serologic test for syphilis should also be obtained if clinically indicated. An electrocardiogram and cranial CT scan should be performed. Transthoracic and/or transesophageal echocardiography is indicated when cardiac emboli are suspected.

Patients with anterior circulation TIAs who have no obvious cardiac etiology and no contraindications for vascular surgery should be screened with duplex ultrasonography for significant carotid artery stenosis. These patients represent a subgroup of TIA patients known to have an improved outcome with carotid endarterectomy; they should be identified as early as possible.

EMERGENCY DEPARTMENT MANAGEMENT

All patients with a diagnosis of TIA should be placed on a cardiac monitor and have potentially correctable causes (e.g., hypoglycemia) immediately addressed. If infective endocarditis is suspected, serial blood cultures should be obtained and appropriate antibiotic therapy initiated. Extended cardiac monitoring is indicated for patients with suspected dysrhythmias.

Medical therapy is indicated for patients with posterior circulation TIAs, those with anterior circulation TIAs who have less than 50% stenosis on carotid duplex scanning, and patients who are not candidates for carotid endarterectomy. Medical treatment options are limited to antiplatelet therapy and anticoagulation.

Antiplatelet therapy with aspirin (30 to 1500 mg/d) reduces the incidence of nonfatal stroke, nonfatal myocardial infarction, and death from all vascular causes in patients with TIAs. Because the lower dosages require several days to achieve maximal platelet inhibition, therapy in the emergency department should be initiated with 300 to 325 mg/d. The ESPS-2 trial found dipyridamole (200 mg b.i.d.) to have an additive protective effect when used with low-dose (50 mg/d) aspirin, with a combined 37% reduction in recurrent stroke in patients with previous stroke or TIA.⁷ This is the first study to report an independent effect of dipyridamole when used with aspirin.

Ticlopidine (Ticlid, 250 mg b.i.d.), an antiplatelet agent inhibiting adenosine diphosphate (ADP)-dependent platelet activation, is slightly more effective than aspirin alone in preventing recurrent TIAs. Because of concern over side effects (diarrhea, rash, neutropenia) and increased cost, its use should be reserved for patients who cannot tolerate aspirin or continue to have TIAs while on aspirin.^{3,10} Clopidogrel (Plavix, 75 mg daily) is a newer ADP inhibitor and, though structurally similar to ticlopidine, does not cause neutropenia. Its role as a primary or secondary agent in the treatment of TIA is still unclear, given its cost and the small (0.5%) improvement it provides in reducing risk for stroke, AMI, and vascular death in patients with atherosclerotic vascular disease compared with aspirin alone.

Although heparin has traditionally been used in selected patients with TIA, no prospective randomized study of significant size has demonstrated a clear benefit. Its use is probably best reserved for “high-risk” patients. These are patients with crescendo TIAs, vertebrobasilar TIA, recurrent TIA while receiving maximum antiplatelet therapy, high-grade carotid stenosis, or a suspected cardiac source for emboli. Because the use of anticoagulants is controversial, neurologic consultation is advisable when initiating heparin therapy.

A subset of patients with TIAs have surgically correctable carotid stenosis and represent an important group for the emergency physician to identify. Those with greater than or equal to 50% carotid stenosis on duplex scanning are potential candidates for endarterectomy and should begin medical therapy in the emergency department pending a final decision. Carotid angiography is typically used to define the specific characteristics of these lesions before surgery and in cases in which duplex scanning is inadequate.

The North American Symptomatic Carotid Endarterectomy Trial (NASCET) found that symptomatic patients with high-grade (70% to 99%) stenosis randomized to carotid endarterectomy had a 17% reduction in the risk of ipsilateral stroke after 2 years, compared with the optimal medical treatment group. Carotid endarterectomy was usually performed within 2 days after the TIA, and no patients died or had a stroke during this interval. The data comparing surgical to medical therapy for patients with moderate (30% to 69%) stenosis found a smaller risk reduction (10.1%) at 5 years for those with 50% to 69% stenosis and no benefit from surgery for those with less than 50% stenosis.² The beneficial effect of endarterectomy for high-grade stenosis is further supported by the European Carotid Surgery Trial.⁸

DISPOSITION

Patients who have an anterior circulation TIA and who are potential surgical candidates should not be discharged without an evaluation of the carotid arteries. If duplex scanning is unavailable, the patient should be admitted (either to an inpatient setting or to an emergency department clinical decision unit) and started on antiplatelet therapy while undergoing frequent neurologic assessments. Carotid duplex scanning should be performed as soon as possible and vascular consultation requested for patients determined to have greater than or equal to 50% stenosis.

Patients with an anterior circulation TIA who are not “high risk” (as defined previously) and have less than 50% carotid stenosis on duplex scanning may be discharged home on antiplatelet therapy, with close follow-up. High-risk patients should be admitted and neurologic consultation obtained to address the issue of anticoagulation. Patients with suspected dysrhythmias require a monitored bed and evaluation for ischemic heart disease, as appropriate.

Standard protocols for patients with TIAs should be jointly developed with neurologic specialists in each institution. Active collaboration can ensure the provision of efficient and consistent patient care and facilitate future modifications as new treatments become available.

COMMON PITFALLS

- Failure to recognize a TIA when the symptoms are remote in time from the emergency department presentation. Establishing the diagnosis becomes more difficult when the patient is unable to recall the specific events surrounding the TIA.
- Discharging patients with anterior circulation TIAs before determining whether there is a potentially surgically correctable carotid lesion. This carries a high medicolegal risk.
- Failure to consider heparinization in high-risk patients: those with crescendo TIAs, vertebrobasilar TIA, recurrent TIA on maximal antiplatelet therapy, high-grade

carotid artery stenosis, or presumed cardioembolic source

Ischemic Stroke
