Teratogenicity has not been associated with quinidine, procainamide, or disopyramide.⁷ Of these, quinidine has the longest history of use in pregnancy. Quinidine and procainamide are considered safe during pregnancy.⁷ Disopyramide has a more limited history and has been shown to cause contractions in pregnancy; thus, cautious use is indicated.⁷

Class IB Agents

Lidocaine is not known to be teratogenic. The risk of lidocaine is minor when appropriate doses are utilized. In large doses, it has been associated with low Apgar scores and neonatal lidocaine toxicity.⁷ Mexiletine is structurally related to lidocaine and freely crosses the placenta. Data in pregnant women are limited, but mexiletine has not been associated with teratogenicity.⁷

Class IC Agents

Flecainide and propafenone cross the placenta, but neither has been shown to cause fetal adverse effects or teratogenicity.⁷ These agents should be used cautiously, as they have not been extensively studied in humans.⁷

Class II Agents

Beta-blockers, particularly propranolol, have been used with considerable experience in pregnancy. No teratogenicity is demonstrated with these agents, and they are considered safe for use.⁷ Some adverse effects have been noted, including intrauterine growth retardation (IUGR), fetal bradycardia, premature labor, neonatal hypoglycemia, respiratory depression, and bilirubinemia.⁷ If necessary, glucagon may be given during labor to counteract the bradycardic and hypoglycemic effects of beta-blockade.⁷

Class III Agents

Amiodarone and its metabolite, desethylamiodarone, have limited ability to cross the placenta. Amiodarone has a high iodine content and has been associated with fetal goiter, neonatal hypothyroidism (approximately 9% of exposures), and growth retardation. Other reported adverse effects include fetal bradycardia, prolonged QT, prematurity, and possibly death. Given these effects and the prolonged half-life of amiodarone, it should be used in pregnancy only when absolutely necessary.⁷

Limited data are available on the use of sotalol during pregnancy. It has not been shown to be teratogenic, but transient neonatal bradycardia has been reported. It should be used cautiously and infants monitored for bradycardias.⁷

Ibutilide has not been studied in pregnant women. In high doses, it has been demonstrated to be teratogenic in animal studies. Due to limited data and potential teratogenicity, ibutilide is not recommended in pregnancy.⁷

Class IV Agents

The greatest experience with calcium channel blockers in pregnancy has been with verapamil. It has not been shown to be teratogenic and is generally considered safe in pregnancy, as are the other calcium antagonists.⁷ Intravenous use carries an increased risk of maternal hypotension and subsequent fetal hypoperfusion. Animal studies have suggested a relationship between diltiazem and skeletal deformities and even fetal death. Because of this, verapamil is the drug of choice among calcium antagonists.⁷ It should be noted, however, that adenosine and beta-blockers are preferred over calcium antagonists in the management of supraventricular tachycardia in pregnancy.⁷

Antihypertensive Agents

Fetal wastage in untreated patients with mild chronic hypertension is up to 16%. In those with severe hypertension (greater than 160/100), it is as high as 40%. Therapy must be monitored carefully to prevent maternal hypotension and resultant placental hypoperfusion.^{2,8}

Angiotensin Converting Enzyme Inhibitors

The three most common angiotensin converting enzyme inhibitors are captopril, enalapril, and lisinopril. These agents are avoided in pregnancy because during the last half of pregnancy they are associated with severe fetal renal toxicity that can lead to *in utero* anuria and oligohydramnios, structural defects of the cranium and kidneys, and hypotension and anuria in the newborn.²

Diuretics

The thiazide diuretics and furosemide are not teratogenic but should be used cautiously. An increase in perinatal mortality and congenital defects has been associated with these agents, probably related to decreased maternal plasma volume, resulting in placental hypoperfusion.^{2,8}

Methyldopa

The most commonly used antihypertensive agent is methyldopa. It has been the drug of choice for more than 30 years; it is effective and lacks fetal or neonatal

adverse effects.⁸

Beta-Blockers

Propranolol is the most commonly used beta-blocker for hypertension in pregnancy. Atenolol is cardioselective but may have a higher risk of IUGR than propranolol, especially when started in the first trimester.⁸ Labetalol is a combined alpha- and beta-blocker and appears to be without risk of teratogenicity.⁸ Labetalol has been shown to increase pulmonary surfactant and may be advantageous, especially in premature infants.^{2,8} As with beta-blockers, neonates should be monitored for bradycardias for 24 to 48 hours.⁸

Hydralazine

Hydralazine is a vasodilator with a direct effect on arterioles. It is the drug of choice to control acute exacerbations of hypertension.^{2,8} Hydralazine has been found to be safe and without risk of teratogenicity.⁸ Changes in fetal heart rate occur when the drug is given, but they are apparently without significant sequelae.⁸

Calcium Channel Blockers

Nifedipine should be reserved for cases in which other agents have failed to control hypertension in pregnancy. It has been shown to be teratogenic in animal models at high doses. No excess teratogenicity has been found in human models. IUGR and fetal death have been reported.⁸

Cough and Cold Preparations

Antihistamines

Diphenhydramine in pregnancy has been associated with a number of minor anomalies. It is not recommended in pregnancy.³ The antihistamines chlorpheniramine, pheniramine, and tripeleminamine have not demonstrated teratogenicity and are probably safe.³ Brompheniramine has been shown to cause birth defects and should not be used.¹¹ Astemizole was studied prospectively in a group of 114 women in which the incidence of major malformation was found to be within the expected rate for the general population. Astemizole was not associated with perinatal complication or IUGR.²⁰ Although the power of this study was limited, the results are encouraging. Further study is necessary to determine fetal risk.

Decongestants

Sympathomimetic drugs such as ephedrine, phenylephrine, phenylpropanolamine, and pseudoephedrine are commonly used decongestants and are combined with other agents to alleviate symptoms of allergy and upper respiratory tract infection. Pseudoephedrine is known to be teratogenic in animals; no human teratogenicity has been reported.³ Phenylpropanolamine has been implicated in the causation of gastroschisis when used during the first trimester.²² Although otherwise considered not to be teratogenic, sympathomimetics have been shown to be associated with minor malformations such as inguinal hernia and clubfoot.²² Some of these agents have been shown to cause significant tachycardias and hypertensive episodes with even a single therapeutic dose.²² These effects may be particularly damaging in pregnancy; thus, decongestant medications should be used cautiously.

Expectorants

Guaifenesin is safe for use during pregnancy. Iodinated compounds should be avoided to prevent fetal goiter as a result of iodine crossing the placenta.

Antitussives

Dextromethorphan is safe for use in pregnancy.

Gastrointestinal Medications

Antacids

Antacids are used by 30% to 50% of women for the relief of heartburn during pregnancy; most are well tolerated.⁴ There are limited data concerning the effect of antacids on the fetus. No teratogenicity is observed in animal studies. Currently, the use of most aluminium-, magnesium-, and calcium-containing antacids are acceptable for use in pregnancy at therapeutic doses.⁴ Sodium bicarbonate should not be used, as it can cause metabolic alkalosis and fluid overload in both the mother and the fetus.⁴ Compounds containing magnesium trisilicate, when used in high doses, can cause nephrolithiasis, hypotonia, respiratory distress, and cardiovascular compromise in the fetus.⁴

Mucosal Protectants

Sucralfate is not systemically absorbed and is therefore commonly used during pregnancy.⁴ In one study, sucralfate was demonstrated to completely relieve symptoms of heartburn and reflux more effectively than lifestyle changes in controls.⁴

Histamine H₂ Receptor Antagonists

Few published safety reports on the use of cimetidine in pregnant women exist. The Michigan Medicaid Surveillance Study reported 460 newborns exposed to cimetidine. No association between cimetidine and congenital defects could be demonstrated.⁴ Ranitidine is the only H₂ receptor antagonist whose efficacy has been studied in pregnancy. Twice-daily doses reduced symptoms and antacid use compared with the baseline. Little literature is available on the use of famotidine in human pregnancy. Animal studies show no evidence of teratogenicity or fetotoxic effects.⁴ Safety data are limited in the use of nizatidine during pregnancy. Data from animal studies are conflicting, but there have been reports of abortions, low fetal weights, and malformations with high doses.⁴

H₂ receptor antagonists thus appear to be well tolerated during pregnancy, with the possible exception of nizatidine, and are efficacious in the treatment of heartburn in pregnancy. The use of these drugs should be limited to those patients not responding to lifestyle changes, antacids, and sucralfate.⁴

Promotility Agents

Metoclopramide has not been associated with teratogenicity in animals. In the Michigan Medicaid Surveillance Study, 192 newborns were exposed to metoclopramide; 10 major birth defects were reported and eight were expected based on the general population rate of malformation, which was not statistically significant.⁴ Further study is needed to assess fetal safety. Metoclopramide has been found to increase milk production and has been used as a lactation stimulant.⁸ Cisapride was recently evaluated for safety during pregnancy in a Canadian cohort study. One hundred twenty-nine women were exposed to cisapride during pregnancy. The investigators found no difference in rate of minor or major congenital malformation between this cohort and the control group. Although the power of this study was limited, the investigators feel that cisapride can be used safely in pregnant women when non-systemic drugs and H₂ receptor antagonists fail to control symptoms.⁴

Proton Pump Inhibitors

Omeprazole crosses the placenta, but animal studies fail to show evidence of teratogenicity.¹⁷ A recent Swedish cohort study failed to demonstrate an effect on the rate of congenital malformation when omeprazole was used during pregnancy. The investigators concluded that the present data indicate no evidence of teratogenicity with omeprazole use and that the individual risk of an exposed pregnancy is negligible.¹³ No reports are available to date on the safety of lansoprazole

during pregnancy.⁴

Antiemetics

The use of antiemetics should be considered after conservative measures to alleviate nausea and vomiting have failed. Pyridoxine has been found to be useful for nausea and vomiting during pregnancy for a few days, but the effect decreases over time. Pyridoxine is not known to be teratogenic.⁸

Trimethobenzamide, prochlorperazine, and promethazine are commonly prescribed antiemetics. These agents have been studied and have not been shown to be teratogenic.^{3,8} The use of phenothiazines is associated with a small risk of hypotension, and they should be reserved for patients with hyperemesis gravidarum.

Laxatives

Agents acting locally in the gastrointestinal tract are safe for use during pregnancy. These include castor oil, senna, bisacodyl, milk of magnesia, magnesium citrate, Epsom salts, and the phosphate salts of sodium and potassium. Stool softeners such as the docusates are safe for use in pregnancy.³

Hypoglycemics

Insulin is safe in pregnancy. Oral hypoglycemics are contraindicated because they cross the placenta and may cause fetal hypoglycemia.³

Local Anesthetics

Most local anesthetics have not been shown to be teratogenic and are safe for use in pregnancy.²¹ Bupivacaine and mepivacaine should be used cautiously and may be associated with fetal bradycardia. It is recommended that all local anesthetics be used in the minimum dose required for effective pain control.²¹

Combination tetracaine, epinephrine, and cocaine (TAC) is contraindicated in pregnancy because epinephrine and cocaine are suspected teratogens.

Immunizations

Few vaccines have been officially tested in pregnant women. Because of the theoretical risk to the fetus, live vaccines should not be administered during pregnancy or to those likely to become pregnant in the ensuing 3 months.²⁸ It is also best to avoid any form of immunization during the first trimester, if possible.²⁸ High fevers during the first trimester have been associated with neural tube defects, and this may occur as a result of immunization. Commonly used immunizations that are safe for use in pregnancy include tetanus toxoid, tetanus–diphtheria toxoid, tetanus immune globulin, rabies human diploid cell vaccine, rabies immune globulin, hepatitis B vaccine, hepatitis B immune globulin, varicella zoster immune globulin, and pooled immune globulins. Hepatitis A vaccine should be used only if clearly indicated; it is FDA category C mainly because of the risk of febrile response.²⁸ The influenza vaccine may be given in the second or third trimesters.²⁸

Psychotropics

Antidepressants

Tricyclic antidepressants (TCAs) are widely prescribed in reproductive-age women. There is no significant association between first-trimester use of TCAs and congenital malformation.¹⁵ One study demonstrated antidepressant withdrawal symptoms in newborns of women who took TCAs.¹⁵

Selective serotonin reuptake inhibitors (SSRIs), such as sertraline and fluoxetine, are popular agents for the treatment of depression. Studies show no increase in rates of major malformations, miscarriage, stillbirth, or prematurity in groups taking SSRIs compared with controls.^{1,15,16} There is little information available on the safe use of newer agents such as moclobemide, venlafaxine, and nefazodone during pregnancy.¹

Amphetamines can cause clinically significant maternal hypertension and have potential teratogenic effects. The use of stimulants during pregnancy should be avoided because they have not been shown to be safe.¹

Mood Stabilizers

Lithium is associated with an increased risk of cardiovascular abnormalities.^{1,15} The “floppy-baby” syndrome, in which the infant is hypotonic, cyanotic, and sucks poorly is felt to be the result of lithium toxicity. Lithium has also been reported to effect neonatal thyroid function.¹

Carbamazepine and Valproic Acid

See the section on [anticonvulsants](#).

Antipsychotics

The best studied neuroleptic agents in pregnancy are the phenothiazines and haloperidol. Several large, prospective studies have failed to demonstrate significant teratogenic risk.¹⁵ Some authorities recommend discontinuation of antipsychotics 5 to 10 days prior to delivery to decrease the chances of neonatal extrapyramidal symptoms.¹⁵ Information on the safety of the newer antipsychotics, such as clozapine, risperidone, olanzapine, and zuclopentixol, is predominantly in the form of case reports. Thus far, no evidence of teratogenicity has been reported.¹

HYPERBARIC OXYGENATION

Hyperbaric oxygenation is the treatment of choice in the pregnant patient experiencing decompression sickness, arterial gas embolism, severe carbon monoxide poisoning, or gas gangrene. The use of hyperbaric oxygenation may be life-saving for the mother and prevent fetal abnormality or demise in these circumstances.¹²

COMMON PITFALLS

- Consider every female of reproductive age (ages 10 to 50?) a potential antenatal patient.
- There should be a clear medical indication every time a drug is used in pregnancy.
- Use the lowest effective dose.
- Discourage self-medication.
- Use agents that have been widely used in pregnancy (over newer agents).
- Explain how to take all prescribed drugs.
- Drugs that are absolutely contraindicated include brompheniramine, warfarin, the quinolones, and the tetracyclines.
- Denying pharmacologic therapy to a patient for a *bona fide* medical condition because she is also pregnant does not help her and may place the mother and fetus at risk for adverse outcome.

CHAPTER 72

Complications of Induced Abortions

James L. Jones and Andrew M. Kaunitz

[Emergency Department Evaluation](#)
[Differential Diagnosis and Emergency Department Management](#)
[Postabortion Bleeding](#)
[Postabortion Infection](#)
[Continuing Pregnancy](#)
[Medical Termination of Pregnancy](#)
[Chapter References](#)

Approximately 1.6 million abortions are performed in the United States annually, making abortions among the most frequently performed surgical procedures in the United States.^{12,13} Each year, approximately 3% of all reproductive-age American women have abortions.¹¹ These women tend to be young and unmarried.

Since abortions became legal in the early 1970s, the average gestational age among women having them has declined. Currently, approximately one-half of all abortions are performed before the eighth week of pregnancy, and more than 85% are done in the first 12 weeks of pregnancy.⁶ Nearly 99% of induced abortions are accomplished by curettage, and almost 90% are performed in outpatient settings.

After legalization of abortions, deaths from induced abortion plummeted in the United States.^{3,19,20} The risk of death associated with induced abortion in the first 8 weeks of pregnancy is one per 200,000 abortions,¹ a death rate 20 times lower than that associated with childbirth.¹⁵

Serious complications of legal abortion are infrequent.⁷ In one study based on 170,000 first-trimester procedures, a major complication rate of less than one per 1000 abortions was noted.¹⁰ Nevertheless, because so many abortions are performed, it is not unusual for physicians working in emergency settings to encounter problems related to legal termination of pregnancy.

Abortion complications likely to be encountered by emergency physicians reflect the techniques employed during the abortion, the gestational age of the pregnancy, the underlying medical status, and the age of the patient. Common complications of induced abortion include hemorrhage, intrauterine infection and sepsis, intrauterine blood clots, retained products of conception, continuing pregnancy, and ectopic pregnancy. Gynecologic referral or consultation is appropriate for patients presenting with these clinical problems.

EMERGENCY DEPARTMENT EVALUATION

The workup of patients with potential complications of induced abortion should include a history emphasizing gestational age at termination, method used for the abortion, and the nature of the current complaint. If possible, the physician who performed the procedure should be contacted to ensure that the history is accurate.

Physical examination of the patient should include the patient's vital signs, with a tilt test for orthostasis. A general physical examination is performed, with attention to the abdominal and pelvic examination. A bimanual examination is performed after a vaginal speculum examination. A pelvic ultrasound may be helpful if the examination is inadequate or if the patient is obese. An ultrasound may also be helpful in identifying a hemoperitoneum and in ruling out incomplete evacuation of the uterus or an ectopic pregnancy. Emergency department physicians should remember that an enlarged corpus luteum may be mistaken in this clinical setting for an ectopic pregnancy.

Initial laboratory studies should include a complete blood cell count. A type and screen may also be ordered if the patient gives a history of heavy vaginal bleeding or if an operative procedure is anticipated. A urine pregnancy test performed soon after an abortion should be positive and provides little information to the clinician. A single quantitative human chorionic gonadotropin (hCG) drawn after a termination of pregnancy also provides little information. Serial quantitative hCGs, drawn 48 hours apart, may be helpful if there is any question of a continuing or an ectopic pregnancy. If a serial quantitative hCG level rises or plateaus, this would be suspicious for an ectopic or failed attempted abortion.

DIFFERENTIAL DIAGNOSIS AND EMERGENCY DEPARTMENT MANAGEMENT

Postabortion complications include postabortion bleeding, acute hematometra, hemorrhage, postabortion infection, continuing pregnancy, incomplete evacuation, and ectopic pregnancy.

Postabortion Bleeding

Excessive postabortion vaginal bleeding is usually of uterine or cervical origin. A vaginal speculum examination allows determination of the source of the bleeding. Even minor cervical lacerations from the use of a tenaculum for cervical manipulation can present as delayed vaginal bleeding. Minor cervical bleeding can be controlled with topical application of silver nitrate or Monsel's solution during a vaginal speculum examination. More recalcitrant bleeding may require placement of a suture or the use of electrocautery.

If evaluation of the vagina and cervix is negative and blood is coming from the cervical os, the uterus is the source of bleeding. Uterine bleeding in this setting is usually due to retained products of conception or acute hematometra. The history and a bimanual pelvic examination to determine the size of the uterus may help differentiate an acute hematometra from retained products of conception. The risk of hemorrhage is greater with medical approaches to abortion, such as methotrexate.⁹

Acute Hematometra

Acute hematometra occurs in 0.2% to 1.0% of abortions.¹⁴ Typically, severe and progressive lower abdominal cramping occurs within several hours of the abortion. Vaginal bleeding may be minimal, because the hematoma is obstructing the outflow tract. The pelvic examination reveals a markedly distended and tender uterus. Hypotension, anemia, and fever are not present. Prompt suction evacuation of the uterus can be performed without anesthesia or cervical dilation. Symptomatic relief occurs on evacuation of the blood. Unless the patient is hypertensive, ergonovine maleate or methylergonovine (0.2 mg i.m.) should be administered to induce contraction of the uterus. Alternatively a 10-mg prostaglandin E2 suppository can be given rectally.

Retained Products of Conception

Retained products of conception after an induced abortion may result in bleeding, infection, or both. Occurring in approximately 1% of suction curettage patients, this complication is found more often after the use of local, rather than general anesthesia.⁷ Typically, within 1 week of the abortion the patient complains of cramping and heavy bleeding, which may be accompanied by fever. It may be difficult to distinguish between conditions caused by retained products of conception and infection.

Reaspiration of the uterus will confirm the diagnosis. If the pelvic examination reveals an enlarged uterus, significant amounts of fetal or placental tissue may be present. In this setting, it would be wise to perform the uterine evacuation in an operating room. If the patient is febrile, the possibility of intrauterine infection should be strongly considered, and antibiotics should be initiated before the patient undergoes uterine evacuation.

Other Causes of Postabortion Bleeding

Rarely, bleeding continues despite appropriate medical therapy. Persistent, unexplained uterine bleeding should alert the clinician to the possibility of a bleeding

diathesis. The most common bleeding diathesis among women of reproductive age is von Willebrand disease.

Uterine perforation may also present as heavy vaginal bleeding. Perforation of the uterine fundus with a blunt probe or cervical dilator usually does not cause significant complications and often can be managed with close observation alone. Perforation with a curette or suction cannula risks injury to abdominal contents and requires laparoscopy or laparotomy to rule out bowel injury.¹⁷ Heavy vaginal bleeding from a uterine perforation associated with injury to the pelvic vasculature may result in a broad-ligament hematoma. In this setting, prompt, exploratory laparotomy may be appropriate.² Finally, uterine bleeding may be a presenting sign of an underlying postabortion infection.

Postabortion Infection

The legalization of abortion has greatly reduced morbidity and mortality from septic abortion.³ Risk factors for postabortion infection include retained products of conception, gonococcal or chlamydial endocervical infections, and procedures not performed in aseptic conditions. Uterine tenderness, fever, and excessive bleeding occurring 3 to 7 days postoperatively are the hallmarks of postabortion infection. Sepsis and shock are uncommon. The organisms responsible for postabortion infections are similar to those that cause pelvic infections in nonpregnant women. Antibiotic guidelines for treating pelvic inflammatory disease are applicable to postabortion infections and include ceftriaxone (250 mg in a single i.m. dose) with doxycycline (0.1 g PO twice daily for 14 days), or amoxicillin/clavulanate (Augmentin) and doxycycline (see [Chapter 82](#), "Pelvic Inflammatory Disease"). Coverage against anaerobic pathogens should be included in any antibiotic regimen.

The primary treatment for postabortion infection is suction curettage. Antibiotics should be administered in advance of the procedure. Because of an increased risk of hemorrhage, reaspiration of an infected uterus should be performed in an operating room and the patient admitted for intravenous antibiotic therapy.

Infection after Illegal Abortion

Few young physicians practicing in the United States have cared for women experiencing complications of criminal abortion. If the movement to outlaw abortion succeeds, however, emergency physicians will need to learn lessons first taught in the days of illegal abortion. In that era, deaths from illegal abortion often outnumbered maternal deaths associated with childbirth. Self-induced abortions were often attempted using catheters, knitting needles, or open wire coat hangers. When catheters were used, soap, Lysol, and detergents were the agents most commonly introduced into the uterus. After infusion of these noxious substances into the pregnant uterus, necrosis of the intrauterine contents, thrombosis of uterine and pelvic vasculature, hemolysis, and disseminated intravascular coagulation commonly occurred. Abortions also were attempted by physicians with inadequate training, or instrumentation was done by nonmedical personnel. Uterine perforation was common.

Women experiencing complications of illegal abortion tend to present later than women with complications of legal abortion.⁸ In addition, such women often deny uterine instrumentation.⁴ Both of these factors can combine to make evaluation and treatment of complications of illegal abortion particularly challenging.

Ledger's recommendations regarding the evaluation and management of patients with suspected septic abortion remain useful.¹⁸ High-spiking fevers are characteristic of women with septic abortions. Hypotension and leukopenia strongly support the diagnosis of sepsis. Blood cultures and frequent monitoring of the urinary output are appropriate. During vaginal speculum examination, a Gram stain of any cervical leukorrhea present should be obtained, because it may suggest a gonococcal or clostridial infection. Swabs for *Chlamydia* and *Neisseria gonorrhoeae*, as well as conventional aerobic culture, should also be performed. A bimanual pelvic examination not only assesses uterine size, but also determines whether there is evidence of extrauterine infection. Both advanced gestation (greater than 12 weeks) and extrauterine extension are associated with the most serious infections and may therefore require therapy more extensive than intravenous antibiotics and uterine curettage.

In patients at risk for serious infection, supine and upright radiography should be obtained, searching for intraperitoneal or myometrial gas. The presence of such gas mandates intraabdominal surgical evaluation so the possibility of bowel and uterine damage can be assessed. Rarely, radiographs of women with sepsis after illegal abortion demonstrate layered myometrial gas in an "onion skin" pattern. This finding indicates myometrial necrosis caused by clostridial infection and mandates laparotomy with hysterectomy.

Women with infections after illegal abortion but without the previously described signs or symptoms should be managed with antibiotic therapy and uterine curettage (see section on [infections after legal abortion](#)).

Continuing Pregnancy

Continuation of pregnancy after abortion is the result either of failure to abort an intrauterine pregnancy or of ectopic pregnancy.¹⁶ Performing the abortion at or before 6 weeks' gestational age or the presence of a uterine anomaly increases the risk of failure. The absence of chorionic villi in the abortion specimen, continuing symptoms of pregnancy, progressive lower abdominal pain, and a plateau or increase in serial quantitative serum hCG levels suggest a continuing pregnancy. It is important to remember, however, that sensitive urine pregnancy tests may remain positive for weeks after termination of a first-trimester pregnancy (see [Chapter 70](#), "Pregnancy Testing").

Physical examination may suggest an ongoing intrauterine pregnancy. This diagnosis should be confirmed with pelvic ultrasonography, using a vaginal probe if possible. If ultrasonography fails to reveal an intrauterine pregnancy, an ectopic pregnancy should be assumed (see [Chapter 74](#), "Ectopic Pregnancy").

Medical Termination of Pregnancy

Medical methods of abortion were originally developed for nonsurgical management of ectopic pregnancy and are gaining wide acceptance as primary methods of abortion, especially before 8 weeks' gestation.⁹ The currently available methods include methotrexate, which is used with or without misoprostol, an oral prostaglandin. RU-486, or mifepristone, is not approved for use in the United States. Side effects are minimal and include mild nausea and stomatitis. There is an increased risk of incomplete evacuation of the uterus with medical abortion, and the time to resolution of the pregnancy is prolonged compared with dilation and evacuation. In a series of 300 patients, approximately 9% of women undergoing medical termination of pregnancy subsequently required dilation and evacuation.⁵

Emergency physicians are frequently called upon to evaluate patients with vaginal bleeding. This entity ranks among the top ten reasons for a visit to the emergency department (ED).²⁷ After menarche, vaginal bleeding is most often an integral part of the normal reproductive cycle. However, it may also signal the presence of serious illness, particularly if the patient is pregnant. Assessment of patients with vaginal bleeding is complex because of the broad range of diagnostic possibilities, from completely benign (e.g., normal menses) to life-threatening (e.g., ectopic pregnancy).

With the increased availability of certain bedside diagnostic techniques, including ultrasensitive, rapid tests for beta human chorionic gonadotropin (bhCG) and ultrasound (US), the role of the emergency physician in diagnosing and treating the various causes of pathologic vaginal bleeding has become more prominent in recent years. There has also been an increasing trend toward outpatient management of clinically stable patients with threatened or completed abortion, and even unruptured ectopic pregnancy. For these patients, the bulk of their medical care occurs in the ED. As a result, the level of medical sophistication required to manage these cases in the ED has increased as well.

DIFFERENTIAL DIAGNOSIS

Vaginal bleeding in the pregnant patient evokes a unique differential diagnosis compared with the nonpregnant state. In addition, the stage of pregnancy is important to determine, as the differential diagnosis of vaginal bleeding changes significantly over the course of the gestation. This chapter focuses on vaginal bleeding in the early stage of pregnancy (i.e., less than 20 weeks' gestation). Ectopic pregnancy is dealt with in [Chapter 74](#). The causes of vaginal bleeding in early pregnancy are shown in [Table 73.1](#).

TABLE 73.1. Differential Diagnosis of Vaginal Bleeding in Early Pregnancy

There is a complex interaction between fetal and maternal hormones that is required for successful fertilization, migration, and implantation of the embryo, and development of the embryo and fetus to a viable stage. Disruption of the normal hormonal environment, maternal illness, abnormal physical characteristics of the fallopian tubes or uterus, and fetal chromosomal abnormalities can all result in fetal loss.

CLINICAL PRESENTATION

Patients frequently present to the ED with a complaint of abnormal vaginal bleeding that may be accompanied by lower abdominal or lower back pain. One of the essential early components of the initial evaluation, and a major branch point in the diagnostic process, is to determine whether the patient is pregnant. Often, the patient is unaware of the pregnancy, particularly if her usual menstrual cycles are irregular.

Pregnancy is frequently complicated by vaginal bleeding. Approximately 20% to 25% of all pregnancies manifest vaginal bleeding at some point, yet more than half of these pregnancies continue to term.^{11,18} First-trimester bleeding accounts for over 80% of bleeding during pregnancy.

The exact clinical presentation depends on the underlying cause. However, patients present with variable amounts of vaginal bleeding, ranging from slight "spotting" to massive hemorrhage. The severity of bleeding is not helpful in diagnosing a specific condition, although it has important implications for the hemodynamic stability of the patient. The location and nature of the patient's pain occasionally suggest one diagnosis over another. Pain from ectopic pregnancy progressively increases until the point of rupture. The resulting hemoperitoneum may cause left shoulder pain (Kehr's sign) due to irritation of the diaphragm by free intraperitoneal blood. On pelvic examination, adnexal tenderness and an adnexal mass can often be palpated. Patients with threatened abortion have crampy pelvic pain, with radiation to the lower back as the uterus contracts and the cervix dilates. The uterus may be slightly tender and irritable, but the adnexa are nontender. Completed abortion usually results in progressive diminution of pain and bleeding as the cervix closes and the uterus contracts. Incomplete abortion is associated with more severe pain and bleeding because retained products of conception (POCs) prevent uterine contraction and hemostasis. Septic abortion is associated with fever, pelvic pain, and uterine tenderness. Depending on the stage of infection, the patient may manifest all of the typical findings of gram-negative septic shock.

The normal physiologic adjustments of pregnancy include expansion of plasma volume, dilutional anemia, increased cardiac output, resting tachycardia, mild hypotension, and respiratory alkalosis. These physiologic changes alter the clinical presentation of a pregnant patient with significant hemorrhage. Because of the

expanded plasma volume, up to 40% of blood volume can be lost before the typical signs of shock occur. Conversely, uterine blood flow is at increased risk when maternal hemorrhage occurs as blood is shunted preferentially from the placental to the maternal circulation.¹⁶ Serious fetal distress can occur while the mother remains relatively asymptomatic.

Psychological Effects of Spontaneous Abortion

Most patients with spontaneous abortion experience a normal sense of grief for the loss of an anticipated child. However, a significant number of patients who experience spontaneous abortion are at risk for developing a major depressive episode within the following 6 months. Spontaneous abortion often evokes guilt regarding minor trauma or other actions that most likely bear no relation to the miscarriage. In addition, the abrupt change in the patient's hormonal milieu resembles the postpartum state, during which depression is relatively common. Risk factors for developing major depression include nulliparity and a history of infertility. Maternal age, trimester in which the miscarriage occurs, and socioeconomic status are not predictive of depression following spontaneous abortion.²⁰

Implantation Bleeding

It is traditionally taught that after the fertilized ovum completes its migration through the fallopian tube toward the uterus, the process of embedding the morula in the uterine lining produces a small amount of vaginal bleeding. This is expected to occur within the first 4 weeks of pregnancy and may be misconstrued as an abnormally light and late menstrual period. Although there is little clinical or experimental evidence that implantation bleeding actually occurs, it would account for the relatively common occurrence of vaginal bleeding in very early pregnancy, at a time before other causes typically present.

Ectopic Pregnancy

Ectopic pregnancy must be considered in all cases of vaginal bleeding in early pregnancy, as it is by far the most lethal condition to be considered. The incidence of ectopic pregnancy has increased significantly over the past 20 years and is particularly high in patients who have undergone treatment for infertility and in patients with a history of a previous ectopic pregnancy, tubal infections or surgery, and intrauterine device (IUD) use.¹

The clinical presentation of ectopic pregnancy ranges from dramatic to subtle, depending on whether the ectopic has ruptured, as well as its location and size. Patients with a ruptured ectopic pregnancy may present in hemorrhagic shock, with massive hemoperitoneum and variable amounts of vaginal bleeding. At the other extreme, the ectopic pregnancy may be relatively asymptomatic and be discovered during elective US examination. It may be particularly difficult to distinguish between an ectopic pregnancy and a complete abortion, because, in both cases, the uterus is empty on US examination and the bhCG levels may be lower than expected by dates. The reader is also referred to [Chapter 74](#), "Ectopic Pregnancy."

Spontaneous Abortion

Abortion is defined as the death and subsequent passage of a fetus weighing less than 500 g or a fetus of less than 20 weeks' gestational age. The true incidence of spontaneous abortion is unknown, as many occur prior to a missed menstrual period and before the diagnosis of pregnancy can be made clinically. Estimates of the overall rate of spontaneous abortion range from 31% to 78%.¹⁷ Of those pregnancies that become clinically apparent, approximately 20% will threaten to abort and 10% will spontaneously abort. There is a biphasic distribution of spontaneous abortion. During the first 10 weeks, fetal demise, with subsequent miscarriage, is most commonly due to fetal chromosomal abnormalities. Analysis of aborted material reveals that almost 70% have trisomies at various locations, representing new mutations. A second peak occurs from weeks 14 to 18, during which maternal illness, uterine abnormalities, placental factors, and incompetence of the cervix are primarily responsible. Spontaneous abortion in the second half of pregnancy is almost exclusively attributable to incompetence of the cervix and premature labor.¹⁷ Several additional risk factors have been identified, including a history of pelvic inflammatory disease (PID), infertility, previous spontaneous abortion, and lower level of education.²³

The pathophysiology of spontaneous abortion is incompletely understood. Immunologic factors account for 30% of cases. Antiphospholipid antibodies have been implicated as a cause of recurrent abortion that may be amenable to treatment with low-dose salicylate and corticosteroids.⁷ If both parents share many human leukocyte antigens, the trophoblast may not induce the production of blocking maternal antibodies that prevent immunologic rejection of the fetus. Thus, consanguinity also results in a higher rate of spontaneous abortion. Uterine abnormalities that may preclude normal gestation include large leiomyomas, or septate uterus. Cervical incompetence occurs when the cervix progressively thins and dilates due to gravitational forces, previous trauma, or premature labor. It is a more important factor in the mid- and third trimesters and may result in recurrent abortion. Chronic maternal illnesses, such as renal failure, diabetes (diabetic ketoacidosis), drug abuse, and malnutrition, are associated with increased fetal loss. All of these conditions tend to produce recurrent spontaneous abortion. Fetal chromosomal abnormalities are common and are not usually recurrent, so that subsequent pregnancies may be normal. Episodic maternal illnesses, such as abdominal trauma, use of certain drugs and medications, and infections are commonly associated with fetal loss. Of particular importance among infections are pyelonephritis, listeriosis, toxoplasmosis, rubella, cytomegalovirus, and herpes simplex I and II (TORCH syndrome).⁶

The underlying cause of the spontaneous abortion usually cannot be determined in the ED, and parents should be reassured that their actions did not cause the miscarriage. They should be referred for genetic counseling to determine the prospects for future normal pregnancies. Patients with recurrent abortion should be referred to an infertility specialist if they wish to conceive successfully.

Spontaneous abortion can be categorized into four distinct entities:

1. Threatened abortion
2. Complete abortion
3. Incomplete abortion
4. Missed abortion

In addition, patients may present to the ED with complications following therapeutic abortion, self-induced abortion, and criminal abortion. Septic abortion may complicate any of these entities but is more common with incomplete abortion or criminal abortion.

Threatened Abortion

Threatened abortion is marked by the onset of vaginal bleeding or lower abdominal pain, without cervical dilation, during the first half of pregnancy. Patients present with vaginal bleeding that ranges from spotting to profuse, and they may have gradual onset of lower abdominal contractions and pain. Approximately 20% of pregnancies present with some degree of vaginal bleeding during pregnancy. Of these, half will spontaneously abort and half will continue past 20 weeks' gestation. The threatened abortion may be considered inevitable when the cervix is dilated and membranes are ruptured or visible in the cervical os.

There have been numerous attempts to identify a simple test that can distinguish between those threatened abortions that have a chance of continuing and those that are destined to abort. The advantages of such a test are that a patient can be counseled immediately regarding the likely outcome of the pregnancy, unnecessary prolonged bedrest can be avoided, and arrangement for elective D and C can be made.

Norms for several serum markers of pregnancy have been established, including hCG, human placental lactogen (hPL),²⁴ progesterone,^{8,9} CA-125,^{21,22} and early pregnancy factor (EPF).²⁶ Levels of these markers vary significantly when the fetus or placenta fails to develop normally. CA-125 is released by exposed decidua and is undetectable in normal pregnancies but elevated when there is decidual damage. One study found that all patients with vaginal bleeding for more than 3 days and elevated levels of CA-125 proceeded to spontaneous abortion.²¹ Conversely, EPF has been found to be reduced in abnormal pregnancies and may be useful in predicting viability of the pregnancy. Unfortunately, there is sufficient overlap between the results seen in normal pregnancies and those seen in abnormal pregnancies that these tests cannot be relied on completely. The most promising marker is serum progesterone. A serum progesterone level less than 14.2 ng/mL in asymptomatic and 10.5 ng/mL in symptomatic patients suggests failure of the pregnancy,⁸ whereas another study found that levels greater than 11 ng/mL indicate a good prognosis for viability when no definite intrauterine pregnancy was seen on US.³⁰ However, serum progesterone levels are not routinely available in the ED, and the clinical utility of these tests remains to be established.

Probably the most useful prognostic factor is the presence or absence of a detectable fetal heartbeat on US in a grossly normal-appearing fetus after 9 weeks'

gestation. If the heartbeat is absent, all of the pregnancies will eventually abort. If a heartbeat is present, approximately 95% of the pregnancies will continue until at least 20 weeks.¹⁸

Another finding on US that may be highly accurate in later pregnancy complicated by threatened abortion is the measurement of cervical length. In one study, ¹⁹ cervical length less than 20 mm predicted spontaneous abortion with 100% accuracy.

Pregnancies that survive an episode of threatened abortion are at higher risk for congenital malformations, low birth weight, prematurity, low APGAR scores, and postpartum hemorrhage in the mother.³³

Complete Abortion

Complete abortion occurs when all fetal and placental components are expelled from the uterus. Typically, this occurs after a period of threatened abortion, although it may be mistaken as a menstrual period if it occurs during the first month of pregnancy. Occasionally, a patient brings the aborted material to the ED. This material should be examined by a pathologist to determine whether fetal tissue and chorionic villi are present or whether abnormalities such as partial molar pregnancy exist.

The distinction between complete abortion and ectopic pregnancy is often difficult. In both cases, serum hCG will be elevated to a level somewhat lower than expected for dates and the uterus may be firm and smaller than expected for dates. Depending on the size of the abortus and the amount of time since the abortion was completed, the cervical os will be open to varying degrees in a complete abortion, in contrast to an ectopic pregnancy. Clinically completed abortion patients often experience a diminution of abdominal pain and vaginal bleeding once the POCs have been expelled. In contrast, patients with ectopic pregnancy most often experience progressive symptoms, including worsening pain and evidence of continued blood loss and hemoperitoneum. However, the clinical distinction may require a period of observation to establish whether the symptoms are increasing or abating. Obviously, presence of expelled POCs is important in making this distinction, and all POCs should be examined by a pathologist. Occasionally, a decidual cast is passed during an ectopic pregnancy, and this may be mistaken for POCs. The presence of fetal tissue or chorionic villi should be confirmed by pathologic examination to avoid this error. In ectopic pregnancy, ultrasonic examination may reveal a complex adnexal mass, but often ectopic pregnancy must be inferred by the absence of an intrauterine pregnancy. In both cases, a small amount of blood may be seen but no POCs are visualized within the uterine cavity. It is important to identify the uterine endometrial stripe on US that is present in complete abortion but absent in ectopic pregnancy.

Rarely, in heterotopic pregnancy, an ectopic pregnancy can coexist with a complete abortion. Consequently, pelvic US is essential in all cases of clinically diagnosed complete abortion to examine the adnexa and to determine whether any residual material remains in the uterus.

Incomplete Abortion

Incomplete abortion occurs when some, but not all, of the POCs are expelled vaginally. This occurs more commonly after the tenth week of gestation, whereas complete abortion is more common prior to the tenth week. Because the placental surface is larger and the uterus is unable to completely contract, this condition often is associated with more active bleeding and pain than is completed abortion. Examination of passed tissue is indicated to verify that it is actually of placental or fetal origin rather than just clotted blood or a decidual cast. In most cases, fetal demise has occurred up to 2 weeks previously, and US examination reveals no identifiable fetal structures, but rather, an amorphous collection of tissue and blood.

Missed Abortion

Missed abortion occurs when there is fetal demise but uterine contractions do not occur and the fetus is retained for 4 weeks or more. There may be scant vaginal bleeding at the onset, but this resolves and the patient is often asymptomatic. Most missed abortions terminate spontaneously within 2 weeks of diagnosis. The uterus stops enlarging and may decrease in size. Secondary symptoms of pregnancy, such as breast enlargement, regress and bhCG levels fall progressively. No fetal heartbeat is seen on US, and variable degrees of abnormality are seen, depending on the duration of fetal demise and subsequent degeneration. Often, the placenta is visualized but there is no fetal tissue within the gestational sac.

Prolonged retention of a missed abortion can result in disseminated intravascular coagulation (DIC). This complication is seen more often when the fetal demise occurs during the second trimester, but it can occur at any time during pregnancy and mandates a more aggressive approach in management.

Septic Abortion

Serious infection can occur whenever the cervix opens and the uterus is exposed to vaginal flora. All forms of spontaneous and therapeutic abortions may be complicated by infection, but the risk is greatest when tissue remains in the uterus (missed abortion or incomplete abortion) or when the uterus has undergone instrumentation (amniocentesis, D and C, criminal abortion). The most common infecting agents are *Escherichia coli*, *Streptococcus fecalis*, and, occasionally, *Clostridia perfringens*.² Patients present with a septic appearance, including fever, chills, abdominal pain, and weakness. Although the white blood cell count is often elevated in normal pregnancy, elevation beyond 16,000/mL is abnormal and reinforces the diagnosis of septic abortion. On pelvic examination, there is often a purulent vaginal discharge, cervical motion tenderness, and an exquisitely tender uterus. Extension of the infection to produce peritonitis can occur.

Therapeutic Abortion

In recent years, therapeutic abortion is produced pharmacologically rather than surgically. For pregnancies between 4 and 8 weeks, administration of various combinations of misoprostol and mifepristone result in abortion in 92% to 97% of early pregnancies (less than 50 days). Many of these therapeutic abortions are managed on an outpatient basis because of the inherent delay in producing a pharmacologic abortion. Some of these patients subsequently present to the ED with a completed abortion or with complications of abortion. Complications include incomplete abortion (1.8%) and prolonged bleeding (0.4%).²⁸ Management is identical to that of complete or incomplete abortion, depending on the success of the procedure. The reader is also referred to [Chapter 72](#).

Molar Pregnancy

Hydatidiform mole, invasive mole, and choriocarcinoma are three forms of trophoblastic disease that may present with vaginal bleeding. The incidence of molar pregnancy is one in 1,800 to one in 5,000 pregnancies and is higher in elderly primiparas and Asians. Both malignant and benign forms of trophoblastic disease are characterized by high levels of bhCG, which is a reliable serum marker for following the progression of the disease.

Patients with a molar pregnancy present with a variety of symptoms, but almost all experience vaginal bleeding at some point during the pregnancy. Other clinical findings suggestive of complete molar pregnancy include uterine size that is large for gestational age (50%), more frequent occurrence of hyperemesis gravidarum (26%) due to excessive bhCG production, occurrence of preeclampsia or eclampsia in the first or second trimesters (12% to 27%), and, rarely, vaginal passage of grapelike clusters of hydropic vesicles.²⁵ In addition, patients with molar pregnancy may present with pulmonary insufficiency, hyperthyroidism, ascites, and multiple, large theca lutein cysts.

The incidence of these findings is much lower in cases of partial molar pregnancy, and many of these cases go undetected. Diagnosis of this condition is essential because of its malignant potential and relative curability by chemotherapy. Approximately 5% of partial molar pregnancies undergo malignant transformation. There are rare case reports of a molar pregnancy coexisting with a twin fetus that can develop normally to term. Management of these cases is clearly difficult and should be in the hands of high-risk obstetrics specialists.

Diagnosis of molar pregnancy is made by an US that shows a characteristic "snowstorm" or "soap bubble" pattern of uterine contents, by the presence of very high (greater than 100,000-U) serum levels of bhCG, or by pathologic examination of curetted material.

Metastases from systemic embolization of trophoblastic material occur in 15% to 20% of cases. Consequently, the level of serum hCG is monitored until it normalizes. If the hCG level fails to normalize within 6 weeks, chemotherapy is initiated, with good cure rates.

Bleeding from Vaginal Lesions

Occasionally, vaginal bleeding may occur during pregnancy from nonobstetric causes such as vaginal or cervical erosions, trauma, infection, adenomas, and carcinomas. Bleeding from these causes is usually of the spotting type, and careful examination of the vaginal walls and cervix usually reveals the cause. Carcinoma of the cervix can certainly occur during childbearing years, and PAP smear or formal biopsy is indicated for suspicious lesions. Endocervical polyps can grow under the hormonal stimulation of pregnancy. They may bleed spontaneously or as a result of relatively minor trauma. Vaginal candidiasis may be associated with a small amount of bleeding as the vaginal mucosa becomes friable. A standard wet mount helps distinguish between the normal increase in vaginal secretions during pregnancy and candidiasis.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Unstable Patients with Vaginal Bleeding

All patients presenting with vaginal bleeding require at least urgent medical evaluation, and occasional patients require immediate resuscitation. As in all emergency presentations, patients with massive blood loss from any source require stabilization and resuscitation prior to eliciting historic details or performing laboratory investigations. Patients with evidence of massive blood loss, as reflected by significant hypotension, tachycardia, diminished alertness, syncope, or pallor, or obvious massive vaginal blood loss require the immediate infusion of crystalloid (up to 2 L) and should have two large-bore intravenous lines placed for this purpose. Blood should be obtained for immediate determination of hemoglobin level and coagulation profile, and to type and crossmatch for possible transfusion. If crystalloid infusion is insufficient in restoring normal vital signs and mental status, infusion of type O-negative blood is indicated pending the availability of crossmatched blood. Coagulation defects are corrected by infusion of whole blood or fresh-frozen plasma and platelets as required. Frequent reassessment of vital signs, monitoring of cardiac rhythm and pulse oximetry, supplemental oxygen, and placement of a Foley catheter are indicated to gauge the patient's response to resuscitation.

As resuscitation continues, evaluation of the source of blood loss can be made. Pelvic examination often reveals a large amount of clotted blood, which should be removed with ring forceps. Occasionally, POCs are evident, protruding from the cervical os, and, if possible, these should be removed with ring forceps as well to allow the uterus to contract. Vaginal or cervical lacerations can be sutured. If blood loss continues to be brisk, the vaginal vault can be tightly packed with gauze as a temporizing measure to tamponade bleeding. Infusion of oxytocin will cause uterine contraction and may reduce blood loss but will also trap any POCs that remain in the uterus. Urgent consultation with an obstetrician is indicated to provide definitive care and admission. Performing a D and C can control most vaginal hemorrhage. Rarely, the only means of controlling hemorrhage entails invasive procedures such as emergency hysterectomy or embolization or ligation of the internal iliac arteries.^{29,32}

Stable Patients with Vaginal Bleeding

The vast majority of patients presenting with vaginal bleeding have no, or only minor, evidence of the hemodynamic effects of blood loss. Bleeding is often associated with crampy lower abdominal or lower back pain due to uterine contractions. A systematic approach combining history, physical findings, and appropriate laboratory and imaging techniques will reveal an accurate diagnosis in a high percentage of these cases.

It is essential to determine whether the patient is pregnant, and this is readily and rapidly accomplished by measuring serum or urine bhCG. Bedside qualitative testing for hCG is indicated in all reproductive-age females presenting with vaginal bleeding, abdominal or back pain, syncope, or menstrual irregularity. The only appropriate reasons for omitting qualitative hCG testing are the presence of an obvious pregnancy, a previously positive pregnancy test, and a previous hysterectomy.¹⁸ All forms of birth control, including tubal ligation, have a measurable failure rate, especially if patient compliance is less than optimal. Consequently, hCG testing should be conducted regardless of a history of birth control. hCG testing is highly accurate (serum 100%, urine hCG 99%) in diagnosing pregnancy by the time of the first missed menstrual period (hCG 50 to 250 IU/L). Currently used tests for hCG are sensitive to a level of 25 IU/L. The use of quantitative hCG is essential in interpreting US results in early pregnancy and should be obtained routinely if the qualitative test is positive.

History

Once the presence of pregnancy is established, essential historic information includes the time of the last normal menstrual period, previous pregnancies and parity, complications of previous pregnancies, amount and duration of bleeding, whether any fetal tissue has been passed, and symptoms referable to blood or volume loss, such as syncope, weakness, fatigue, dizziness, difficulty breathing, or chest pain.

It is also important to elicit information regarding medications, allergies, and medical and surgical histories, particularly treatment for infertility that predisposes to heterotopic pregnancy.

Physical Examination

After a general physical examination, abdominal and pelvic examinations are indicated in all cases of vaginal bleeding occurring during the first 20 weeks of pregnancy. A pelvic examination should be deferred during the second half of pregnancy because of the risk of precipitating massive bleeding from a placenta previa.

An abdominal examination may reveal evidence of peritoneal irritation, including diminished bowel sounds, involuntary guarding, and rebound tenderness due to hemoperitoneum. After the twelfth week, the uterus may be palpable. Fetal heart tones are audible with a fetoscope by the twelfth week and should be recorded as a routine component of the vital signs.

A pelvic examination reveals variable amounts of blood in the vaginal vault. The character of the blood should be noted, because bright red blood indicates continuing hemorrhage, whereas a brownish discharge suggests that bleeding has stopped spontaneously. The presence of blood clots indicates more significant bleeding than does an unclotted bloody discharge. After evacuating the blood by swabbing or suction, the vault is inspected for bleeding lesions. The cervix is examined for lesions, tenderness on movement (Chandelier's sign), softening and bluish discoloration (Chadwick's sign); for patency of the external and internal ostia to ring forceps; and for active bleeding. POCs that are visible in the os are removed, if possible, with ring forceps. Bimanual examination of the uterus gives an estimate of gestational age and reveals tenderness or masses. Adnexal masses such as corpus luteum cysts are common in pregnancy, but a tender adnexal mass suggests ectopic pregnancy. Exquisite uterine tenderness to palpation suggests endometritis and possible septic abortion.

Pelvic Ultrasound

One of the most important changes in the management of vaginal bleeding in early pregnancy is the use of portable bedside US performed by emergency physicians. Numerous studies validate the accuracy and efficiency of the use of US in this setting.^{4,10} Transabdominal US can detect intrauterine pregnancy by the fifth to sixth week, and transvaginal US can detect it by weeks 4.5 to 5.0. It is essential to determine whether the uterus contains a normal fetus. The typical findings in early pregnancy include visualization of an endometrial stripe, the yolk sac by the fifth week, and the fetal pole and fetal heartbeat by weeks 5.5 to 7.0.³

TREATMENT OF SPECIFIC CONDITIONS

Fetomaternal Hemorrhage during Spontaneous Abortion

Theoretically, fetomaternal hemorrhage (FMH) can occur by the end of the fourth week of pregnancy. Studies to determine the incidence of FMH during spontaneous abortion reveal conflicting results. One study found an incidence of 0%,¹⁵ and another found an 11% incidence of positive Kleihauer-Betke tests in patients with threatened abortion.³¹

Most authors now recommend that RhoGAM be administered to Rh-negative mothers who present with threatened or other forms of abortion. During the first trimester, "mini RhoGAM" is given at a dose of 50 µg i.m.; later in pregnancy, a regular dose of 300 µg is used.

Threatened Abortion

Management in this case includes admission to the hospital for spontaneous abortion to occur or for D and C. Treatment for threatened abortion is largely supportive. The standard recommendations to avoid sexual intercourse and vaginal douching and to remain at bedrest for 48 hours are unproved in terms of efficacy in preventing spontaneous abortions but are somewhat intuitive. Administration of exogenous hCG has been shown experimentally to be more effective than bedrest in preventing threatened abortion and may prove useful clinically in the future.¹³ Treatment with exogenous progesterone has been found ineffective.

Complete Abortion

Management of complete abortion is controversial. In the past, virtually all of these patients underwent D and C to remove all potentially retained tissue and blood. Recently, many of these patients have been successfully managed expectantly with analgesia and other supportive measures. Although D and C results in fewer days of bleeding, it requires admission and a surgical procedure with some attendant risks, particularly uterine perforation, as well as greater cost. This decision can be guided by US. Patients with fluid only in the uterine cavity can be managed expectantly; those with fluid and solid POCs should undergo D and C.⁵

Incomplete Abortion

Bleeding and pain generally are more severe with incomplete abortion than with other forms of abortion. Consequently, parenteral analgesia is often indicated, and the extent of bleeding and need for transfusion should be determined. Pelvic examination often reveals retained POCs in the cervical os, and these should be removed by ring forceps, if possible. This often allows the uterus to contract more completely, producing hemostasis. Visualization of retained placenta by US generally mandates removal by D and C or suction curettage, as these patients are at risk for profuse, prolonged bleeding and infection. Some patients with incomplete abortion can be managed conservatively. One study found that if no POCs were seen on US, neither D and C nor expectant management resulted in any complications. However, if POCs were visualized on US, conservative management resulted in a much higher complication rate (40% vs. 2.5%) compared with D and C.¹⁴

Septic Abortion

Treatment depends on the degree of sepsis but should always include culture and sensitivity of the discharge, parenteral antibiotics, and admission for evacuation of the uterine contents after the patient has been resuscitated and therapeutic serum levels of antibiotics are obtained. Occasionally, patients with septic abortion may require vigorous resuscitation with fluid infusion, central venous pressure monitoring, pressors, and high-dose antibiotics for septic shock and rapidly progressive infection. Emergency hysterectomy may be required, so emergent obstetric consultation is indicated. Antibiotic treatment should include broad-spectrum anaerobic and gram-negative coverage.

DISPOSITION

Pregnant patients who present with significant anemia or massive vaginal bleeding requiring infusion of more than 1 L of crystalloid or blood to restore normal vital signs, and those with ongoing significant blood loss or vaginal packing, require immediate consultation with an obstetrician and admission to the hospital. Patients with vaginal bleeding beyond the twentieth week are often admitted directly to the obstetric service for monitoring and investigation.

Patients with suspected ruptured ectopic pregnancy require admission and operative treatment. However, hemodynamically stable patients with an unruptured ectopic pregnancy may be managed as outpatients in consultation with the obstetrician, with administration of cytotoxic agents and the provision of early obstetric follow-up.

Patients in whom no clear diagnosis can be made may require admission to the hospital for further investigation, such as laparoscopy or hysteroscopy, to determine the cause of bleeding.

Abortion

Spontaneous complete abortion patients with minimal bleeding and pain can be discharged home after a brief period of observation and instructions to return to the ED if bleeding or pain increases or if fever occurs. They can be followed by an obstetrician within 24 hours in an outpatient setting. Psychological counseling should be offered for patients demonstrating a severe grief reaction to the fetal loss. Patients with recurrent abortion should be referred for genetic counseling as well.

The vast majority of patients with threatened abortion are currently managed as outpatients. Although the efficacy is unproved, standard discharge instructions recommend 24 to 48 hours of bedrest and avoidance of sexual intercourse or vaginal douching. Patients are instructed to return to the ED if bleeding or pain worsens, or if fever occurs, and to bring any passed fetal or placental tissue with them if abortion occurs. Follow-up within 24 to 48 hours is arranged with an obstetric specialist.

Patients with inevitable abortion are admitted to the labor and delivery service, under the care of an obstetrician, for completion of the abortion. All patients with septic abortion are admitted to the hospital for administration of parenteral antibiotics and, ultimately, removal of the fetus and placenta. Patients in septic shock are managed in an intensive care setting and may require large volumes of fluids, invasive monitoring, and pressor agents to reverse shock.

Disposition of patients with incomplete abortion is more controversial. Traditionally, these patients were admitted for D and C. Recently, studies have shown that expectant management may be as safe and effective as D and C in managing these cases. This decision should be made in consultation with the obstetric specialist who will follow the patient. Adequate pain management must be ensured if the patient is to be managed as an outpatient.

COMMON PITFALLS

- The emergency physician should be aware that a significant number of patients who experience spontaneous abortion are at risk for developing a major depressive episode within the following 6 months.
- One of the most common pitfalls is the failure to suspect pregnancy as the etiology of abdominal pain or vaginal bleeding in reproductive-age females. Often, patients provide inaccurate information regarding sexual activity, compliance with birth control, and the timing of the last menstrual period. It is essential to determine whether the patient is pregnant, and the best means of accomplishing this is by routinely measuring bhCG in all reproductive-age females with abdominal pain or vaginal bleeding.
- In mothers with uncertain dates, a US done at 5 weeks' gestation may visualize a yolk sac that is mistaken for an empty gestational sac. Subsequent therapeutic evacuation of the uterus may terminate a viable pregnancy.
- Failure to administer appropriate doses of RhoGAM to block maternal isosensitization may result in erythroblastosis fetalis in subsequent pregnancies after FMH during spontaneous abortion. Although studies show conflicting results on the incidence of FMH, it is prudent to administer RhoGAM to Rh-negative mothers with vaginal bleeding beyond the fourth week of pregnancy.
- Ectopic pregnancy: Passage of a decidual cast that is present with ectopic pregnancy may mimic passage of fetal and placental tissue. Similarly, patients who have undergone D and C may still harbor an ectopic pregnancy if only the uterine decidual cast is removed at D and C. Consequently, it is essential to verify the pathologic examination of tissue obtained through spontaneous abortion or D and C. The absence of chorionic villi and fetal tissue on pathologic examination should prompt further investigation for possible ectopic pregnancy.
- A pseudogestational sac may be seen in 10% to 20% of ectopic pregnancies. This may be misinterpreted as the "double-ring sign" of an intrauterine pregnancy, causing the diagnosis of ectopic pregnancy to be inappropriately dismissed.
- Diagnosis of heterotopic pregnancy is difficult. The presence of a viable intrauterine fetus on US may cause the clinician to incorrectly exclude the possibility of concurrent ectopic pregnancy. This is particularly true in patients undergoing ovarian stimulation treatment for infertility, because, in this group, the incidence of heterotopic pregnancy may be as high as one in 100.
- *Molar pregnancy*: Failure to submit aborted material for pathologic examination may result in failure to diagnose a partial molar pregnancy. Consequently, the opportunity to intervene with chemotherapy may be lost or long-delayed.

One of the leading causes of maternal morbidity and mortality in the United States is ectopic pregnancy. It is also a major factor in decreasing the future fertility of the affected woman and is aptly called an unqualified disaster in human reproduction.⁹ Fetal wastage is virtually 100%. Unfortunately, the frequency of ectopic pregnancies in the United States has increased by fivefold since 1970.³ Pooled data indicate that the current incidence of ectopic pregnancy is 16.8 per 1000 pregnancies (1.7% of all pregnancies in women in the United States will be ectopic).³³ Furthermore, it is estimated that of 100 women with a history of ectopic pregnancy, approximately 50% will be infertile, 35% to 40% will subsequently have a successful pregnancy, and 10% to 15% will experience a second ectopic pregnancy.²⁰

Ectopic pregnancy is the result of implantation of a fertilized ovum at a site other than the endometrium of the uterine cavity. The most frequent site of implantation is the lateral two-thirds of the fallopian tube (80%) (Fig. 74.1). About 15% implant in the medial one-third. Interstitial or cornual implantation occurs in approximately 3% of ectopic gestations. Interstitial and abdominal implantations carry the greatest risk of mortality because of their hemorrhagic tendencies.¹⁹ Extratubal ectopic gestations occur in about 5% of cases: in the ovary (3%), within the abdominal cavity (2%), or in the cervix (rare). Combined intrauterine and extrauterine gestations (heterotopic pregnancy) were formerly very rare, with an estimated incidence of one in 30,000 pregnancies.³⁴ Combined pregnancies are now estimated to occur in up to one in 3000 normal patients and 1 in 100 patients being treated with assisted reproductive technologies.¹²

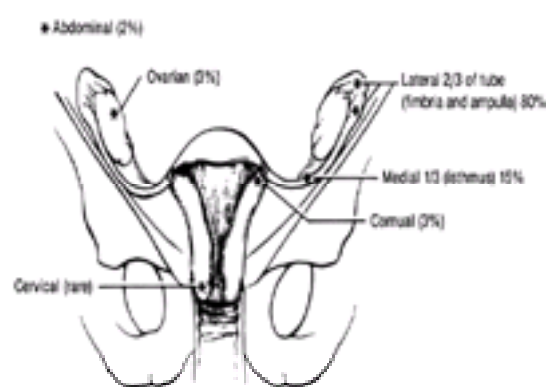

Figure 74.1. Sites of implantation in ectopic pregnancy.

The most common predisposing factors include intrinsic or extrinsic abnormalities of the fallopian tube and abnormal development of the embryo itself. Abnormalities of the fallopian tube have been extensively studied and are believed to be the most important cause of ectopic pregnancies. The most common source of tubal pathology is pelvic inflammatory disease (PID).³¹ The risk of ectopic pregnancy is known to be several times more likely among women with a history of salpingitis.³² All pathogens, including *Chlamydia* and gonococci, are believed to cause tubal distortion and scarring, which adversely affect tubal patency and motility. Subacute infection with less virulent organisms may actually increase the amount of residual tubal pathology because diagnosis and treatment may be delayed.¹³ Up to 64% of fetuses associated with ectopic pregnancy are abnormal.²² However, it is not known whether these abnormalities cause altered transit through the fallopian tube or whether they result from the poor growth environment of the ectopic implantation site.²⁷

There are multiple risk factors for developing an ectopic pregnancy. Table 74.1 lists several important population characteristics. The numerical risk assigned to each population characteristic applies to a pregnant woman with that particular characteristic. Table 74.1 is most useful in assessing the relative risk a woman has of harboring an ectopic gestation if she is known to be pregnant. However, up to 42% of women with ectopic pregnancy have no historic risks factors.³³

Population Characteristic	Ectopic Pregnancies As a Percentage of Total Pregnancies in Each Population Group
Overall	0.94
Age	
15-19 yr	0.45
20-29 yr	0.82
30-39 yr	1.42
Contraception	
Oral contraceptives	0
Barriers	0.002
IUD	14.0
One or more episodes of salpingitis (by laparoscopy)	6.9
Prior tubal sterilization	16.0
Prior ectopic pregnancy	11.2

Adapted from Westrom L, Bengtsson L, Harth PK. Incidence, trends and risks of ectopic pregnancy in a population of women. *BMJ* 1981;282:15.

TABLE 74.1. Rates of Ectopic Pregnancy for Various Population Subgroups

Age at the time of conception is a relative risk factor for developing an ectopic pregnancy. The percentage of pregnancies that are ectopic increases with maternal age and is threefold greater in the older age group than in the younger.²⁵

Fourteen percent of all pregnancies in women with an intrauterine device (IUD) are ectopic. The IUD does not prevent ovulation, as does the oral contraceptive, but interferes with intrauterine implantation of the ovum. Therefore, a woman wearing an IUD is potentially at risk for tubal implantation if her ovum becomes fertilized. Additionally, IUD wearers are frequently subjected to delayed diagnosis of ectopic pregnancy.²⁷ Health-care providers may confuse the symptoms caused by an ectopic pregnancy with those related to the mechanical or inflammatory response of an IUD (which indeed may be identical) and fail to consider the possibility of an ectopic gestation in an IUD wearer.¹⁴

PID is almost universally accepted as the major causative factor for ectopic pregnancies. An epidemic of PID is occurring in the United States.⁷ Major risk factors for PID are age in the 20s, divorce, and marital separation.²⁹ Rates for non-White women are 1.4 to 2.5 times higher than those for White women.

Ectopic pregnancy must be considered after tubal sterilization procedures. Sixteen percent of women who become pregnant after tubal sterilization have an ectopic gestation. In most cases, this probably represents partial recanalization with access of the sperm to the ovum but impaired passage of the fertilized ovum to the uterine cavity. Like IUD wearers, patients who have had prior tubal sterilization are frequently subjected to a delay in diagnosis of ectopic gestation. Physicians often neglect to consider this diagnosis early in the presentation.

Women who have had an elective abortion within the preceding 2 weeks and present with symptoms referable to the genital tract are at risk of having an undiagnosed ectopic pregnancy. Confirmation of the products of uterine extraction is necessary to exclude the diagnosis of ectopic pregnancy. This is a frequent problem in large urban clinics with a high incidence of therapeutic abortions performed with unreliable follow-up.²⁸

The major life-threatening condition associated with an ectopic pregnancy is intraabdominal hemorrhage with shock. Refractory hemorrhagic shock is the cause of death in approximately 85% of fatalities from ectopic pregnancy.¹⁰ Misdiagnosis by physicians contributes to one-half of the fatalities.¹⁰ It is common for an emergency physician to evaluate a patient with a ruptured ectopic pregnancy with a history of several prior visits for abdominal pain or vaginal bleeding.

CLINICAL PRESENTATION

Any patient with lower abdominal pain or vaginal bleeding with a positive pregnancy test in the first trimester should be suspected of having an ectopic pregnancy. The “classic” triad of amenorrhea, vaginal bleeding, and abdominal pain is neither sensitive nor specific for ectopic pregnancy. Only 15% of patients with ectopic pregnancies present with this classic picture. Only 14% of patients with the classic constellation of signs and symptoms actually have an ectopic gestation.²⁶

Abdominal pain is the most common symptom and is reported in more than 97% of patients. Abnormal vaginal bleeding is present in 55% to 86% of cases.^{1,15,21,28,30} A “normal” menstrual history is obtained in 15% to 30% of patients. Abdominal pain occurs *without* bleeding in up to one-third of patients. It should be emphasized that consideration of an ectopic pregnancy is based on a history of abdominal pain and a positive pregnancy test in the first trimester. The quality, character, and location of the pain are highly variable.¹⁵ It may be cramping, colicky, steady, or dull. Flank or lower back pain may be noted, or tenesmus may occur from rectal irritation caused by blood in the cul-de-sac.⁶ The pain may be localized to either lower quadrant or may be generalized, suggesting hemoperitoneum.^{1,15} Profuse vaginal hemorrhage occurs in the minority of cases and suggests rupture of a cornual implantation.⁷

Vital signs are often normal, except in those patients with significant blood loss. This will be manifested by orthostatic hypotension, tachycardia, or frank shock. Paradoxical bradycardia may be seen. Any woman of childbearing age who presents with signs of hemorrhagic shock without historic or physical evidence of trauma has a ruptured ectopic pregnancy until proved otherwise. Fever is seldom present.

Tenderness on pelvic examination is the most common sign and is present in 83% to 97% of cases.^{1,15,21,28} The physical findings depend on whether intraperitoneal irritation has occurred from leakage or rupture of the ectopic gestation.

A palpable mass may represent the ectopic gestation or be felt on the side opposite the ectopic gestation, possibly representing a corpus luteum cyst rather than the ectopic pregnancy.²¹ Transmigration of the fertilized ovum to the opposite tube is presumed to have occurred in these cases.¹⁷

A recent study utilized sophisticated statistical methods to identify findings on history and physical that are predictive of ectopic pregnancy. Patients with ectopic pregnancy were more likely to have moderate-to-severe sharp abdominal pain with abdominal or pelvic tenderness and a small uterus on physical examination. Peritoneal signs were uncommon but highly predictive of ectopic pregnancy. Risk factors strongly predictive of ectopic pregnancy included infertility, use of an IUD, tubal ligation, or other pelvic surgery. Patients with these characteristics are at especially high risk for ectopic pregnancy. However, no combination of factors confirmed or excluded the diagnosis of ectopic pregnancy with a high degree of certainty.⁸

DIFFERENTIAL DIAGNOSIS

Given the broad spectrum of patient complaints and physical findings, the differential diagnosis of ectopic pregnancy is proportionally broad. The most common pelvic conditions that share clinical aspects of ectopic pregnancy include PID, threatened or incomplete abortion, corpus luteum or follicular cyst, ovarian cyst with a twisted pedicle, endometriosis, gastrointestinal disorders, dysfunctional uterine bleeding, mittelschmerz, and intrauterine pregnancy.

PID is the diagnosis most commonly confused with ectopic pregnancy.¹³ The signs and symptoms may be identical and the same population is at risk. A significant percentage of normal intrauterine pregnancies are associated with pelvic pain and vaginal bleeding in the first trimester, as are almost all cases of nonviable intrauterine pregnancies. Rupture of a corpus luteum cyst of pregnancy is associated with a positive pregnancy test, pain, and a tender pelvic mass—identical symptoms of an ectopic pregnancy. Serous cul-de-sac fluid may help to differentiate the two.

Gastrointestinal disorders to be differentiated include appendicitis, diverticulitis, irritable bowel syndrome, and gastroenteritis. Nephrolithiasis should also be considered.

Patients who merit special consideration are those with a history of tubal ligation or other pelvic surgery, an IUD in place or recently removed, or a recent history of an elective or spontaneous abortion. An especially high risk group is those undergoing treatment of infertility with embryo transfer procedures or ovulation-inducing agents. These patients are at increased risk of mortality because of the *failure to consider ectopic pregnancy*.

EMERGENCY DEPARTMENT EVALUATION

The evaluation of suspected ectopic pregnancy may be organized into three general categories based on hemodynamic stability ([Table 74.2](#)).

CATEGORY A
Patients presenting in hypovolemic shock
CATEGORY B
Patients of reproductive age presenting with complaints and physical findings indicative of an acute abdomen but who are hemodynamically stable
CATEGORY C
Patients presenting with abdominopelvic complaints suggestive of an ectopic pregnancy but who are clinically judged to be at low risk of immediate deterioration

TABLE 74.2. Categories for Evaluating Suspected Ectopic Pregnancy Based on Hemodynamic Stability

The history should emphasize the patient’s reproductive past, menstrual history, and risk factors, and a chronologic review of the nature and intensity of the symptoms.

The physical examination should focus on changes associated with normal pregnancy and signs of peritoneal inflammation or significant blood loss. Uterine size, adnexal masses, appearance of cervix and os, and rectal examination should be noted. Serial abdominal examinations may aid in the assessment. A pelvic examination should be repeated only as necessary because of the concern that overly aggressive palpation may precipitate rupture.

Laboratory studies should include a urinalysis and a pregnancy test. For patients in categories A and B (see [Table 74.2](#)), a hematocrit and a blood bank specimen are necessary. Other laboratory tests are nonspecific and seldom useful in establishing the diagnosis of ectopic pregnancy.

Sensitive urine pregnancy tests with a human chorionic gonadotropin (hCG) threshold of 20 IU/L should be used as a screening test for possible ectopic gestation. The current generation of urine hCG assays using monoclonally derived, enzyme-tagged antibodies meets this sensitivity requirement. These assays allow detection of pregnancy at 1 week postconception (3 weeks' gestation). Almost all patients with an ectopic pregnancy will have a positive pregnancy test if the threshold for hCG is 20 IU/L.⁴ The chance for a false-negative result exists when the serum hCG level is low and the urine is dilute (specific gravity less than 1.010).² A patient highly suspected of harboring an ectopic gestation with a dilute urine and a negative urine pregnancy test should have a serum b-hCG radioimmunoassay.

Patients in category C (see [Table 74.2](#)) may benefit from quantitative serum hCG level determinations. Serum b-hCG levels rise exponentially during the first 6 weeks of gestation and peak at approximately 100,000 mIU/mL. A single quantitative serum b-hCG value serves as an objective substitute for a menstrual history (i.e., it dates the pregnancy). This becomes important because one-third of patients with an ectopic pregnancy cannot recall the date of their last menstrual period. The irregular bleeding associated with ectopic gestation clouds certainty about the duration of amenorrhea in others. Serial quantitative serum b-hCG levels double every 2 days in early *intrauterine* pregnancies. Abnormal gestations, both intrauterine and extrauterine, have prolonged doubling times.¹⁸ Patients in whom serum b-hCG levels do not increase by more than 66% (1.66-fold increase) in 48 hours are likely to harbor an abnormal pregnancy and should have further evaluation.²³ Serial serum quantitative b-hCG determinations can be used in stable patients to more accurately detect a nonviable intrauterine or ectopic gestation.

The gestational sac of a normal intrauterine pregnancy becomes visible with transabdominal ultrasonography at 5 to 6 weeks' gestation, corresponding to a quantitative b-hCG of 6000 to 6500 mIU/mL.¹⁶ With transvaginal sonography, a gestational sac is commonly visualized when the b-hCG level exceeds 1000 mIU/mL.

This level of b-hCG is often referred to as the discriminatory zone.^{18,19} Intrauterine pregnancy or findings suggestive of an ectopic gestation may be seen with very low b-hCG levels. b-hCG levels should therefore not be used as a basis for delaying ultrasonography when ectopic pregnancy is suspected. Ultrasonography is operator dependent and has a high incidence of nonspecific findings with gestational ages earlier than 5 to 6 weeks. With transvaginal ultrasonography, a gestational sac is identified and localized outside the uterus in about 62% of ectopic pregnancies.³³ False-negative and false-positive results occur in up to 25% of patients.⁵ Although a positive diagnosis of ectopic pregnancy can be made by identifying an extrauterine gestation, this is a rare finding. In practice, ultrasonography is more helpful in excluding the diagnosis when it demonstrates an intrauterine pregnancy, because the combined gestation is so rare.

The correlation of ultrasonographic findings with quantitative serum b-hCG levels increases the accuracy of diagnosis in ectopic pregnancy. This is especially true if the quantitative b-hCG level is above the discriminatory zone.^{18,19} The absence of a gestational sac with a serum b-hCG titer above the discriminatory zone has a sensitivity of 100%, a specificity of 96%, a positive predictive value of 86%, and a negative predictive value of 100% for the diagnosis of ectopic pregnancy.²⁴ The ultrasonographic absence of an intrauterine sac, with hCG levels below the discriminatory zone, does not allow the definitive diagnosis of an ectopic pregnancy.

In summary, urine hCG testing screens for pregnancy and ultrasonography locates it. A single quantitative serum b-hCG assay is used to date the pregnancy and increase the accuracy of ultrasonographic results, while serial quantitative levels merely tell the clinician whether the pregnancy is behaving in a normal biochemical manner.

Because pregnancy can be biochemically detected at approximately 1 week of gestation but may not be located reliably with ultrasonography until 5 to 6 weeks of gestation, a 4- to 5-week period of uncertainty exists. During this period, a pregnancy can be detected but often cannot be located by noninvasive means. Laparoscopy performed on all patients in the period of uncertainty results in a high incidence of unnecessary diagnostic laparoscopies for normal intrauterine pregnancies.²⁶ Therefore, patients in category C (see [Table 74.2](#)) during the period of uncertainty, who are stable and reliable, are best evaluated by serial serum quantitative b-hCG level, provided that an initial sonogram is nondiagnostic. Failure of b-hCG levels to increase normally places a patient at higher risk for an ectopic or other abnormal pregnancy.

Culdocentesis is a simple, rapid, and accurate method of detecting intraperitoneal blood. It may be used when ultrasonography is not immediately available or when ultrasonography results are equivocal. A positive test is one in which nonclotting blood is aspirated from the cul-de-sac with a hematocrit higher than 15%. A "dry tap" is nondiagnostic. A negative tap occurs when clear fluid is obtained. When positive, the test will identify a ruptured or leaking ectopic pregnancy with high sensitivity and moderate specificity.¹¹ Patients in categories B and C are likely to benefit from both ultrasonography and culdocentesis. However, if either modality delays operative intervention in category A patients, it should not be used, because findings will not alter management, but delay treatment.

EMERGENCY DEPARTMENT MANAGEMENT

Management is guided by the patient's hemodynamic status, reliability for follow-up, and the availability of ultrasonography ([Fig. 74.2](#)).³³ *Patients in category A* should be treated for hemorrhagic shock: The patient should be placed in the Trendelenburg position and administered high-flow oxygen by nonrebreather mask. Two large-bore peripheral intravenous lines should be established and crystalloid infusion begun. Baseline blood samples should be obtained in addition to a clot tube for the blood bank. Transfusion with O-negative, type-specific, or fully crossmatched blood should be considered after crystalloid infusion, depending on the infusion urgency and response of the patient to initial therapy. Immediate gynecologic consultation for laparotomy should be obtained.

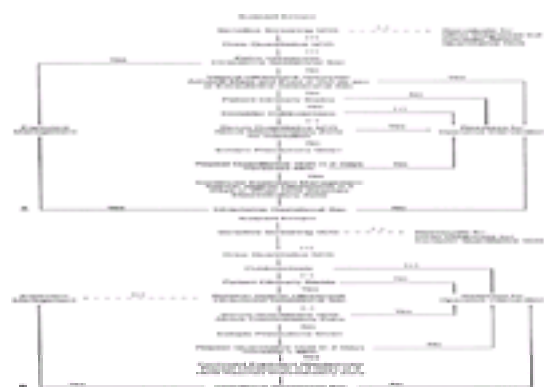

Figure 74.2. Algorithm for evaluation and management of suspected ectopic pregnancy. (A) When ultrasonography is not readily available. (B) When ultrasonography is available. (From Wolcott HD, Stock RJ, Kaunitz AM. Ectopic pregnancy. In: Benrubi G, ed. *Obstetric and gynecologic emergencies*. Philadelphia: JB Lippincott Co, 1994, with permission.)

Patients in category B are stable but have potential for rapid progression to category A. Anticipation of fluid resuscitation and rapid confirmation of the diagnosis dictate the course of evaluation and management. One or two large-bore intravenous lines should be established. Baseline blood studies include complete blood cell count, Rh typing, and typing and screening for potential blood replacement. A sensitive urine pregnancy test must also be performed. Ultrasonography should be used if immediately available. Culdocentesis is used if ultrasonography results are nondiagnostic or if ultrasonography is not available. Patients in category B, by definition, have an acute abdomen. Therefore, they warrant urgent consultation.

Patients in categories A and B present few problems in evaluation and management. *Patients in category C*, who are stable and ambulatory, pose the greatest diagnostic and management problems. [Figure 74.2](#) provides a useful management scheme. The evaluation of a possible ectopic pregnancy starts with a urine pregnancy test on *all* women of childbearing age who present with abdominopelvic pain. The *only exception* is the woman who has had a hysterectomy. The presence of an IUD, tubal ligation, a partner with a vasectomy, or incidental trauma should not deter consideration of an ectopic pregnancy. The diagnosis should be pursued until reasonably ruled out.

DISPOSITION

Role of the Consultant

Given the broad spectrum of presentations and the lack of pathognomonic findings in suspected ectopic pregnancy, there should be a low threshold for requesting consultation from the gynecology, radiology, and surgery services.

Consultation should be obtained for patients in category A or B. Early notification of consulting services may allow early mobilization of operating room personnel. The timing for consultation in category C patients is more flexible and dependent on local resources, consultant availability, and whether the patient has a previously established relationship with a gynecologist. Category C patients with a positive culdocentesis should *not* be discharged from the emergency department before specialty consultation. Category C patients with a negative or diagnostic culdocentesis fall into a gray zone, and the timing of consultation depends on the patient's symptoms and potential for clinical deterioration. Other category C patients in whom culdocentesis was omitted because of minimal symptoms may be discharged with careful instructions and outpatient follow-up.

Indications for Admission

All patients in categories A and B require admission. Category C patients may be discharged with gynecologic follow-up in 48 hours, except in the following instances:

- Positive culdocentesis
- Progressive symptomatology or physical findings
- When no intrauterine pregnancy can be visualized on ultrasonography in a symptomatic patient with a reliable menstrual history that dates the pregnancy at 5 to 6 weeks' gestation or in a patient with a quantitative serum b-hCG level above the discriminatory zone
- Patients unreliable for follow-up

The usual timing of follow-up is 48 hours, the standard sampling interval for quantitative serum b-hCG levels. Most outpatients will be evaluated by this method. All patients discharged from the emergency department with ectopic pregnancy in the differential diagnosis should be placed in an Expectant Management Register to ensure follow-up, track serial hCG levels, or call-back for an emergency department recheck, should that be necessary. A management system should also be in place to follow up on the products of uterine extraction in women who undergo uterine evacuation procedures in the emergency department for suspected incomplete abortion. If the pathology report shows "no chorionic villi," ectopic pregnancy is the likely diagnosis and the patient should return for further evaluation.

Alternative Therapy for Unruptured Ectopic Pregnancies

Patients with unruptured ectopic pregnancies may be treated using alternative therapeutic options. Methotrexate may be used for these cases when given orally, intramuscularly, or intravenously, along with leucovorin rescue to prevent toxicity to bone marrow. Regimens exist that include single-dose methotrexate/leucovorin with minimal toxicity to the patient.

Patients treated medically for ectopic pregnancy may experience abdominal pain 3 to 7 days after treatment. This is thought to be secondary to methotrexate-induced tubal abortion. It may be difficult to differentiate expected pain from pain due to rupture of a persistent EP. Patients presenting with abdominal pain in this timeframe following methotrexate administration should have a complete blood count and ultrasound to rule out significant free fluid in the cul-de-sac, and should be evaluated for other causes of abdominal pain. The patient may need consultation and/or admission to the hospital for observation. Hemodynamic instability and/or falling hematocrit would require surgical intervention.

Stable patients with an ectopic pregnancy and no cardiac activity on ultrasound may be followed with serial examination and repeat quantitative b-hCG levels. If the levels continue to fall, no invasive interventions may be necessary. In addition to the repeat b-hCG levels, repeat transvaginal ultrasonic scanning should be considered to ensure reabsorption of the embryo.¹

Transfer Considerations

In general, patients should be transferred only if there is no operating facility and an ectopic pregnancy has been diagnosed or if an ectopic pregnancy is strongly suspected but diagnostic resources are unavailable. Stable patients and patients in hypovolemic shock who undergo successful volume resuscitation may be transferred with appropriate personnel. Intravenous access is necessary.

It is important that the receiving physician be provided with all available information so that he or she may contribute to the management and transfer plan.

COMMON PITFALLS

- The most common pitfall is failure to consider the diagnosis of ectopic pregnancy, especially in women with few symptoms.
- Ultrasonography, culdocentesis, and serum b-hCG level determinations are of limited sensitivity and specificity.
- In making a diagnostic decision, clinical findings consistent with ectopic pregnancy should outweigh any single negative test result.
- Delays have been documented in cases that involve women who have undergone tubal sterilization, women with an IUD in place or recently removed, and women who have undergone a recent spontaneous or therapeutic abortion. Ectopic pregnancy does occur in these groups and must be ruled out.

Asthma in Pregnancy

Asthma complicates 0.4% to 1.3% of pregnancies,¹³ and there is evidence that the percentage is increasing.¹ The effect of pregnancy on the asthma is variable, and the course in one pregnancy may not be predictive of that in subsequent pregnancies. In a survey of retrospective studies that included more than 1000 patients, asthma was unchanged in half, improved in 29%, and worsened in 21%.²⁵ The severity of asthma before pregnancy appears to correlate with the response to pregnancy. If the asthma is mild before pregnancy, its severity is usually unchanged; in patients with severe asthma before pregnancy, the asthma may become even worse.¹⁰ When the disease is sufficiently controlled to obviate hospitalization, the tendency for poor fetal growth among similarly complicated pregnancies requiring hospitalization was not observed.²¹

Fetal mortality has been associated with severe asthma (uncontrolled episodes of wheezing).¹¹ Older studies showed that poor control of asthma was associated with increased fetal mortality. However, in more recent studies that included severe asthmatics and the use of β_2 agonists, theophylline, and corticosteroids to maintain adequate control of asthma, maternal deaths were eliminated and fetal loss was reduced to that of the general population. It has become apparent that the control of asthma is essential to improve maternal and fetal outcome, even if corticosteroids are required.^{13,21} Congenital malformation rates are not increased among infants of asthmatic mothers.

The National Institutes of Health published its report of the Working Group on Asthma and Pregnancy in 1992. This provides an excellent review of the management of asthma in pregnancy.¹⁶

Pulmonary Physiology During Pregnancy

Mechanical and hormonal changes that occur during pregnancy affect the respiratory system. Respiratory rate is relatively unchanged, but tidal volume is increased, resulting in hypocapnia and a tendency toward chronic respiratory alkalosis. Arterial $p\text{CO}_2$ values of 27 to 32 mm Hg are normal for pregnancy, compared with 38 to 45 mm Hg for nonpregnant women. The importance of this fact is that a pregnant woman with respiratory symptoms and an arterial $p\text{CO}_2$ of 40 mm Hg or higher has at least mild pulmonary failure. A compensatory renal bicarbonate loss occurs, with a reduction of serum levels to 18 to 21 mEq/L during pregnancy (normal, 24 to 30 mEq/L). This partially compensates for the respiratory alkalosis, but a slightly alkaline pH of 7.40 to 7.47 is normal during pregnancy. The bicarbonate loss results in a lower buffering capacity, which assumes importance in clinical conditions such as diabetic ketoacidosis, in which the need for buffering of metabolic acids is strong (see the later section, "[Diabetes in Pregnancy](#)").

Lung compliance is unchanged in pregnancy, but airway conductance is increased and total pulmonary resistance is reduced. Total breathing capacity, forced vital capacity, peak expiratory flow rate (PEFR), and forced expiratory volume in 1 second (FEV_{-1}) are not affected by pregnancy. Because of elevation of the diaphragm, functional residual capacity and residual volumes are somewhat reduced.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of asthma in the pregnant patient is essentially the same as in the nonpregnant patient (see [Chapter 146](#)). Specific to pregnancy, the differential diagnosis of severe respiratory distress includes recurrent pulmonary emboli, acute left ventricular heart failure with pulmonary edema due to peripartum cardiomyopathy, and amniotic fluid embolism.

Peripartum cardiomyopathy is associated with the onset of congestive heart failure among women with no prior history of heart disease. Although it can occur during the last month of pregnancy or within the first 5 months after delivery, most cases are found in the first 3 months postpartum.²⁶ It is more common among older, Black

multiparas, frequently those who have experienced preeclampsia. The presence of mural thrombi with resulting pulmonary embolism is not uncommon. The cause is unknown.

Amniotic fluid embolism typically presents with severe respiratory distress, cyanosis, shock, and disseminated intravascular coagulation. The onset of symptoms is sudden and catastrophic. Patients are frequently not resuscitable. An important feature in the diagnosis is that bronchospasm is rare with this entity.

EMERGENCY DEPARTMENT EVALUATION

Clinical evaluation of a pregnant patient with acute asthma is very similar to that of a nonpregnant woman. The physical examination should include evaluation of the level of consciousness and of the use of accessory respiratory muscles, measuring the pulse and respiratory rates, looking for pulsus paradoxus (more than a 10-mm Hg drop in systolic blood pressure during inspiration), auscultation of the lungs, and measurement of FEV₁ or PEF. The following physical findings may indicate severe airway obstruction and the need for hospitalization:

Altered sensorium
Tachycardia greater than or equal to 120 to 130 beats per minute
Respiratory rate of greater than 30 breaths per minute
Pulsus paradoxus of more than 18 mm Hg
FEV₁ less than 1 L
An arterial pCO₂ level exceeding 40 mEq/L

Although these findings often correlate with severity of disease, their presence can be seen with less severe asthmatic attacks, or they may even be absent when severe airway obstruction is present.⁹ The amount of wheezing does not always correlate with the severity of functional derangement. Caution is appropriate when trying to judge the severity of an asthmatic attack based on physical findings. However, an FEV₁ of less than 1 L is a fairly reliable indicator of severe airway obstruction, and an arterial pCO₂ exceeding 40 mEq/L reliably predicts respiratory failure after the first trimester of pregnancy.

Laboratory Evaluation

Laboratory evaluation for an acute asthmatic attack may include a complete blood cell count with differential, sputum analysis, arterial blood gas (ABG) analysis, and pulmonary function testing.

A routine ABG analysis for all asthmatic patients is controversial. Some authors recommend routine ABG determination, while others base the need on clinical findings or response to initial therapy. However, among pregnant women, it is probably safest to obtain an ABG analysis, unless the attack is obviously mild or response to therapy is rapid. Severe hypoxia or hypercapnia, both potentially detrimental to the fetus, should be rapidly detected and treated. There should be no adverse risk to the fetus when the oxygen saturation is greater than or equal to 95%. Mild asthma reflects a normal or slightly reduced pCO₂, whereas more severe airway obstruction results in normal or elevated pCO₂ with arterial hypoxemia. In normal pregnancy, ABGs reflect a compensated respiratory alkalosis resulting from hyperventilation.¹³ The pH generally ranges from 7.40 to 7.47 and the PaCO₂ from 25 to 32 mm Hg. Arterial PO₂ is normally 100 mm Hg, or slightly higher.

Probably the most reliable indicator of severity of airway obstruction and response to treatment is the FEV₁ or PEF. An FEV₁ of less than 1 L can be an indication of severe airway obstruction and need for hospitalization. Repeat ABG analysis is often of little value when the FEV₁ is greater than 1 L.

Chest Radiography

Although routine chest films are not recommended in the evaluation of asthma during pregnancy, they should be done if pneumonia or pneumothorax is suspected and for patients who do not respond to standard therapy. Proper shielding of the abdomen is important.

Exposure of the developing fetus to radiation can potentially lead to birth defects (first trimester only), fetal growth retardation, microcephaly, and mental retardation when such exposure is excessive.³ An exposure of 5 rad or less is thought to be safe for the developing fetus; a routine posterolateral chest film exposes the fetus to less than 0.04 rad.³ When the abdomen is shielded with a lead apron, radiation exposure to the fetus is negligible.

Chest radiographs are altered by pregnancy. The diaphragm elevates progressively during pregnancy. This elevation causes the heart to rotate on its axis and shift to the left. As a result, cardiac size appears increased, making the identification of moderate cardiomegaly difficult. As a result of increased pulmonary blood flow, lung markings may also be increased, erroneously suggesting the diagnosis of mild congestive heart failure.

EMERGENCY DEPARTMENT MANAGEMENT

The management of asthma in the pregnant patient is essentially the same as in nonpregnant patients. Treatment with theophylline, b₂ agonists, or corticosteroids should not be withheld because of pregnancy. It has become apparent that the control of asthma, even if corticosteroids are required, is essential to improve maternal and fetal outcomes.¹³ A suggested management outline is shown in [Figure 75.1](#). The Centers for Disease Control and Prevention has recommended that patients with chronic asthma, including pregnant women, receive yearly influenza immunization, but that, in pregnant patients, this be limited to the second and third trimesters.⁶

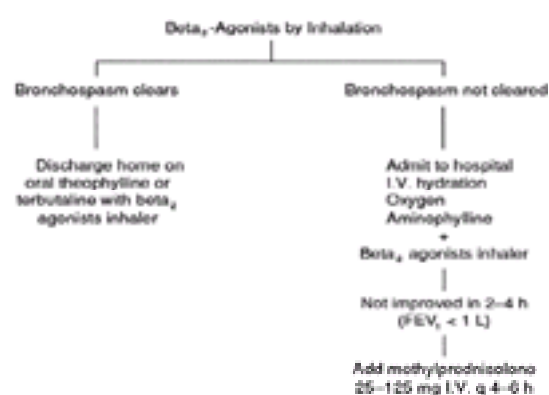

Figure 75.1. Suggested management of asthma in pregnancy.

Drugs Used to Treat Asthma in Pregnancy

Drugs used to treat asthma in pregnancy are listed in [Table 75.1](#) and [Table 75.2](#).

CONSIDERED SAFE
Aminophylline
Theophylline
β-Adrenergic agonists
Terbutaline
Isoetharine
Albuterol
Metaproterenol
Corticosteroids
Prednisolone
Prednisolone
Methylprednisolone
Beclomethasone dipropionate (by inhalation)
Cromolyn sodium
CONTROVERSIAL
Epinephrine
CONTRAINDICATED
Iodine expectorants

TABLE 75.1. Medications Used to Treat Asthma during Pregnancy

Drug	Dose	Comments
β-AGONISTS		
Inhaled budesonide	8-12 mg	After 15-30 min a second dose of 8-12 mg may be given. Repeat dose depending on second dose should be adjusted to the hospital for intensive aminophylline and corticosteroid therapy.
Rhinal	5-10 µg/4-8 puffs	Repeat every 4-6 h.
Metaproterenol	5-10 µg/4-8 puffs	Repeat every 3-4 h.
Methylprednisolone	8-16 mg IV solution in 17-ml saline	Repeat every 6 h.
beclomethasone	8-16 µg IV solution in 17-ml saline	Repeat every 6 h. Total use every 12 h is limited and then every 3-4 h.
AMINO-PHYLLINE		
Loading dose*	5-10 mg/kg (not to exceed 400 mg)	Over 20-30 min.
Maintenance dose	8-12 mg/kg/d	
CORTICOSTEROIDS		
Methylprednisolone	8-12 mg IV	Repeat every 4-6 h. High-dose therapy with 12 mg every 6 h may be preferred, because it will result in a more rapid improvement. Repeat after improvement and stop as soon as controlled with a prednisone 8-16 mg/d. Repeat prednisone over next 1-2 wk.

*Based on current pregnancy weight.

TABLE 75.2. Drugs Used to Treat Acute Asthma in Pregnancy

b-Adrenergic Agonists

Selective b_2 agonists are potent bronchodilators and the initial treatment of choice in acute asthma during pregnancy. Although b_2 agonists can be given by subcutaneous injection, intravenous (i.v.) infusion, or aerosol inhalation, the aerosolized method is preferred. Inhalation by nebulizer or metered dose produces a more rapid onset of action, minimizes adverse systemic effects, and is as effective as i.v. therapy.²⁶ Although isoetharine has been used with success, more selective b_2 agonists, such as metaproterenol and albuterol, are recommended. For maximal benefit, the aerosol should be slowly inhaled over 5 to 6 seconds, followed by a short period of breath holding, and then slowly exhaled. Even patients who take b_2 agonists on an outpatient basis may respond to this inhalation therapy.

There are no reports linking the use of b_2 agonists with congenital birth defects. These agents do cross the placenta and can result in fetal tachycardia, usually less than 175 beats per minute. Long-term use during pregnancy has not been associated with adverse perinatal outcome. Infants followed up to 12 months of age have shown no harmful effects.⁴

Certain b_2 -adrenergic agents (e.g., terbutaline) are used to inhibit uterine contractions as therapy for preterm labor. These agents can precipitate pulmonary edema in otherwise healthy women. Fortunately, pulmonary edema has not been reported with treatment of asthma. Diabetic ketoacidosis has also been associated with b_2 -adrenergic therapy for preterm labor. These agents are best avoided among pregnant diabetic women with asthma. Patients with migraine headaches should probably not be given parenteral terbutaline.

Epinephrine

The use of epinephrine in pregnancy is controversial. Greenberger and Patterson¹³ favor subcutaneous epinephrine as the treatment of choice during pregnancy. Chung and Barnes⁷ advise that epinephrine is best avoided during pregnancy because of its ability to decrease uterine blood flow and, possibly, to cause congenital malformations. Epinephrine has been associated with an increased incidence of fetal malformations when used in the first 4 months of pregnancy.¹⁵ In monkeys treated with intraarterial epinephrine, uterine artery vasoconstriction and reduced uterine perfusion were demonstrated.¹⁷ However, intraarterial injection of epinephrine in monkeys may have little or no application to the subcutaneous use of epinephrine among pregnant women. Selective b_2 agonists, on the other hand, cause either no change or an increase in uterine blood flow.¹⁵ There are no advantages, and there are possible disadvantages, to the use of epinephrine over the more selective b_2 agonists. Although controversial, epinephrine use in pregnancy should be replaced by the more selective b_2 agonists.

Theophylline

Theophylline is less effective as a bronchodilator than the b_2 agonists, but when it is used in combination with them, there is an additive effect, because they have different modes of action. During pregnancy, patients who do not respond to b_2 agonist therapy should be considered for hospital admission and intravenous therapy with aminophylline. Aminophylline is the water-soluble salt of theophylline, which readily crosses the placenta and induces fetal levels similar to or higher than maternal levels.² No teratogenic effect has been demonstrated in human studies. In the newborn, metabolism and excretion of theophylline are limited, resulting in a half-life two to three times that in an adult. After delivery, newborns can maintain adult therapeutic levels (1020 µg/mL) for up to 18 hours.² Neonatal toxicity can occur in the absence of maternal toxicity, owing to increased neonatal sensitivity and slower elimination of the drug.² To avoid such toxicity, the dose of aminophylline should be reduced in pregnancy. Patients who are not currently taking theophylline should receive a loading dose of 5 to 6 mg/kg, not to exceed 400 mg intravenously over 20 to 30 minutes. In patients who have taken the drug sporadically, half the loading dose should be used; it is best to eliminate it completely if the patient has adhered to an adequate oral regimen. One must remember that the loading dose is based on *actual* body weight and the maintenance infusion is based on *ideal* body weight, rather than current pregnancy weight.

A continuous infusion dose should not exceed 0.5 mg/kg/h to avoid fetal toxicity. Smokers and adolescents (younger than age 20) rapidly metabolize aminophylline and may require a higher dose (0.7 mg/kg/h). Higher doses can be used during pregnancy if serum levels are followed. The serum theophylline level should be measured about 10 hours after therapy is initiated and daily thereafter. Therapeutic levels for theophylline are 10 to 20 µg/mL. However, during pregnancy, levels higher than 12 µg/mL should be avoided to prevent toxicity to the baby. Hyperactive fetal movement and fetal tachycardia may be seen when theophylline levels exceed these limits. Toxicity in the newborn, including tachycardia, jitteriness, and irritability, is only occasionally observed, but can occur even with neonatal blood levels that are therapeutic in the adult. Thus, the recommendations regarding dosage reduction are even more important in late pregnancy, or whenever delivery is likely.

Corticosteroids

Most patients respond to a b_2 agonist alone or in combination with i.v. aminophylline. If improvement (FEV₁ remains less than 1 L) is not apparent, corticosteroid therapy is recommended. During pregnancy, there should be no hesitation to add corticosteroids in the management of asthma. The early administration of corticosteroids is an important part of therapy when asthma is severe or resistant. Patients who are already taking oral corticosteroids for asthma should receive i.v. corticosteroids as part of the initial therapy. Although methylprednisolone (25 mg i.v. every 4 to 6 hours) is effective, high-dose corticosteroid therapy (e.g., 125 mg methylprednisolone every 6 hours) may be preferred, because it results in a more rapid improvement.¹⁴ Improvement should occur within 1 hour after corticosteroid treatment is started, with maximal effect in 6 to 8 hours.

Cortisol and other corticosteroids freely cross the placenta, but they are rapidly converted by the fetoplacental unit into a less active form, cortisone.¹⁹ After maternal ingestion, prednisone is rapidly converted to its active form, prednisolone. However, prednisolone is poorly transferred across the placenta, and fetal levels are considerably lower than maternal levels.

Corticosteroids have been shown to induce fetal malformations in certain animal species (cortisone acetate has been demonstrated to induce cleft palate in rabbits).⁸ Corticosteroids, including prednisone, have been used extensively during pregnancy and have little, if any, effect on the developing fetus.⁴ They are not considered teratogenic in humans. For patients with severe asthma, corticosteroid therapy is preferable and causes less fetal or maternal risk than poorly controlled asthma during pregnancy.

An inhaled corticosteroid, beclomethasone dipropionate, has permitted significant reduction or discontinuation of prednisone in corticosteroid-dependent asthmatic patients. The use of a topically active corticosteroid with minimal systemic effects appears logical for use in pregnancy. Inhaled beclomethasone and its metabolites that appear in the systemic circulation are highly protein bound, accounting for the lack of systemic effects. Little systemic absorption occurs after the use of two puffs (100 mg) four times daily. However, when used in dosages exceeding those recommended, beclomethasone has been shown to cause adrenal suppression.^{23,24} The use of a spacer should be considered to reduce oropharyngeal candidiasis, improve respiratory tract penetration, and reduce potential systemic effects.

Available information suggests that beclomethasone dipropionate is safe during pregnancy when administered in recommended doses. Greenberger and Patterson¹² reported the safe use of beclomethasone during 45 pregnancies.

Disodium Cromoglycate (Cromolyn Sodium)

Cromolyn sodium inhibits release of histamine from mast cells and is useful as a prophylactic agent in some patients with asthma. It is not effective for treatment of acute asthmatic attacks. It is poorly absorbed after inhalation, so the amount available for transfer across the placenta is insignificant. Studies in both animals and humans have failed to show any teratogenic or other adverse effects when cromolyn sodium is used throughout pregnancy.⁷

Newer Drugs for the Treatment of Asthma

Several drugs, marketed over the past 5 years but with limited data concerning safety in pregnancy, may have roles under specific situations.²² Nebulized ipratropium might be used for acute asthmatic symptoms not responding to β_2 -agonist therapy. Nedocromil probably can be continued in a patient with persistent asthma who was well-controlled on it prepregnancy. Inhaled salmeterol could definitely be considered for the gravida inadequately controlled on moderate doses of inhaled steroids.

Antibiotics

Bacterial pneumonia and bronchitis can initiate an acute asthmatic attack. If sputum analysis demonstrates polymorphonuclear leukocytes and few or no eosinophils, infection must be suspected. Treatment with ampicillin or erythromycin (500 mg PO every 6 hours) or with a cephalosporin such as cefaclor (250 mg PO every 8 hours for 10 days) is recommended. Erythromycin may slow aminophylline metabolism and necessitate a lower continuous infusion dose. Antibiotic therapy should not be used unless there is evidence of infection. Patients with pneumonia or a febrile respiratory tract infection may benefit from i.v. antibiotic treatment.

Supportive Therapy

Because most patients with acute asthma are dehydrated, i.v. hydration with 5% dextrose in 0.5 normal saline at 100 to 125 mL/h is beneficial. Oxygen by nasal cannula at 2 to 3 L/min should be administered after an initial ABG analysis is obtained. Patients with carbon dioxide retention may benefit from humidified oxygen at 3 to 7 L/min by Venturi mask to deliver optimal oxygen without causing further carbon dioxide retention. A pO_2 of greater than 70 mm Hg or an oxygen saturation greater than or equal to 95% should be achieved. Oxygen administration to reduce hyperventilation, even with mild asthma in pregnancy, may be beneficial. Human studies suggest that maternal hyperventilation resulting in reduced pCO_2 and maternal alkalosis may decrease fetal oxygen tension by inducing uterine artery vasoconstriction and causing a shift of the oxyhemoglobin dissociation curve to the left.²⁶

DISPOSITION

During pregnancy, patients who develop pneumonia or require i.v. therapy for an acute asthmatic attack should be considered for hospital admission. The same patients could benefit from consultation with specialist(s) in maternal-fetal, pulmonary, or internal medicine. The attending obstetrician or obstetric service should be notified. Although procedures vary among institutions, many obstetric services prefer to have all pregnant patients admitted to their service, with specialists in internal medicine or pulmonary medicine acting in a consultative role.

COMMON PITFALLS

- Judging the severity of an asthmatic attack based on physical findings may be misleading.
- Appropriate treatment with theophylline, β_2 agonists, and corticosteroids should not be withheld because of pregnancy. It is apparent that the control of asthma, even if corticosteroids are required, is essential to improve maternal and fetal outcomes.
- Although controversial, epinephrine use in pregnancy should be replaced by the more selective β_2 agonists.
- Perinatal toxicity to theophylline can occur in the absence of maternal toxicity, owing to the baby's increased sensitivity and slower elimination of the drug. To avoid such toxicity, the i.v. dose of aminophylline should be reduced in pregnancy.
- Oxygen administration, even with mild asthma in pregnancy, should be used to reduce hyperventilation. This may be beneficial, because human studies suggest that maternal hyperventilation and alkalosis can reduce the amount of oxygen released to the fetus.¹⁸

Sickle Cell Disease in Pregnancy

Compared with normal pregnancies, those complicated by sickle cell anemia (SS disease) are associated with significantly higher rates of maternal and perinatal morbidity and mortality.^{9,10,12,13} With improved prenatal care, maternal mortality has declined from a rate as high as 30% to the current rate of about 2%.¹¹ It must be appreciated, however, that this 2% rate is more than 200 times the general maternal mortality rate in this country. Maternal morbidity is primarily due to vasoocclusive "crises," which result from abnormal, sickled transformation of erythrocytes (frequently the result of infection, hypoxemia, acidosis, or dehydration), sludging and obstruction of blood flow to the microcirculation, and resultant ischemia (causing pain) and infarction. The etiology of maternal mortality among these women is related to the same pathophysiology and includes congestive heart failure (2% to 20%), pulmonary embolism (including embolism from infarcted bone marrow, 20% to 40%), and preeclampsia, which is a common complication of this disorder.

The overall fetal wastage is approximately 30%, owing to an increased risk of spontaneous abortion, stillbirth, prematurity, and intrauterine growth retardation. This increase in pregnancy wastage is probably related to thrombotic events in the placenta, as well as to maternal morbidity. Pathologic features in the umbilical vein have been found with maternal SS disease.³

The frequency and severity of vasoocclusive crises vary greatly among parturients. Although controversial, many authors believe that pregnancy worsens the disease, with an increase in frequency of such crises, especially during labor and the postpartum period.⁸ Prompt recognition and intervention are vital for optimal maternal and fetal outcomes.

Sickle cell–thalassemia (SThal) disease and sickle cell–hemoglobin C (SC) disease are treated similarly to sickle cell disease in pregnancy, although the obstetric courses with these hemoglobinopathies are typically not as severe as with SS disease.

CLINICAL PRESENTATION

During pregnancy, most crises are vasoocclusive and occur most often in the latter half of pregnancy. They follow a typical pattern of recurring attacks of sudden pain, most often affecting the extremities, abdomen, chest, and vertebrae.

Although infrequent in pregnancy, hemolytic crisis is characterized by the sudden onset of severe anemia and a low reticulocyte count. Aplastic crisis is usually self-limited and associated with infection, especially with parvovirus B-19. This has proved fatal in pregnancy when sensitization from prior blood products prohibits transfusion.

DIFFERENTIAL DIAGNOSIS

When a known SS disease patient presents to the emergency department with pain, the physician must determine whether it is due to the usual vasoocclusive pathophysiology. If so, is it associated with an infection? If not, is the pain caused by a surgical or obstetric disorder ([Table 75.3](#))? The diagnosis of vasoocclusive crisis is one of exclusion, and other causes of pain may become clear only after failed response to management. Consultation with a perinatologist or hematologist is prudent.

PREGNANCY-RELATED	MEDICAL
Threatened abortion	Pneumonia
Ectopic pregnancy	Pyelonephritis or cystitis
Ovarian cyst with or without torsion	Drug addiction
Degenerating leiomyoma	Thrombophlebitis
Abruptio placentae	Pulmonary embolism
Severe preeclampsia	
	SURGICAL
	Appendicitis
	Cholelithiasis
	Pancreatitis

TABLE 75.3. Differential Diagnosis for Vasoocclusive Sickle Cell Crisis

A reason for the pain crisis should always be sought. First on the list is infection. This will be discovered in about 25% of SS gravidas and is associated with one-third of all maternal deaths in SS patients. In pregnancy, the most common infections are pneumonia, cystitis or pyelonephritis, and osteomyelitis. After delivery, endometritis should always be considered. *Escherichia coli* and *Salmonella* replace pneumococci as the major offending organisms in bacterial sepsis. *Mycoplasma* should also be considered in cases of pneumonia.

EMERGENCY DEPARTMENT EVALUATION

Diagnostic laboratory tests include complete blood cell count with reticulocyte count, clean-catch urinalysis with culture, and hemoglobin electrophoresis for percentage of hemoglobin A. Crisis is unlikely if the hemoglobin A percentage is higher than 40% to 50% (which in SS and SC patients always represents red cells persisting from a prior transfusion). Other laboratory tests should be based on potential organ complications, with recommendations by the appropriate specialist.

Hemodilution of pregnancy normally causes a relative lowering of the hematocrit. Also, the white blood cell (WBC) count may increase to 10,000 to 16,000/ μ L in the absence of infection. Both total and segmental leukocytes increase during pregnancy, as well as with infection and vasoocclusive crisis. However, a substantial rise in the WBC count with an increase in band (nonsegmented) leukocyte level above 1000/ μ L is often seen with significant bacterial infection. Nucleated red blood cells, common with the intense hemolysis that is part of SS disease, may be counted as WBCs in certain automated systems; this fact must be considered in evaluating high "WBC" results.

A complete physical examination is mandatory. Ultrasonography is recommended if the differential diagnosis includes any of the pregnancy-related problems listed in [Table 75.3](#). After initial emergency department evaluation, continuous electronic fetal monitoring is indicated after the pregnancy has reached a gestational age of about 24 weeks.

EMERGENCY DEPARTMENT MANAGEMENT

All pregnant women with SS disease should be admitted to the hospital if there is any suspicion of crisis or infection. Care should be in a medical center with a specialist and subspecialist who are knowledgeable in the management of the gravida with SS disease. If these facilities are not readily available, the patient should be stabilized and transferred to the nearest perinatal center where maternal–fetal medicine and hematology subspecialists are available.

Management of SS disease in a pregnant patient is similar to that in a nonpregnant patient and involves rest, adequate nutrition, hydration, oxygen, and analgesia:

1. The patient should be admitted to the hospital or transferred to the appropriate center, when indicated.
2. Hydration, in the absence of congestive heart failure, should be provided (D₅LR 1000 mL over 2 hours and then 125 to 150 mL/h).
3. Acetaminophen is the preferred analgesic for milder pain. If narcotics are required, satisfactory results usually can be achieved with a combination of meperidine (50 to 100 mg) or butorphanol (1 to 2 mg) in combination with promethazine (25 mg) given intravenously or intramuscularly. Although the potential for narcotic

addiction is high with SS disease, adequate analgesia should not be withheld if the likelihood for actual pain is high.

4. Prophylactic antibiotics are not indicated, but appropriate antibiotics should be initiated immediately if infection is suspected or diagnosed by physical examination or laboratory testing.
5. Oxygen should be delivered by nasal cannula at 2 to 4 L/min.
6. Unless the patient has severe preeclampsia or congestive heart failure, invasive central monitoring and Foley catheterization are to be avoided, to minimize the risk of iatrogenic infection.
7. Partial exchange transfusion has been considered the cornerstone of management for the prevention as well as treatment of crisis during pregnancy.^{5,6} Initially performed as a cumbersome, manual technique, most such procedures are now done by continuous-flow erythrocytapheresis.⁷ With the added risk of acquired immunodeficiency syndrome transmission through blood products (with current blood-banking practices, only about one in a half-million transfusions), the risks versus benefits of this therapy must be carefully explained to the patient. Some specialists are now restricting partial exchange transfusions to patients with severe or recurrent crises. Most vasoocclusive crises are now managed without the use of simple blood transfusion(s). The transfusion of two to four units may still be required when the initial hematocrit is less than 15% or for women in active labor with crisis.⁴ With the multiple-unit transfusions, there are also risks of alloimmunization complicating future crossmatching or causing a delayed transfusion reaction.²

DISPOSITION

As with other medical complications in pregnancy, it is most appropriate to consult the patient's obstetrician or the obstetric service in teaching hospitals. Consultation with maternal-fetal medicine or hematology is then at the obstetrician's discretion. Maternal-fetal medicine physicians can play an important role in the management of SS disease and other medical problems in pregnancy, because of their obstetric background and expanded training in the field of high-risk pregnancy. Genetic counseling is extremely valuable, because prenatal diagnosis is possible¹ and has recently been expanded to preimplantation diagnosis in at-risk women undergoing *in vitro* fertilization.¹⁴

Indications for Admission

Any pregnant woman with SS disease who is suspected of having a crisis or infection should be admitted to the hospital.

Transfer Considerations

Care of the SS parturient is best done at a center with appropriate subspecialists experienced in the management of SS disease. If such subspecialists are not readily available, strong consideration for transfer is indicated. Hydration, oxygen, and appropriate analgesics should be initiated before transfer. Because of the decrease in oxygen tension with altitude, ground transportation is ideally suited for most transports. Helicopters fly at about 2000 feet above ground level for flights less than 100 miles and 3000 to 5000 feet for flights over 100 miles. Fixed-wing aircraft are theoretically pressurized to ground level.

Sickle Cell Trait in Pregnancy

One in 12 Black Americans carries the sickle cell trait (SA hemoglobin). This condition is asymptomatic, with normal hemoglobin concentrations. Sickling occurs only with severe hypoxia (pO₂ less than 15 mm Hg). General anesthesia is well tolerated.

During pregnancy there is no increase in maternal mortality or fetal loss. Although still asymptomatic, these SA patients may become more anemic than expected during pregnancy. As with SS disease, prenatal diagnosis is available when both partners are hemoglobin S (or C or thalassemia) carriers.

The only increased risk during pregnancy is a doubling in the expected risk of asymptomatic and clinical urinary tract infections in SA gravidas, so appropriate surveillance with urine cultures should be performed.¹² This risk is due to reduced oxygen tension in the renal medulla, causing local sickling with ischemia. The result is renal disease manifest by hematuria and an inability to concentrate urine.

Diabetes in Pregnancy

Prior to the discovery and beginning availability of insulin in 1921, pregnancy was uncommon among diabetic women and was associated with high maternal and fetal mortality rates. With modern prenatal care and improved glycemic control, maternal mortality now is nearly as low as that of the general population and perinatal mortality has decreased to 3% to 5%. Although much improved, this perinatal mortality rate is still above the 1% to 2% seen in the general population.¹

The incidence of major malformations, now the major cause of perinatal death, is three to four times higher among offspring of diabetic women and accounts for almost half of all their perinatal losses. It is believed that these anomalies are caused by hyperglycemia during embryogenesis. Using rat and mouse embryo cultures, hyperglycemia (but not hypoglycemia) has been demonstrated to cause birth defects in rodents.⁴ Maternal glucose readily crosses the placenta, so that maternal (and thus fetal) hyperglycemia during human organogenesis may also explain the increased risks of fetal malformations. Insulin is a large molecule that does not cross the placenta. The fetus does not begin its own insulin production until 9 to 11 weeks' gestation. However, fetal hyperinsulinemia, produced in response to fetal hyperglycemia, acts as a major fetal growth factor, leading to the excessive fetal growth that is so often an undesirable finding in poorly controlled diabetic pregnancies.⁹

Improvement in pregnancy outcome among diabetic women now depends on achieving a euglycemic state before the time of conception and for the subsequent 6 to 8 weeks, during which the majority of organogenesis occurs. Diabetic embryopathy thus evolves early in gestation, probably by the seventh week of pregnancy. Because women often do not see their obstetricians until after this critical time, it is the role of family physicians, internists, and emergency physicians to inform and advise women of childbearing age of the importance of achieving optimal glycemic control before pregnancy. Ideally, this degree of metabolic stability should be in place before contraceptive efforts are dropped in anticipation of the planned pregnancy. Maintaining excellent control during early pregnancy, when gestational nausea frequently upsets the gravida's ability to follow a consistent meal plan, is especially challenging. Only through patient education and physician awareness can the perinatal mortality and morbidity rates among diabetic women be minimized.^{4,5,9,11}

PATHOPHYSIOLOGY

Accelerated Fasting Ketosis

The developing fetus depends primarily on glucose for energy requirements and on amino acids for protein synthesis. Glucose is transferred across the placenta by facilitated diffusion. Fetal glucose levels are only 10 to 20 mg/dL below maternal levels. In part, owing to the siphoning of glucose by the fetus, maternal glucose levels after a 12- to 14-hour fast are 15 to 20 mg/dL lower during pregnancy. This results in a decreased insulin release with an elevated blood level of ketoacids.

Ketoacid levels are up to four times higher in normal pregnancy after an overnight fast. The term *accelerated starvation ketosis* describes the fasting hypoglycemia, decreased insulin concentration, and ketonemia. The lower glucose concentration after an overnight fast explains the frequent occurrence of hypoglycemic symptoms when breakfast is skipped. For this reason, it is important that pregnant women have some caloric intake in the mornings. Quickly evolving ketosis represents the ease by which the dreaded diabetic ketoacidosis (DKA) may appear.

Insulin Requirements during Pregnancy

During the first half of pregnancy, insulin requirements are typically stable or may decrease due to (1) the transplacental siphoning of glucose by the fetus, (2) the decreased oral intake resulting from gestational nausea and vomiting, and (3) the early-pregnancy estrogen and progesterone elevations, which cause (except in the type 1 diabetic woman) beta-cell hyperplasia and increased insulin secretion.

Over the second half of pregnancy, insulin requirements can increase by 100% or more over prepregnancy levels. Human placental lactogen, produced in large quantities by the placenta and a major cause of gestational diabetes, is structurally related to growth hormone and is the most important cause of insulin resistance during pregnancy.

Classification

In 1949 White described a classification to help determine the likely outcome and aid in the management of diabetic women during pregnancy. The classification is based on (1) duration of disease, (2) age at onset, and (3) underlying vascular involvement ([Table 75.4](#)).

Class	Age at Onset (yr)	Duration (yr)	Vascular Disease	Treatment
A	Any	Any	0	Diet and insulin
B	>20	<10	0	Insulin
C	10-19	10-19	0	Insulin
D	≤10	≥20	Benign retinopathy	Insulin
F	Any	Any	Nephropathy	Insulin
R	Any	Any	Retinopathy	Insulin
H	Any	Any	Heart disease	Insulin

GESTATIONAL DIABETES			
Class	Fasting Glucose Level		Postprandial Glucose Level
A-1	<105 mg/dL	and	<120 mg/dL
A-2	≥105 mg/dL	or	≥120 mg/dL

From American College of Obstetricians and Gynecologists. Management of diabetes mellitus in pregnancy. ACOG technical bulletin no. 16. Washington, DC: ACOG; 1981.

TABLE 75.4. Classification of Diabetes in Pregnancy

The emergency physician may be called on to treat pregnant diabetic women for complications relating to normal pregnancy as well as for special problems associated with diabetes.

Diabetic Ketoacidosis

DKA during pregnancy is associated with a 50% (per episode) fetal loss rate. Early recognition and treatment improve both maternal and fetal outcomes. During pregnancy, DKA may develop rapidly, with relatively low serum glucose levels of only 200 to 300 mg/dL. The readily available free fatty acids (ketogenic substrates) and the accelerated renal loss of bicarbonate related to hypocarbia, both normal pregnancy findings, are factors favoring this rapidity of development. ²

DIFFERENTIAL DIAGNOSIS

Hypoglycemic Coma

Onset is usually rapid, without other symptoms that are associated with DKA. The serum concentration of glucose is low. Urine ketones are negative.

Nonketotic Hyperosmolar Coma

Dehydration is the major problem, with a blood urea nitrogen level greater than or equal to 70 mg/dL commonly found. Hyperglycemia is marked, with levels as high as 1000 mg/dL.

Alcoholic Ketoacidosis

These patients are usually not diabetic but are often alcoholics with poor nutrition. Ketosis is present, but the serum glucose level is normal.

Uremic Acidosis

Ketosis is mild or not present.

Starvation Ketosis

The differential diagnosis between starvation ketosis and DKA is made difficult because of the accelerated starvation ketosis seen during pregnancy (see previous discussion of [pathophysiology](#)). The accelerated metabolic response to starvation in pregnancy results in serum ketone levels that are up to four times higher than in the nonpregnant state. The presence of ketonemia or ketonuria (usually mild) with low or normal serum glucose levels suggests starvation ketosis, and excludes DKA. Treatment consists of increasing dietary or intravenous (i.v.) carbohydrates.

EMERGENCY DEPARTMENT EVALUATION

It is important to identify an infectious site that could precipitate DKA. Most patients have an altered sensorium, ranging from drowsiness to coma. Other physical findings include evidence of dehydration and rapid, shallow respiration, often with a fruity breath odor due to acetone.

Because home glucose monitoring by capillary blood is standard care for the diabetic woman during pregnancy, a careful review of recent glucose values, if available, is often beneficial.

Laboratory Tests

Initial blood studies should include complete blood cell count; serum determinations of glucose, electrolytes, bicarbonate, urea nitrogen, creatinine, and ketones; and arterial blood gas analysis. A Foley catheter should be placed and left to monitor urine output and urine ketone concentration; urinalysis with culture should be ordered. Other laboratory tests and cultures should be obtained as indicated by history and physical examination. The serum tests and arterial gases should be repeated every 2 hours during the initial phase of treatment.

EMERGENCY DEPARTMENT MANAGEMENT²

Regular insulin (6 to 10 U) should be administered by i.v. push, and then a continuous infusion of insulin in normal saline (50 U regular insulin in 500 mL saline [1 U/10 mL]) is begun at 6 to 10 U/h. If the serum glucose value does not fall by 30% in 2 hours, the insulin dose rate should be doubled. Because the gravida with DKA generally presents with a fluid deficiency of 3 to 6 L, 1,000 mL sodium chloride 0.45% should be given over the first hour, and then 300 to 500 mL/h. When serum glucose reaches 250 to 200 mg/dL, the insulin infusion rate should be halved and the i.v. fluid type should be changed to dextrose 5% in sodium chloride 0.45%. When the serum glucose value falls to less than 150 mg/dL and the serum ketone level is decreasing, insulin should be given at a basal rate of 1 to 2 U/h.

If the pH remains less than 7.30 and is not rising, the insulin dose should be increased, despite a falling blood glucose value. Dextrose 5% in water should be infused at 200 mL/h in order to avoid hypoglycemia and possibly even cerebral edema, a usually irreversible and fatal condition that may be precipitated if severe hyperglycemia is reversed too rapidly.

Rapid correction of acidosis in the pregnant woman is important because of the tremendous fetal risk. *In utero* fetal resuscitation may occur with correction of maternal hyperglycemia and acidosis. For mild acidosis (pH greater than 7.10), bicarbonate is generally not given. If pH is less than 7.10, 88 mEq sodium bicarbonate in 1,000 mL sodium chloride 0.45% should be administered.

DKA is accompanied by a shift in the potassium from the intracellular to the extracellular compartment. A normal or even elevated serum potassium level before initiation of treatment may mask total body potassium depletion. Once the acidosis is becoming corrected, hypokalemia may become obvious. To avoid hypokalemia, potassium chloride (40 mEq/L) should be added to the i.v. fluids when the serum potassium level, measured every 2 hours, falls into the mid-normal range.

The effects of maternal acidosis on the fetus are not fully understood. However, DKA is frequently associated with sudden fetal death. Postulated mechanisms include the following:

- Acidosis may have a direct effect on the fetus. Although no large studies are available, it appears that fetal distress may result from maternal acidosis. The likely explanation is that an unfavorable tenacity for oxygen to fetal hemoglobin develops in the presence of acidosis (Bohr effect). Case presentations have demonstrated decreased fetal heart rate variability and late decelerations (both signs of fetal distress) among monitored fetuses during the course of maternal DKA. With correction of maternal hyperglycemia and acidosis, fetal monitoring returned to normal.
- Dehydration resulting in hypovolemia with decreased placental perfusion can lead to fetal hypoxia and lactic acidosis.
- High lactic acid levels may predispose the fetal brain to hypoxic injury.
- Fetal hyperglycemia increases the fetal oxygen demand.

When the fetus has reached a viable gestational age (24 weeks), continuous electronic fetal monitoring is generally used. If the fetus appears compromised, cesarean delivery should be delayed until the mother is metabolically stable. Fortunately, correction of the maternal acidosis and hyperglycemia may also correct the fetal compromise and allow pregnancy to continue.

DISPOSITION

Role of the Consultant

Under optimal conditions, consultation with one physician qualified to manage both the pregnancy and the DKA would provide the most efficient care for patient management. Such management is possible in centers where maternal–fetal medicine physicians are available. However, in many hospitals, care must be divided between internists or endocrinologists for management of the DKA and an obstetrician to oversee the fetal condition.

Transfer Considerations

Patients with DKA should not be transferred until therapy has begun and the condition is stable or improving. Continuing care should be at a facility that has an obstetrician or maternal–fetal medicine physician available to assess fetal status.

OTHER PROBLEMS ASSOCIATED WITH DIABETES IN PREGNANCY

Urinary Tract Infection or Pyelonephritis

Urinary tract infections are more common during pregnancy among diabetic women. Early diagnosis and treatment of bacteriuria and cystitis can prevent the development of pyelonephritis. Pyelonephritis, a common antecedent of DKA during pregnancy, requires hospital admission for administration of i.v. antibiotics and metabolic surveillance (see later section, "[Urinary Tract Infection in Pregnancy](#)," for treatment recommendations).

Preeclampsia

The frequency of preeclampsia is greatly increased among women with diabetes. Compared with a 5% to 8% incidence in the normal population, as many as 25% of pregnancies among diabetic women become complicated by preeclampsia.¹⁴ Patients may present with asymptomatic hypertension or with complaints such as headache, epigastric or right upper quadrant pain, visual disturbances, and eclamptic seizures. The combination of preeclampsia and diabetes significantly increases the risk of perinatal loss. Immediate consultation with the obstetric service is advised if blood pressure elevation (greater than or equal to 140/90) is detected.

Yeast Vulvovaginitis

Vaginal pruritus caused by yeast infection is frequently seen among diabetic women during pregnancy. Presenting complaints include vaginal itching, dysuria, and dyspareunia. The diagnosis is confirmed by culture or microscopic identification of mycelia or pseudohyphae on direct microscopy in a potassium hydroxide 10% preparation. During pregnancy, miconazole nitrate 2% cream (Monistat) applied daily for 7 days or clotrimazole 100-mg vaginal tablets at bedtime for 7 days provides prompt resolution in most patients.

Significant Decrease in Fetal Movement

Pregnancy among diabetic women is associated with an increased risk of stillbirth. Decreased fetal movement may be an early warning sign of impending fetal demise. Any pregnant woman who perceives a significant decrease in fetal movement after the twenty-fourth week of pregnancy should be evaluated. Immediate consultation with the obstetric service for antepartum fetal heart rate testing is prudent.

Myocardial Ischemia

Any diabetic woman with complaints suggesting myocardial ischemia should be thoroughly examined. Ischemic heart disease is unusual among diabetic women during pregnancy, it but carries a grave prognosis. Most such patients have been at least 30 years of age. The outcome in one study of 12 women with myocardial infarctions occurring either before or during pregnancy reported a 66% maternal mortality rate.¹² Because of the poor prognosis, termination of pregnancy with permanent sterilization is recommended for any diabetic woman with ischemic heart disease.

Childbirth Complicated by Macrosomia with Possible Shoulder Dystocia

The delivering physician should be able to perform appropriate maneuvers for safe delivery if shoulder dystocia occurs. The possibility of this complication, often associated with poor control of glucose levels, should always be considered prior to attempted vaginal delivery of a diabetic woman.

Visual Loss Due to Diabetic Retinopathy

The pregnant woman with preexisting diabetes should have an ophthalmic examination for early detection of diabetic retinopathy. Although once thought to be hastened by pregnancy, background diabetic retinopathy may not adversely be affected by it.⁷ Some women with long-standing, poorly controlled diabetes also have proliferative retinopathy, which (unless prepregnancy laser therapy has been performed) has the potential for vitreous hemorrhage and permanent loss of vision. Delivery is indicated in such women if progressive visual loss occurs. Macular edema has been recognized among pregnant diabetic women and is usually associated with hypertension and proteinuria.¹³

Preterm Labor

b-Sympathomimetic drugs, such as terbutaline, used to treat preterm labor can cause extreme elevations in glucose levels and even DKA in diabetic women. If treatment of preterm labor is necessary, i.v. magnesium sulfate has no effect on blood glucose and is the drug of choice.

Maternal Glucose Control

The ability to make frequent capillary blood glucose measurements at home has reduced both maternal and perinatal mortality and morbidity.⁹ Home glucose monitoring has become an important part of prenatal care for diabetic women, especially those requiring insulin.^{6,16} Such glucose determinations are made one to four times daily, depending on recent glucose control. When a diabetic gravida presents to the emergency department, the physician should inquire about the availability of recent data from home glucose monitoring.

Capillary blood glucose determinations have shown a good correlation with plasma samples, especially in the fasting state. However, after carbohydrate ingestion, values differ from plasma levels by as much as 15%, with capillary values being higher.¹⁵

Urine testing for glucose has no role in the management of diabetes during pregnancy. Even during normal pregnancy, glucose can occasionally be detected in the urine. The cardiac output increases by 40% during pregnancy, accompanied by a similar increase in renal perfusion and glomerular filtration rate. These increases lead to more filtered substrate, in this case, glucose. If tubular reabsorption is not equally increased, glucosuria may be present, even at low blood glucose levels. It is necessary for the pregnant diabetic to rely on capillary glucose monitoring to determine optimal insulin dosage. Thus, urine testing for glucose has been virtually abandoned during pregnancy. However, there remains a place for the home measurement of urine ketones, especially when hyperglycemia is persistent.

Insulin Management during Pregnancy

Most diabetic women require split-dose or multiple injections of regular and NPH insulin to achieve adequate control. Traditionally, the total dose of insulin is given as two-thirds in the morning and one-third at night. The starting morning dose consists of two-thirds NPH and one-third regular; the evening dose is one-half NPH and one-half regular. This "ideal" insulin regimen will vary, depending on capillary glucose surveillance. During pregnancy, perinatal morbidity and mortality are related to the degree of glycemic control; therefore, the goal of insulin therapy during pregnancy is blood glucose levels that are essentially in the euglycemic range (fasting, 60 to 90 mg/dL; 2 hours after each meal, 90 to 120 mg/dL).

Oral Hypoglycemic Agents

The level of glycemic control achieved with oral agents is not satisfactory during pregnancy. These agents readily cross the placenta and may lead to stimulation of fetal insulin secretion. High fetal insulin concentration is associated with fetal macrosomia and resultant myocardial hyperplasia, stillbirth, and delayed fetal lung maturation. For these two reasons, oral hypoglycemic agents have no use in pregnancy. On the other hand, oral agents have not been associated with birth defects among humans.

DISPOSITION

Role of the Consultant

Diabetes in pregnancy is a high-risk situation for mother and fetus. Optimal prenatal care requires either a maternal–fetal medicine physician or an obstetrician experienced in the management of diabetes in pregnancy. Maternal–fetal medicine physicians are specially trained in the management of such pregnancies. If such a subspecialist is not available, the combined efforts of an obstetrician to oversee management of the pregnancy and an internist to assist in insulin adjustments are advised.

Indications for Admission

Admission is indicated when poor glucose control remains uncorrected after 3 to 4 days of home glucose monitoring and insulin adjustment, as well as when complications are present, including hyperemesis gravidarum, DKA, preeclampsia, pyelonephritis, dehydration, and febrile illness (viral or bacterial).

COMMON PITFALLS

- The main cause of fetal loss among diabetic women is birth defects. This risk can be reduced only by achieving euglycemic control at the time of conception and throughout the first 7 to 10 weeks of pregnancy.
- Because perinatal outcome is related to glycemic control, acceptable blood glucose levels during pregnancy are significantly lower than for the nonpregnant woman.
- Urine glucose testing during pregnancy is altered by the increased glomerular filtration rate and has been abandoned.
- During pregnancy, DKA can occur with blood glucose levels as low as 200 to 300 mg/dL.
- As a result of accelerated starvation ketosis, ketones in the urine and even in the blood can occur with normal blood glucose levels.

GESTATIONAL DIABETES

Approximately 3% of pregnant women will develop gestational diabetes. Because of the insulin resistance caused by the placental hormone, human placental lactogen, the maternal response at meals is characterized by hyperinsulinemia and higher glucose concentrations than in the nonpregnant state. Some women cannot increase their insulin secretions to meet this demand and will develop hyperglycemia after meals. These women have gestational diabetes. Only about 15% of gestational diabetics will eventually develop fasting hyperglycemia and require insulin therapy. Human placental lactogen production is a reflection of placental mass, so carbohydrate intolerance in gestational diabetes is generally not present until after 26 to 28 weeks of pregnancy. Because these women are euglycemic during early pregnancy, there is no increased risk for fetal malformations.

DIAGNOSIS

Most experts recommend gestational diabetes screening for all women during pregnancy, a practice currently followed by practically all obstetricians in the United States.³ A 50-g oral glucose load is given without regard to the last meal, and a serum glucose determination is made 1 hour later. A value higher than 140 mg/dL is considered abnormal, and a 100-g oral 3-hour glucose tolerance test (OGTT), following 3 days of unrestricted activity and carbohydrate intake, is performed.

The currently accepted upper limits of normal serum glucose values for this OGTT are 105, 190, 165, and 145 mg/dL fasting and 1, 2, and 3 hours after ingestion, respectively. If two or more values are elevated, the diagnosis of gestational diabetes is made, the woman is prescribed a diabetic diet, and glucose surveillance is begun. Selective screening, a lower 1-hour glucose screening threshold, and somewhat lower acceptable values for the 3-hour OGTT have recently been proposed and challenged.¹⁰

EMERGENCY DEPARTMENT MANAGEMENT

The diet typically prescribed is a 30- to 35-cal/kg (ideal body weight) American Diabetic Association diet. The woman is then followed with fasting and 2-hour postprandial serum glucose determinations every 1 to 2 weeks, although the necessity of measuring the postpartum value has been questioned if the fasting values remain normal.⁸ Gestational diabetes is associated with two major risks. Fifteen percent of women will develop fasting hyperglycemia (greater than or equal to 105 mg/dL) and require insulin. Fetal macrosomia with resulting birth trauma is a major risk. When delivering a patient with gestational diabetes, the physician should be able to perform appropriate maneuvers if shoulder dystocia occurs. Hypoglycemia may develop in the newborn soon after delivery. Approximately 60% of gestational diabetics develop overt diabetes later in life.

Urinary Tract Infection in Pregnancy

Urinary tract infection (UTI) is one of the most common medical complications in pregnancy and is a frequent cause of emergency department visits.^{1,9} Females have a higher rate of UTIs than males, presumably because of the shorter urethra, the easy entry of bacteria into the bladder during sexual intercourse, and incomplete bladder emptying. The physiologic changes of pregnancy worsen the risk for UTI and render the upper tract more susceptible to infection.

In pregnancy, the bladder has decreased tone and increased capacity. These changes increase stasis and the risk for vesicoureteral reflux, especially in women who had urologic procedures as children to correct such reflux.² The ureters are physiologically dilated, due to a decrease in ureteral muscle tone and peristalsis, secondary to progesterone increases during pregnancy. In addition, there is ureteral compression by the enlarged pregnant uterus and the enlarged ovarian veins, and the urine is made nutritionally rich from nutrients filtered by the glomeruli in excess of the tubular capacity for their resorption.

The typical microbiologic isolates in UTI are similar in pregnant and nonpregnant patients.¹¹ *Escherichia coli* accounts for over 75% of all isolates. Other gram-negative aerobes, such as *Klebsiella* and *Proteus*, are also commonly isolated. Both enterococci and group B streptococci have been implicated in UTI. *Staphylococcus saprophyticus* is also an occasional uropathogen.

CLINICAL PRESENTATION

In pregnancy, UTI may be divided into asymptomatic bacteriuria (ASB), cystitis, and pyelonephritis. Both untreated ASB and cystitis may progress to upper tract (renal) infection, especially pyelonephritis.

By definition, the pregnant patient with ASB has no urinary tract symptoms. Four percent to 7% of all pregnant women have bacteria in their bladders without symptoms. The importance of this fact is that if the ASB is left untreated, about 25% of pregnant patients will develop pyelonephritis during pregnancy, labor, or the immediate puerperium. This percentage represents most of the 1% to 2% of all gravidas who will suffer from pyelonephritis.⁴ Therefore, all pregnant patients ideally should be screened for ASB at the time of the first prenatal visit. Many women, however, do not seek prenatal care, early or ever, and many of these same women use the emergency department for various complaints.

Although there are no studies clearly showing a favorable cost-to-benefit ratio, a urinalysis or urine culture performed on such women during an emergency department visit for any complaint would probably be prudent. The usual definition of ASB requires that a single pathogen be isolated at a concentration greater than 100,000 colony-forming units (CFUs) per milliliter; however, the pregnant patient in the emergency department who has an uncontaminated urinalysis with bacteria and leukocytes should be treated. Eradication of ASB will largely prevent progression to pyelonephritis.

Cystitis commonly presents as urinary frequency, urgency, and dysuria. Suprapubic discomfort and tenderness are variably noted. However, UTI confined to the bladder does *not* result in fever or costovertebral angle tenderness. A urine culture with a single pathogen at greater than 100,000 CFU/mL is considered pathognomonic for infection. However, it has been clearly shown that, in symptomatic patients, a concentration of greater than 100 CFU/mL in the *bladder* urine is sufficient to confirm the diagnosis and justify treatment. The caveat here is that care must be taken to exclude vulvovaginal contamination, lest the diagnosis of cystitis be overcalled. The spun (and occasionally unspun) urine sediment reveals numerous leukocytes and rod-shaped bacteria, which may or may not be motile. Appropriately and promptly treated patients with cystitis typically respond quickly and have a good prognosis. Inadequate or delayed therapy may result in progression to pyelonephritis and its possible complications.

Classically, the gravida with pyelonephritis presents with chills, fever, flank pain, nausea, vomiting, urinary frequency and urgency, and dysuria.⁹ The presence of fever with costovertebral angle tenderness in a patient with a positive, uncontaminated urinalysis or urine culture is diagnostic. As noted, the prevalence rate of pyelonephritis in pregnancy is 1% to 2%. This infection is always serious, but it can be more so in the pregnant patient. Gravid women may develop preterm labor, which may result in preterm delivery. Although the direct mechanism linking pyelonephritis and preterm labor has not been elucidated, it is postulated that bacterial endotoxin may result in cytokine or prostaglandin release from the decidua or membranes,⁸ or that some bacteria release precursors of prostaglandins that are important in the initiation and maintenance of labor. Pyelonephritis, therefore, may lead to perinatal wastage.

Pyelonephritis may have other serious consequences in pregnancy.¹⁰ Approximately 20% of gravidas with this infection have transient renal dysfunction with decreased creatinine clearance.⁴ About 15% of these gravidas have bacteremia, so blood cultures are prudent. Uncommonly, septic shock may develop, even after treatment has begun.⁷ Prolonged fetal bradycardia, not representing fetal distress but due to maternal hypothermia, also may be seen.⁵ Adult respiratory distress syndrome has been reported as a consequence of urosepsis in such patients.³ Very rarely, acute renal failure may result from pyelonephritis during pregnancy.¹³

EMERGENCY DEPARTMENT MANAGEMENT

Because ASB may progress to cystitis and pyelonephritis during pregnancy, gravid women who have not received prior prenatal care or undergone prior urinary screening tests should have a urinalysis to exclude ASB. Initially, a clean-catch urine specimen can be obtained; however, vulvovaginal contamination is common in pregnant women, and graphic instructions should be given to promote proper collection technique. Catheterization should be avoided if possible. In an uncontaminated urine specimen (no or few epithelial cells), the presence of rod-shaped bacteria indicates ASB. Such a urine specimen should be sent for culture. More than 100,000 CFU/mL of a single urinary pathogen is considered diagnostic. Treatment, however, should begin with the urinalysis findings and not await the culture results.

Treatment for ASB in the pregnant patient consists of 7 to 10 days of amoxicillin (500 mg PO every 6 hours), nitrofurantoin (100 mg PO three to four times per day), or

a short-acting sulfonamide (with or without sulbactam). Because both nitrofurantoin and sulfonamides can displace bilirubin from its albumin-binding sites, with resultant neonatal hyperbilirubinemia, these two drugs should be avoided in the third trimester. Amoxicillin is the drug of choice in the third trimester. In areas where a high percentage of gram-negative aerobes (such as *E. coli*) show ampicillin resistance, cephalexin (250 mg every 6 hours) is an acceptable alternative.⁶

Patients with symptoms of cystitis should likewise provide a clean-catch urine specimen for urinalysis and culture. The presence, in an uncontaminated specimen, of leukocytes and rod-shaped bacteria confirms the diagnosis of cystitis. A urine culture should also be done; in symptomatic patients, only greater than 100 CFU/mL are required to demonstrate an infection. Although catheterization should be avoided, it may be necessary in symptomatic patients from whom an uncontaminated specimen cannot be obtained. Treatment of cystitis is the same as that of ASB.⁶

Pyelonephritis requires prompt and appropriate attention. The diagnosis of pyelonephritis is most commonly made with the finding of a positive urinalysis, fever, and costovertebral angle tenderness. Because of the possible complications of renal infection, pregnant patients with pyelonephritis should, with rare exception, be hospitalized. Many of these patients are dehydrated. Clinical management includes intravenous (i.v.) hydration, i.v. antibiotics, antipyretics, and close observation for septic shock and renal dysfunction.

Because the predominant pathogens are gram-negative aerobes, ampicillin (2 g i.v. every 6 hours) or ceftriaxone (1 to 2 g/d) is a good initial drug. Again, however, if a high percentage of the gram-negative aerobes (especially *E. coli*) shows resistance to ampicillin, then cefazolin (1 g i.v. every 6 hours) is the drug of choice. With the exception of patients who appear septic, are allergic to the initial therapy, or are not responding to the initial therapy, aminoglycosides should be avoided because of the high prevalence of transient renal dysfunction.¹⁵ If the patient appears septic, therapy with ampicillin or cefazolin plus an aminoglycoside (1.0 mg to 1.5 mg/kg every 8 hours) should be initiated. All pregnant patients who receive aminoglycosides should have a serum creatinine level determined to exclude renal dysfunction, and then serum monitoring of aminoglycoside levels.¹⁶ Ciprofloxacin is not recommended for use in pregnancy, because adequate human studies are not available.

If the patient does not respond within 48 hours, the clinician should consider the possibility of a resistant organism or urinary tract obstruction. Antibiotic changes appropriate to now-available culture and sensitivity data, intravenous pyelography, or ultrasonography may be appropriate.

DISPOSITION

Patients with cystitis or pyelonephritis are at risk for preterm labor and delivery.⁸ Therefore, any pregnant patient with these infections should be evaluated for contractions and have her cervix examined. After midpregnancy, the presence of frequent contractions (more than 3 per hour) should be ruled out with an external fetal monitor. The preterm presence of frequent contractions or of an effaced or dilated cervix should prompt an evaluation by the obstetric consultant. Like pyelonephritis, preterm labor is an indication for admission and treatment with both antibiotics and tocolytic agents, such as terbutaline or magnesium sulfate. In the presence of urosepsis and overzealous hydration, pulmonary edema may be precipitated by the use of i.v. catecholamines, such as terbutaline.

An important consideration for pregnant patients with any UTI is follow-up. Pregnant patients with a prior UTI have a high rate of recurrence. In a retrospective analysis of pyelonephritis, 60% of patients required rehospitalization for a UTI.¹² Close follow-up with repetitive urine cultures to identify ASB for the remainder of pregnancy is important to prevent reinfection. If ASB is subsequently found, it should be treated as outlined previously. Another option to prevent reinfection in patients with a prior UTI is antibiotic suppression, usually accomplished with nitrofurantoin (100 mg PO every night), for the remainder of the pregnancy; such a regimen has been shown to reduce recurrence of bacteriuria to 8%.¹⁴ Because close monitoring or suppression is commonly necessary, the patient's obstetrician should be notified of the infection or arrangements made to ensure prenatal care and appropriate follow-up.

Infections in pregnancy affect not only the infected patient, but also the fetus and the course of the pregnancy. The stage of pregnancy influences the physician's choice of therapy. Those who care for pregnant women must modify both their approach and their treatment of infections in this population. Physicians often need to choose more aggressive management, because infections are tolerated less well in pregnancy. An example is the pregnant patient with pyelonephritis who requires hospitalization for antibiotic treatment, whereas most nonpregnant patients with this disorder can be managed as outpatients. The choice of drug therapy is also guided by information regarding teratogenicity and toxicity to the fetus. The way drugs are prescribed in pregnancy may differ from therapy for nonpregnant patients. The presenting signs and symptoms of infection of various organ systems in the pregnant patient are usually identical to those in the nonpregnant patient. However, special considerations regarding diagnostic procedures and management are key to resolving infections with the least morbidity to the pregnant patient and fetus.

RESPIRATORY TRACT INFECTIONS

Pneumonia

In the preantibiotic era, maternal mortality from antepartum pneumonia was high. More recently, antibiotic therapy has contributed to an overall downward trend in both maternal and fetal morbidity and mortality, although pneumonia remains a potentially serious complication of pregnancy. There is no evidence that pregnancy places the mother at increased risk for acquiring a respiratory tract infection. Therefore, pregnant patients presumably encounter the same risks as nonpregnant patients in comparable health. Underlying chronic diseases, especially asthma, and maternal smoking may influence the incidence of pneumonia in pregnancy as in the nonpregnant patient.¹⁵

Cough, sputum production, and fever are the hallmarks of pneumonia. Physical examination often reveals a mildly ill patient with fever. Auscultation and percussion confirm the presence of infiltrates or lobar consolidation. Evaluation should consist of obtaining a sputum sample to check for white blood cells and perform a Gram stain and culture. Blood cultures should be performed, along with a complete blood cell count and differential. The diagnosis is supported by a chest radiograph with abdominal shielding to evaluate the extent of infiltrates. For the fetus, there is minimal radiation (usually less than 1 rad) with an anteroposterior, lateral, and occasional oblique chest film. Lobar consolidation is more consistent with bacterial infection, while patchy infiltrates are seen with a viral infection. The two most common organisms that cause pneumonia in this population are *Streptococcus pneumoniae* and *Mycoplasma pneumoniae*.

Treatment usually includes admission and intravenous antibiotics. Although pneumonia can be treated in the outpatient setting in the nonpregnant patient, normal physiologic changes of pregnancy decrease functional residual lung capacity in the gravid patient. Because of less reserve, hospitalization for most pregnant patients with pneumonia is prudent. Although there are no studies indicating that pregnant patients with pneumonia are sicker than nonpregnant patients, there remains a risk for the development of fulminant illness, including septic shock and acute respiratory distress syndrome. Optimal therapy for pneumococcal pneumonia (penicillin V potassium [Pen Vee-K], 500 mg PO four times daily for 7 to 14 days) differs from therapy for mycoplasmal infection (erythromycin, 250 to 500 mg PO four times daily for 14 days). An effort should be made to distinguish the two, using history, physical examination, and serologic and laboratory information.

Viral Infections (Respiratory)

Viral infection in general, but particularly influenza, predisposes to bacterial superinfection. Patients should be watched closely for worsening symptoms. Influenza vaccination is not contraindicated in pregnancy and is, in fact, recommended for women with underlying medical conditions.¹ Other upper respiratory tract infections such as laryngitis and bronchitis in previously healthy patients without chronic asthma are caused by various viral agents. These usually do not require antibiotic therapy. Symptomatic and supportive care with particular attention to hydration is often sufficient. Some infections may create enough inflammatory response in the respiratory tract to constitute reactive airway disease. Appropriate symptomatic treatment is indicated. Upper respiratory tract viral infections are also the most common precursors of acute bacterial sinusitis via a variety of mechanisms. The symptoms, evaluation, and treatment of sinusitis do not differ based on pregnancy status, with the exception of abdominal shielding for radiographs when needed.

Tuberculosis

Tuberculosis is another respiratory tract infection that may be detected in pregnancy. It is often asymptomatic, but it should be suspected in a patient with lethargy, respiratory complaints, and recent immigration from an endemic area. A chest radiograph demonstrates patchy parenchymal infiltrates with adenopathy and pleural effusion. Although tuberculin skin testing is valuable in pregnancy, definitive diagnosis relies on demonstration of *Mycobacterium tuberculosis* in sputum culture. Multidrug therapy with isoniazid (300 mg PO daily) plus rifampin (600 mg PO daily) for a minimum of 9 months is the regimen of choice for active disease.¹⁴ Ethambutol (2.5 g PO daily) should be added if drug resistance is suspected. Pyridoxine (vitamin B₆, 50 mg PO daily) should be administered concomitantly with isoniazid to prevent potential neurotoxicity. Rifampin has been reported to cause hemorrhagic disease of the newborn. To prevent this complication, prophylactic administration of vitamin K in the third trimester is recommended. Streptomycin should not be used, due to the risk of fetal ototoxicity. The patient should be referred to her obstetrician or the local health department for follow-up of drug toxicity, congenital disease in the newborn, and chemoprophylaxis of the infant.⁹

Pneumocystis carinii Infection

In the pregnant woman with respiratory compromise who is positive for human immunodeficiency virus (HIV) infection, the differential diagnosis must include *Pneumocystis carinii* pneumonia (PCP). Although there are no pathognomonic clinical features, the fever, dyspnea, and hypoxemia seen in patients with PCP are usually quite profound. Rales are frequently absent. The chest radiograph shows diffuse interstitial pneumonitis and air bronchograms. Definitive diagnosis relies on demonstration of the organism in lung tissue by means of percutaneous or open lung biopsy or bronchoalveolar lavage. Hospitalization is warranted for oxygen

therapy, supportive care, and antibiotic treatment with trimethoprim–sulfamethoxazole or pentamidine. If left untreated, PCP is universally fatal.

Summary

The most important consideration in the pregnant patient with an upper respiratory tract infection, regardless of theoretical expectations of the clinical course of the infection, is the concern that adequate oxygenation be maintained. Maternal hypoxia affects fetal oxygenation. Although some recommend that all pregnant patients with pneumonia undergo PO₂ assessment, clinical judgment must be used in deciding which patient does *not* need an arterial blood gas analysis. Overall, if there is a question regarding adequate oxygenation, an arterial blood gas analysis should be performed.

VIRAL INFECTIONS

Viral syndromes in pregnancy pose variable risks to the unborn fetus. Maternal morbidity and mortality are rare. Therefore, emergency department management involves supportive care and prevention of communication to other potentially pregnant women (including personnel and other patients).

Torch

TORCH (toxoplasmosis, other [hepatitis B virus, varicella zoster], rubella, cytomegalovirus, and herpesvirus) is discussed below.

Varicella (chickenpox) is associated with a pathognomonic vesicular outbreak. *Rubella (German measles)* is rare but may cause malaise and generalized fatigue. Viremia and transmission by respiratory droplets can occur before a rash develops for varicella (10 to 21 days) and after exposure in rubella infections (10 to 21 days). The diagnosis of varicella is most often made clinically on the basis of the pathognomonic skin eruption, although serologic confirmation is available. The diagnosis of rubella is made by a fourfold rise in immunoglobulin-G (IgG) serum titers or IgM-specific tests. Serum for IgG determination should be drawn initially and then 2 to 3 weeks later, with both specimens run simultaneously to assess increasing IgG titer over time.⁶ Infection in early pregnancy (first trimester) causes the most fetal harm and can result in congenital abnormalities of the cardiac, neurologic, musculoskeletal, and ophthalmic systems. These patients should be referred to an obstetrician for counseling and follow-up. It is critical that the patient call her obstetrician before entering the office to avoid exposing other patients to the virus. Rubella vaccine for nonimmune patients should not be administered in pregnancy or within 3 months prior to conception.

Infection in late pregnancy by either virus seldom affects pregnancy outcome. In the immunosuppressed state of pregnancy, however, evolution of *varicella pneumonia* should always be considered. Varicella pneumonia in pregnancy increases the risk of maternal complication and death, with mortality as high as 40%. The patient suspected of having varicella pneumonia should be admitted to the hospital because acute respiratory distress syndrome may develop rapidly.

Peripartum varicella infection (from 5 days before delivery through 2 days after delivery) places the fetus at high risk for morbidity and mortality. Passive transmission of protective maternal antibodies to the disease has not yet occurred in this window. In addition, premature labor is always a concern, particularly in the presence of infection. Attempts should be made to determine whether the patient is in labor by asking about contractions (abdominal tightening and back pain). Patients who are suspected of being in labor should be sent to the labor and delivery room for evaluation.

Varicella zoster immune globulin (VZIG) should be administered to susceptible pregnant women within 96 hours of exposure to the disease in hopes of tempering the severity of the illness. There is *no* evidence that administration of VZIG to this population will prevent maternal viremia, fetal infection, or congenital varicella syndrome. VZIG can be obtained from the American Red Cross.

Most adults infected with *cytomegalovirus (CMV)* are essentially asymptomatic. Unfortunately, CMV is the most common cause of intrauterine infection. Documented in 0.5% to 2.5% of all deliveries, CMV infection has a wide range of effects, ranging from rare but significant neurologic damage in the fetus to simply producing an asymptomatic carrier state accompanied by viral shedding. In light of the difficulty of diagnosis due to its asymptomatic presentation and low incidence of fetal morbidity, clinicians are limited to obtaining laboratory data and confirming seroconversion.

Toxoplasmosis, a protozoan infection, is usually asymptomatic. Rarely, the patient may present with a mononucleosis-like picture. Most infections are self-limited without significant complications. Many newborns are asymptomatic. No increase in fetal death is observed. For the rare affected newborn, a constellation of central nervous system and ophthalmic problems may be noted. If toxoplasmosis or CMV infection is suspected in pregnancy, the patient should be referred for counseling and serologic testing.

Mumps virus, a paramyxovirus, is transmitted by respiratory secretions. Typically, the patient presents with fever, malaise, myalgia, and anorexia, followed by parotitis in 24 hours. Treatment of mumps is supportive, and there is no observed increase in maternal morbidity or mortality. Mumps infection in the first and second trimesters may be associated with increased fetal loss. However, there is no fetal congenital disorder clearly associated with maternal mumps infection.

Human parvovirus B19 is the etiologic agent of erythema infectiosum (fifth disease). Presentation in adults is frequently that of a flulike illness with fever, adenopathy, arthralgias, and arthritis, particularly of the hands. Rash is usually absent. Up to 20% of those infected may remain asymptomatic. Serologic testing for IgG- and IgM-specific antibodies to human parvovirus B19 is available and should be used if exposure is suspected. Parvovirus infection is associated with an increased risk of fetal hydrops and stillbirth.¹² It has been described, as well, in conjunction with a variety of fetal anomalies (causation is unclear) and congenital anemia. The patient should be referred to an obstetrician for counseling, follow-up serologies, and ultrasonography. Infection appears to confer lifelong immunity.

Herpesvirus infection in pregnancy raises concern for neonatal transmission associated with vaginal delivery. From 4% to 8% of infants delivered through the infected birth canal of a mother with recurrent herpes will acquire the infection. The neonatal infection rate approaches 50% with vaginal delivery if the maternal herpes outbreak is primary. Approximately 25% of infants infected during delivery will die of disseminated disease. Patients often complain of pain from acute lesions of the perineum. Accurate emergency department diagnosis is critical for management in later stages of pregnancy by the patient's obstetrician. A herpes culture should be obtained from the base of suspicious lesions with a cotton-tipped swab. (Calcium alginate swabs have been found to inactivate the herpesvirus.) Accurate documentation of the status of the membranes is paramount. If uterine contractions and rupture of the membranes have occurred, the patient should be transferred immediately to the labor suite. The emergency physician should provide supportive care, including analgesics and suggestions about hygiene (e.g., Burow's solution soaks to the perineum). The use of acyclovir in pregnancy has been reported in over 300 cases.² Although there is no indication of fetal toxicity, use of acyclovir continues to be dictated by the severity of maternal illness. Acyclovir therapy may be indicated for disseminated herpes simplex virus (HSV) or varicella pneumonia. Routine use to ameliorate severity or duration of recurrent outbreaks has not been studied in pregnant subjects, although suppressive doses are used frequently in HIV-positive gravidas with severe or frequent herpes outbreaks.

Viral hepatitis in pregnancy in the United States follows the same disease course as in nonpregnant patients. Fetal morbidity and mortality are not increased.¹¹ Diagnosis is made by serologic identification of specific viral antigens and antibodies. Symptoms include malaise, nausea, vomiting, fatigue, and nonspecific gastrointestinal symptoms. The symptoms of hepatitis are similar to those of morning sickness.

Jaundice, icteric sclera, and dark urine may be seen. However, spider angiomas and palmar erythema are normal findings in pregnancy. Serum transaminase levels are not altered in pregnancy, so elevated values may indicate hepatitis. A threefold to fourfold elevation of alkaline phosphatase levels is usual in pregnancy due to placental production. Acute hepatitis A virus (HAV) may be diagnosed by detecting IgM anti-HAV serologically, whereas hepatitis B virus (HBV) is seen with hepatitis B surface antigen. Hepatitis B e antigen should also be determined if the surface antigen for hepatitis B is positive, because "e" positivity correlates with infectivity and indicates an increased risk for fetal transmission.

Therapy for pregnant patients is similar to that for nonpregnant patients. Hospitalization is recommended for the patient who is unable to maintain fluids or who is severely debilitated. All patients with elevated coagulation studies (prothrombin time, partial thromboplastin time) require hospitalization.

For pregnant women at high risk for hepatitis B, immune-specific vaccine and globulin can be given safely during pregnancy for preventive purposes. The usual dose for hepatitis B vaccine is 1 mL intramuscularly, followed by repeat doses 1 and 6 months later. Because the vaccine is made of purified proteins, placental transmission is not a risk. Prophylaxis given at the same time as the vaccine can be administered as an intramuscular injection of hepatitis B–specific immunoglobulin (0.06 mL/kg as soon as possible after exposure). Pregnant women exposed to hepatitis A should be given gamma globulin prophylactically (0.62 mL/kg within 2

weeks of exposure).

Hepatitis C (blood-borne non-A, non-B hepatitis) is diagnosed by the detection of either hepatitis C-specific antibody or hepatitis C-specific RNA. Seventy-five percent of patients are asymptomatic and anicteric.¹⁰ The distinction between hepatitis C and other viral liver infections is important because up to 50% of patients with hepatitis C maintain abnormal chemical markers for liver disease more than 1 year after diagnosis. This is presumptive of chronic active hepatitis and predisposes the patient to cirrhosis. Pregnancy does not appear to alter the course of disease. Vertical transmission to the fetus has not been reported in the absence of detectable hepatitis C-specific RNA. Interferon treatment is contraindicated in pregnancy.¹⁰

Hepatitis D (delta hepatitis) can infect only in the presence of hepatitis B. Acute coinfection is not usually more virulent than hepatitis B alone and presents with a similar clinical picture. However, superinfection, which occurs when delta hepatitis develops in a chronic carrier of hepatitis B, generally leads to more severe disease, including cirrhosis and portal hypertension. Serologic detection of hepatitis D is limited because the anti-delta antibody is transient unless chronic infection develops. Management strategy for delta hepatitis involves the prevention of hepatitis B infection through vaccination.

Clinically, hepatitis E (enteric non-A, non-B hepatitis) presents with gastroenteritis and hepatitis similar to HAV. Routine serologic testing is unavailable at this time. Hepatitis E should be suspected in any gravida with appropriate history in whom tests for HAV, HBV, and HCV are negative. The course of the disease in pregnancy is not well documented. Treatment is generally supportive.

Hepatitis G, also known as GBV-C, has been described. It frequently coexists with hepatitis C and, similarly, is transmitted parenterally. Vertical transmission to the fetus, however, is much more common with hepatitis G. Its clinical role in acute and chronic liver disease is unclear.¹⁷

GASTROINTESTINAL INFECTIONS

Nausea and vomiting can occur at any time in pregnancy, although morning sickness typically occurs in the first trimester. If accompanied by diarrhea or malaise, the differential diagnosis includes viral gastroenteritis (rotavirus, Norwalk virus) and bacterial food poisoning. Nausea, vomiting, and chronic fatigue may also suggest the possibility of hepatitis.

Gastroenteritis in pregnant patients is similar to gastroenteritis in nonpregnant patients. Viral gastroenteritis has a variable incubation period and is brief and self-limited. Symptoms include nausea and vomiting with or without a low-grade temperature. Therapy is usually supportive, with fluids and rest. Of major concern in pregnancy, however, is dehydration and the ability to maintain oral intake. In the patient with a large amount of ketonuria, hospitalization may be recommended for intravenous supplementation and correction of electrolyte imbalance.

Bacterial gastroenteritis (caused by *Salmonella*, *Shigella*, *Campylobacter*, *Staphylococcus*, *Bacillus cereus*, *Clostridium*, or *Vibrio* species) may occur in pregnancy. Symptoms begin abruptly with nausea and crampy abdominal pain, often followed by diarrhea. High fever (greater than 38.5°C [101.3°F]) and chills are often present. The volume of diarrhea may be large. Mucus and blood may be present. Diagnosis is made from fresh stool cultures. Dehydration may be significant, and hospitalization is often necessary. Antibiotics for *Salmonella* and *Shigella* infections are not standard in the healthy adult nonpregnant population but should probably be initiated in pregnant patients who are moderately to severely affected, because therapy may decrease the duration of symptoms. Ampicillin (500 mg PO four times daily for 5 days) is recommended. Although not often seen in residents of the United States, parasitic infections in pregnant women can be found in recent immigrants from Southeast Asia and Latin America and in travelers. Parasitic infections may be less well tolerated by pregnant women because of altered immune function. Seemingly benign intestinal infections in the nonpregnant patient may cause increased morbidity during pregnancy. Fatal peritonitis with invasive parasitic disease has been described.⁵ Additionally, some parasites cross the placenta to infect the fetus. Parasites are most often spread by the fecal-oral route. Symptoms range from mild gastrointestinal complaints of constipation and flatulence to severe illness with massive bloody diarrhea and fever. History and physical examination may also reveal a variety of constitutional signs and symptoms, especially anorexia, weight loss, hepatomegaly, jaundice, and skin lesions. Besides supportive care, treatment of specific infections depends on the expected course. Unfortunately, many agents used to treat parasitic infections are also teratogenic. [Table 76.1](#) lists parasitic infections that require treatment and drug regimens considered safe in pregnancy.⁵

Parasite	Common Source	Characteristics	Diagnosis and Treatment	Stage in Pregnancy
<i>Toxoplasma gondii</i>	Undercooked meat, cat feces	Systemic, opportunistic	Diagnosis: IgG and IgM antibody; treatment: pyrimethamine-sulfadiazine	Second trimester
<i>Cryptosporidium parvum</i>	Cow, pig	Systemic, opportunistic	Diagnosis: stool culture; treatment: nitroimidazole	Second trimester
<i>Cyclospora cayentensis</i>	Cow, pig	Systemic, opportunistic	Diagnosis: stool culture; treatment: trimethoprim-sulfamethoxazole	Second trimester
<i>Isospora belli</i>	Cow, pig	Systemic, opportunistic	Diagnosis: stool culture; treatment: trimethoprim-sulfamethoxazole	Second trimester
<i>Sarcocystis hominis</i>	Cow, pig	Systemic, opportunistic	Diagnosis: stool culture; treatment: trimethoprim-sulfamethoxazole	Second trimester
<i>Microsporidia</i>	Cow, pig	Systemic, opportunistic	Diagnosis: stool culture; treatment: albendazole	Second trimester
<i>Strongyloides stercoralis</i>	Soil	Systemic, opportunistic	Diagnosis: stool culture; treatment: ivermectin	Second trimester
<i>Trichostrongylus axei</i>	Soil	Systemic, opportunistic	Diagnosis: stool culture; treatment: ivermectin	Second trimester
<i>Oxyuris equi</i>	Soil	Systemic, opportunistic	Diagnosis: stool culture; treatment: mebendazole	Second trimester
<i>Enterobius vermiciformis</i>	Soil	Systemic, opportunistic	Diagnosis: stool culture; treatment: mebendazole	Second trimester
<i>Trichuris trichiura</i>	Soil	Systemic, opportunistic	Diagnosis: stool culture; treatment: mebendazole	Second trimester
<i>Ascaris lumbricoides</i>	Soil	Systemic, opportunistic	Diagnosis: stool culture; treatment: mebendazole	Second trimester
<i>Clonorchis sinensis</i>	Raw fish	Systemic, opportunistic	Diagnosis: stool culture; treatment: praziquantel	Second trimester
<i>Monoilimonas</i>	Raw fish	Systemic, opportunistic	Diagnosis: stool culture; treatment: praziquantel	Second trimester
<i>Opisthorchis viverrini</i>	Raw fish	Systemic, opportunistic	Diagnosis: stool culture; treatment: praziquantel	Second trimester
<i>Paragonimus westermani</i>	Raw fish	Systemic, opportunistic	Diagnosis: stool culture; treatment: praziquantel	Second trimester

<i>Paragonimus</i> </				

Quinolone therapy must be avoided, because these drugs are teratogenic in animal models. Follow-up is important.

When pyelonephritis is suspected by the presence of fever and flank pain, complications such as septic shock and preterm labor may occur. All pregnant patients with pyelonephritis should be admitted for intravenous hydration and antibiotic therapy with a cephalosporin or an aminoglycoside.

Urethritis should be considered in patients with dysuria, white blood cells in the urinalysis, and *negative* urine cultures. A urethral culture for *Chlamydia trachomatis* should be done. Erythromycin is appropriate therapy.

SKIN INFECTIONS

Pthirus pubis (crab louse) and *Sarcoptes scabiei* (scabies) may present a problem in pregnant patients. Crab lice can be found in pubic hair, usually attached at the base of a hair or adjacent skin, and are transmitted through close physical contact. These nits can be found in other areas of the body as well, such as axillary and perianal hairs and eyelashes. The scabies mite causes pruritus from focal skin burrowing and intradermal deposition of eggs. Irritation is most often found on the back of the arms and legs and between the fingers. Excoriations may be the most obvious sign. Diagnosis is made by inspection, using a hand lens, of the high-yield areas. Because these infections are spread by intimate contact, family members need to be examined as well.

Other recommendations for improving hygienic situations should be given, such as washing all infected clothing, including bed sheets, and treating appropriate contacts. Both skin infections can be transmitted from mother to child through intimate contact. The finding of the crab louse should alert caretakers to the possibility of the presence of other venereal diseases, such as gonorrhea and chlamydial infection. Pyrethrins (RID), applied at night and washed off in the morning, are acceptable in pregnancy. Lindane (Kwell) has caused concern because of its suspected neurotoxic effect. If pyrethrins are not effective, referral to an obstetrician should be made for supervised lindane use in symptomatic patients.

VAGINAL, CERVICAL, AND OTHER LOWER GENITAL TRACT INFECTIONS

Vaginitis and Cervicitis

Lower genital tract discharge is most often vaginal but may be due to cervicitis. Evaluation of the vagina and cervix should include a speculum examination, testing the pH of vaginal secretions with phenolphthalein paper (Nitrazine), wet mount, and cultures of the cervix for *Neisseria gonorrhoeae* and *Chlamydia*. The differential diagnosis for a vaginal discharge in a pregnant patient should also include rupture of the membranes. This should be suspected in all pregnant patients, and a careful history obtained. Was a gush of fluid present? Is clear fluid present? Are contractions present? If there is suspicion of ruptured membranes, an assessment should be performed.

Pregnancy may be accompanied by a vaginal discharge that is physiologic or abnormal. Many women note an increase in asymptomatic vaginal secretions. A physiologic vaginal discharge occurs in pregnancy due to increased hormonal status; it is normally white and nonirritating and may drain onto the undergarments. Wet mount evaluation is remarkable for an acidic pH (less than 4.5) and numerous epithelial cells.

Pathologic vaginal irritations are caused by *Trichomonas vaginalis*, *Candida*, and bacterial vaginosis (previously called nonspecific vaginitis or *Gardnerella vaginalis* infection) (see [Chapter 85](#)).

It has been suggested that *T. vaginalis* may play a role in the pathogenesis of preterm labor and premature rupture of the membranes.⁸ At this point, however, no consistent recommendations exist. Treatment for *T. vaginalis* infection may be initiated for patients who are symptomatic with annoying malodorous and copious discharge. Motile organisms can be seen on microscopic analysis of secretions, and the pH is higher than 4.5. Single-dose therapy with metronidazole (2 g PO) is recommended, although multidose therapy (250 mg PO three times daily) should be used for recurrent cases. Sexual partners should be treated to prevent reinfection. The treatment of pregnant women with metronidazole (when used after 12 weeks of pregnancy) results in no increased risk of complications. *T. vaginalis* or bacterial vaginosis may suggest that the patient has a concomitant sexually transmitted disease (caused by *N. gonorrhoeae* or *Chlamydia*). The emergency physician may want to culture for these at the same visit.

Candida albicans is normally present in 10% to 20% of patients. In physiologic quantities, its presence causes no symptoms. With overgrowth of *Candida*, a patient's chief complaint is often pruritus with or without notable discharge. The vulva may also be irritated and result in extreme itching. The classic "cottage cheese" discharge is seen in only 10% to 20%. Hyphae and buds on the wet mount potassium hydroxide slide confirm the diagnosis. The vaginal pH is less than 4.5. Antifungal vaginal cream (clotrimazole [Gyne-Lotrimin] or miconazole nitrate 2% [Monistat], one applicator per vagina at bedtime for 5 to 7 nights), is recommended. Nystatin is not recommended. However, if no other agent is available, nystatin is not contraindicated but must be used twice daily for 14 days. Candidal vaginal infections are not associated with obstetric complications. Only symptomatic patients need to be offered treatment.

More than half of all patients with bacterial vaginosis are symptomatic. Symptomatic patients present with a chief complaint of a fishy, foul odor instead of vulvar or vaginal pruritus or discharge. Examination is remarkable for the lack of inflammation of vulva or vagina, hence the name *vaginosis*. Diagnosis is confirmed by (1) a positive amine test when potassium hydroxide is added to a slide with vaginal secretions, (2) a wet mount showing "clue" cells (epithelial cells studded with bacteria), (3) *Lactobacillus* morphotypes less than background bacteria, and (4) pH higher than 4.5. All patients should be offered treatment with metronidazole (500 mg PO twice daily for 5 to 7 days after first trimester) or clindamycin (300 mg PO three times daily for 7 days). Alternative therapy with intravaginal clindamycin cream or metronidazole gel may be considered, although systemic oral therapy may reduce the risk of pregnancy complications, while intravaginal treatment may not. Evidence suggests that patients with bacterial vaginosis are at increased risk for preterm premature rupture of the membranes, preterm labor, intraamniotic infection, and postpartum endometritis.⁸

Cervical infection (cervicitis) is characterized by cervical friability, erythema, ulcers, and discharge that is cloudy or purulent. *N. gonorrhoeae* and *Chlamydia* cause both symptomatic and asymptomatic cervicitis, and either may present as a yellow-green cervical discharge. However, both gonococcal and chlamydial infections may produce *no* mucopurulent discharge. A finding of excessive white blood cells on the wet mount examination in the presence of no visible pathogens should alert the clinician to the possibility of a sexually transmitted disease.

Gonorrhea and Chlamydial Infection

Although 75% to 90% of women with gonorrhea are asymptomatic, aggressive diagnosis and treatment are important. Obstetric complications from gonorrheal infections include premature rupture of membranes, preterm delivery, and chorioamnionitis (infection of the uterine cavity with a fetus *in utero*). Specimens from women with other venereal diseases (trichomoniasis, bacterial vaginosis, and chlamydial infection) and from patients with mucopus or complaints of a vaginal discharge should be cultured. All partners of culture-positive women need to be identified and treated. Patients with known exposure to *N. gonorrhoeae* or *Chlamydia* should be offered antibiotic therapy. Pregnant women with sexually transmitted diseases are also at risk for acquiring HIV infection.

The emergency department evaluation may include a Gram stain of endocervical material for gram-negative diplococci, but culture is the only means by which definitive diagnosis can be made. Cervical cultures are positive in 80% of patients with gonorrhea. Simultaneous chlamydial cultures should be performed, because 20% to 50% of all patients with gonorrhea have concomitant chlamydial infection. Although culture on select media was the standard for detection of *N. gonorrhoeae* and *Chlamydia* in the past, amplification techniques with ligase chain reaction (LGR) or polymerase chain reaction (PCR) are more reliable, widely available, and, often, less costly. Rapid antigen detection methods have not proved to have high yields.

Treatment of gonorrhea in pregnancy consists of ceftriaxone (125 mg i.m. in a single dose), cefixime (400 mg po in a single dose), or spectinomycin (2 g i.m. in a single dose) for those who cannot tolerate cephalosporin, and concomitant macrolide therapy for chlamydial infection (erythromycin [500 mg po four times daily for 7 days] or azithromycin [1 g po in a single dose]). Alternative therapy with amoxicillin (500 mg po three times daily for 7 days) is acceptable if erythromycin cannot be tolerated. Tetracyclines and the quinolones are contraindicated in pregnancy because of possible adverse fetal effects. The effect of *Chlamydia* on obstetric outcome is less clear; with cervical chlamydial infection, the goal is to prevent neonatal transmission. This occurs in 60% of newborns born to infected mothers and is manifested as conjunctivitis (50%) or late neonatal pneumonia (10%). It is most important to eradicate chlamydial infections in patients who are close to delivery. If a

patient far from term demonstrates a chlamydial infection, treatment may also be offered at this time.

Other Sexually Transmitted Diseases and Lower Genital Tract Infections

Other lower genital tract infections, such as lymphogranuloma venereum, granuloma inguinale, and chancroid, are rare in the United States.

Human Papillomavirus Infection

The incidence of human papillomavirus (HPV) infection, a lower genital tract infection, has risen dramatically in the past decade. HPV may be isolated by DNA identification in a number of tissues, including cervix, vagina, and vulva. It manifests itself most often as genital warts. Of the more than 60 serotypes, three are associated with cervical dysplasia and carcinoma (the so-called high oncogenic risk serotypes 16, 18, 33). There are no current recommendations to treat HPV infections in pregnancy. Cytotoxic agents such as podophyllin or 5-fluorouracil are contraindicated in pregnancy. Cesarean delivery is not indicated to prevent neonatal exposure to lower genital tract HPV. For patients with condylomata of sufficient size that vaginal delivery may be obstructed, referral should be made to an obstetrician who is capable of performing electrocautery, cryotherapy, or laser ablation of the lesions.

Syphilis

Syphilis in pregnancy is diagnosed either from a positive screening nontreponemal antibody test (Venereal Disease Research Laboratory [VDRL] test or rapid plasma reagin [RPR] test), followed by a positive fluorescent treponemal antibody absorption test (FTA-ABS), or when serologic tests are ordered because of clinical suspicion (painless lower genital tract lesions). The Centers for Disease Control and Prevention recommends penicillin G benzathine (2.4 million units i.m.). Subsequent treatment depends on the duration and stage at diagnosis. Pregnant patients allergic to penicillin should be desensitized before treatment. Transmission to the fetus is possible at any gestational age. Fetal complications include intrauterine death, preterm labor, and development of early congenital syphilis. Treatment should be initiated as early as possible, and all pregnant patients should have a screening test for syphilis.

Human Immunodeficiency Virus Infection

The majority of women infected with HIV are of reproductive age. The presence of other sexually transmitted diseases, particularly those characterized by genital ulcers or inflammation, increases the risk of HIV acquisition and transmission. Pregnant women with HIV are susceptible to the same spectrum of opportunistic infections as nonpregnant patients. Particular awareness for persistent HSV, PCP, central nervous system toxoplasmosis, esophageal candidiasis, and CMV retinitis with vision loss is paramount. The detection of acquired immunodeficiency syndrome (AIDS)-related neoplasms and infections may be obscured by the normal findings of pregnancy. HIV positivity does not appear to affect the course of pregnancy, nor does pregnancy appear to influence the early progression of HIV.³ The 1994 report of the AIDS Clinical Trial Group protocol number 076 (ACTG-076) clearly demonstrates the safety and benefits of zidovudine use during pregnancy complicated by HIV infection, primarily a substantial reduction in the perinatal transmission of HIV.⁴ The benefits of combination therapy with antiretroviral agents and viral protease inhibitors are well established in the nonpregnant population. Thus, multidrug regimens in pregnancy are also recommended.³

INFECTIONS RELATED TO PREGNANCY

Chorioamnionitis

All fevers in pregnancy need to be explained. It is crucial to exclude chorioamnionitis, an infection of the amniotic cavity with the fetus *in utero*. If the diagnosis is *not* made, complications occur, including premature rupture of membranes, preterm labor, maternal sepsis, fetal sepsis, and maternal or fetal death. The diagnosis is suggested by fever and uterine tenderness without contractions. Fetal tachycardia may also be present due to maternal fever. Leukocytosis is often present; and if the membranes are ruptured, the fluid may be foul smelling. If chorioamnionitis is suspected, an obstetrician should be consulted to admit the patient to the hospital for antibiotic therapy, amniocentesis, or delivery. Appropriate laboratory studies include complete blood cell count, urinalysis and urine culture, blood cultures, and cervical cultures for *N. gonorrhoeae* and *Chlamydia*.

Wound Infection

Various other infections may occur after vaginal or cesarean delivery. Wound infection after cesarean delivery may occur early (12 to 48 hours after delivery) or later (4 to 8 days after delivery). In either case, the presentation involves fever and wounds that appear infected. Early infections are more virulent. Cellulitis of the skin margins may be present and tender. Group A or group B streptococci or clostridia are seen in early infection. Infected wounds should be opened entirely, drained, and packed. Dressings should be changed during delayed healing. Patients with large wound infections should be admitted so they can receive antibiotics (ampicillin or cephalosporins) and wound care.

Late wound infections are also accompanied by fever and frequently drain infected material. They are most often caused by mixed organisms. Opening and packing the wound should suffice. The fascia should be examined to assess its integrity. Admission is indicated; patients with wounds that do not improve within 24 hours of debridement should receive broad-spectrum antibiotics.

Episiotomies may become superficially infected, or the fascia may become involved in more extensive infection. For superficial infection with local erythema and tenderness, the perineal incision should be opened to allow drainage and spontaneous healing. No attempt should be made to repair the infected wound. Sitz baths in warm water with or without salt are helpful for cleaning and symptomatic relief. If an abscess is suspected, the patient should be referred for incision and drainage.

Necrotizing fasciitis, a deep infection involving the fascia, is a serious process. Spread along fascial planes occurs quickly and results in sepsis and sometimes death. The key to diagnosis is the appearance of cool, necrotic skin, often with a serosanguineous exudate. If this condition is suspected, an obstetrician or surgeon should be notified and plans made for admission, antibiotic therapy, fluid and electrolyte support, and immediate debridement in the operating room.

Postpartum endometritis is associated with fever, uterine tenderness, and foul lochia. It may occur after vaginal or cesarean delivery. Urinary tract infection with suprapubic tenderness needs to be excluded. Complete blood cell count, urinalysis, and blood cultures may be helpful. An obstetrician should be consulted.

High blood pressure (BP) complicates 8% to 10% of all pregnancies, 20% of pregnancies in young nulliparas, and 40% to 50% of the pregnancies of women carrying twins.¹⁷ Preeclampsia, a hypertensive disorder characterized by vasospasm and coagulation abnormalities, is a leading cause of fetal and maternal morbidity and death. Eclampsia occurs in approximately one of 2000 (0.05% to 0.2%) deliveries, and the incidence of it is higher in women who do not have appropriate prenatal care.^{3,16}

Historically, maternal mortality from eclampsia, the most severe form of hypertension in pregnancy, ranges from 1% to 20% of all deliveries, although most current reports place mortality at approximately 5%.²⁴ In such severe forms of preeclampsia–eclampsia, intracerebral hemorrhage has been identified as the final event in over 50% of the patients who die. The mother is also at risk from the repeated seizure activity, which may lead to aspiration pneumonia, pulmonary edema, acute renal failure, or hypoxemia and acidemia.²¹ Abruptio placentae and subsequent maternal disseminated intravascular coagulopathy (DIC) may also be present. Finally, cardiovascular collapse may occur from overaggressive treatment or massive intracerebral hemorrhage.

The effects on the fetus are similarly dramatic. Combined with the compromised uteroplacental perfusion caused by the characteristic vasospasm, the effects of multiple convulsions result in 10% to 28% fetal mortality.³

Causes of hypertension in pregnancy are multiple. The American College of Obstetrics and Gynecology in 1972 attempted to unify these entities by identifying four categories of hypertension associated with pregnancy:

1. Preeclampsia–eclampsia
2. Chronic hypertension
3. Preeclampsia superimposed on chronic hypertension
4. Transient hypertension

Hypertension in this definition is a level of 140/90 mm Hg or an increase of 30/15 mm Hg from baseline. In 1988, the World Health Organization (WHO) defined preeclampsia as BP exceeding 140/90 mm Hg after the twentieth week and proteinuria exceeding 0.3 g/24 h. The presence of edema is not a factor in the WHO definition.

PATHOPHYSIOLOGY

The pathophysiology of preeclampsia–eclampsia is unclear. Several theories have been proposed, most of which involve the uteroplacental circulation. Normal pregnancy is characterized by an increase in prostaglandin I₂ (prostacyclin). In patients with preeclampsia–eclampsia, vasospasm peripherally may be stimulated by an increase in the vasoactive prostaglandin, thromboxane, with a simultaneous lower-than-normal production of prostacyclin.¹⁷ The severe vasospasm that occurs exceeds the ability of the cerebral autoregulatory system, and seizure activity results.

Another suggested theory is based on the supposed presence of a single recessive or dominant gene with subsequent inadequate placentation.⁹ The hypoxia and hypoperfusion that result disturb the functioning of the placental endothelial cells, with changes in circulating vasoactive substances and the sensitivity of the vascular bed to same.⁹

It does appear that both mother and fetus contribute to the risk of preeclampsia. When a woman becomes pregnant by a man who has been the father of a preeclamptic pregnancy in a different woman, the risk of preeclampsia is 1.8 times that of normal.¹⁴

CLINICAL PRESENTATION

Preeclampsia–Eclampsia

Preeclampsia is a condition of pregnancy that occurs most often after the twentieth week of gestation. In nulliparous patients it occurs most commonly near term. By definition, it is characterized by hypertension, proteinuria, generalized edema, and any of the following: hemoconcentration, hypoalbuminemia, hepatic dysfunction, coagulation abnormalities, and increased urate levels. Preeclampsia may progress rapidly to the convulsive phase of the disease, eclampsia.¹⁷

This life-threatening complication is usually preceded by warning signs and symptoms, such as headaches, epigastric pain, hyperreflexia, visual disturbances, and rising blood pressure (BP). Seizures may appear, however, without any warning signs or symptoms in a patient without previously recognized preeclampsia.³ Factors predisposing to preeclampsia–eclampsia include nulliparity, diabetes mellitus, multiple gestations, extremes of age, hydatidiform mole, fetal hydrops, and genetic inheritance.¹⁷ Preeclampsia regresses rapidly after delivery, and its signs and symptoms usually abate within 48 hours postpartum. The risk of eclampsia does continue postpartum, however, as 13% to 37% of cases have been reported in the postpartum period. The differential diagnosis of altered mental status in a postpartum patient should include eclampsia. Although there have been reported cases of postpartum seizures attributed to eclampsia up to 23 days postpartum, the vast majority occurs within the first 24 hours after delivery.

The HELLP syndrome, a variant of preeclampsia, is characterized by hemolytic anemia (H), elevated liver enzymes (EL), and low platelets/thrombocytopenia (LP), as well as by the classic hypertension, edema, and proteinuria.³

It is possible for patients to suffer from seizures even in the mild form of preeclampsia. A division of preeclampsia into mild and severe forms is useful for both disposition and prognosis. Severe preeclampsia exists when any of the following are present in a patient with a BP of 140/90 mm Hg and proteinuria greater than 0.3 g/24 h:

1. BP greater than or equal to 160/110 mm Hg on two occasions 6 hours apart with patient at rest
2. Proteinuria greater than 5 g/24 h

3. Urinary output less than or equal to 400 mL/24 h
4. Cerebral or visual disturbances
5. Epigastric or hepatic pain
6. Pulmonary edema or cyanosis
7. Platelet count lower than $100 \times 10^3/\mu\text{L}$.

Chronic Hypertension

BP greater than or equal to 140/90 in the period before pregnancy or before the twentieth week of gestation is considered chronic hypertension. Hypertension diagnosed for the first time during pregnancy and persisting beyond the forty-second postpartum day is also classified as chronic hypertension.¹⁷ Differentiation of chronic hypertension from preeclampsia is important, as the latter necessitates inpatient management, while the former may be treated on an outpatient basis. Chronic hypertension typically occurs in the older, multiparous woman, often with a history of hypertension in a previous pregnancy. The presence of chronic hypertension increases the risk of developing superimposed preeclampsia, abruptio placenta, intrauterine death, and accelerated or malignant hypertension.

Preeclampsia Superimposed on Chronic Hypertension

Any existing hypertensive disease predisposes the gravid woman to the development of preeclampsia–eclampsia. Rather than being defined by a specific value, this diagnosis is usually made if the BP increases by 30 mm Hg (systolic) or 15 mm Hg (diastolic) in the presence of proteinuria or generalized edema.

Transient Hypertension

Transient hypertension is defined as the development of hypertension during pregnancy or within the first 24 postpartum hours without other signs of preeclampsia or preexisting hypertension. The BP usually returns to normal within 10 days after delivery, but elevated BP has a high rate of recurrence in later pregnancies. It may also be predictive of eventual hypertension.¹⁷

DIFFERENTIAL DIAGNOSIS

The diagnostic dilemma in a gravid patient with hypertension revolves primarily around distinguishing between chronic hypertension, transient hypertension, and preeclampsia. Transient hypertension is characterized by the presence of increased systolic or diastolic pressures in the absence of any other of the classic signs of preeclampsia (i.e., generalized edema or proteinuria). The patient with chronic hypertension will have a history of hypertension that antedates the twentieth week of pregnancy. Causes of hypertension in this group of patients are similar to those in the nonpregnant patient population.

Although eclampsia may exist simultaneously with chronic hypertension, seizures prior to the twentieth week of gestation or after 48 hours postpartum are generally not considered attributable to eclampsia and should be worked up and treated as in the general population. Some causes to consider include idiopathic epilepsy, trauma, systemic lupus erythematosus, chronic alcohol use, dialysis, electrolyte or metabolic disturbances, ischemic encephalopathy, drug withdrawal, infection, toxin exposure, primary brain or metastatic tumor,⁷ stroke, intracranial hemorrhage, psychogenic (pseudoseizure), or status postepidural anesthesia.^{3,8}

EMERGENCY DEPARTMENT EVALUATION

Preeclampsia–eclampsia should be suspected in the presence of headache, blurred vision, scotomata, epigastric pain, diastolic BP greater than 100 mm Hg, increasing serum creatinine, consumptive coagulopathy, or abnormal transaminases.

Postpartum eclampsia may occur in up to 30% of patients with preeclampsia, usually within the first 12 to 24 hours and rarely beyond the forty-eighth hour. Anecdotal reports of seizures occurring 3 to 23 days postpartum have been attributed to eclampsia, but they are controversial.⁸ Patients with late postpartum eclampsia frequently present with complaint of headache, visual disturbances of several days' duration, or epigastric discomfort followed by convulsions. Hypertension is present, as are the characteristic proteinuria and edema.

Computerized tomography of eclamptic encephalopathy shows low attenuation areas in the cortex, with consistent involvement of the posterior areas and occasionally the basal ganglia. In more severe cases, intracerebral hemorrhage may be present.^{8,15}

Laboratory testing should include an evaluation of electrolytes, including sodium and bicarbonate, as well as liver function tests, to rule out the presence of the HELLP syndrome. A complete blood count with platelets and DIC screen may be indicated. The urine should be screened for protein; an electrocardiogram and a chest radiograph are indicated to search for hypertensive complications, such as ischemia or congestive heart failure. The fetus should be monitored continuously for signs of distress.

EMERGENCY DEPARTMENT MANAGEMENT

Chronic Hypertension and Transient Hypertension

In the vast majority of cases (90%), mild-to-moderate (preexisting) essential hypertension is associated with good outcome for both mother and child.⁴ Conditions that may prompt pharmacologic management include advanced maternal age (over 40 years of age), evidence of end organ damage, intrauterine growth retardation, history of previous perinatal death, or hypertension of greater than 15 years' duration. The presence of any one of these factors should prompt consideration of pharmacologic intervention, regardless of the BP.

Treatment of the hypertensive disorders of pregnancy varies according to the BP and the presence of other signs and symptoms of preeclampsia–eclampsia. The only definitive care for preeclampsia–eclampsia is delivery of the fetus. Pharmacologic therapy serves as a temporizing measure only.

For the emergency physician who is not an expert in the treatment of preeclampsia–eclampsia, hydralazine is the first-line drug of choice for BP control (where the diastolic BP is less than 110 mm Hg). Magnesium sulfate is the drug of choice for the control of seizures.¹⁶ The final step in the treatment of preeclampsia–eclampsia involves termination of the pregnancy with the least harm to the infant and mother. In cases in which there is evidence of advanced disease or of impending eclampsia, delivery is indicated, regardless of the age of the fetus. In these cases, evacuation of the uterus is the only measure that will halt the advance of the disease.¹⁷ Delivery should also occur if there is evidence of fetal distress.

For milder cases of the disease, or in cases in which it is unclear whether preeclampsia is present, temporizing measures, such as bedrest or prophylactic MgSO₄ therapy, may be indicated.

While the course of preeclampsia is usually gradual, 16% of cases of eclampsia occur without warning. It is advisable that all eclamptic patients (especially those with less than 36 weeks' gestation) be managed at a tertiary care center with the capability of managing high-risk obstetric and neonatal cases.¹²

Initial Treatment for Eclampsia

- Maintain oxygen delivery to both mother and fetus.
- Minimize the aspiration risk by placing the mother in the left lateral decubitus position.
- Invasive hemodynamic monitoring is indicated only for patients with complications such as pulmonary edema or continued oliguria.¹⁷
- In most cases, volume replacement therapy is not indicated except as needed to maintain urine output of 1 to 2 cc/kg/h. Because of the capillary leaks that accompany preeclampsia, aggressive fluid therapy may actually precipitate pulmonary or cerebral edema.⁴
- Monitor urine output using a Foley catheter.

- Treat the seizure with one of the following established protocols.

Seizure Therapy

Magnesium Sulfate. Magnesium sulfate is the drug of choice for eclampsia in the United States.²⁰ Several regimens have been proposed, the most common being Pritchard's (intramuscular) and Zuspan's (intravenous).¹⁹ A comparison of these protocols favors the use of Pritchard's protocol in an effort to raise and maintain maternal magnesium levels sufficiently high to be of benefit.¹⁶ The goal of therapy is to raise the maternal magnesium plasma level to 5 to 8 mg/dL. A commonly used loading dose of 4 g will achieve such a therapeutic maternal plasma level; the effect, however, is transient, and the level will fall within 60 minutes. Thus, a more recent recommendation is a loading dose of 6 g initially, followed by 2 to 3 g intravenously (i.v.) per hour.¹⁷ The specific regimens are detailed in [Table 77.1](#).

Magnesium Sulfate Dosing Regimen	
PRITCHARD (INTRAMUSCULAR)	
Loading dose:	4 g i.v. over 3-5 min plus 10 g i.m.
Maintenance dose:	5 g i.m. every 4 h
ZUSPAN	
Loading dose:	4 g i.v. over 5-10 min
Maintenance dose:	1-2 g i.v. every hour

TABLE 77.1. Drug Therapy for Eclampsia

Continue the magnesium sulfate administration until 24 hours after delivery. Signs of improvement will include a decrease in BP, improvement in sensorium, and an increase in urine output. Magnesium is excreted by the kidney, so in those cases in which urinary output is decreased or in the presence of renal failure, magnesium doses should be adjusted to avoid toxicity. When magnesium toxicity is suspected ([Table 77.2](#)), calcium gluconate 1 g may be administered slowly. The effect of the calcium is transient; therefore, continuous monitoring of the patient is warranted. Although there may be an initial decrease in BP for the first 30 to 45 minutes after the initiation of $MgSO_4$ therapy, the drug itself is not an antihypertensive agent. As such, one of the medications detailed below should be added to the treatment regimen to control the BP and minimize further end organ damage.

Serum Level (mg/dL)	Clinical Effects
1.5-2.5	Normal
4-8	Therapeutic for seizure prophylaxis
8-12	Loss of patellar reflexes, double vision, flushing, somnolence, slurred speech
15-17	Muscle paralysis
30-35	Cardiac arrest

TABLE 77.2. Effects of Magnesium Sulfate on the Mother

Postdelivery, fetal magnesium may have equilibrated with the mother's, causing hypotonia, respiratory depression, or hypotension. Calcium gluconate may be administered to the infant in those cases.²¹

Dilantin. Phenytoin has historically been the drug of choice in Europe for the control of eclamptic seizures. It provides prolonged seizure protection and has an antihypoxic effect.¹¹ Recently, however, phenytoin does not appear to be as effective in controlling eclamptic seizures as magnesium sulfate. When compared with $MgSO_4$, phenytoin has no effect on labor outcome.¹³

In cases in which status epilepticus due to eclampsia occurs, intubation and muscular paralysis are indicated. Other options include the administration of a short-acting barbiturate such as sodium amobarbital (250 mg) or a benzodiazepine.

Antihypertensive Therapy

The goal of antihypertensive therapy is to reduce BP without adverse effects on the fetus. Acute antihypertensive treatment is indicated when the diastolic BP is greater than 105 mm Hg; the goal is to reduce it to 90 to 100 mm Hg. Placental hypoperfusion must be avoided.¹⁷ Targets for BP control include a systolic BP of 140 to 150 mm Hg and a diastolic pressure between 90 and 100 mm Hg. Specific medications to be used in the treatment of this disorder include the following.

Hydralazine. Hydralazine is a vasodilator and the most commonly used agent. It is recommended as the first-line agent. Although it may be used as continuous intravenous medication, intermittent bolus injections appear to be more sensible. The initial bolus is 5 mg over 1 to 2 minutes, with repeated doses of 5 to 10 mg every 20 to 30 minutes as indicated by initial response. Once the desired effect is obtained, additional doses are repeated as necessary.

If a total dose of 20 mg is administered without therapeutic response, other hypertensive agents should be considered. Side effects of hydralazine include hypotension (reported more often in preeclampsics than in gravidas with chronic hypertension), headache, tremulousness, nausea, vomiting, and tachycardia. Neonatal thrombocytopenia has also been reported.

Diazoxide. A potent arteriolar vasodilator, diazoxide is recommended for the occasional patient who is refractory to hydralazine. The use of 30 mg "miniboluses" is recommended; they may be administered every 5 minutes as needed. Diazoxide may cause arrest of labor, which can be overcome by oxytocin. Other effects include maternal and neonatal hyperglycemia due to suppression of insulin release and displacement of highly protein bound drugs (like Dilantin), resulting in increased toxicity.

Labetalol. Labetalol is both an alpha and beta blocker and appears to have a faster onset of action and an absence of reflex tachycardia when compared with hydralazine. Follow the initial dose of 10 mg i.v. with a doubled dose every 10 minutes until the desired BP is achieved or until 300 mg is injected. Continuous infusion may be started at 1 to 2 mg/min (no more than 1 mg/kg) to control BP and run at 0.5 mg/min for maintenance.

Nifedipine. The oral calcium channel blocker nifedipine is no longer recommended for the emergency control of hypertension. It has potent uterine muscle relaxant properties that can increase the risk of uterine atony and postpartum hemorrhage.

Nitroprusside. A potent vasodilator, nitroprusside is reserved for patients who are unresponsive to more conventional therapy. Nitroprusside has a rapid onset of action and is reversible with discontinuation of therapy. The drug is metabolized to cyanide and thiocyanate, which may cross the placenta. Low doses of

nitroprusside have not been associated with clinically evident fetal toxicity.

Captopril. The angiotensin converting enzyme inhibitor captopril is reserved for postpartum use, as it has been demonstrated to have adverse effects on the renal perfusion of the fetus.

Nimodipine. An intravenous calcium channel blocker, nimodipine has been suggested as both an antihypertensive and an antiseizure medication in the setting of eclampsia.¹ It causes a decreased vascular resistance, and, therefore, a decreased mean arterial pressure, without affecting peripheral oxygen delivery. Initial reported studies on the use of nimodipine as single-agent therapy for eclampsia are promising but small.

Diuretics. Overall, diuretics are not used as first-line therapy. They cause little harm to the fetus. Most patients experiencing the sequelae of preeclampsia–eclampsia, however, are hemoconcentrated and not in need of further volume contraction. Because the uteroplacental circulation may already be compromised, diuretics should be reserved for those patients with documented congestive heart failure or fluid overload.¹⁷

Prevention

A number of randomized trials have demonstrated the benefit of low-dose aspirin therapy in reducing the incidence of gestational hypertension in pregnant women at risk for this condition.¹⁸ Although more recent trials in larger patient populations show less of a protective effect, the benefit in a high-risk group of patients (previous preeclampsia, chronic hypertension, multiple gestation, and diabetes mellitus) appears to outweigh the small increase in bleeding complications and abruptio placentae associated with salicylate use.^{4,5}

Magnesium sulfate is well established as prophylaxis for eclampsia.^{6,19} Concerns over the delay of spontaneous or induced labor have not been validated.¹³ In patients who are preeclamptic and receiving MgSO₄, the incidence of eclampsia falls from 1.2% to 0.3%.

Another suggested prophylactic measure is the use of calcium supplementation during pregnancy. Although the mechanism of action is unclear, the rates of hypertensive disorders among nulliparous women receiving such supplementation (e.g., 2 g daily) during pregnancy were shown to be lower than in the control group.²

DISPOSITION

Hypertension (Chronic and Transient)

Nonmedical management should be considered for individuals not at high risk for preeclampsia–eclampsia. In certain cases—in which the patient has a history of hypertension preceding the pregnancy, and the systolic BP is 140 mmHg or the diastolic BP is 90 to 99 mmHg in the appropriate clinical setting (after 20 weeks' gestation)—patients may serve a short stay in the hospital to rule out preeclampsia and be discharged home with close follow-up.

Role of the Consultant

Because the definitive therapy for eclampsia is delivery of the fetus, an obstetrician should be consulted as soon as the diagnosis is entertained. In cases in which preeclampsia is suspected or newly diagnosed, the need for admission should be determined after discussion with the obstetrician. Discharge should occur only if close follow-up is feasible.

Indications for Admission

Patients with severe preeclampsia and eclampsia must be admitted to monitored settings after appropriate consultation with the obstetrician. Some cases of early preeclampsia and hypertension in pregnancy may be managed on an outpatient basis if follow-up is available and the patient is compliant. Such decisions should follow appropriate emergency department interventions, including discussion with the obstetrician.

Transfer

Except in those cases in which a higher level of care is needed, patients experiencing symptomatic preeclampsia or those with eclamptic seizures are not candidates for transfer. The dynamic nature of the disease, the need for continuous monitoring during therapy, and the high fetal and maternal mortality make this disease inappropriate for interfacility transfer.

COMMON PITFALLS

- Making the diagnosis of preeclampsia may be difficult for the emergency physician, because the three classic clinical signs—hypertension, proteinuria, and edema—may not occur simultaneously, may be present as part of another disease process, or may be present as part of a normal pregnancy.¹⁷
- The emergency physician must be aware of and monitor the patient's serum magnesium levels during treatment for eclampsia to prevent overtreatment as well as undertreatment.
- When BP is measured by different observers at different times, the values may vary. Characteristically, the BPs reflect the altering vasospasticity and cardiovascular reactivity of the patient. Higher pressures should not be disregarded in the face of subsequent lower observed pressures.²³
- Seizure activity in the third trimester of pregnancy or immediately after delivery that is not responsive to magnesium sulfate mandates immediate computed tomography scan and lumbar puncture to exclude other etiologies of seizures.²²

Although women in the second half of pregnancy (greater than 20 weeks' gestation) commonly have their own physician, some emergent problems require intervention and stabilization by the emergency physician and rapid consultation with an obstetrician. Because a potentially viable second "patient" exists after 23 to 24 weeks, the approach must consider alterations in physiology, differential diagnosis, medications and doses, as well as the potential need to rescue the fetus to prevent its demise. The most common problems of late pregnancy encountered in the emergency department (ED) are vaginal bleeding, shortness of breath, and coma or seizure.

VAGINAL HEMORRHAGE IN LATE PREGNANCY

Vaginal bleeding after 20 weeks of gestation is not uncommon, occurring in about 4% of pregnancies.¹⁰ It can, however, be frightening to the patient as well as the physician. Definitive treatment, if required, should be performed by an obstetrician. The emergency physician must stabilize the patient hemodynamically and should be aware of the differential diagnosis, the studies necessary to define the problem, as well as the indications for transfer if limited facilities exist for management of the premature or distressed newborn.

Abruptio placentae, separation of part of the placenta from the uterine wall, accounts for about 30% of bleeding in the second half of pregnancy. Risk factors include hypertension, increased maternal age, and a history of smoking. In addition, abdominal trauma with transmission of forces to the uterus may cause shearing of the placenta from its attachments. Cocaine use has also been implicated as a cause of placental abruption.³ *Placenta previa*, which accounts for about 20% of third-trimester bleeding, is a placenta that overlaps the cervix to varying degrees. Placenta previa is more common with a uterus scarred from previous cesarean section and with advanced maternal age. Of placentas that overlie the cervix at 20 weeks' gestation (up to 20% of pregnancies), less than 10% of these remain so at delivery.⁷ The other 50% of patients who experience late bleeding often have no definite cause identified. It is believed that most episodes of bleeding represent small marginal separations of the placenta, but this cannot usually be proven. Other causes include vaginal or cervical trauma, lower genital tract infections, polyps, or hemorrhoids.

The pregnant patient undergoes several changes in cardiovascular physiology that are crucial to remember. Maternal blood volume expands by about 1.5 L during a normal pregnancy, resulting in a dilutional anemia that is physiologic (hematocrit 32% to 34%). Pregnant patients also manifest a baseline increase in heart rate (90 to 100 beats per minute) and stroke volume, resulting in a cardiac output 30% to 40% higher at term than seen in the nonpregnant state. Systematic vascular resistance is decreased, however, and the net hemodynamic result of these changes is a blood pressure lower than the nonpregnant state. Finally, the uteroplacental bed does not have any autoregulatory function; placental blood flow is determined strictly by maternal blood pressure and cardiac output. Because of the expanded intravascular volume, signs of extensive blood loss can occur late, and significant fetal hypoperfusion may exist before maternal signs of shock are apparent. Pregnancy is also associated with a rise in concentration of many clotting factors (especially fibrinogen), resulting in an hypercoagulable state.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The patient with bleeding after 20 weeks' gestation may present with a spectrum from painless spotting or bloody mucoid discharge to dark or exsanguinating bleeding and severe uterine pain. Placenta previa is most often seen as bright red, painless vaginal spotting. The bleeding is rarely severe (except during labor or after pelvic examination with probing of the cervical os). The patient may be aware of an abnormal placental location. The patient with *abruptio placentae* more often has dark, variable bleeding, accompanied by uterine tenderness and irritability, manifested by intermittent or steady cramping. Bleeding between the placenta and uterine wall may result in significant occult blood loss, with maternal tachycardia or even hypotension, but without evidence of significant external bleeding. Fetal distress (heart rate out of the normal range of 120 to 160 beats per minute) may also occur if a significant degree of separation has occurred. *Abruptio placentae* may also trigger maternal coagulation, resulting in evidence of consumptive coagulopathy, with bleeding from needlesticks, urine, and other sites.

EMERGENCY DEPARTMENT EVALUATION

The patient with vaginal bleeding should first be assessed hemodynamically. With significant maternal blood loss, fluid resuscitation is begun. Blood should be sent for complete blood cell count, prothrombin time, partial thromboplastin time, and fibrinogen levels. The patient's blood should be typed and crossmatched, and fresh-frozen plasma or fresh whole blood may be needed. The mother's Rh type should be determined and a Kleihauer-Betke test sent to determine whether significant fetomaternal transfusion has occurred.¹ The fetus should be evaluated for signs of distress: bradycardia less than 120 beats per minute, tachycardia more than 160 beats per minute, decelerations after uterine irritability, or loss of beat-to-beat variability during continuous fetal monitoring.

History should include known obstetric problems or ultrasonographic diagnoses. Other historical information includes amount of bleeding, passage of clots, character of blood (bright red or dark, older blood), presence of uterine cramping or pain, prior cervical or vaginal lesions or infection, drug use, and history or evidence of abdominal trauma (including domestic violence). The abdominal examination should confirm uterine size as well as the presence of contractions or tenderness to palpation. Vaginal examination *should not be performed* in the ED if adequate obstetric backup is available, and should be preceded by ultrasonography whenever possible to diagnose or exclude placenta previa.

Ultrasonography remains the diagnostic modality of choice for late-pregnancy bleeding.¹² The major purpose of ultrasonography is to locate the placenta and its relationship to the cervix. Additionally, information regarding gestational age and general fetal well-being may be obtained. Transabdominal ultrasound (TAS) is usually performed first, but is noted to have a false positive rate of 2% to 6% for placenta previa. False positives can be caused by obesity, a posterior placenta, a full bladder, or a focal myometrial contraction. Endovaginal sonography (EVS) eliminates many of these false positives and has been proven safe in many studies. While TAS is easily performed in the ED, the role of EVS in the ED assessment of vaginal bleeding in late pregnancy is less well defined.¹¹

On the other hand, the ultrasonography findings in abruption are variable and are affected by the type of abruption (retroplacental, subchorionic) and the timing of the study in relationship to the onset of bleeding. Retroplacental bleeding may have a sonographic appearance very similar to that of a normal placenta, creating an area of thickened placenta or an area mistaken for a fibroid or contraction. Marginal bleeding may be recognized sonographically as a hematoma, though the amount of apparent blood collection seen may significantly underestimate true losses. Evidence of abruption by ultrasound is helpful to the obstetrician in developing a care plan for the patient, and can be followed with serial examinations. A negative study does not eliminate abruption from the differential, and, in fact, a patient with late pregnancy bleeding and an ultrasound negative for placenta previa is often assumed to have abruption. With abruption, fetal monitoring becomes the primary tool for

management decisions.¹¹

A vaginal examination is ideally performed after ultrasonography in an operating suite capable of converting to an emergent surgical delivery with fetal resuscitation in the event that severe bleeding is triggered. If immediate obstetric consultation is not available, patients with significant bleeding should be prepared for transport to a facility that is able to provide a wide range of resuscitative services. If the bleeding is not severe, a cautious vaginal examination in the ED is rational, preferably after placenta previa has been excluded with ultrasonography. The purpose of the examination is to exclude hemorrhoidal bleeding or vaginal or cervical lesions that cause bleeding. Neither fingers nor instruments should be placed in the cervical os, because uncontrolled bleeding from a placenta previa can be triggered by such manipulation.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Prehospital triage of the woman with bleeding after 24 weeks' gestation (a uterus above the umbilicus provides a rough measure) should be to a facility that can manage a potentially high-risk or premature delivery. Management consists of assessment of the amount of bleeding from evidence at the scene and degree of bleeding at the perineum (if a private evaluation of this can be made), administration of maternal supplemental oxygen, positioning of the patient on her left side, and intravenous administration of fluids en route.

The ED should ideally be a place of cardiovascular stabilization and triage only. If the mother has hemodynamic compromise secondary to hemorrhage, fluid resuscitation should be initiated rapidly with crystalloid. Appropriate bloodwork is initiated, including coagulation tests, as noted earlier. In the mother with rapid exsanguination, O-negative blood transfusion may be required. Fresh whole blood or packed cells with fresh-frozen plasma may be needed if abruptio placentae is suspected, because this can cause consumption of clotting factors. Fetal heart rate should be quickly measured, with initiation of continuous monitoring if possible. Rapid transport to the obstetric suite is the goal.

In the patient with less emergent bleeding, referral to the obstetric unit is preferred for definitive diagnosis. The standard method of evaluation is ultrasonography followed by vaginal examination in a delivery suite, where the discovery of a fetus-threatening placenta previa can be treated with rapid delivery. In the patient with a presumed or visible abruptio placentae, admission to a high-risk prepartum unit for continuous monitoring after labor deck diagnosis is appropriate. A cautious vaginal examination in the ED may be appropriate, particularly in a hospital where transfer will be needed if no simple bleeding source is found. Continued fetal well-being should always be documented if the patient spends any significant time in the ED, because hypovolemia is frequently detected by signs of fetal distress before maternal vital sign changes. If the mother is Rh-negative (with an unknown or Rh-positive father) or if a positive Kleihauer-Betke test is positive for fetomaternal hemorrhage, RhGAM should be administered in a dose determined by the number of milliliters of fetal cells calculated to be in the maternal circulation (300 µg/15 mL fetal red blood cells).¹⁴

Interfacility transfer to a high-risk unit should be accomplished after initial diagnosis or assessment by an obstetrician and is usually performed by specialized obstetric or high-risk neonatal transport units. In general, predelivery transport is safest and is associated with the best outcome, but it must be accomplished in a controlled fashion, with personnel capable of supporting the mother and managing fetal distress or a premature delivery en route.

COMMON PITFALLS

- Vaginal examinations should be limited to visual inspection of the perineum and vaginal vault to look for obvious noncervical bleeding sources. Fingers or instruments should *never* be placed in or near the cervix, because uncontrolled bleeding from a placenta previa can result.
- Coagulopathy should be considered in patients with severe hemorrhage, because clotting factors are consumed when significant bleeding occurs with abruptio placentae, and coagulopathy can seriously compromise the mother's ability to limit uterine bleeding.

SHORTNESS OF BREATH IN LATE PREGNANCY

Breathlessness is a common symptom in pregnancy. A respiratory alkalosis is common, with normal P_{CO_2} levels in pregnancy of 27 to 32 mm Hg. "Dyspnea," the sensation of increased breathing effort, is likewise common, particularly in the first two trimesters. It usually improves after about 28 weeks and is thought to be related in some women to progesterone-induced stimulation of the respiratory center. The alveolar–arterial P_{CO_2} gradient increases to a mean of about 14 mm Hg near term in the sitting position and may be as high as 20 mm Hg in the supine position. Arterial–alveolar gradients greater than 20 mm Hg are clearly abnormal, but those between 10 and 20 mm Hg are difficult to interpret.¹³

Respiratory physiology in pregnancy shows important changes in response to the stress of illness or injury. Oxygen consumption normally increases by 25%, and residual volume is impaired, particularly in late pregnancy, resulting in poor reserve when a pulmonary insult occurs. The fetus is more sensitive than the mother to a hypoxic insult, because fetal hemoglobin is "left shifted." Tachypnea causes an alkalosis that leads to constriction of the uteroplacental vascular bed and decreased fetal blood flow.¹³

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Respiratory distress presents in pregnancy much as it does in the nonpregnant patient. Predominant signs include increased rate or depth of breathing, use of accessory muscles or other evidence of increased work of breathing, and cyanosis if oxygenation is significantly impaired. Increased respiratory effort may be combined with other clinical evidence of infection in the patient with sepsis or another infectious cause. Wheezing may be caused by asthma, but amniotic fluid embolus, pulmonary embolus (PE), or simple pneumonia must also be considered.

Differentiating normal pulmonary changes of pregnancy from respiratory distress caused by illnesses requiring treatment may be difficult. PE occurs with increased frequency in pregnancy due to the hypercoagulability and stasis induced by pregnancy, as well as the vessel trauma that occurs at delivery. Amniotic fluid embolus is a rare but frequently fatal cause of respiratory distress and cardiovascular collapse due to amniotic fluid (with antigenic foreign debris) entering the maternal circulation and being filtered in the pulmonary vascular bed. Other potential causes of respiratory distress include asthma,⁶ respiratory insufficiency from systemic infection or sepsis, pneumonia, or other nonpregnant etiologies.

EMERGENCY DEPARTMENT EVALUATION

Assessment of the pregnant patient with respiratory distress is similar to that of nonpregnant patients. A pertinent history includes prior respiratory risk factors such as asthma, smoking, or hypercoagulability independent of pregnancy itself. Proximate symptoms should be sought, such as fever, sputum production, and the nature and location of associated chest pain. Physical examination focuses on the lungs and clues to bronchospasm, local or diffuse consolidation, or fluid overload. Vital signs include an accurate respiratory rate, temperature, and pulse oximetry as an initial screen. In any patient with increased work of breathing, arterial blood gases (ABGs) are necessary to accurately assess oxygenation (P_{O_2}) and ventilation (P_{CO_2}). Chest radiography is safe and usually necessary in the pregnant patient with respiratory symptoms of significance. X-ray beams with a margin greater than 10 cm from the fetus give a negligible radiation exposure, and shielding can be done in late pregnancy to minimize exposure and reassure the patient.

PE remains a significant cause of maternal morbidity and mortality in pregnancy. The period of highest risk for thromboembolism remains unsettled in the literature. Recent studies suggest that most deep venous thromboses associated with pregnancy occur in the antepartum period, though two-thirds of PEs are noted in the postpartum period. Increased venous stasis, in combination with increases in coagulation factor levels, and interactions are the most important risk factors. Other factors, such as prolonged bedrest, prior thrombotic disease, and intercurrent illness, also contribute. The clinical presentation can be confusing, as many normal, near-term patients give a history of dyspnea and leg discomfort and have tachypnea and lower extremity swelling on examination. Because of the immediate morbidity and mortality associated with PE and the longer term implications of having the disease (prolonged heparin therapy, prophylaxis during subsequent pregnancies, future use of contraceptives), the emergency physician treating pregnant patients with significant respiratory complaints should be aggressive in pursuing the diagnosis.

The workup for PE in pregnancy proceeds in a stepwise fashion, and does not deviate much from the workup in nonpregnant patients. Chest radiography is indicated, and ABGs are usually assessed, though results of the latter can be difficult to interpret, as outlined earlier. Ventilation–perfusion (V/Q) scanning is often the initial

study of choice, followed by angiography if the V/Q scan neither confirms nor rules out PE. The total amount of radiation exposure during workup for PE is small if shielding is used and should never be a barrier to making a diagnosis. A patient undergoing chest x-ray, V/Q scanning, and angiography (brachial approach) has an average fetal exposure of 0.5 rad, a level not considered to pose any fetal risk.^{4,8} Some authors favor lower extremity studies (ultrasonography or impedance plethysmography) prior to angiography in patients with low- or intermediate-probability V/Q scan results. A positive noninvasive study ends the workup, and the patient is treated for PE. However, a normal lower extremity study is inconclusive and requires subsequent angiography. About half of patients with equivocal V/Q scan results and negative lower extremity studies have angiographically proven PE.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

The pregnant patient with respiratory distress requires pulse oximetry, supplemental oxygen, adequate fluids, and positioning on her left side to maximize uterine perfusion. This can be initiated in the prehospital phase, although little else can or should be done (as with other patients with respiratory distress) until a definitive diagnosis is made. Respiratory support and control of ventilation should be prompt if it is indicated, because the fetus is disproportionately affected by respiratory acidosis or hypoxia. Conservative and prompt therapy for hypoxia and increased work of breathing is recommended, because pregnancy impairs normal maternal compensatory mechanisms and reserve. The threshold for admission or intubation of pregnant patients with respiratory distress is *much lower* than in nonpregnancy.

Treatment of asthma in pregnancy is similar to that in nonpregnancy (see [Chapter 75](#)). Inhaled β -agonists are the mainstay of acute therapy. Epinephrine can be used if these fail, but it has the theoretic disadvantage of α -stimulation (which causes uterine contraction). Both inhaled prophylactic corticosteroids and oral prednisone are safe, and their use should be encouraged.

Treatment of PE is problematic because warfarin is contraindicated in pregnancy. In the ED, intravenous heparin should be started when the diagnosis of PE is made, with an intravenous load of 70 to 100 U/kg (5,000 to 10,000 U). The subsequent infusion dose is 1000 U/h, aiming for an activated partial thromboplastin time 1.5 to 2.5 times control.⁸ Because warfarin (Coumadin) causes a multitude of fetal abnormalities, heparin, which is too large to cross the placenta, is given subcutaneously, usually twice daily, to maintain anticoagulation until 2 to 6 weeks postpartum. Patients who have received thrombolytic treatment for massive pulmonary embolism without adverse fetal outcome have been reported.² The role of low-molecular-weight heparin is evolving, and there are limited data that it is safe in pregnancy. However, no clear consensus recommendations regarding its use in pregnant patients have emerged.⁸

Patients with significant respiratory impairment should usually be managed jointly by an obstetrician and an internist. Fetal well-being is optimized by maintaining maternal oxygenation and acid–base balance aggressively and by minimizing the work of breathing.

COMMON PITFALLS

- Failure to appreciate the lack of respiratory reserve in late pregnancy
- Failure to aggressively treat asthma due to fear of harming the fetus
- Reluctance to pursue all ancillary studies that are appropriate in the pregnant woman with possible PEs due to concerns about fetal radiation exposure

SEIZURES AND ALTERED LEVEL OF CONSCIOUSNESS

Clinical Presentation and Differential Diagnosis

Central nervous system problems such as seizure and coma have a wide differential diagnosis in pregnancy. The most common cause of seizures in pregnancy is epilepsy. In about 40% of women with epilepsy, seizure frequency increases in pregnancy; this is particularly common in patients with poor prior control.⁵ “Noncompliance” is believed to be a common cause, although several factors may be at work, including decreased medication intake due to nausea and maternal concerns about teratogenicity of antiseizure medicines. Indeed, the risk of congenital defects is increased two- to threefold in patients with epilepsy. The relative contribution of drugs needed to manage seizures, epilepsy itself, or prolonged acidosis from maternal seizures is unknown.

The differential diagnosis of seizures in a nonepileptic patient should include eclampsia; other primary central nervous system events, including thrombotic or hemorrhagic stroke; and drug toxicity (cocaine, cyclic antidepressants, and isoniazid most commonly cause seizures). Rarely, an amniotic fluid embolus or a PE can present as seizure.

Coma has a similar differential diagnosis, with a postictal state due to seizure from epilepsy or eclampsia as the most common consideration. Stroke must be considered in the patient whose condition does not reverse rapidly or who has a focal deficit. Pregnant diabetics have increased metabolic demands as well as peripheral insulin resistance, and they may be more prone to either hyperglycemia or hypoglycemia. Overdose is not uncommon in pregnancy and should be considered in the patient with a decreased level of consciousness or a picture consistent with a toxic syndrome.

EMERGENCY DEPARTMENT EVALUATION

Assessment of the seizing patient usually consists of emergent interventions to ensure an adequate airway and oxygenation and to stop the seizure. Focal signs should be noted. Once the seizure is terminated, clues to eclampsia (hyperreflexia, proteinuria, persistent hypertension, and marked edema) should be sought. Obstetric history (including symptoms of preeclampsia), history of epilepsy or diabetes, compliance with current medications, use of other current medications, including alcohol and antidepressants, and risk factors for thrombosis are all determined. The physical examination should include a detailed neurologic examination for focal findings and trauma. Evaluation of the comatose patient also includes all of the aforementioned, in addition to a determination of the depth of coma.

When appropriate, laboratory studies should include rapid glucose determination and measurement of antiseizure medication levels. A toxicology screen may be useful in the patient with suspected overdose, as may be an electrocardiogram (to detect cardiac effects of cyclic toxicity).

Computed tomography is rarely useful in the known epileptic or in the eclamptic whose neurologic examination normalizes with standard therapy. It may be useful to detect intracranial hemorrhage, however, in the patient with focal or persistent deficits or continued coma. In all other patients, it is a standard part of the evaluation of the patient with an otherwise unexplained, sudden central nervous system event.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Airway protection is paramount in the comatose patient and in the patient with seizures. Intubation should be considered early, because the fetus suffers disproportionate injury from hypoxia, hypercarbia, and acidosis. Treatment of seizures of unknown etiology can be accomplished safely in pregnancy with either benzodiazepines or phenytoin. Both of these have been reported to be effective in eclamptic seizures, but if the clinical diagnosis is eclampsia, magnesium sulfate is still the medication of choice (and discussed more fully in [Chapter 77](#)).

Benzodiazepines, while contraindicated as Food and Drug Administration category D drugs, are safe for acute use and preferable to hypoxia and acidosis of persistent seizure activity. If respiratory depression occurs in the mother, intubation should be performed. Due to the changes in phenytoin pharmacokinetics, a regimen has been proposed of a 10 mg/kg initial intravenous load (not to exceed 50 mg/min), followed by 5 mg/kg given intravenously 2 hours later. If seizure activity is sustained, completion of the total 15 mg/kg load should be performed more promptly.⁹

In general, while the differential considerations may be altered by pregnancy, emergent treatment of the comatose patient or patient with seizures is unchanged. Indeed, it is even more important to minimize the hypoxic, hypercarbic, and acidotic insults of seizure or coma in pregnancy, due to the increased susceptibility of the fetus to these metabolic derangements. Admission is required for control of persistent seizures and for management of the comatose patient. Both a neurologist and an obstetrician may need to be involved, unless the patient has clear evidence of eclampsia.

COMMON PITFALLS

- Eclampsia should be considered in any comatose patient or patient with seizures in the third trimester, and clues to this systemic disease should be sought.

- Hypertension and coma may be seen in hemorrhagic central nervous system events, and a computed tomographic scan should be considered if the patient with presumed eclampsia does not respond promptly to magnesium sulfate.

The past century witnessed a marked improvement in prenatal and obstetric care. During the past 60 years, maternal mortality has decreased markedly from 582 per 100,000 live births in 1935 to 7.5 per 100,000 live births in 1982, with this number remaining relatively constant through 1996.^{4,6} From the viewpoint of safer care during labor, the outstanding advance during the twentieth century has been the great increase in the proportion of in-hospital deliveries.⁶

The degree to which the emergency physician interacts in the process of labor and delivery varies among institutions, depending on the availability and readiness of inpatient obstetric services. The role of the emergency physician may be only to determine the patient is in active labor and to order transport directly to the labor and delivery area. Alternatively, in a hospital with little or no obstetric services, the emergency physician may be called on to manage a complicated delivery and neonatal resuscitation until transfer to a more comprehensive facility is possible.⁷

Labor is defined as the coordinated effective sequence of involuntary uterine contractions resulting in progressive effacement and dilatation of the cervix. This, coupled with the voluntary bearing-down efforts of the mother, results in *delivery*, the actual expulsion of the products of conception.

Labor is normally divided into three stages. The first stage begins when uterine contractions reach sufficient force to cause dilatation and effacement of the cervix and ends when the cervix is completely dilated. Although the average duration of the first stage of labor averages 8 hours in the nulliparous patient and 5 hours in the parous woman, there is marked individual variation.⁶ The second stage of labor begins when the cervix is completely dilated and ends with delivery of the infant. The duration of this stage is highly variable, with a median of 50 minutes in nulliparas and 20 minutes in multiparas.^{6,7} In general, if the second stage lasts greater than 2 hours, abnormal labor has developed.⁶ The third stage of labor begins after delivery of the infant and ends with delivery of the placenta, with the placenta usually delivering spontaneously within 20 to 30 minutes.^{7,9}

The cardinal movements of labor describe the positional changes the fetus undergoes that allow the fetal head to pass through the pelvis. A normal delivery involves fetal engagement, descent, flexion, internal rotation, extension, external rotation, and expulsion.^{6,7,9} (Fig. 79.1).

Figure 79.1. Mechanism of labor and delivery for vertex presentations. **(A)** Engagement, flexion, and descent. **(B)** Internal rotation. **(C)** Extension and delivery of the head, using the modified Ritgen maneuver. After delivery of the head, the infant's nose and mouth should be suctioned and the neck checked for encirclement of the umbilical cord. **(D)** External rotation, bringing the thorax into the anteroposterior diameter of the pelvis. **(E)** Delivery of the anterior shoulder. **(F)** Delivery of the posterior shoulder. Note that after delivery, the head is supported and used to gently guide delivery of the shoulder. Traction should be minimized.

CLINICAL PRESENTATION

Peripartum events that require emergent attention include fetal distress, preterm labor, and imminent delivery. Timely recognition and intervention are essential for good maternal and fetal outcomes.

Fetal Distress

During the third trimester, normal baseline fetal heart rate is 120 to 160 beats/min, with heart rate varying considerably from beat to beat.^{2,6,7} Rates above or below this range may indicate fetal distress. Fetal tachycardia occurs when fetal heart rate is greater than 160 beats/min.^{6,7} Brief accelerations in fetal heart rate (i.e., those lasting less than 20 seconds) occur commonly during labor and are probably a physiologic response to fetal movement.^{2,6} In contrast, persistent fetal tachycardia commonly occurs in response to maternal fever or medications but may also indicate early fetal distress.^{2,6}

Fetal bradycardia occurs when fetal heart rate falls below 120 beats/min.^{6,7} Like brief accelerations in fetal heart rate, decreases in fetal heart rate that reach their nadir with the peak of the contraction and end with or slightly after the end of a contraction (early decelerations) are physiologic and are probably the result of vagal nerve stimulation due to compression of the fetal head.^{2,6} In contrast, decelerations that persist significantly after a contraction (late decelerations) and those that occur independently of uterine contractions (variable decelerations) are ominous and may represent uteroplacental insufficiency and cord compression, respectively.^{2,6} If prolonged fetal monitoring during labor is necessary in the emergency department (ED), fetal heart rate should be assessed at the end of and for 60 seconds after a contraction at 15-minute intervals during the first stage of labor and at 5-minute intervals during the second stage.^{2,6}

Preterm Labor

Preterm labor, that is, labor occurring prior to the completion of 37 weeks of gestation, is a major cause of preterm delivery, a complication that affects approximately 5% to 10% of all births.^{1,13} Early identification of preterm labor allows timely intervention aimed at stopping or at least slowing the process. *Preterm labor*, as in term labor, is defined as uterine contractions with sufficient intensity, duration, and frequency to produce progressive effacement and dilatation of the cervix. Uterine contractions alone, therefore, do not indicate labor is occurring.^{6,9}

Imminent Delivery

Imminent delivery occurs late in the second stage of labor and is heralded by an uncontrollable urge to push by the laboring woman and, with descent of the fetus, the urge to defecate. Signs on examination include rectal or perineal bulging and crowning of the fetal head.⁶

DIFFERENTIAL DIAGNOSIS

Abdominal cramping in women at or near term should prompt the consideration of labor. *True labor* is characterized by a regular sequence of uterine contractions that results in dilatation and effacement of the cervix and descent of the fetus. More common in late pregnancy and parous women, *false labor*, or Braxton-Hicks contractions, are characterized by brief, irregular contractions not accompanied by descent of the fetus or changes in the cervix ([Table 79.1](#)). Although false labor may stop spontaneously, it may rapidly convert to the effective contractions of true labor. A period of observation is, therefore, frequently necessary.⁶ The passage of blood-tinged cervical mucus, or “*bloody show*,” is a rather common and dependable sign of the approach of labor. Bloody show must be distinguished from more active vaginal bleeding during labor, which suggests placenta previa or abruption and in which vaginal examination is contraindicated.^{6,7}

Consideration	True Labor	False Labor
Contractions	Regular, ↑ severity and frequency	Irregular, no change in severity, frequency
Discomfort	Abdominal, lower back	Lower abdominal
Sedation	No effect	Relieves discomfort
Cervix	Progressive change over time	No change over time

Adapted from Cunningham FG, et al, *Williams' Obstetrics*, 19th ed. Norwalk, CT: Appleton & Lange, 1993.

TABLE 79.1. True Versus False Labor

Spontaneous rupture of the membranes (SROM) usually occurs during the course of active labor but occurs before labor in approximately 8% of cases.⁶ SROM is indicated by the passage of a variable amount of normally clear or slightly turbid fluid from the vagina and may be verified if amniotic fluid is seen extruding from the cervical os or is found in the vaginal fornix on sterile speculum examination.^{6,7} Amniotic fluid may be differentiated from vaginal fluid by placing a drop of fluid on Nitrazine paper. The pH of amniotic fluid is 7.0 to 7.5; that of vaginal fluid is between 4.5 and 5.5. A pH above 6.5 is consistent with ruptured membranes.⁶ Detection of ruptured membranes is important for three reasons: Labor may be imminent; if the presenting fetal part is not already fixed in the pelvis, cord prolapse and compression are likely; and the risk of intrauterine infection is increased if delivery is delayed for 24 hours or more.^{6,7,9} Rupture of the membranes before the onset of labor at any stage of gestation is referred to as *premature rupture of the membranes* (PROM).⁶ When PROM occurs prior to 37 weeks' gestation, it is termed *preterm premature rupture of the membranes*.^{6,9}

EMERGENCY DEPARTMENT EVALUATION

The evaluation of a patient over 20 weeks' gestation who presents to the ED complaining of contractions, SROM, or bloody show includes a history, physical examination, and ancillary studies as indicated. The pace of the evaluation is determined by the stage of labor, maternal and fetal well-being, and the probable disposition of the patient. The patient interview covers prior obstetric and gynecologic history, as well as general medical and surgical history, including any intercurrent illness. The current pregnancy is reviewed for prenatal care and complications. The quality, frequency, and severity of contractions are elicited. The occurrence of bloody show (as distinguished from vaginal bleeding) or SROM is detailed.⁷

The physical examination focuses on both maternal and fetal health. Maternal vital signs are assessed and a general physical examination performed. Elevated blood pressure, particularly when accompanied by headache or visual disturbances, proteinuria, or epigastric or right upper quadrant pain, suggests preeclampsia.⁶ Fever may indicate amnionitis, pyelonephritis, or other infectious complications.

The abdominal examination focuses on estimating fetal age and location. Between 20 and 34 weeks' gestation, measurement of fundal height (i.e., the distance from the pubic symphysis to the fundus) in centimeters approximates the gestational age in weeks.⁶ The maneuvers of Leopold, found in any standard obstetric text, are performed during the latter months of pregnancy to assess fetal lie, position, and presentation. *Lie* refers to the relation of the long axis of the fetus to that of the mother and is either longitudinal (greater than 99% of term pregnancies) or transverse. *Presentation*, or presenting part, refers to that portion of the fetus that is foremost in the birth canal and is the part felt through the cervix on sterile vaginal examination. In longitudinal lies, the presenting part is usually either the fetal head (vertex or cephalic presentation) or the feet or buttocks (breech presentation). *Position* refers to the relation of the presenting part to the birth canal and may be either left or right.^{6,7} At or near term, vertex presentation occurs in about 96% of all pregnancies, but is more variable before term. At 29 to 32 weeks, 14% of all pregnancies have sonographically been determined to be breech; at 33 to 36 weeks, the number falls to approximately 9%.⁶

Unless there has been bleeding in excess of a bloody show or PROM is suspected, a sterile digital (not speculum) vaginal examination is performed to assess the progress of labor and confirm fetal presentation and position. Palpation of the cervix is used to assess effacement, dilatation, and fetal station.^{6,7} *Cervical effacement*, or thinning, is estimated by comparing the palpated length of the cervical canal with that of the nongravid or uneffaced cervix (about 2 cm) and is expressed as a percentage from 0% to 100%. The completely effaced cervix is usually less than 0.25 cm thick.^{6,7} *Cervical dilatation* is the average diameter of the cervical os on palpation, with 10 cm representing full dilatation.^{6,7} *Fetal station* refers to the level of the presenting fetal part in the birth canal in relation to the ischial spines (which define “0” station). The birth canal above and below the spines is divided into fifths: +5/5 station indicates that the presenting part has reached the perineum. If the vertex is at 0 station or below, engagement of the fetal head has usually occurred; that is, the biparietal plane of the fetal head has passed through the pelvic inlet.⁶

If there is a question of PROM, a sterile speculum examination is done prior to digital examination to determine the presence of amniotic fluid in the vagina, as previously noted. Because the incidence of chorioamnionitis, the most common complication of PROM, is directly proportional to the number of digital vaginal examinations performed following membrane rupture, if amniotic fluid is identified, digital examination is deferred.^{6,9} If bleeding in excess of a bloody show has occurred, vaginal examination is contraindicated in the ED.⁷

In addition to the tests associated with SROM, blood should be sent for hemoglobin or hematocrit, and maternal blood type, if not on record. Urine should be examined for glucose and protein, if indicated.⁶

Fetal evaluation primarily involves Doppler assessment of the fetal heart rate, as discussed previously. Ultrasound may augment the process. The region of the abdomen in which fetal heart sounds are heard most clearly varies with fetal presentation and the degree to which the presenting part has descended. After engagement, fetal heart sounds are loudest below the umbilicus in vertex presentations and above in breech presentations. To avoid confusion of maternal and fetal heart sounds, the maternal pulse should be palpated as the fetal heart rate is auscultated.⁷

MANAGEMENT OF DELIVERY

Although transfer to the labor and delivery suite is always preferable to delivery in the ED, occasionally there will be inadequate time to safely effect transfer.⁹ Imminent delivery occurs late in the second stage of labor and is characterized by uncontrollable bearing-down movements of the mother; pressure on the rectal tissue, resulting in the urge to defecate; and perineal bulging, with eventual crowning of the fetal head.^{6,7}

When delivery is imminent in the ED, a large-bore intravenous line of crystalloid solution should be started and the patient placed on a stretcher with her hips and knees partially flexed, the thighs abducted, and the soles of the feet placed firmly on the stretcher. An inverted bedpan placed beneath the patient's buttocks will provide additional space for delivery.⁷ Although complete sterility is not a priority, when time permits, the perineum should be cleansed, the perineal area draped, and the physician gowned and sterilely gloved.^{6,7} Eye protection and a mask should also be worn by the physician.

The mechanism of labor consists of engagement of the presenting part, flexion, descent, internal rotation, extension, external rotation or restitution, and expulsion (see [Fig. 79.1](#)). Maternal expulsive efforts are usually spontaneous and effective, and delivery of the infant occurs spontaneously. Occasionally, maternal coaching is necessary to help coordinate bearing-down efforts. In this case, the mother is instructed to take a deep breath at the beginning of each contraction, hold it, and push throughout the duration of the contraction. Pushing should not extend beyond the completion of the contraction.⁶

Normal Spontaneous Vertex Delivery

Spontaneous vertex delivery includes three phases: delivery of the head, delivery of the shoulders, and delivery of the body and legs. Gentle, gradual, controlled delivery is desirable to avoid maternal and fetal injury. As the fetal head delivers via the process of extension, the physician places one hand over the occiput, providing gentle pressure for control. When the fetal head distends the vaginal introitus to a diameter of 5 cm or more, the other hand, preferably draped with a sterile towel, may exert forward pressure on the chin of the fetus through the perineum just in front of the coccyx in a modified Ritgen maneuver (see [Fig. 79.1C](#)). This maneuver extends the neck at the proper time, protecting the maternal perineal muscles. The head is gently supported during subsequent delivery of the forehead, face, chin, and neck.

After the head has been delivered, the infant's face is quickly wiped and the mouth and nose suctioned with a bulb syringe to minimize the chance of aspiration during delivery of the thorax. A finger is then passed around the fetal neck to assess for nuchal cord, found in 25% of deliveries. If found, the cord is gently loosened and slipped over the infant's head. If this cannot be done easily, the cord is doubly clamped and cut and the infant delivered *promptly*.^{6,7}

In most cases, the infant's shoulders are born spontaneously. Delivery may be aided by grasping the sides of the head and exerting gentle downward traction until the anterior shoulder appears beneath the symphysis pubis. The head is then gently lifted upward to aid delivery of the posterior shoulder (see [Fig. 79.1](#)). The remainder of the body usually follows without difficulty. After the shoulders have been freed, delivery may be assisted by *gentle* traction on the head, if necessary. Injury to the neck or brachial plexus can occur from direct pressure on the axilla or oblique traction on the neck during delivery.^{6,7}

After delivery, the neonate is held with the head slightly lower than the body to facilitate drainage of accumulated mucous and bronchial secretions while the nose and mouth are thoroughly suctioned.⁹ The neonate is kept at or slightly below the level of the perineum until clamps are applied to the umbilical cord 4 to 5 cm and 2 to 3 cm away from the fetal abdomen. The cord is then cut, usually 30 to 60 seconds after delivery.^{6,7} The newborn is quickly dried and bundled to prevent cooling.^{7,9}

The placenta is delivered during the third stage of labor, usually spontaneously and within 5 to 30 minutes of delivery.^{6,9} Signs of placental separation include a globular, firmer uterus that rises in the abdomen as it contracts, a sudden gush of blood, and lengthening of the umbilical cord. Intraabdominal pressure produced by the mother's bearing-down efforts may be enough to effect complete expulsion of the placenta. If maternal force alone is insufficient, delivery may be aided by applying gentle pressure through the abdominal wall to lift the uterine fundus cephalad while keeping the umbilical cord slightly taut. This maneuver is repeated until the placenta appears at the introitus, when it is gently lifted out of the vagina. Trailing membranes are gently removed with traction. Excessive traction on the placenta should never be used and can result in inversion of the uterus. Following delivery, the placenta is examined for completeness.^{6,7,9}

After delivery of the placenta, gentle uterine massage and an oxytocic agent are used to stimulate uterine contractions. Oxytocin is the most commonly used oxytocic. Typically, 20 U of oxytocin is added to 1000 mL of normal saline and given intravenously at a rate of 10 mL/min for several minutes until the uterus is firmly contracted and bleeding is controlled. The infusion rate is then reduced to 1 to 2 mL/min. Oxytocics should not be used before delivery of the placenta, because resultant uterine contractions may entrap the placenta or an undiagnosed second twin.^{6,7,9}

Episiotomy

Prior to the early 1990s, greater than 60% of women in the United States received an episiotomy during childbirth, most as a routine procedure.¹⁶ Its use was justified by the prevention of severe perineal tears, better future sexual function, and a reduced incidence of urine and fecal incontinence.^{10,16} More recent studies, however, have determined that the routine use of episiotomy results in an equal or greater incidence of third- and fourth-degree perineal lacerations, postpartum perineal pain, urinary incontinence, and dyspareunia.^{10,14,16} Therefore, the routine use of episiotomy has been abandoned for a more selective approach.^{6,7,10} Indications for selective episiotomy include breech delivery, shoulder dystocia, occiput posterior presentations, and imminent perineal tear.^{6,7}

Generally, the midline episiotomy is preferred over the mediolateral in the ED because of ease of performance and repair, less blood loss, and more rapid and comfortable healing.^{6,7} The episiotomy should be timed so that it precedes trauma to the maternal tissues and fetus but avoids excessive blood loss before delivery. With vertex presentations, the episiotomy should be performed when the fetal head begins to distend the perineum and the fetal head becomes visible to a diameter of 3 to 4 cm during a contraction.^{6,7} The incision may be made with a scalpel or scissors and extends through the skin, subcutaneous tissue, vaginal mucosa, urogenital septum, and the superior fascia of the pelvic diaphragm. If a scalpel is used, a tongue blade should be placed between the infant's head and maternal perineum while the perineum is incised.⁷

Repair of the episiotomy is deferred until after the placenta is delivered and after inspection and repair of the cervix and upper vaginal canal. Absorbable suture is used, with the goals of restoring anatomy and achieving hemostasis with a minimum of suture material. A variety of techniques are used and can be found in several standard textbooks.^{6,7}

COMPLICATED DELIVERIES

Preterm Labor

If preterm labor exists and delivery is not imminent, consultation is advised, with immediate transfer to the labor and delivery area for monitoring and assessment of fetal maturity. When appropriate obstetric facilities are not available, attempts to arrest labor should be initiated in the ED.⁷

Although a number of drugs and other interventions have been used to inhibit preterm labor, unfortunately, none has been found to be completely effective.^{1,6,13} Initial management includes supplemental oxygen, placing the mother in the left lateral decubitus position, and intravenous hydration with 500 mL of crystalloid solution.^{1,7,9} If contractions persist and cervical changes are documented despite these basic interventions, pharmacologic tocolytic therapy is indicated ([Table 79.2](#)).^{1,6,7,9,13} Although tocolytic therapy has not been shown to inhibit preterm labor for greater than 48 hours, this brief delay may allow maternal transfer to a tertiary care center or delay delivery sufficiently to improve fetal maturation with glucocorticoids.^{1,6,13} In addition to the first-line tocolytics noted in [Table 79.2](#), nifedipine has been demonstrated to be a potentially effective tocolytic with few adverse fetal effects.^{1,6,13} Because fetal viability is rare prior to 24 weeks' gestation and fetal outcome at 34 to 37 weeks is similar to that at term, tocolytic therapy is generally not recommended outside of this age range.^{1,13}

Agent	Initial Dose	Subsequent Dose ^a
Tetbutaline ^b	0.25 mg subcutaneously, or 2.5–5.0 µg/min i.v. infusion	May repeat every 20 to 40 min, or 7.5–5.0 µg/min every 20 min
Ritodrine	50–100 µg/min i.v. infusion	750 µg/min every 10 to 20 min to maximum dose of 750 µg/min
Magnesium sulfate	4–6 g i.v. over 20 min	2–4 g/h i.v. infusion

^aExcept as noted, endpoint is cessation of uterine contractions or signs of drug toxicity.
^bAlthough commonly used as a first-line tocolytic, tetbutaline is not approved by the Food and Drug Administration for this use.

TABLE 79.2. Tocolytic Agents⁷

Preterm PROM may herald the onset of preterm labor and is a risk factor for the development of intrauterine infection. All women with preterm PROM, therefore, should be admitted for assessment of labor and consideration for antibiotic, tocolytic, and fetal maturation therapy.^{6,9}

Fetal Distress

If fetal distress is suspected on the basis of changes in fetal heart rate, changing maternal position, typically into the lateral recumbent position, and administration of maternal oxygen may be beneficial.^{2,7} In the absence of bleeding, a vaginal examination should be performed to rule out cord prolapse.^{2,7} If immediate obstetric services are not available, tocolytic therapy to decrease uterine contractions and improve fetoplacental blood flow until delivery can be accomplished should be considered.^{2,7} The definitive therapy for persistent fetal distress is delivery of the infant, either vaginally or by cesarean section.^{2,6,7}

Cord prolapse usually occurs at the same time as rupture of the membranes and is diagnosed by palpation of the umbilical cord on vaginal examination or by visualization of the cord protruding through the introitus. Cord prolapse occurs during labor in approximately 0.2% of pregnancies and is more frequently seen with abnormal fetal presentation, multiple gestations, low birth weight, and prematurity.^{6,17} The management of cord prolapse is directed at sustaining fetal life until delivery is accomplished, usually by cesarean section. If immediate obstetric services are not available, tocolytic therapy may be instituted.^{7,12} Compression on the umbilical cord is minimized by placing the patient in the knee–chest or deep Trendelenburg position and exerting manual pressure through the vagina to lift and maintain the presenting part away from the prolapsed cord.^{7,9} Some physicians recommend instilling 500 to 700 mL of saline into the bladder to maintain cord decompression.^{7,12}

Shoulder Dystocia

Complicating less than 2% of all vaginal deliveries, *shoulder dystocia* refers to impaction of the fetal shoulders in the pelvic outlet after delivery of the head in vertex presentations.^{3,8,18} Although more common in infants weighing greater than 4000 g, shoulder dystocia cannot be reliably predicted from any antepartum risk factors.^{6,8,18} Impaction of the fetal shoulders and thorax in the maternal pelvis prohibits adequate respiration, and compression of the umbilical cord frequently compromises fetal oxygenation, making shoulder dystocia a serious and, at times, fatal complication of delivery.^{9,18}

The goal of management is to minimize the time between delivery of the head and delivery of the body. Assistance, including that of an obstetrician and pediatrician, should be sought.^{7,18} Excessive traction on the fetal head and fundal pressure should be avoided, because these maneuvers can worsen shoulder impaction and increase the incidence of permanent brachial plexus injury in the infant.^{6,9,18}

Several techniques to manage shoulder dystocia have been described that result in successful delivery in a significant number of cases. Use of the McRoberts' maneuver has been well documented and consists of hyperflexion of the maternal thighs onto the maternal abdomen.^{6,7and8,18} Alternatively, moderate suprapubic pressure may be applied to the maternal abdomen by an assistant while gentle traction is exerted on the fetal head.^{6,7,18} Recently the “all-fours” maneuver has been described and consists of placing the mother on her hands and knees to effect delivery without the aid of additional maneuvers.³ If none of these techniques is successful, rotational manipulation of the fetal shoulders, aided by a wide midline episiotomy, may effect delivery. These maneuvers are described elsewhere.^{6,7,9,18}

Breech Presentation

When compared with cephalic presentations, breech delivery is associated with an increased incidence of preterm delivery, low birth weight, umbilical cord prolapse, uterine and congenital abnormalities, and perinatal morbidity and mortality.^{6,7,20} Breech delivery should be suspected in preterm deliveries and is confirmed by demonstrating the firm ballotable head in the uterine fundus. Sonography can also be used to confirm breech presentation.⁶

Breech delivery is difficult because successively larger and less compressible parts of the fetus are born, culminating in delivery of the fetal head, which may be trapped by an incompletely dilated cervix. In addition, umbilical cord prolapse is more common. In general, delivery is easier and perinatal morbidity and mortality reduced when the breech infant is born spontaneously at least to the level of the umbilicus. Techniques for assisting and extracting the breech infant differ with the type of breech presentation and are detailed in several textbooks.^{6,7}

Meconium-stained Amniotic Fluid

Meconium-stained amniotic fluid occurs in approximately 8% to 15% of all deliveries and results in meconium aspiration syndrome in 2% to 6% of these neonates.^{5,19} When meconium-stained fluid is identified during delivery, it is generally agreed that thorough suctioning of the infant's nares and mouth with a bulb syringe or DeLee suction trap should be performed prior to delivery of the shoulders.^{5,6,19} Subsequent suctioning of the hypopharynx under direct visualization, followed by intubation with suctioning of the lower airway, is indicated in depressed neonates, those who have passed thick or particulate meconium, and those in which inadequate oropharyngeal suctioning was performed during delivery.^{5,6} Whether vigorous infants with thinly meconium-stained fluid require intratracheal suctioning is controversial.^{5,6,19}

Perimortem Salvage

Perimortem cesarean section should be performed in any woman who suffers a cardiac arrest after 24 weeks' gestation and is unresponsive to brief resuscitation.^{11,15} Fetal survival is related to fetal maturity, time from maternal death to delivery, the effectiveness of cardiopulmonary resuscitation on the mother, and, in certain circumstances, the availability of neonatal intensive care facilities.^{7,11} The chances of fetal survival are greatest if delivery is completed within 5 minutes of maternal arrest.¹¹ Following cesarean delivery, maternal resuscitation may be improved through increased maternal venous return.¹¹

Prior to cesarean section, maternal resuscitation should be aided by placing the mother in the left lateral decubitus position at 15 degrees or by manually displacing the uterus off the inferior vena cava. Maternal oxygen via an endotracheal tube, cardiac compressions, and fluid resuscitation, if indicated, are initiated and continued throughout the procedure.^{11,15} Delays to assess fetal heart tones or gestational age should be avoided.¹⁵ Emergent obstetric and pediatric consultation should be requested concurrent with initiation of the procedure.¹⁵ Because cesarean delivery may improve maternal hemodynamics, maternal resuscitation should be continued after delivery.

DISPOSITION

The best place for delivery is in the labor and delivery suite. In hospitals with full obstetric services, unless the patient is crowning, there is usually time to transport

the mother to the in-house obstetric unit.⁹

Patients in preterm labor and those in whom other complications of pregnancy have been identified should be delivered in a tertiary care center whenever possible. Generally, antepartum maternal transport is more desirable than postpartum, especially with fetal prematurity.^{1,9,13} The issue of transfer to an appropriate facility is best decided in consultation with the attending obstetrician. Parity, progress of labor, fetal and maternal condition, time involved in transport, the sophistication of in-house services, and response to initial therapy are factors to consider in deciding the appropriateness of transfer. Indications for transfer include preterm labor, PROM, preeclampsia–eclampsia, third-trimester bleeding, multiple gestations, and known fetal abnormalities. Ultimately, the transfer decision is made on a case-by-case basis, preferably in consultation with an obstetrician. When the decision is made to transfer the patient, minimally an ACLS unit should be used. Aeromedical transport or the presence of a qualified nurse or physician may also be indicated.

COMMON PITFALLS

- Failure to recognize imminent delivery may lead to a transfer that places mother and infant at increased risk for poor outcome.
- Failure to recognize meconium-stained amniotic fluid and to perform meticulous airway care during and immediately after delivery may lead to subsequent fetal aspiration, morbidity, and mortality.
- Manipulation of the fetus during delivery should be gentle and smooth. Excessive traction, particularly to accomplish shoulder delivery, may lead to significant fetal injury, often with long-term disability.
- Excessive traction to the umbilical cord during delivery of the placenta can cause uterine inversion or tearing of the placenta.

The postpartum patient presenting to the emergency department may be suffering from any of a diverse number of diseases exclusive to or more prevalent in the postpartum period. Many of these problems are life-threatening.

In the third trimester, maternal blood volume is 35% to 50% above normal, the plasma volume is increased by 1,200 mL, and the red blood cell volume by 250 mL. Cardiac output is increased by about 1.5 L/min; 600 mL/min of blood flows through the placental site at term. Consequently, uterine and ovarian veins handle a 60-fold increase in volume during pregnancy. In addition, the hypercoagulable state of pregnancy and the trauma from delivery predispose to body-wide thrombosis in the puerperium, experienced as deep venous thrombosis (DVT) or cerebrovascular accident.⁹

The postpartum uterus returns to its nonpregnant anatomic shape and position by loss of cellular fluid and protein and consequent reduction in cell size. This involution is ongoing during the weeks after delivery. Most involution (about 40%) occurs in the first week postpartum. The uterus resumes its intrapelvic position by 2 weeks and normal size by palpation at 6 weeks postpartum. Vaginal bleeding generally diminishes several hours after delivery to a red-brown discharge, which may last through day 3 or 4 postpartum. A mucopurulent discharge may wax and wane over 4 to 6 weeks.⁹

The mean time to ovulation is 70 to 75 days in nonlactating mothers and 190 days in those who lactate; elevated prolactin levels are responsible for the delay in women who nurse. Menstruation resumes by about 12 weeks in most nonlactating women (mean, 7 to 9 weeks) but may be delayed in breastfeeding mothers up to 36 months.⁹

POSTPARTUM HEMORRHAGE

CLINICAL PRESENTATION

The causes of postpartum hemorrhage may be divided into early (less than 24 hours) and late (greater than 24 hours, less than 6 weeks) presentations ([Table 80.1](#)). Early postpartum hemorrhage is most often due to uterine atony. Bleeding can be brisk, and shock can develop rapidly. Maternal vital signs are often falsely reassuring, and blood loss can be hidden within the uterus and/or pelvis, making recognition of significant bleeding difficult in some cases.¹⁸ Late causes of hemorrhage include infection, delay in placental site involution, and retained placental parts. There may also be a normal, transient increase in bleeding in the second postpartum week due to sloughing of the eschar that covers the placental attachment site.^{7,13}

EARLY HEMORRHAGE (<24 H)
Uterine atony
Genital tract laceration
Retained placental parts
Placenta accreta
Hematoma
Uterine inversion
Uterine rupture
Coagulopathy
LATE HEMORRHAGE (UP TO 6 WK)
Infection (endometritis)
Retained placental parts
Delayed placental site involution
Sloughing of placental site eschar

TABLE 80.1. Causes of Postpartum Hemorrhage

DIFFERENTIAL DIAGNOSIS

Early Postpartum Hemorrhage

Uterine atony is responsible for most cases of early postpartum hemorrhage. Failure of the uterine corpus to contract properly allows continued blood loss from the placental site. Myometrial dysfunction occurs more frequently if the uterus has been overdistended (multiple gestations, hydramnios, multiparity, macrosomia); if there has been precipitous or prolonged labor, general anesthesia, or previous postpartum hemorrhage; if leiomyomas or amnionitis is present; or if fetal demise or amniotic fluid embolus occurs. Adherent fragments of placenta can also interfere with myometrial contractile function.

Minor pelvic trauma occurs in almost all deliveries. However, some vaginal and cervical lacerations may lead to severe hemorrhage. Pelvic vessels can be injured in the process of delivery, causing a pelvic hematoma. Vulvar hematomas are the most common; because the bleeding is bounded by superficial fascial planes, the hematoma usually dissects to the skin and is visible. Deeper vaginal hematomas can be occult and accumulate a significant amount of blood, distending into the pelvic space under the peritoneum. Patients may present with complaints of rectal pressure. Retroperitoneal hematomas are the least common but most dangerous

type of hemorrhage. They are associated with significant blood loss, usually the result of trauma to a branch of the hypogastric artery, and can present with shock.

Retained placenta is a common cause of both immediate and late postpartum hemorrhage. Premature, assisted delivery of the placenta increases the risk for retained fragments, with resultant impairment of full uterine contraction and development of hemostasis. *Placenta accreta*, an abnormally deep attachment of the placenta to the myometrium, is suspected if placental delivery is difficult and no cleavage plane between placenta and uterus is found at manual exploration.⁹

Uterine inversion is uncommon.¹⁵ Inversion is usually recognized soon after delivery of the placenta, and is more likely if traction is exerted on the umbilical cord. If the uterine corpus passes through the cervix, the inversion is complete; if not, it is incomplete, and may be occult. The patient presents with acute onset of abdominal pain, hemorrhage (average loss, 2 L), and shock. Often, hypotension occurs before significant visible blood loss.³¹

Uterine rupture is catastrophic and often results in fetal and even maternal demise, although the clinical spectrum of morbidity is broad. Factors associated with a rupture include previous curettage, cesarean section (especially with a high uterine incision) or rupture, hydramnios, multiple fetuses, and placenta accreta. Although more common in a previously scarred uterus, rupture of the nonscarred uterus does occur.

Coagulopathy can complicate postpartum hemorrhage that occurs from any source. Additionally, abruption, amniotic fluid embolus, and pregnancy-induced hypertensive disease can cause consumptive coagulopathies that then cause postpartum hemorrhage.

Late Postpartum Hemorrhage

The differential diagnosis of late postpartum hemorrhage includes endometritis, retained placental parts, placental site subinvolution or eschar sloughing, and resumption of menses.

EMERGENCY DEPARTMENT EVALUATION AND TREATMENT

The evaluation of the patient with postpartum bleeding should begin with an assessment of the extent of blood loss and the presence of hypovolemia and shock. If present, shock is treated as the rest of the evaluation proceeds. In all cases of significant immediate postpartum bleeding, laboratory studies should include a complete blood count and coagulation studies. Early establishment of vascular access is critical. The patient is typed and crossmatched, and fresh-frozen plasma should be available.¹⁸

Abdominal and bimanual examinations are necessary to identify the size, position, shape, and tone of the uterus, and the placenta (if available) should be inspected for completeness. If the uterus feels boggy and uterine atony is suspected, manual massage is performed: One hand massages in a circular fashion on the abdomen, with intravaginal fingers massaging the uterus upward. Massage may cause temporary uterine contraction, with recurrent bleeding after relaxation.⁷ Pharmacologic treatment (Table 80.2), started concomitantly, includes drugs that cause increased uterine muscular tone (oxytocin, prostaglandins, and ergot alkaloids). Intravenous infusion of oxytocin is first-line treatment.

Drug	IM Dose	IV Administration	Side Effects
Oxytocin	10 U	20-30 U in 1 L NS at 20 mL/h	Hypotension if given as bolus; cramping
Ergonovine maleate	0.2 mg		Cramping
Methyl-ergonovine	0.2 mg		Cramping
15-methyl-prostaglandin	0.25 mg		Nausea and vomiting
NS, normal saline.			

TABLE 80.2. Medical Management of Uterine Atony

If bleeding continues, the birth canal should be inspected for trauma. Vaginal or cervical lacerations longer than 2 cm or those that are bleeding are repaired. Adequate exposure is needed, which can require general anesthesia.²⁷ With persistent bleeding or a placenta that appears incomplete, digital exploration of the uterine cavity may be indicated to look for retained placental fragments or uterine rupture. If placental elements remain, an obstetrician is consulted for uterine cavity curettage with a gauze sponge over the fingers.⁷

Management of uterine inversion includes manual restoration of uterine anatomy, followed by removal of the placenta if it remains attached. Manual replacement through the vagina is usually successful. The uterus is compressed between both hands intravaginally and gradually replaced. General anesthesia or tocolytics may be required to allow adequate uterine relaxation. Only after replacement of the uterus is oxytocin started.³¹

Refractory bleeding from any source may require emergent surgical intervention or arterial catheterization and embolization. Uterine rupture, once diagnosed, almost always requires surgery. Retroperitoneal hematomas frequently require surgery or embolization. Increasingly, angiographic embolization is being utilized in refractory cases of bleeding. Very high success rates for embolization have been cited, even cases that have failed traditional surgical intervention. Availability (time to catheter placement) and comfort and skill levels of the personnel involved can influence its use.

Imaging

Ultrasonography may aid in narrowing the differential in stable patients with both early and late postpartum hemorrhage. Ultrasound of the uterine cavity can be used to help rule out retained placental tissue by demonstrating a normal uterine stripe. Ultrasound may also be able to distinguish between retained tissue (echogenic mass) and a large intrauterine clot (sonolucent). Occult hematomas can be identified and those patients rapidly triaged to angiography and subsequent embolization. Computed tomography (CT) scanning, although more time consuming, may also show hematomas that would be amenable to percutaneous drainage.²³ It is unclear whether the advent of rapid spiral CT scanning will change imaging algorithms for patients with postpartum hemorrhage.

Curettage

Traditional therapy of late postpartum hemorrhage has been curettage. However, placental tissue is often not retrieved, and bleeding may worsen after the procedure. With the ability of uterine ultrasound to rule out retained placental parts, initial therapy now relies on pharmacologic management, using the drugs in Table 80.2. If bleeding stops, the patient is observed. Curettage may be indicated if bleeding persists or if retained placenta is seen by ultrasound.⁷ Endometritis should be considered if late bleeding is accompanied by fever or abdominal tenderness (discussion follows).

DISPOSITION

Many causes of early postpartum hemorrhage are best treated in the labor and delivery suite, where obstetric surgical facilities, including general anesthesia and skilled personnel, are available. In the emergency department, treatment of the unstable patient begins with vascular access, aggressive fluid therapy, oxytocin, and mobilization of appropriate resources. The disposition of a patient with late postpartum hemorrhage depends on the amount of bleeding, the response to initial therapy, and the probable cause of the bleeding. Decisions are best made in consultation with the patient's obstetrician.

COMMON PITFALLS

- Visually estimating blood loss is not an accurate method. Young women may have significant blood loss without developing typical signs of hypovolemia, making recognition of significant bleeding difficult in some cases.
- Be aware that intravenous boluses of oxytocin can cause hypotension.
- Uterine atony is the most common cause of postpartum hemorrhage. If it responds rapidly to manual massage, oxytocin should be given as well to prevent subsequent relaxation.
- Genital tract lacerations are the second most common cause of postpartum hemorrhage. Blood loss may be excessive if these are not considered and ruled out by visual inspection early on.

PUERPERAL FEVER

CLINICAL PRESENTATION

Fever above 100.4°F (38°C) on any 2 of the first 10 days postpartum (not including the first 24 hours) is considered significant. This definition may cause delay in the diagnosis of potentially life-threatening infections in patients who either do not mount a fever to 38°C, or who develop serious bacteremia and sepsis in the first 24 hours postpartum. Persistent fever after the first 24 hours of the postpartum period warrants investigation.

Fever may be classified as early (less than 48 hours) or late (greater than 48 hours, less than 6 weeks). Patients may present with symptoms and signs that make the diagnosis obvious, such as findings associated with respiratory or urinary tract infection. Many causes of puerperal fever, however, have nonspecific presentations. Lower abdominal pain may be due to persistent contractions or inflammation. Vaginal discharge can be scant or profuse in the face of metritis or normal involution. Abdominal tenderness and foul-smelling lochia are nonspecific signs, as are tachycardia and decreased bowel sounds. Wound sites should always be examined for tenderness, dehiscence, induration, edema, erythema, and discoloration.²⁵ Mastitis presents initially with fever, flulike symptoms, and, usually, a localized, painful site in the affected breast, with erythema and induration. There have also been reports of toxic shock syndrome from *Staphylococcus aureus* mastitis.¹¹ Septic thrombophlebitis may present with refractory fever or symptoms of pulmonary embolism (PE).

DIFFERENTIAL DIAGNOSIS

Early infections (within 48 hours) most often occur in the uterus and peritoneum following cesarean section (often polymicrobial) or are related to the urinary or respiratory tracts. Late infections (after more than 48 hours) include uterine infection following vaginal delivery (usually the result of ascending endogenous organisms), abdominal and episiotomy wound infections, breast infections, and complications of uterine infection (such as abscess or thrombophlebitis). Anaerobic bacteria, *Chlamydia*, *Mycoplasma*, and *Ureaplasma urealyticum* are often responsible for late infections.²⁸ Table 80.3 outlines common causes of puerperal fever.

Site	Example	Comment
Pelvic	Endometritis	Single most common cause of puerperal fever; suggest especially after cesarean section
	Wound infection	Requires local exploration and opening
	Toxicity	
	Pelvic abscess	Diagnosed by ultrasound
Urinary	Septic thrombophlebitis	Support with labors to respond to antibiotics for endometritis
	Pyelonephritis	Culture and UA for diagnosis
Pulmonary	Metritis	Consider sepsis or general infection
	Pneumonia	
Breast	Engorgement	Within 24-36 hours; diffuse, bilateral induration and tenderness
	Milk stasis	
	Mastitis	Fever, flulike symptoms, local erythema and tenderness
Other	Bacteremia	
	Sepsis	
	Endocarditis	
	UTI with local symptoms	

TABLE 80.3. Causes of Puerperal Fever

Endometritis is infection of the endometrium (the decidua and adjacent myometrium), but often the process extends beyond the uterus into the parametrial tissue, causing a diffuse pelvic cellulitis. The incidence of postpartum uterine infection is 1% to 6% in vaginally delivered women.⁷ Cesarean section increases both the frequency and the severity of infection: Endometritis occurs in up to 10% to 20% of patients undergoing cesarean section, despite prophylactic antibiotics.²⁵ Other risk factors include premature rupture of membranes, prolonged time from rupture of membranes to delivery, the number of cervical examinations performed, intrauterine manipulation, preterm labor, and low socioeconomic status. Endometritis can lead to sepsis, peritonitis (rare), adnexal infections (most often perisalpingitis), pelvic abscess, septic pelvic thrombophlebitis, parametrial phlegmon, and toxic shock syndrome. Salpingitis is uncommon.⁷

Most endometritis is the result of ascending (polymicrobial) infection of normal cervicovaginal flora or preexisting genital tract infection. The placental attachment site and the tissue trauma associated with delivery provide good growth media for bacteria. The role of *Chlamydia* in postpartum endometritis is unsettled.²⁰

Wound infections complicate 1.5% to 13.0% of deliveries. Most infections are caused by skin or genital tract flora. Common pathogens include *S. aureus*, groups A and B streptococci, *Escherichia coli*, *Proteus* spp., and anaerobes (especially *Clostridium* and *Bacteroides*). If cesarean section is performed emergently or amnionitis is present, a higher rate of wound infection is noted. Many patients initially are diagnosed with endometritis, but despite antibiotic therapy continue to spike temperatures because they require debridement and drainage. Complications of wound infection include synergistic bacterial gangrene (especially with clostridial species), necrotizing fasciitis (most commonly a group A beta-hemolytic streptococcal infection), wound dehiscence, and toxic shock syndrome.^{4,7}

Episiotomy and pelvic floor infections complicate less than 1% of deliveries. The fascial anatomy dictates the depth and spread of the infection and may obscure the findings. Causative bacteria include streptococci and staphylococci, gram-negative enterics, and *Bacteroides* spp. Most infections are superficial and mild, limited to the skin and superficial fascia in the area adjacent to the episiotomy. More extensive disease can involve Scarpa's fascia, causing a potentially life-threatening necrotizing fasciitis.⁹

Septic pelvic thrombophlebitis develops from an infection of the placental site and associated thrombosed myometrial veins. Once established, the process can proceed beyond the local venous system to include the vena cava. Most often the process is unilateral, usually right-sided. Septic pelvic thrombophlebitis is most common following cesarean section.⁷

One percent to 2% of postpartum women develop mastitis, which is usually seen between weeks 2 and 6 after delivery. *S. aureus* is the most common causative agent.

Engorgement of the breasts consists of distended, firm, nodular breasts in the first 24 to 48 hours postpartum, while lacteal secretion is developing. The condition is painful and often associated with mild transient fever. Milk stasis is the result of incomplete emptying of the milk glands. This noninfectious process can complicate the evaluation of the febrile postpartum patient and can progress to sporadic infectious mastitis.

EMERGENCY DEPARTMENT EVALUATION

After a detailed obstetric history is taken, the examination focuses on the genital tract, wounds, the breasts, and the urinary and respiratory systems. Examination may reveal tenderness of the lower abdomen and a purulent or foul-smelling lochia. The uterus is tender and possibly boggy, with parametrial thickening and pain. If an adnexal mass is palpable, it might represent an abscess or an infected hematoma. The entire perineum and genital tract are inspected for signs of infection from a laceration or episiotomy. A rectovaginal examination should help identify parametritis or other abscesses or hematomas. Although unusual, a retroperitoneal abscess is

suggested if there is diffuse hip or pelvic pain, fever, a tender rectal area, and painful ambulation.

Laboratory evaluation should include blood cultures, a complete blood count, and a urinalysis. Endometrial culture should be considered but may be difficult to interpret because of cervical contamination. Chest x-ray may be indicated; plain films of the pelvis may reveal soft-tissue gas if fasciitis is present.

Imaging studies may be helpful in puerperal fever, particularly when the source is unclear or there is no clinical response to 48 to 72 hours of appropriate antibiotic therapy. CT scanning in endometritis shows intrauterine debris, fluid, and gas in some patients. Ultrasound may reveal endometrial gas, which is sometimes associated with infection but is also seen in clinically well women. Ultrasound, CT scanning, and magnetic resonance imaging can be helpful in the diagnosis of several occult, intrapelvic, infectious sources, such as abscess, infected hematoma, and septic thrombus. Generally, ultrasound is the first-line test of choice; a CT scan can be performed if initial ultrasound is negative. Pelvic venography may be required to diagnose septic thromboses. ^{3,17}

EMERGENCY DEPARTMENT MANAGEMENT

Endometritis is treated empirically, without endometrial cultures, and the patient is followed closely. If the patient is toxic or has underlying medical problems (e.g., diabetes) or the clinician suspects anaerobic infection, clindamycin and gentamicin or clindamycin and a second-generation cephalosporin (cefoxitin) are given. Single-agent parenteral therapy has also been suggested: Cefoxitin, cefotaxime, mezlocillin, and piperacillin successfully treat the most common aerobic pathogens and some anaerobic pathogens. Ampicillin–sulbactam (Unasyn), ticarcillin–clavulanate (Timentin), and imipenem are also effective single, broad-spectrum antibiotics. ^{8,19}

Although most require admission, in patients with mild endometritis, oral agents are appropriate: The quinolones have the broadest range of activity against the pathogens likely to be involved in infection. ¹⁹ Patients with endometritis who do not respond to treatment within 48 to 72 hours require further workup to detect resistant organisms, wound infection, abscess formation, infected hematomas, and septic thrombophlebitis. Treatment of wound infection may include opening and debriding the area under adequate anesthesia. If more than local cellulitis is suspected, exploration under general anesthesia should be considered. ²⁵ Fascial necrosis is a surgical emergency requiring immediate consultation: Mortality approaches 100% in patients treated with antibiotics alone and drops to 50% with combined surgical and pharmacologic treatment. Abscesses and some superficial hematomas can be incised and drained.

If septic thrombophlebitis is suspected, heparin and antibiotics for 7 to 10 days are usually necessary. The incidence of heparin-related bleeding in the postpartum state is low (1% to 2%). ⁹

Mastitis is usually sufficiently treated with a penicillinase-resistant antibiotic. ¹ With prompt treatment, mastitis usually resolves within 48 hours. If an abscess has formed, incision and drainage is necessary. ¹² If breast infection is not present but milk stasis develops, more efficient emptying of the breast is needed. Nursing should continue, and treatment includes breast support, ice, and analgesia. If the patient is not breastfeeding, and conservative methods are insufficient to relieve pain, suppression of lactation may be helpful. Bromocriptine has been withdrawn for lactation suppression, but other agents are available. Consultation with the obstetric service is indicated.

DISPOSITION

The disposition varies with the type and severity of illness. If the patient is toxic (from any source), inpatient parenteral antibiotic therapy is indicated. Patients with abscesses, septic thrombophlebitis, or complicated wound infections also require inpatient therapy.

COMMON PITFALLS

- Necrotizing fasciitis is life-threatening; it requires emergent surgical consultation, aggressive debridement, and antibiotic therapy. Despite prompt, appropriate treatment, mortality is significant.
- Failing to consider nongynecologic sources of postoperative infections, such as urinary tract infection, may lead to a delay in diagnosis and inappropriate initial therapy.
- Do not assume that breast pain and fever in the first 2 to 4 days postpartum are caused by mastitis. Engorgement often causes these symptoms and does not require antimicrobials.

MEDICAL DISEASES

The postpartum patient may suffer exacerbations of a medical condition. Also, the onset of many diseases occurs during the weeks after delivery, including previously subclinical thyroid disease and autoimmune disorders. Postpartum ischemic necrosis of the anterior pituitary (Sheehan syndrome) may develop if severe postpartum hemorrhage with shock has occurred. ⁹

HYPERTENSIVE DISEASE

Pregnancy-related hypertension is classified as preeclampsia and eclampsia, chronic hypertension, preeclampsia superimposed on chronic hypertension, and transient hypertension. ⁶ The occurrence of these diseases antepartum is discussed in [Chapter 77](#).

NEUROLOGIC DISEASE

Half of all thromboembolic events in women under age 40 in the United States occur in relation to pregnancy and the puerperium. The risk of both hemorrhagic and ischemic *stroke* is at its maximum in the 6 weeks postpartum, and stroke remains responsible for a significant number of maternal deaths. The increased risk of ischemic stroke seems to be due to spontaneous thrombosis, possibly related to heightened coagulability. The relative risk of maternal cerebral artery occlusion is 8.7 (95% confidence interval, 4.6 to 16.7) in the postpartum period. The middle cerebral artery is the most common site of occlusion. Predisposing factors such as preeclampsia, chronic hypertension, diabetes, and hypotensive episodes are found in about one-third of patients. Stroke can present as new-onset seizure, and if so, must be differentiated from eclampsia. Embolic sources should be considered in pregnant patients suffering an acute ischemic stroke. ¹⁴ CT scanning, performed acutely and followed by lumbar puncture if needed, is used to exclude hemorrhage. ²¹ *Cortical venous thrombosis* is also reported, particularly 1 to 4 weeks postpartum. Initial symptoms are variable and may include headache, lethargy, and vomiting. Seizures are common (up to 30%), and hemiplegia may occur (gradual onset). Care is supportive, although prophylactic anticonvulsant therapy is usually given. Most authors do not recommend anticoagulation, as bleeding frequently follows clot resolution. Mortality may be as high as 20%, despite aggressive supportive treatment. ^{21,24}

Postpartum women also have an increased incidence of idiopathic *Bell's palsy*. The course and expression of the disease are unaltered by pregnancy. In a distinct syndrome known as *postpartum cerebral angiopathy*, the patient presents with headache, vomiting, seizures, and focal neurologic signs. Angiography shows multiple areas of segmental narrowing in the cerebral arteries; these usually clear spontaneously.

THROMBOEMBOLIC DISEASE

The risk of thromboembolic disease in pregnancy is roughly five times higher than in the nonpregnant population. Though most thromboses develop in the antepartum period, recent data indicate that two-thirds of pulmonary embolisms occur in the postpartum period. PE remains a significant cause of maternal death. Virchow's triad—stasis, changes in maternal coagulation, and vessel damage from delivery (especially cesarean section)—predisposes to thrombosis development. ²⁶

Diagnosing DVT and PE can be difficult in the puerperium. Leg edema and calf soreness are common postpartum. Arterial blood gas analysis shows a normal respiratory alkalosis secondary to hormone stimulation. Pelvic thrombosis is often clinically silent until PE occurs. A protocol of ventilation–perfusion scanning, noninvasive lower extremity studies, and pulmonary angiography may be needed to make or exclude the diagnosis (see discussion in [Chapter 78](#)). Treatment includes intravenous heparin and is similar to treatment in nonpregnant patients. Postpartum patients with DVT or PE usually require a total daily dose of 25,000 to

40,000 U of heparin.^{4,21}

PERIPARTUM CARDIOMYOPATHY

Peripartum cardiomyopathy is the development of cardiac failure in the last month of pregnancy or in the first 5 postpartum months, in the absence of an identifiable cause for the cardiac failure or of prior demonstrable heart disease. The incidence is reported to be between one in 1,300 and one in 15,000 deliveries. Ninety-seven percent present in the first 2 postpartum months. The disease is more common in older multiparous women and in patients with twin gestations. Patients often have superimposed preeclampsia, obesity, or coexisting obstetric infection or anemia. Clinically, patients present with left ventricular failure. Renal insufficiency can also be seen. Most patients have nonspecific but abnormal electrocardiograms, demonstrating ST-T wave changes, left ventricular hypertrophy or bundle-branch block, atrial fibrillation, and atrial and ventricular premature contractions. An echocardiogram shows four-chamber enlargement and abnormalities of left ventricular contractility. The workup is directed at excluding other causes of heart failure. Primary therapy is bedrest, sodium restriction, digoxin, and diuretics. Anticoagulation is considered if cardiac dilatation is pronounced. Patients can become refractory to medical management, and overall maternal mortality ranges from 25% to 50% in the long term. Ten percent to 20% of patients die during their first hospitalization. If the heart size returns to normal, the prognosis is good; cardiomyopathy that persists after 6 months is a poor prognostic sign. PE is a common complication.^{10,16}

POSTPARTUM PSYCHIATRIC DISEASE

A woman's risk of psychiatric admission peaks in the first postpartum year. Fifty percent to 70% of postpartum patients experience "maternity blues." Typically starting on postpartum day 3 or 4, this is a mild depression most prevalent in the first 2 weeks. It is probably a normal reaction to the stresses of childbirth. Common symptoms include tearfulness, irritability, and lability.⁹

Clinically diagnosable depression occurs in about 7% to 10% of women; in half of these patients, the symptoms were not present during or before the pregnancy. Risk factors include maternal personality traits such as anxiety, neuroticism, and cognitive style; poor marital adjustment; poor social support systems; and an excess of life events. Stresses during the pregnancy and labor may also contribute.^{5,22,30}

Postpartum psychosis is rare (0.25% incidence). Usually, the disease has a rapid onset in the first few days postpartum; mania is a common presentation. Postpartum psychosis is thought to represent exacerbation of preexisting disease. The duration of illness is usually 2 to 3 months.⁹

THERAPEUTIC DRUGS IN LACTATION

Most drugs ingested by the mother are secreted in breast milk in levels that are not thought to be pharmacologically significant to the infant. Two rules prevail: The infant will receive 1% to 2% of the maternal dose of most drugs, and the higher the maternal blood drug level, the higher the breast milk concentration of the agent. Antibiotics are among the most commonly prescribed agents and may alter the infant's bowel flora, interfere with culture results from an infant's infectious workup, and cause allergic reactions and drug sensitization. Scheduling maternal dosages just after nursing or just before the infant goes to sleep may minimize fetal exposure.² [Table 80.4](#) summarizes the relative risks of therapy with some common drugs.

Compatible	Caution or Temporary Cessation Required	Contraindicated
Ibuprofen	Metronidazole (12 ^h -24 ^h)	Cytotoxic agents
Acetaminophen	Radiopharmaceuticals	Bromocriptine
Aminophylline	Salicylates	Ergotamine
ACE inhibitors	Antihistamines	Lithium
Propranolol	Phenothiazines	Gold salts
Coumadin	Benzodiazepines	Methimazole
Prednisone	Ephedrine	
Digoxin	Pseudoephedrine	
Antibiotics	Haloperidol	
Oral contraceptives	Cimetidine	
Alcohol		
Caffeine		

*Applies to standard, normal dosages; high dosages of some agents may be potentially harmful to the infant.
ACE, angiotensin-converting enzyme.

The spectrum of gynecologic diseases that can present with abdominal pain is substantial. The emergency department (ED) physician must differentiate gynecologic from nongynecologic, acute from chronic, and benign from catastrophic causes in a timely, accurate, and efficient manner.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The approach to the woman with pelvic pain should be systematic and address three important questions:

1. What type of pain does the patient have?
2. Is the patient pregnant?
3. What nongynecologic etiologies need to be considered?

The presentations of various gynecologic causes of pelvic pain can be grouped by the different clinical syndromes commonly seen ([Table 81.1](#)). The skill of diagnosis resides in the ability to recognize patterns.²² Visceral nerves innervating the abdominal and pelvic organs, as well as the visceral peritoneum, cause dull, aching, poorly localized pain. The somatic nerves innervate the parietal peritoneum (as well as the overlying muscle and skin). Stimulation of these nerves causes the more classic sharp “peritoneal pain,” with well-localized peritoneal irritation exacerbated by movement.¹ The type of pain also governs the appropriate ancillary studies to obtain.

MILD VISCERAL	
PID (acute)	Appendicitis (rare, usually)
Ovarian cyst (distended)	Cystitis/urethritis/epididymitis
Abdominal distention	Hepatitis
Myomata	Colic (intestinal)
Endometriosis	Diverticulitis (rarely)
Endometritis	Peritonitis
Ectopic pregnancy (ruptured)	Embryotomus
Endometriosis	
SEVERE VISCERAL	
Ovarian torsion	Infection/inflammation
Ectopic pregnancy	Salmonella
PID (severe)	Intra-abdominal bacteria
	Typhoid fever
	Bowel obstruction
	Gallbladder colic
	Renal colic
SUDDEN PERITONEAL	
Ectopic pregnancy	Ruptured spleen
Ovarian cyst rupture	Ruptured abdominal
Hydrocele rupture	Aneurysm
Pyosalpinx rupture	Ruptured viscus
Abdominal trauma	Other ruptured viscus
	(trauma or blood clot)
PROGRESSIVE PERITONEAL	
PID	Appendicitis
	Inflammatory bowel disease
	Cytomegalovirus/mononucleosis

TABLE 81.1. Causes of Pelvic Pain in Women

Mild Visceral Pain

Mild visceral pain is dull, aching pain with tenderness localized to the visceral organ involved. The purpose of the physical examination is to localize the most likely source involved. The differential consists of various causes of infection or inflammation, such as uncomplicated pelvic inflammatory disease (PID), ovarian cyst distention, menstrual cramping, uterine myomata, and endometriosis, as well as infections of the gastrointestinal and urinary systems (discussion follows).

Pelvic Inflammatory Disease

PID is discussed more fully in [Chapter 82](#). Uncomplicated PID pain is most often bilateral. The pathogenesis of PID remains unclear. It appears to result from the ascension of bacteria to the upper female genital tract. The ensuing signs and symptoms are a result of the inflammatory reaction.²³ Onset is more frequent within 1 week of menses (possibly because ascendance of infection occurs more readily when the cervical os is open during menstruation), but the pain may be subacute and develop over several days. Uncomplicated PID is characterized by a dull lower abdominal pain. If infection extends beyond the endometrium and tubes, pain can become more severe and peritoneal irritation is seen. Clinical signs and laboratory parameters tend to be nonspecific, a fact that makes diagnosis difficult.²⁵ They can include fever, vaginal discharge, cervical motion tenderness, uterine or adnexal tenderness, and, rarely, a mass. Risk factors include multiple sex partners, prior PID, young age, and either no contraception or the use of an intrauterine device.^{12,13} More recently, there has also been reported an increased risk of PID with vaginal douching.²⁷ Mild symptoms of low abdominal pain and uterine tenderness may be the only signs of PID, although pathologic changes may still be significant with clinically mild disease. PID may be difficult to differentiate from surgical diseases, such as appendicitis.

Two complications of PID alter the clinical presentation. *Fitz-Hugh-Curtis syndrome (perihepatitis)* occurs when inflammation of the liver capsule causes adhesions to develop between the liver and surrounding abdominal wall. It occurs in about 4% to 14% of all cases of salpingitis, and may precede PID signs and symptoms in up to 20% of cases. Fitz-Hugh-Curtis can also occur after an acute episode of perihepatitis as a result of a recent PID infection, although in many cases there may be no history of PID or sexually transmitted disease (STD).³ The pain associated with Fitz-Hugh-Curtis is in the right upper quadrant, and is pleuritic and often severe. The pain may also radiate to the right shoulder. Neither anorexia nor a significant increase in hepatocellular enzymes is usually seen. The differential includes acute cholecystitis, pulmonary embolus, and pneumonia, as well as pyelonephritis and urinary calculus.¹⁹

Tubeovarian abscess (TOA) may occur with severe PID, particularly when caused by or associated with anaerobic organisms. TOA is the most common intraabdominal abscess in premenopausal women. TOAs represent the most serious and dangerous complication of adnexitis. The mortality of PID has been reported to be as high as 8.6% when associated with rupture.¹⁴ Some TOAs are detected when PID fails to resolve with appropriate antibiotic treatment. In a recent study, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* were evident in 28% of women with TOA.¹⁷ In other cases, sterile hydrocele or pyosalpinx results from a remote acute infection. Risk factors for TOA include PID risk factors as well as recent surgery or instrumentation.²⁶ The most common signs and symptoms include abdominal

pain, fever, and a palpable pelvic mass.¹⁷ Patients usually have continued, severe pain after treatment for PID (often unilateral), but a pelvic mass is palpated only if the patient is not too tender. Rupture of an abscess causes sudden, frank pain due to peritoneal contamination, and it is a gynecologic emergency.

Dysmenorrhea

Primary dysmenorrhea occurs in adolescents, usually within 1 to 2 years of menarche. Pain due to myometrial contractions occurs just before or coincident with menstruation, and it is described as severe, crampy, and suprapubic. It tends to occur with every menstrual period and may be incapacitating, particularly for the first 1 to 2 days of menses. Physical examination shows midline tenderness over the uterus with otherwise normal findings. Secondary dysmenorrhea can occur at any age in a menstruating woman and is most often associated with endometriosis. The rate of dysmenorrhea decreases with increasing age. In a study of 165 university students aged 17 to 19, dysmenorrhea caused absenteeism or loss of activity at least once for 42% of the women studied. The most significant associated risk factors were early age at menarche, long menstrual periods, smoking, alcohol intake, and weight (greater than the 90th percentile).¹⁰

Sexual abuse has also been strongly associated with dysmenorrhea and chronic pelvic pain. In a study of 581 nonpregnant women ages 18 to 45 with complaints of dysmenorrhea and chronic pelvic pain, there was a childhood incidence of sexual abuse of 26% and an adult incidence of 28%.¹¹

Uterine Myomata

Fibroid tumors of the uterus are common, particularly during later reproductive years. Myomata often cause heavy, irregular, and crampy menses. These tumors may undergo ischemia, necrosis, hemorrhage, or torsion. Torsion causes a sharp increase in severity of visceral pain. Physical examination in a patient with fibroids reveals a tender, enlarged, and often irregular uterus. Myomata may also interfere with fertility and increase the risk of spontaneous abortions.⁹

Endometriosis

Endometriosis is the implantation of hormonally responsive endometrial tissue outside of the uterine cavity. Implants can occur anywhere in the abdomen or pelvis as well as other areas of the body. More extensive lesions tend to correlate with severity of reported pelvic pain.^{6,20} The cyclical nature of the associated symptoms can sometimes be of assistance in the history. Approximately 50% will flare with menses. Symptoms are those of secondary dysmenorrhea in older women, with dyspareunia and abdominal, pelvic, or back pain due to stretch of contiguous organs or masses of endometrial tissue. Complications such as rupture of an endometrioma can lead to sudden pain from free peritoneal bleeding.

Severe Visceral Pain

Clinically severe visceral pain is characterized by poorly localized, nonperitoneal pain with disproportionately severe signs and symptoms, such as vomiting, pallor, restlessness, and diaphoresis. Several potential surgical diseases may cause this clinical picture, but the lack of peritoneal signs may give the clinician false reassurance that the disease process is less urgent.

Adnexal Torsion

Torsion of the ovary or other adnexal structures is a gynecologic emergency. Common predisposing factors include pregnancy, ovarian hyperstimulation syndrome, and ovarian or paraovarian cyst disease. Almost always, the ovary is enlarged; malignancy is rare. Follicular cysts are the most common type of cyst found on laparoscopic examination.⁵ The pain associated with torsion is generally intense, severe, and unilateral, with frequent radiation to the back or thigh. The pain may be associated with nausea and vomiting, and an adnexal mass is often palpable. Because the ovary and the kidney have the same innervation (T₁₀₋₁₁), the clinical picture is very similar to that of renal colic. Other nongynecologic causes of severe visceral pain include bowel ischemia and bowel obstruction.

Sudden Somatic Pain

Ectopic Pregnancy

Ectopic pregnancy (EP) is discussed in [Chapter 74](#); it is the most common concern in the woman with sudden somatic pain. It is important to remember that while catastrophic pain in association with missed menses and vaginal bleeding is the classic presentation for EP, other clinical features are seen in EP. As skills at early diagnosis improve, diagnosis of EP without frank intraperitoneal rupture is becoming more common. Early stretch and growth of the ectopic gestation in the fallopian tube can result in mild pain caused by tubal distension and contraction. Intermittent leakage of blood, which often precedes rupture by several days, will cause mild, focal, and intermittent peritoneal irritation, which is often poorly characterized by the patient.

In a recent study of 441 patients, in which 13% were diagnosed with an EP, the signs and symptoms that were most predictive of EP were pain reported as moderate to severe, lateral or sharp, peritoneal signs, cervical motion tenderness, or lateral or bilateral abdominal or pelvic tenderness. Risk factors predictive of EP included a history of infertility or use of an intrauterine device, prior tubal ligation, or other pelvic surgery.⁷ Because of the diversity of presentations, almost half of ectopic pregnancies are still missed on initial physician contact.²

Mittelschmerz

Mittelschmerz is unilateral adnexal pain at the time of ovulation, resulting from leakage of blood or fluid from the graafian follicle. Sudden, sharp, well-localized peritoneal irritation is usually found without fever, hypotension, or signs of inflammation or infection. An adnexal mass is infrequent. Occasionally, symptoms can be severe and generalized, but they classically decrescendo and resolve within 24 to 48 hours. In some patients, midcycle pain is recurrent and predictable.

Ovarian Cyst Disease

Ovarian cyst disease may occur at any age. There are several types of cysts, including simple, functional cysts, which may contain follicular fluid or blood; corpus luteal cysts; and benign or malignant cysts, including dermoids, endometriomas, and serous and mucinous cysts. Corpus luteum cysts are extremely vascular. Rupture of a cyst may lead to a significant and life-threatening amount of hemoperitoneum.²³ Cysts are particularly common during pregnancy when differentiation of rupture from other catastrophic problems, such as EP, may be difficult. With cyst rupture, rapid onset is characteristic and local peritoneal irritation is common, but fever or systemic signs are rare. On physical examination, there is often a tender, unilateral, adnexal mass and focal peritonitis. Cervical motion tenderness due to adjacent pelvic irritation is common and should be differentiated from PID, TOA, EP, or even appendicitis. Ovarian cysts may also cause pain if the cyst distends rapidly, or cause severe ischemic pain if torsion occurs. Because most low-dose oral contraceptives do not prevent ovulation, cyst problems are also seen in patients taking birth control pills, although there remains a protective measure against cysts by oral contraceptives.

Visceral Pain with Progression

Some inflammatory and infectious conditions progress to peritoneal irritation as they extend beyond the confines of the original organ. PID and appendicitis are the common disorders that do not remain well contained within their visceral origins. PID (discussed earlier and in [Chapter 82](#)) and appendicitis (discussed in a later section and in [Chapter 41](#)) are most classic for this history. While each frequently presents with mild pain either in the right lower quadrant (more common in appendicitis) or bilaterally (more common in PID), peritoneal signs develop over time in each. This can be reflected in cervical motion tenderness, and even progression to guarding and percussion pain in the lower abdomen. The progression in appendicitis is usually over 12 to 24 hours, while that in PID may occur over several days or not at all.

Chronic Pelvic Pain

Pain of 6 months' or greater duration is a difficult diagnostic and management problem. Chronic pelvic pain has most commonly been associated with endometriosis and PID. The most common primary complaints in patients with chronic pelvic pain include dysmenorrhea, intermenstrual pain, deep dyspareunia, gastrointestinal and urologic symptoms, and pelvic tenderness. Cul-de-sac nodularity and a fixed, retroverted uterus are the most common physical findings and are characteristic of

endometriosis and chronic PID. Chronic pelvic pain affects approximately one in seven U.S. women, with a prevalence rate of 14.7% in a study of more than 5263 women.¹⁶ In a recent study of adolescent girls with chronic pelvic pain not responding to conventional therapies, such as nonsteroidal and hormonal therapies, more than 69% (two-thirds of the study population) were diagnosed with endometriosis.¹⁵

Pregnancy-Related Causes of Abdominal Pain

Once pregnancy has been established or is highly suspected, a differentiation must be made between pregnancy-related and non–pregnancy-related causes of acute pelvic or abdominal pain.

Miscarriage at any stage can cause pelvic pain. Examination of the cervical os may differentiate a threatened abortion (closed os) from an abortion in progress, with products of conception in the cervix or vagina. Septic abortion presents with a tender, boggy, palpable uterus and fever. Ruptured corpus luteum cysts are common in pregnancy, presenting with sudden unilateral pain that is usually mild and localized. In rare cases, pain may be diffuse if cyst fluid or blood contaminates the entire abdominal cavity. Adnexal torsion also occurs with increased frequency during pregnancy. Traction on the round ligament and other pelvic structures as the uterus grows can cause significant but transient pain.

Other causes of pelvic pain in pregnancy include appendicitis (the most common surgical emergency in pregnancy) and processes unrelated to the pregnancy. Pyelonephritis is more common in pregnancy and should always be considered. Diagnosis of most such diseases, including appendicitis, becomes more difficult as pregnancy progresses, because the uterus obscures the examination and distorts the location of the affected organ. Delays in surgical management in pregnancy result in increased morbidity for both the mother and the fetus.²

Gastrointestinal and Urologic Causes of Abdominal Pain

Appendicitis is a common cause of abdominal pain and should be considered along with gynecologic etiologies of abdominal pain in females. The classic presentation of appendicitis is pain that begins in the periumbilical or epigastric area and becomes more localized to the right lower quadrant, with anorexia. Appendicitis in women is particularly difficult to diagnose, reflected by the 35% false-negative appendectomy rate for women in reproductive years. Cervical motion tenderness may occur in either PID or appendicitis because organs are close to each other and movement of adjacent organs is frequently painful. Pyuria occurs in 10% to 20% of both PID and appendicitis because of the proximity of the ureter to both organs. The presence of significant bilateral adnexal tenderness and a longer symptom duration (greater than 3 days) may suggest PID, but laparoscopy may be required to differentiate the two. Ultimately, clinical differentiation may be difficult.²⁴

Diverticulitis is characterized by alteration in bowel habits and left lower-quadrant, colicky, recurrent abdominal pain, particularly in middle-aged and older patients.

Cholecystitis must be differentiated from Fitz-Hugh–Curtis syndrome, because both can present with more severe, steady upper abdominal pain of relatively sudden onset. Ultrasound is useful to identify calculi in the gallbladder.

Urologic causes of pelvic pain include pyelonephritis and renal calculi. Pyelonephritis usually causes unilateral pain in the lower abdomen and flank. Suprapubic tenderness and costovertebral angle tenderness are frequently elicited. Evaluation of the urine specimen for bacteria and leukocytes is supportive. Renal calculi cause severe visceral pain that is colicky and unilateral. The patient may have a history of renal calculi. Hematuria is almost always present. An intravenous pyelogram or ultrasound is diagnostic.

EMERGENCY DEPARTMENT EVALUATION

History

An appropriate history includes a description of the pain—onset, progression, quality, character, intensity, and radiation—as well as the reason for the ED presentation. The menstrual history includes gravidity, parity, date, and duration of the last two menstrual periods; regularity; any recent menstrual abnormalities; as well as time of menarche and menopause, when applicable. A history of STDs, use and type of contraceptives, recent vaginal discharge, breast symptoms, dyspareunia, and urinary complaints should be obtained. Gastrointestinal complaints must also be evaluated, including nausea, vomiting, diarrhea, or constipation. A history of fever and chills should be noted.

Physical Examination

The physical examination should be directed but complete. General appearance may be helpful, although individual pain thresholds vary greatly. A patient writhing in pain may have severe visceral pain from renal colic, bowel obstruction, or ovarian torsion. The patient who avoids movement may have peritoneal irritation. Early pain of appendicitis may be dull, poorly localized, and similar to more benign diseases, such as gastroenteritis.¹

Vital signs are useful in recognizing systemic infection, sepsis, or significant hypovolemia. The general examination should look for systemic and supradiaphragmatic etiologies, such as pneumonia and endocarditis. Abdominal, pelvic, and rectal examinations are mandatory in *all women* with pelvic pain.

The abdominal examination should address three important objectives: a search for masses or palpable organs, localized areas of tenderness by quadrant and location, and demonstrating peritonitis. The diagnosis of peritonitis is made by performing maneuvers that move the peritoneum but do not put pressure on visceral organs (heel tap, cough, light percussion, pelvic jarring, and general patient movement). “Rebound” tenderness has been the classic procedure for demonstrating peritoneal irritation, yet it is probably the least accurate for diagnosing peritonitis. Interobserver variability is substantial, and the test causes unnecessary pain in patients with potentially surgical disease.²⁴

The pelvic examination should include inspection of the external genitalia as well as the introitus and cervix. In pregnancy, there is often a bluish hue to the cervix (Chadwick sign). The bimanual examination assesses uterine size, palpable masses, and cervical motion tenderness. The “chandelier sign” occurs when the patient is said to have grabbed the chandelier on movement of the cervix, and is considered a sign of PID. This test is, however, nonspecific and insensitive. Patients with other diseases, such as appendicitis, cyst rupture, and EP, also have pelvic peritoneal irritation and will demonstrate increased pain on movement of the cervix, while patients with mild clinical PID may have minimal cervical motion tenderness. A uterus that is fixed and poorly mobile often indicates adhesions secondary to endometriosis, tumor, or prior infection. Rectal examination involves palpation for masses, induration, nodularity, or blood.

Laboratory Studies

A complete blood count is not useful in the assessment of pelvic pain, but an increased white blood cell count may reflect systemic infection. Chronic blood loss may be suspected if a low hematocrit is obtained. A qualitative, sensitive pregnancy test screening for the beta subunit of human chorionic gonadotropin is essential for evaluation in all women of childbearing age. With a low threshold (less than 50 mIU/mL International Reference Preparation), false-negative pregnancy tests occur in less than 1% of patients, even with an abnormal pregnancy (ectopic or miscarriage).

An uncontaminated (usually catheterized) urinalysis is needed to diagnose a urinary tract infection; it may assist in differentiating renal colic from ovarian torsion. Vaginal wet mount suspension can indicate various causes of vaginitis (rarely a cause of pelvic pain, but possibly a marker for STD exposure). Cervical cultures or tests to detect *Neisseria gonorrhoeae* and *Chlamydia trachomatis* may assist in the diagnosis of PID.

Imaging Studies

Plain radiography is rarely useful in the evaluation of pelvic pain unless perforation, bowel obstruction, or abdominal calcifications are suspected clinically. An *intravenous pyelogram* is useful in providing evidence of obstructive uropathy or in ureteral calculi.

In most cases, *ultrasound* is the imaging modality of choice for pelvic pain. Transabdominal and endovaginal ultrasounds are being used more frequently as

diagnostic adjuncts.

Ultrasound is useful to distinguish between intrauterine and ectopic pregnancies. A gestational sac with a fetal pole should be evident by 5 weeks after the last menstrual period, and a fetal heartbeat should be seen by the seventh to eighth week of gestation. While ultrasound can be exceptionally useful, it is less specific than laparoscopy.

Computed tomography (CT) may be useful in the diagnosis of pelvic pain of otherwise unclear etiology. However, as an initial screening examination, ultrasound is still recommended. Ultrasounds are increasingly being performed in the ED by emergency physicians. One study indicated that the ultrasounds performed by emergency physicians trained in the use of ultrasound have a specificity and sensitivity in ruling out EP and making an accurate diagnosis in most complicated first-trimester presentations to the ED that is comparable to those performed by radiology and obstetric personnel.⁸ In addition, in a recent study of 115 patients, emergency physician-performed ultrasounds significantly reduced the length of stay in the ED.²¹

Other Diagnostic Procedures

Laparoscopy is the gold-standard study in the diagnosis of pelvic pain. It remains the procedure of choice to confirm the diagnosis in the patient who is acutely ill or has an uncertain diagnosis, or in whom surgical disease (e.g., appendicitis) cannot be excluded. In a study of laparoscopic examination of 316 women with acute pelvic pain, more than 76% had an abnormal laparoscopic examination, and 45% of those with abnormal laparoscopic examinations had ectopic pregnancy, while 15.4% had PID, 27% had ovarian cysts, 3.3% had appendicitis, and 13.7% had pelvic adhesions, fibroma uteri, or endometriosis.¹⁸

Culdocentesis in the patient with sudden peritoneal pain may also be helpful to the physician who needs to rapidly diagnose hemoperitoneum or serious infection. Aspiration of nonclotting blood indicates a ruptured EP or other source of bleeding in the pelvis or abdomen; purulent fluid may be indicative of PID or ruptured TOA; a normal culdocentesis yields straw-colored fluid. A dry tap occurs in 10% to 20% and is nondiagnostic.

EMERGENCY DEPARTMENT MANAGEMENT

Sepsis and significant hypovolemia often require urgent management before the diagnosis is clear. Fluid resuscitation begins with intravenous crystalloid in a hypovolemic patient. Broad-spectrum antibiotics for sepsis from a presumed pelvic source should include good anaerobic and gram-negative coverage.

Gynecologic and surgical consultation should be obtained promptly for the patient with peritonitis, hemoperitoneum, or presumed appendicitis. In addition, surgical intervention may be required in patients with severe pain due to ovarian or bowel ischemia, or bowel obstruction.

Traditionally, it is taught that the administration of pain medication sufficient to alleviate the pain may also eradicate the signs needed to determine surgical disease or perform serial examinations. However, studies indicate that pain medicine is safe and useful for patient comfort. Administration of pain medication to patients with acute abdominal pain may quantitatively blunt pain, but it does not qualitatively alter physical signs or interfere with diagnosis. Analgesics such as intravenous opiates may actually allow for more accurate evaluation.⁴ Patients with potential surgical conditions should, ideally, receive an early surgical evaluation before administration of analgesics, but long delays for "observation" of a patient with significant pain should be discouraged.

DISPOSITION

Pelvic pain is caused by a spectrum of diseases. Uncommonly, patients with sudden peritonitis may require rapid stabilization, with laparotomy as a diagnostic and therapeutic tool. At the other end of the spectrum are patients in whom the diagnosis is not determined in the ED. Admission is necessary for potential surgical disease, including appendicitis, selected cases of PID, and ectopic pregnancy associated with significant symptoms. If surgical evaluation is necessary, it should be done in a timely and efficient manner.

Observation may be necessary if a surgical etiology is possible, pain remains severe, or vomiting and other signs of systemic toxicity are worrisome to the clinician. Observation is appropriate for patients with focal peritonitis secondary to presumed cystic rupture or for suspected early appendicitis. If patients are to be observed (increasingly done in EDs), strict criteria for admission should be established and serial examinations should be performed and recorded.

If a patient is discharged from the ED with abdominal pain in which the etiology is uncertain but the patient is stable, *instructions for appropriate and early follow-up are imperative*. Early reexamination should be arranged for those with suspected PID, because the diagnosis is often inaccurate. Any woman with abdominal pain who is discharged from the ED must be instructed to obtain a repeat evaluation if her pain continues or worsens.

Because many causes of pelvic pain, particularly when the pain is chronic, are not amenable to ED diagnosis, there will exist a population of patients for whom exclusion of surgical disease, short-term pain relief, and referral for definitive diagnosis are the appropriate actions in the ED.

COMMON PITFALLS

- Two critical pitfalls are failure to recognize abnormal vital signs, including hypotension and tachycardia, and failure to reasonably account for abnormal vital signs.
- A pregnancy test should be obtained on *all women* of childbearing age, because ectopic pregnancy or other pregnancy-related diseases must be considered. The exception is the woman who has had a hysterectomy.
- Surgical and nonsurgical diseases must be differentiated. The patient with severe pain may have surgical disease (e.g., bowel ischemia or ovarian disease) but lack the peritonitis of the "acute abdomen."
- Clinical presentations may vary for each disease. PID and ectopic pregnancy may present with varying patterns of pain, from very mild and nonspecific to severe peritonitis.
- Cervical motion tenderness is not specific or sensitive for PID. It can be seen with various pelvic diseases and nongynecologic etiologies.
- Pyelonephritis requires confirmation of an abnormal urine with a catheterized specimen to avoid overdiagnosis based on a contaminated urine specimen.
- Even with upper abdominal pain, the pelvic examination is an important part of the physical examination.

ACKNOWLEDGEMENT

The author gratefully acknowledges the contribution of Jean T. Abbott, who cowrote the previous version of this chapter.

[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Pelvic inflammatory disease (PID) comprises a spectrum of inflammatory diseases of the upper genital tract in women. PID may include any combination of endometritis, salpingitis, tuboovarian abscess, or pelvic peritonitis.^{2,6,7,12,19,28} In the majority of cases, sexually transmitted pathogens (*Neisseria gonorrhoeae* and *Chlamydia trachomatis*) are implicated. However, PID may also be caused by other organisms, including anaerobic bacteria, *Gardnerella vaginalis*, *Haemophilus influenzae*, enteric gram-negative rods, *Streptococcus agalactiae*, *Mycoplasma*, and *Ureaplasma urealyticum*.^{5,23,25,31} Over 100 aerobic and anaerobic bacterial strains have been recovered from the pouch of Douglas or high cervical cultures in patients with PID.⁸ Because this disease is sexually transmitted, the peak incidence is during the childbearing years, although PID may be found in female patients of any age. Child abuse must be suspected in any prepubertal female with the diagnosis of salpingitis.

PATHOPHYSIOLOGY

Most pelvic infections originate from colonization of the vagina or cervix. From this site, the pathogens ascend through the cervical os into the lower uterine segment and uterine cavity. Normal cervical mucus presents a natural barrier to vaginal organisms; however, both *N. gonorrhoeae* and *C. trachomatis* appear able to produce uterine infections despite this protection. Certain cervical conditions, including recent menses, surgical cervical procedures, foreign bodies (intrauterine devices), and various hormonal changes during a menstrual cycle decrease the defensive ability of the cervix. The hormonal changes induced by oral contraceptive agents enhance rather than reduce the bacteriostatic properties of the cervix if administered prior to colonization. There is recent evidence that indicates that oral contraceptives may mask the symptoms of chlamydial infection once it does become established.^{6,10,17,25,37,39}

Once entry into the uterus has been gained, inflammation of the uterine lining results. In postpartum patients, the myometrium becomes infected, but in other patients, this inflammation is seldom invasive and is limited to the endometrium. The inflammation may produce uterine bleeding, but in the nonpregnant uterus, the infection is seldom clinically significant. The pathogens then continue their migration through the fallopian tubes. In the case of mycoplasmal infection, ascension may occur by way of parametrial structures rather than through the uterine cavity.

Initial tubal infection is limited to the mucosa of the lumen, but the inflammation rapidly extends through the full thickness of the tubes. This transmural reaction of the fallopian tubes often causes the early pain of pelvic infection. In severe cases, the purulent material from the fallopian lumens exudes through the open fimbriae into the abdominal cavity, producing peritonitis.¹²

The infection of the endometrium and fallopian tubes results in an inflammation of the surrounding parametrial structures. Even though they may not undergo actual infection by the invading pathogens, the proximity to the true infection produces a severe parametritis in many patients.

The inflammation initiated by *N. gonorrhoeae* or *C. trachomatis* frequently overwhelms the normal uterine defense mechanisms and results in infections from opportunistic pathogens, particularly *Bacteroides* species.^{8,10,25,33,37}

Inflammation and stagnation of host defenses, particularly in the fallopian tubes, allow for the possibility of unchecked bacterial growth. A tuboovarian abscess may develop; originating in the fallopian tube, the abscess may extend to involve the fimbriae and ovary as well. The bacterial content of a tuboovarian abscess is mixed, with a preponderance of anaerobes.²⁰

Localized pelvic infection is not the only result of infection with *N. gonorrhoeae* and *C. trachomatis*. Escape through the end of the right fallopian tube and ascent to the right colic gutter may result in inflammation around the liver. The *Fitz-Hugh-Curtis syndrome* (*perihepatitis*) is usually associated with *C. trachomatis* but may occur in 8% to 10% of all cases of salpingitis.

CLINICAL PRESENTATION

A clinical diagnosis of PID may be difficult due to the wide variation in signs and symptoms. Some authorities believe that the examination is notoriously inaccurate in the diagnosis of pelvic infections. No single historical, physical, or laboratory finding is both sensitive and specific for the diagnosis of acute PID. The Centers for Disease Control and Prevention (CDC) estimate that a clinical diagnosis of PID has a positive predictive rate of 65% to 90% for salpingitis.⁶ Mild or nonspecific complaints may go unrecognized by the clinician (e.g., abnormal bleeding, dyspareunia, or vaginal discharge). Most authorities recommend a low threshold for diagnosis of PID because of the long-term effects and potential damage to the reproductive system of women.

Minimum criteria for diagnosis have been published⁶ and appear in [Table 82.1](#). Additional criteria for diagnosis are also listed.

MINIMUM CRITERIA FOR THE DIAGNOSIS OF PID
Ergic treatment of PID should be instituted on the basis of the presence of all of the following three minimum clinical criteria for PID and in the absence of an established cause other than PID: Lower abdominal tenderness Bilateral adnexal tenderness Cervical motion tenderness
ADDITIONAL CRITERIA
For women with severe clinical signs, more elaborate diagnostic evaluation is warranted to avoid incorrect diagnosis and management may cause unnecessary morbidity. These additional criteria may be used to increase the specificity of diagnosis: Oral temperature $\geq 38.3^{\circ}\text{C}$ Abnormal cervical or vaginal discharge Elevated erythrocyte sedimentation rate Elevated C-reactive protein Laboratory documentation of cervical infection with <i>N. gonorrhoeae</i> or <i>C. trachomatis</i>
ELABORATE CRITERIA FOR DIAGNOSING PID
Histopathologic evidence of endometritis on endometrial biopsy Tuboovarian abscess on sonography or other radiologic tests Etiologic abnormalities consistent with PID

From Centers for Disease Control and Prevention. 1986 Guidelines for treatment of sexually transmitted diseases. *MMWR* 1986;35(11):1-11.

TABLE 82.1. Diagnosis of PID

Although attempts have been made to distinguish between features of infection caused by *N. gonorrhoeae* and *C. trachomatis*, they have not been consistent or reliable. *N. gonorrhoeae* salpingitis develops in the first few days after menses, producing a purulent vaginal discharge and severe pelvic pain. *C. trachomatis* infection may occur at any point in the menstrual cycle, and results in less cervical discharge and milder symptoms. Chlamydia is responsible for more significant fallopian tube damage.^{5,26}

History

The patient with pelvic infection almost invariably presents to the emergency department with a complaint of lower abdominal pain. Inflammation of the endometrium, fallopian tubes, and parametrial structures usually produces diffuse bilateral pelvic pain. When questioned, most women describe a dull, constant, poorly localized pain. Because of the sensitive nature and social stigma of sexually transmitted diseases, physicians should be empathetic and tactful in eliciting the patient's history. Pelvic pain is seldom the only presenting complaint. *N. gonorrhoeae* or *C. trachomatis* cervicitis results in a vaginal discharge in greater than 50% of patients, while abnormal vaginal bleeding is seen in 30%. Gastrointestinal complaints, including nausea and vomiting, are less common but may be present. Urinary tract symptoms are common, with 20% of laparoscopically proven pelvic infections associated with irritative voiding symptoms.¹⁰ Pelvic infection should be suspected in patients who complain of *dysuria or suprapubic pain* that occurs only during micturition and is unaccompanied by frequency and urgency. The urinalysis is normal because the bladder urine is not infected.

Physical Examination

A temperature above 38°C (100.4°F) is found in only 33% of patients; fever supports the diagnosis but does not confirm it; nor does its absence preclude the diagnosis of PID. The abdominal examination commonly reveals tenderness in both lower quadrants, although one side may be more tender. Peritoneal signs indicate a more severe infection, with free exudate in the pelvis or abdomen,¹² and intraperitoneal extension should be considered. If perihepatitis is also present, there may be tenderness in the right upper quadrant.

Pelvic examination must be approached carefully if meaningful information is to be gained. Because of pain or previous experience, many patients may not be cooperative.^{4,10} Speculum examination may reveal a vaginal discharge. A markedly inflamed purulent cervix is indicative of an acute cervicitis and is supportive of some degree of pelvic infection. Bimanual examination begins with testing for cervical motion tenderness. Elicitation of pain with either lateral or anteroposterior motion of the cervix is sensitive but not specific for pelvic infection. The emergency physician must remember that other causes of pelvic irritation, including fluid from ruptured cysts and blood from ectopic pregnancies, can also produce this sign.^{10,11} The uterus is frequently firm but tender. *Bilateral adnexal tenderness is one of the most consistent physical findings in studies evaluating diagnostic criteria for salpingitis.*^{1,12,21,25} An adnexal mass may be appreciated but is not a consistent finding in the absence of a tuboovarian abscess. Findings on pelvic examination may be atypical in patients who have had multiple prior infections or tubal ligation. Obstruction of the fallopian tube may prevent extension of the infection beyond the proximal tube, limiting the degree of adnexal tenderness.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of abdominal pain in women should include three possibilities: (1) ectopic pregnancy, (2) PID, and (3) appendicitis. Ovarian cyst, urinary tract infection, hernia, and ovarian torsion should also be considered. Ectopic pregnancy is addressed in [Chapter 74](#). *All women with pelvic pain, regardless of their menstrual history, should have a pregnancy test; the only exception is the woman who has had a hysterectomy.*²⁷ Salpingitis is the most common incorrect diagnosis in missed ectopic pregnancy and should be considered only after ectopic pregnancy has been ruled out.¹ The coexistence of infection and pregnancy is possible but unusual, because, after implantation, a mucous plug forms, preventing the spread of lower genital infections into the upper genital system. However, there is a brief window between insemination and mucous plug formation during which infection may occur. *Appendicitis* may be differentiated from PID by its unilateral nature, but this is by no means diagnostic. Only 82% of patients with clinical presentations consistent with PID actually had pelvic infections on laparoscopic examination.¹²

EMERGENCY DEPARTMENT EVALUATION

When PID is suspected, additional support for the diagnosis may be obtained through laboratory analysis. Although results are not immediately available, cervical cultures for *Chlamydia* and *N. gonorrhoeae* should be done on all patients during the speculum examination. Because results are not immediately available, a system must exist for follow-up of patients whose positive-culture results return to the emergency department after the patient has been discharged.¹⁵

Gonorrhea cultures are obtained by placement of a sterile swab 1 to 2 cm into the endocervical canal, with rotation of the swab for 10 to 30 seconds.¹ Following collection, the swab should be immediately plated on either chocolate agar or Thayer-Martin agar.⁴ Gram stains, cervical mucus enzyme, and antibody detection tests may also be used in the identification of *N. gonorrhoeae*, although these tests are neither as sensitive nor as specific as cultures.^{11,16}

Chlamydia detection techniques include culture, antibody detection (ELISA and fluorescent), and DNA probes.^{9,24,26,32} In contrast to gonorrhea testing, nonculture techniques are the preferred detection procedures for the diagnosis of *C. trachomatis*. Both direct fluorescent antibody tests and ELISA-type antibody tests have been shown to be 70% to 90% sensitive and more than 90% specific in *Chlamydia* infections in women.⁴ DNA probe tests that appear to be highly sensitive and specific have been developed, but their clinical applicability remains to be determined.^{22,26,38}

Additional laboratory studies should include urinalysis to rule out urinary tract infection and a urine or serum pregnancy test.^{11,27} A complete blood count may be obtained for use in some disposition decisions, but the clinician should recognize that the test has limited usefulness. In toxic patients with severe unilateral symptoms, pelvic ultrasonography is indicated to confirm a tuboovarian abscess, although laparoscopy is more accurate.³⁰ The CDC recommends serology for syphilis and the human immunodeficiency virus (HIV).

EMERGENCY DEPARTMENT MANAGEMENT

Treatment regimens are summarized in [Table 82.2](#). The management of acute pelvic infection centers on prompt antibiotic therapy. The goal of treatment is to prevent continued or worsened infection; complications of PID, including ectopic pregnancy and infertility; and chronic infection.^{5,14,18} Selection of the appropriate antimicrobial combination depends on the current recommendations of the local public health department and the CDC.

OUTPATIENT TREATMENT FOR PID	
Regimen A	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen B	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen C	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen D	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen E	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen F	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen G	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen H	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen I	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen J	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen K	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen L	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen M	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen N	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen O	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen P	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen Q	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen R	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen S	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen T	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen U	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen V	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen W	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen X	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen Y	1. Ceftriaxone 1 g IM once daily for 1 day
Regimen Z	1. Ceftriaxone 1 g IM once daily for 1 day

TABLE 82.2. Antibiotic Therapy of PID

Alternate single-dose therapies have been described for the treatment of cervicitis or mild salpingitis. The clinician may consider these therapies more convenient; to date, however, none has been endorsed by the CDC. These regimens have not been advocated for established or severe pelvic infections and should be used cautiously with patients exhibiting more than minimal symptoms. One regimen employing clindamycin 300 mg PO t.i.d., plus ciprofloxacin 250 mg PO b.i.d., for 14 days has been described for moderate PID, although this regimen has also not been advocated for severe infections.³

Practitioners should monitor public health service publications concerning recommendations for antimicrobial treatment of sexually transmitted diseases in their areas because the incidence of *N. gonorrhoeae* and *C. trachomatis* cervicitis and salpingitis varies in different areas. In all regions, however, the two often coexist.^{4,31}

Because concomitant infection is frequent and it is clinically difficult to distinguish one type of infection from the other, management includes empiric treatment with antibiotics active against both pathogens. ^{6,13,19,35,36}

DISPOSITION

Suggested criteria for admission are listed in [Table 82.3](#). Hospitalization is indicated for pregnant patients. A combination of ceftriaxone and erythromycin is considered safe, although the estolate form of the erythromycin must be avoided because it may produce hepatitis. Women with HIV infection are also considered candidates for hospitalization.

1. Toxic appearance*
2. Nausea and vomiting precluding oral therapy*
3. Suspected tuboovarian or pelvic abscess*
4. Pregnancy*
5. Uncertain diagnosis, particularly if other surgical emergencies cannot be ruled out (i.e., ectopic pregnancy, appendicitis)
6. Intrauterine device
7. Nulligravida
8. Failure to improve with outpatient therapy within 72 hours**
9. Peritonitis, spread beyond pelvis*
10. Adolescent (in)compliance/compliance*
11. HIV infection or other immunocompromised conditions
12. Follow-up within 72 hours of initiating antibiotic therapy cannot be arranged*
13. Patient is unable to follow or tolerate an outpatient regimen*

*Note: Some of these criteria are absolute; all should be applied on an individual basis.
**Patients with these criteria should be strongly considered for admission. Patients with the above characteristics but who appear clinically well, are reliable, and can be followed closely as outpatients, need not be admitted to the hospital.
*Critical criteria for outpatient status: 72 hours course of doxycycline or erythromycin or clindamycin or ciprofloxacin, and reduction or absence of pelvic or abdominal tenderness within 3-5 days of initiation of therapy.
From Centers for Disease Control and Prevention. 1998 Guidelines for Treatment of Sexually Transmitted Diseases. *MMWR* 1998;47:15-19.

TABLE 82.3. Criteria for Which Hospitalization Should Be Considered in PID Patients

Outpatient management is appropriate for those patients not meeting criteria for admission shown in [Table 82.3](#). All discharged patients should receive follow-up care to ensure response to treatment. If cultures are obtained, a mechanism should be in place to ensure that patients and their physicians or the public health department are notified of positive results. ¹⁵

COMMON PITFALLS

- The most serious problem is the general insensitivity of the history, physical examination, and laboratory results in the diagnosis of PID.
- All women with abdominal pain do not have PID; a differential diagnosis must be maintained, particularly in regard to ectopic pregnancy and appendicitis.
- If the clinical picture suggests PID, treatment should be initiated early.
- The clinician should question the diagnosis of pelvic infection in any patient with unilateral pelvic pain.
- Pregnancy must be ruled out.
- Urinary tract irritative voiding symptoms may confuse the picture in PID; a pelvic examination is mandatory to rule out PID.
- Serologic testing for syphilis and HIV testing are indicated for most women with sexually transmitted disease.

CHAPTER 83

Non–Pregnancy-Related Vaginal Bleeding

Eric Anderson and H. Trent MacKay

[Clinical Presentation](#)

[Differential Diagnosis](#)

[Emergency Department Evaluation](#)

[Emergency Department Management and Disposition](#)

[Common Pitfalls](#)

[Chapter References](#)

Abnormal vaginal bleeding unrelated to pregnancy is a common gynecologic complaint and may occasionally present as a life-threatening emergency. Such bleeding can be categorized by the source as either uterine or extrauterine. Extrauterine bleeding may be caused by trauma, a foreign body, or a lesion involving the cervix, vagina, vulva, or urinary tract. Abnormal vaginal bleeding may be the first sign of a vaginal or cervical malignancy or may occur after cervical conization or hysterectomy. Postcoital bleeding may be due to a benign cervical lesion, such as a polyp or inflammation caused by an infection, or it may be caused by a previously undiagnosed cervical cancer.

Bleeding caused by a foreign body in the vagina is a relatively frequent presentation in premenarchal girls.⁴ Postoperative bleeding most commonly occurs at the time absorbable sutures dissolve. The usual site of bleeding after hysterectomy is the vaginal cuff, and after cervical conization, bleeding may occur from the operative site. Occasionally, bleeding from urethral prolapse or hematuria may be confused with a gynecologic source.

Uterine bleeding may be either cyclic (menorrhagia) or unrelated to the menstrual cycle (metrorrhagia). It may be dysfunctional (hormonal) in origin, related to a benign or malignant lesion, or caused by a coagulopathy. Endometrial cancer, endometrial polyps, or submucous leiomyomata may cause abnormal bleeding. Bleeding may also be related to pelvic inflammatory disease, coagulopathies associated with leukemia, aplastic anemia, von Willebrand disease, or other hematologic disorders. Functioning ovarian tumors are a rare source of abnormal bleeding.

Dysfunctional uterine bleeding, which is defined as abnormal uterine bleeding in the absence of organic pathology on clinical pelvic examination, is usually related to anovulation with estrogen overstimulation of proliferative endometrium unopposed by the stabilizing influence of progesterone, leading to spontaneous breakdown of the endometrium. The bleeding is typically both excessive and prolonged. Treatment of dysfunctional bleeding is directed at stabilizing the endometrium with a progestational agent, combination oral contraceptive, or, if necessary, high-dose estrogen. Dysfunctional bleeding is most common in the adolescent and in the perimenopausal woman and less common in women aged 20 to 35.¹ Breakthrough bleeding due to oral contraceptives, Norplant, or Depo-Provera, or bleeding from an intrauterine device may also bring a woman into the emergency department.

CLINICAL PRESENTATION

Excessive vaginal bleeding may be defined as bleeding that soaks more than one tampon or pad an hour over several hours. Most women with abnormal bleeding are hemodynamically stable. However, the occasional patient may present with a life-threatening hemorrhage. This situation is particularly likely to occur with bleeding from cervical cancer, postoperative bleeding, and dysfunctional bleeding in adolescents. Many women with dysfunctional bleeding have a history of delayed menses with the onset of heavy, painless vaginal bleeding.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes the many possible sources of both extrauterine and uterine bleeding listed in [Table 83.1](#). Diagnosis is based on the patient's age, history, and pelvic examination findings. Pregnancy should always be ruled out in any woman of reproductive age.

Nonuterine Causes	Uterine Causes
Vulva	Endometrial polyp
Malignant neoplasms	Submucous leiomyoma
Benign neoplastic lesions	Endometrial hyperplasia
Trauma	Endometrial carcinoma
Ulcerative lesions	Chronic endometritis
Urethral caruncle	Intrauterine device
Cervicitis acuminata	Coagulopathy
Vagina	Dysfunctional uterine bleeding
Vaginitis	Breakthrough bleeding
Trauma	
Malignant neoplasms	
Foreign body	
Cervicitis acuminata	
Postoperative	
Cervix	
Malignant neoplasms	
Cervical polyps	
Cervicitis	
Ectropion	

TABLE 83.1. Non–Pregnancy-Related Abnormal Vaginal Bleeding

EMERGENCY DEPARTMENT EVALUATION

The patient's history, including her menstrual history, contraceptive history, and any history of bleeding problems may lead to a diagnosis. A thorough pelvic examination is usually the key to diagnosis. The vulva, vagina, and cervix must be carefully examined for lesions. The size and shape of the uterus and the adnexal structures must be determined by bimanual examination. The anus should be inspected, and a rectovaginal examination, including a guaiac test, should be performed. Transvaginal ultrasound may be useful in identifying anatomic sources of bleeding, such as endometrial polyps or submucous leiomyomata.³ Laboratory tests should include a pregnancy test and complete blood count. Clotting studies are usually not necessary unless suspicion of a bleeding diathesis exists.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Although life-threatening non–pregnancy-related vaginal bleeding is unusual, patients who are hemodynamically unstable require rapid diagnosis and stabilization. Pelvic examination usually reveals the source of the bleeding. A large-bore intravenous line should be started and blood sent for complete blood count and type and crossmatch.

Mild-to-moderate bleeding from a cervical or vaginal lesion can usually be controlled by application of a silver nitrate stick or a cotton swab with Monsel's solution (ferric subsulfate). If control is not obtained, an obvious bleeding vessel or the lesion itself can be sutured with a figure-of-eight stitch of 0 chromic or 0 polyglycolic acid suture. Suturing is also the appropriate method of dealing with postoperative bleeding from the cervix or vaginal cuff or with traumatic lesions with significant bleeding. Consultation with the gynecologist should occur.

If neither of these approaches controls the bleeding, a gauze pack soaked in acetone, phenylephrine hydrochloride 1:200,000, or epinephrine 1:200,000 often provides control. If none of these methods is effective, specialist consultation should be obtained rapidly. Other treatment alternatives include radiologically directed selective arterial embolization, emergency radiation therapy for malignant lesions, and hypogastric artery ligation.

Copious uterine bleeding in the hemodynamically unstable patient can often be rapidly controlled with dilatation and curettage. Gynecologic consultation should be

sought for these procedures.

Pediatric patients with vaginal bleeding should have a vaginal examination with a small instrument, such as a nasal speculum, to search for foreign bodies. If the emergency physician is comfortable with this procedure, it can be performed in the emergency department. The presence of vulvar or vaginal trauma may suggest child abuse or sexual abuse, and requires follow-up by social services and law enforcement agencies.

Dysfunctional uterine bleeding in adolescents and women under age 35 can almost always be controlled with hormonal therapy. In this age group, dilatation and curettage should be reserved for cases not controlled with medication or for situations in which there is a high risk of endometrial hyperplasia. Premenopausal women over age 35 require endometrial sampling before they receive hormonal therapy because of their increased risk of endometrial hyperplasia. Hormonal control of heavy dysfunctional bleeding can be obtained in most cases with any combination oral contraceptive such as Ortho-Novum 1/35 or Ovcon 35, using one pill four times a day for 1 or 2 days until the bleeding slows, then two pills daily until day 5, and then one pill daily for an additional 20 days.

If bleeding is profuse, more rapid control may be obtained with intravenous conjugated estrogen (25 mg every 4 hours for three or four doses), followed by the previously described oral contraceptive regimen.² Patients should continue on combination oral contraceptives for an additional 2 or 3 months and should be referred for gynecologic follow-up before completing the course of medication. If these regimens fail to acutely control dysfunctional bleeding, dilatation and curettage must be performed.

All women over age 35 with dysfunctional bleeding and all postmenopausal women with bleeding other than withdrawal bleeding with estrogen replacement therapy should have an endometrial biopsy.⁵ Although the initial diagnostic procedure may be performed in the emergency department, these patients should be referred for gynecologic consultation.

The occasional patient who presents in the emergency department with breakthrough bleeding on oral contraceptives, Norplant, or Depo-Provera may be reassured as to the benign nature of the bleeding. Control of breakthrough bleeding may be obtained with a 7-day course of conjugated estrogen 1.25 mg, or estradiol 2 mg.⁶

COMMON PITFALLS

- The most common pitfall in the treatment of abnormal bleeding is the unnecessary use of dilatation and curettage for the treatment of dysfunctional bleeding in women under age 35. Almost all adolescents and women under age 35 can be successfully treated with hormonal therapy.
- Pregnancy must be considered in all women of reproductive age.

Unlike hemorrhage, amenorrhea is less likely to be perceived by a patient as an emergency. Despite this reality, patients do present to the emergency department with amenorrhea. *Primary amenorrhea* is defined as the absence of menses by age 16 or by age 14 if secondary sexual characteristics are also absent. *Secondary amenorrhea* is defined as the absence of menses for at least three cycle lengths or for 6 months in a previously menstruating woman.^{2,16} From the point of view of the emergency physician, any delay in menses could be significant, and these definitions are less relevant. There is significant overlap in the workup of primary and secondary amenorrhea, and some authorities no longer utilize these traditional categories for clinical evaluation.¹⁵ Furthermore, evaluation may be warranted in the absence of these somewhat arbitrary criteria in the patient with certain other important signs, such as galactorrhea, hirsutism, or weight loss.

CLINICAL PRESENTATION

While amenorrhea may be the principal reason for a visit to the emergency department, it is most often an important secondary aspect of another chief complaint. It is well established that both history and physical examination are unreliable in the detection of early pregnancy.¹³ Women using various methods of contraception and even those who have had tubal ligation have been found to be pregnant.¹³ It is imperative that pregnancy be eliminated from the differential diagnosis in all women of reproductive age. Pregnancy can be reliably detected using a sensitive blood or urine assay for b-human chorionic gonadotropin (b-hCG). In fact, many emergency departments incorporate a routine inquiry regarding menstruation during the triage process. These triage data serve to alert the emergency physician to the possibility of pregnancy so that radiographs and other potentially harmful diagnostic studies or treatments are not employed, particularly in the first trimester.⁹ Emergencies related to pregnancy are discussed elsewhere in this text.

Due to the sensitivity of the modern pregnancy test (either urine or serum b-hCG), a positive test may be obtained even prior to missed menses. Commonly employed bedside pregnancy tests will become positive at a level between 10 and 50 IU, and a level of 100 U is typically found at the time of the expected but missed menses in a normal pregnancy.¹⁵ Even in the absence of any menstrual irregularity, pregnancy testing may be warranted if potentially harmful procedures or treatments are to be employed. With pregnancy rates as high as 10% to 15% in women presenting to the emergency department with no history of menstrual irregularity, routine screening for pregnancy has been advocated by some authors.^{9,13}

Common physiologic states other than pregnancy may result in amenorrhea. Constitutional delay, for example, may result in primary amenorrhea. The perimenopausal and postmenopausal periods are associated with secondary amenorrhea. Even when such a physiologic state is strongly suggested by the patient's presentation, the emergency physician should not be misled into a false sense of security—pregnancy should always be considered first in the evaluation. This error can easily be made during the period of amenorrhea associated with postpartum lactation. Although lactation provides a contraceptive effect, it is short-lived and unreliable.¹⁵

Patients receiving hormonal contraception may also experience amenorrhea. This is especially true of long-acting formulations such as intramuscular depot-medroxyprogesterone acetate (Depo-Provera) or implanted levonorgestrel (Norplant). Although women who remain amenorrheic throughout their use of these agents are unlikely to become pregnant,¹⁵ pregnancy must again be the first consideration in the emergency department. After a negative pregnancy test, an explanation to the patient and referral back to the primary physician are appropriate.

“Post-pill” amenorrhea is a misnomer. Its incidence is actually similar to the rate of spontaneous secondary amenorrhea in patients with no history of hormonal contraception.^{12,15,16} In addition, rates of fertility among women who have stopped hormonal contraception do not differ significantly from those of the general population.¹⁵ Therefore, all patients who have not resumed normal menstrual function after discontinuation of hormonal contraception should be considered pregnant until otherwise proven. The remainder of the amenorrhea evaluation, however, may be delayed for 6 to 12 months after discontinuation of contraceptive therapy, after which time amenorrhea can no longer be ascribed to the therapy.¹⁵

DIFFERENTIAL DIAGNOSIS

Once pregnancy has been ruled out, the causes of amenorrhea can be divided into disorders of the four compartments that underlie the process of normal menstruation. These are disorders of the uterus and outflow tract, disorders of the ovaries, disorders of the anterior pituitary gland, and disorders of the hypothalamus and higher central nervous system (CNS) centers ([Fig. 84.1](#)).^{3,15} [Table 84.1](#) utilizes this four-compartment model to present the differential diagnosis of amenorrhea. Although many etiologies can result in either primary or secondary amenorrhea, their relative incidence as a cause of each clearly differs. Ovarian causes predominate in primary amenorrhea, whereas hypothalamic causes predominate in secondary amenorrhea.³

Figure 84.1. The four-compartment model for normal menstruation.

Category	Causes
Primary amenorrhea	<ul style="list-style-type: none"> Chromosomal abnormalities Genetic defects Structural defects Functional defects
Secondary amenorrhea	<ul style="list-style-type: none"> Physiological Endocrine Neuroendocrine Structural Functional

TABLE 84.1. Causes of Amenorrhea

EMERGENCY DEPARTMENT EVALUATION

The diagnostic algorithm in the nonpregnant patient with amenorrhea varies only slightly among different authors and has not changed substantially in recent years. [Figure 84.2](#) gives an abbreviated outline of such an algorithm. Clearly, most of the evaluation is not emergent and may be performed in the outpatient setting after specialist referral. However, several causes of amenorrhea in the nonpregnant patient may pose a serious threat to life and deserve special consideration by the emergency physician.

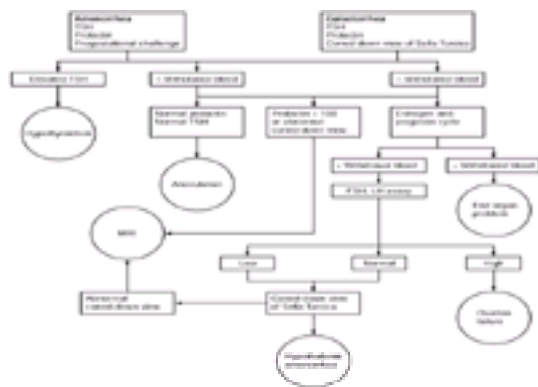

Figure 84.2. Diagnostic algorithm for the amenorrhea in the nonpregnant patient.

Anorexia Nervosa

Anorexia nervosa, characterized by low body weight, disordered eating habits, and distorted body image, may be heralded by amenorrhea.⁶ Common associated clinical symptoms and signs are constipation, abdominal pain, hypotension, hypothermia, dry skin, parotid enlargement, soft lanugo-type hair, and edema.^{6,10} Although low body weight itself may be a major determinant of amenorrhea in these patients, amenorrhea may be present before significant weight loss occurs.^{6,19} From a psychiatric standpoint, these patients are often secretive and deny their symptoms.^{6,10} Therefore, a high level of vigilance is required so that this potentially fatal disorder may be recognized and referred at an early stage.

Bulimia

Bulimia is a syndrome of episodic binge eating followed by self-induced vomiting, fasting, or the use of laxatives or diuretics.¹⁰ It may occur together with anorexia nervosa. Clinical features are few but may include fluctuating weight, dental caries from repeated vomiting, and scars from self-mutilation. Although amenorrhea is less common in bulimics who are not underweight, the possibility of life-threatening electrolyte abnormalities must be considered, most notably hypokalemia.⁶

Intracranial Space-Occupying Lesions

The presence of headaches, galactorrhea, visual field changes, or any other neurologic symptoms or signs in association with amenorrhea may represent an intracranial space-occupying lesion, most commonly of the pituitary gland. In this instance, an imaging study in the emergency department (computed tomography [CT] or magnetic resonance imaging [MRI]) may prevent an undue delay of diagnosis. Although there has been a clear trend toward the use of MRI for the identification of subacute parenchymal lesions,⁸ CT scanning is probably still preferable in the emergency department. Not only is CT more readily available and less expensive, but its increased sensitivity for detecting bleeding and bony pathology⁸ underscores its utility for the emergency physician who treats an undifferentiated population. Once emergent pathology has been ruled out, MRI studies may be pursued on an outpatient basis.

Drug-Associated Amenorrhea

Certain medications may cause amenorrhea. Most exert this effect on a neuroendocrine basis, although certain agents are directly toxic to the ovaries. A list of commonly implicated prescription drugs is included in [Table 84.1](#). Perhaps more important to the emergency physician, drugs of abuse have also been implicated. The causal relationship of heroin and other opiates to amenorrhea is well established.¹ Opiates, either endogenous or exogenous, can suppress ovulation by inhibiting the hypothalamic release of gonadotropin-releasing hormone. The relationships with alcohol and sympathomimetics are less clear, with studies plagued by the confounding variables of nutritional and socioeconomic status.^{7,17,18}

Serious Systemic Illnesses

There are a number of serious systemic illnesses that may present in association with amenorrhea. Systemic illness may interfere with normal menstruation at more than one of the four compartments mentioned earlier. For example, tuberculosis can cause amenorrhea centrally through weight loss and neuroendocrine effects, but it may also directly invade the uterus, causing end-organ damage. Many endocrine diseases disrupt the menstrual cycle at the hypothalamic-pituitary level. In the majority of these cases, there will be other clues, but the amenorrhea itself may enable the emergency physician to ultimately reach the diagnosis. With a list of potential causes so diverse as to include sarcoidosis,¹⁴ type I diabetes mellitus,¹⁴ and even possibly human immunodeficiency virus,^{4,5} a compulsive and broad-minded approach is essential.

In the absence of any of these specific concerns, the evaluation of amenorrhea may be initiated in the emergency department with outpatient follow-up. History should be thorough with respect to menstruation, contraceptive use, and sexual function and should also include an assessment for weight loss, exercise level, and psychosocial stressors. Physical examination should include a pelvic examination in the postmenarchal patient, assessment for galactorrhea, and a screening examination for signs of endocrine or other systemic disease. As always, intimate examinations in the emergency department should be chaperoned and documented as such in the treatment record. After a pregnancy test, blood may be sent for thyroid-stimulating hormone and prolactin levels. If there are signs of virilization, tests for DHEA-S and testosterone levels may be added.

Amenorrhea itself is not necessarily benign. The associated underlying hormonal changes have important implications. Hypoestrogenemia affects mineral metabolism and can lead to significant bone loss and osteoporosis.^{2,20} Young women may be at even greater risk as they are prevented from attaining their desired peak bone

mass.¹¹ There also may be an increased risk of cardiovascular disease in such women. If unopposed estrogen underlies amenorrhea, there is an increased risk of uterine cancer.¹¹ Because of these implications for future health, it is indeed important for all patients presenting to the emergency department to receive follow-up and treatment for amenorrhea.

DISPOSITION

Nonpregnant patients with amenorrhea without evidence of serious systemic illness may be referred for outpatient gynecology follow-up within a week following the emergency department visit. Hospitalization may be required for an underlying systemic illness when identified. Hospitalization may be life-saving in cases of severe anorexia nervosa; however, its routine use in the initial presentation is disputed.⁹

COMMON PITFALLS

- The failure to consider the possibility of pregnancy is the most common pitfall in the evaluation of amenorrhea. All patients with amenorrhea should have a pregnancy test.
- Serious systemic illness should always be considered as a cause of amenorrhea in the nonpregnant patient.
- In the nonpregnant patient with amenorrhea and without symptoms or signs of serious illness, care should be taken to avoid the indiscriminate use of expensive endocrinologic tests or MRI, which can safely be performed during outpatient follow-up.
- All patients who are not admitted to the hospital who present with amenorrhea should be referred for appropriate follow-up. Failure to refer could result in the failure to diagnose a serious underlying pathology or the development of complications.
- Anorexia nervosa is a potentially life-threatening cause of amenorrhea that is easily overlooked. It should always be considered in the evaluation of the nonpregnant patient with amenorrhea.

[Common Pitfalls](#)

[Chapter References](#)

Vaginal discharge is the most common gynecologic symptom in women during reproductive years, and many seek emergency care for the discomfort. Other symptoms of vaginal infection are unpleasant odor, pruritus, burning, superficial dyspareunia, and dysuria. In this age group, the vaginitis is usually due to one of three different causes: a fungus (*Candida* vulvovaginitis), a protozoan (*Trichomonas* vaginitis), or the replacement of the hydrogen peroxide (H₂O₂)–producing, gram-positive lactobacilli of natural vaginal flora with anaerobic bacteria and *Gardnerella vaginalis* in far greater concentrations than they are normally found (bacterial vaginosis). In postmenopausal women, these symptoms are most likely due to atrophic vaginitis. A careful history, pelvic (speculum) examination with pH determination, and microscopic examination of a wet mount slide of the discharge will yield a diagnosis in about 80% of cases ([Table 85.1](#)). While cultures were considered the gold standard for diagnosis in the past, polymerase chain reaction identification of the organisms may be more sensitive, but these methods are more suited to the gynecologist's practice than the emergency department (ED).³

Features of Discharge	Normal	Candidiasis	Trichomonas	Bacterial Vaginosis
Color	Clear white	White	Gray-green-yellow	Gray white
Consistency	Floccular	Clumpy, adherent to vaginal mucosa	Homogenous, occasionally foamy	Homogenous, occasionally foamy
Quantity	Variable, usually scant	Scant to moderate	Profuse	Moderate
pH	<4.5	>4.5	>4.5	>4.5
Amine odor with KOH	Negative	Negative	Usually positive	Positive
Wet mount	Epithelial cells, lactobacilli	WBCs, epithelial cells, spores, yeasts, pseudohyphae, filamentous hyphae, occasional KOH (+) clumps, enlarged cellular elements	WBC, motile trichomonads	Few WBCs, clue cells

TABLE 85.1. Features of Vaginal Discharge

CANDIDA VULVOVAGINITIS

The organism responsible for this infection is an airborne fungus, almost always *Candida albicans*. Its filamentous forms penetrate the mucosal surface, causing hyperemia and lysis of tissue locally. This infection occurs predominantly during reproductive years, with 75% of women experiencing at least one episode in their lifetimes. Fungi can be isolated from the vaginas of 20% to 40% of asymptomatic women and need not be treated. It is commensal until the ecosystem of the vagina is disturbed. Predisposing factors include hormonal shifts (pregnancy and just premenstrual), antibiotic or immunosuppressant (e.g., corticosteroid) use, diabetes mellitus, and immune suppression, such as with acquired immunodeficiency syndrome. Oral contraceptives, once thought to increase risk, do not in the present low-estrogen dosages. *Candida* infections do not occur simultaneously with bacterial vaginosis or *Trichomonas* infection, but may follow treatment. There is no evidence for sexual transmission, and routine treatment of partners is not recommended.

Recurrence is a major problem, occurring in 20% to 80% of women after an apparent cure. In some cases, this may be due to an unidentified host factor, possibly a subtle defect in cell-mediated immunity. Some women appear to be hypersensitive to a small number of organisms. There is a higher incidence of other fungal species in recurrent infections.

CLINICAL PRESENTATION

Patients primarily complain of vulvar itching, burning, external dysuria, and dyspareunia. The quantity of the discharge is variable. It does not have an odor and may not be a presenting symptom. Vulvar signs are erythema, edema, and traumatic excoriation. There may be satellite pustules at the periphery of inflammation. Insert the speculum gently, as the vagina may be very sore. The typically thick, clumpy discharge will be adherent to the walls or may look like thrush patches. The pH of the vagina is less than 4.5.

The most efficient diagnostic test in the ED is to put a small sample of the discharge or a scraping from a plaque or the erythematous border onto a slide and add 1 to 2 drops of a 10% or 20% solution of potassium hydroxide (KOH). This will dissolve the cellular elements (and the microscope lens as well, if a cover slip is not used!). Several fields may have to be scrutinized to identify the mycelia or pseudohyphae, which appear as tangled, branching chains, or the oval spores that are about one-fourth of the size of a white blood cell (WBC). Although the sensitivity of this method varies widely (from 22% to 80%, averaging 65%), the clinical picture coupled with either the patient's self diagnosis or the absence of a watery discharge or amine odor should prompt the ED physician to treat in most cases.¹

TREATMENT

Candida albicans is almost uniformly sensitive to all azoles. Intravaginal agents are inexpensive, available over the counter, effective, and well tolerated by most women. They may be less acceptable to many women than the recently approved single dose (150 mg) of oral fluconazole, which has similar cure rates.¹³ If fluconazole is used in diabetic patients on oral hypoglycemic agents, there may be significant hypoglycemia due to drug interaction. The Centers for Disease Control and Prevention (CDC) still recommends topical therapy as a first line.⁵ [Table 85.2](#) provides a listing of specific preparations and dosing.

Disease	First-Line	Alternative	Partner	Notes
T. vaginalis	Metronidazole 2 g po single dose	Metronidazole 500 mg tid for 7 days	Metronidazole 2 g po single dose	Treat with 2 components: 1. metronidazole 2. benzimidazole After 72 hours, 2 g metronidazole
Bacterial vaginosis	Clotrimazole 100 mg bid for 7 days or Clotrimazole 100 mg po bid for 7 days or Metronidazole 500 mg bid for 7 days or 2% clindamycin cream Vaginal 7 days	Metronidazole 2 g po single dose or Azelastine 1 mg bid for 7 days	None for BV See BV treatment	Trichomonas (chlamydiae) vaginal cream 2%, one application vaginal for seven days if symptoms not improving After 72 hours, 2 g metronidazole or 500 mg bid for 7 days po
Candidiasis	Butoconazole 2% cream 14 days vaginally for 7 days or Fluconazole 150 mg po single dose	Clotrimazole 1% 1 g cream twice vaginally for 7-14 days (OTC)	Candidal cream if dermatitis present	Avoid fluconazole and butoconazole. Treat for 7 days

TABLE 85.2. Treatment of Vaginitis

Recurrence

As noted, recurrence of symptoms after a “cure” is particularly problematic in vulvovaginal candidiasis. The cause may be a hypersensitivity to the organism or to the vehicle in topical agents, noncompliance (more likely with topical preparations), infection with an uncommon fungus species, true azole resistance, reinfection from a symptomatic partner, or risk factors, possibly unidentified. Patients who report several episodes should have their urine checked for sugar, especially if they present before puberty or after menopause.

Sexual Partners

Many studies have found no evidence of sexual transmission, and routine treatment of partners does not reduce the incidence of reinfection; therefore, there is no rationale for treating them. About 10% to 27% of men have a balanoposthitis. They should be treated with either the same topical preparation as the patient or a dermatologic fungicide. Oral treatment has not been evaluated.

Pregnancy

The incidence of vulvovaginal *Candida* infection is increased 10- to 20-fold in pregnancy. Oral fluconazole is not recommended. Clotrimazole is effective and safe.

TRICHOMONAS VAGINITIS

Approximately one-fourth of vaginal infections are caused by *Trichomonas vaginalis*, a unicellular protozoon that is sexually transmitted. It is found in the vagina and 90% of the time in the lower urethra and Skene's ducts. Male partners are usually asymptomatic, but may complain of the symptoms of urethritis. They harbor the organisms in the urethra and paraurethral glands and occasionally in the seminal vesicles, epididymis, and prostate. Trichomoniasis is often concurrent with bacterial vaginosis and gonorrhea, and probably other sexually transmitted diseases as well. Trichomonads are also suspected of being vectors in pelvic inflammatory disease. In any event, because the epidemiology of all sexually transmitted diseases is similar, the emergency physician should either do appropriate screening for gonorrhea, chlamydia, and syphilis or refer the patient for these and for human immunodeficiency virus (HIV) counseling regarding testing and safe sexual practice.

Trichomonads are often noted on urine microscopy in asymptomatic women. One-third of these women will become symptomatic within 3 months. It is prudent to treat them.

Polymerase chain reaction analysis of vaginal secretions has been shown to be very sensitive in identifying *T. vaginalis*. However, on-site wet mount slide microscopy still seems sensitive enough, inexpensive, and practical for ED diagnosis. ^{10,11}

CLINICAL PRESENTATION

The primary symptom of acute *Trichomonas* infection is profuse vaginal discharge. Patients often complain of feeling wet. The discharge is thin and may be white, gray, yellow, or green. It has been classically described as “frothy,” but this is only present 10% to 20% of the time. It is often malodorous. Dysuria is present 20% of the time. Patients with chronic infection may complain only of a malodorous discharge. The examiner frequently notes the discharge on the vulva, which can also be erythematous and edematous. Unlike candidiasis, which can cause extensive involvement of the vulva and perineum, inflammation due to *Trichomonas* is usually limited to the vestibule and labia minora. The vaginal walls are inflamed and the discharge is copious in amount.

A saline wet mount of the discharge should be viewed under low power first to identify areas of relatively few WBCs. In fresh warm preparations, trichomonads will have a twitchy forward motion. They are slightly larger than WBCs. If the slide has an abundance of WBCs, or the typical movement is not seen, a higher power should be tried, dampening down the condenser to give better contrast. If WBCs are clumped on the protozoa or the preparation is cold, only the beating of the flagella may be seen. The wet mount is diagnostic up to 90% of the time. It is characteristic to see many WBCs (also seen in atrophic vaginitis and sexually transmitted diseases, but not in *Candida* or bacterial vaginosis). The pH, using colorimetric paper, will usually be above 5 and can be as high as 7. If KOH is added to the discharge, a “fishy” or amine odor may be present.

TREATMENT

Metronidazole 2 g orally in a single dose has been the standard first-line treatment, but recently 1.5 g has been shown to be equally effective. ¹⁴ A 7-day course of 500 mg daily has similar (95%) cure rates, but compliance is lower. Metronidazole affects the hepatic metabolism of alcohol in the same manner as disulfiram (Antabuse), so patients should abstain from alcohol for 24 hours after the last dose. Metronidazole vaginal gel does not appear to be as effective against *T. vaginalis* and is not recommended.⁷ Patients who are allergic to metronidazole should be treated with topical clotrimazole.

Sexual Partners

It is necessary to treat all sexual partners. There is a 2.5-fold increase in reinfection rates if the sexual partner is not treated.

Pregnancy

Treatment of *T. vaginalis* infection in pregnancy is controversial. Metronidazole has both mutagenic and carcinogenic effects in animal studies. There is no evidence of either in human studies. A metaanalysis of the literature concluded that there is no relationship between metronidazole use in the first trimester and the incidence of birth defects.² That said, it is still prudent for the emergency physician to avoid metronidazole in the first trimester. Intravaginal clotrimazole will improve or relieve symptoms in about 80% of patients. Cure rates are low. Sexual partners should be treated with single-dose metronidazole.

T. vaginalis infection is associated with preterm and low-birth-weight births, particularly in Blacks. ⁸ Because pregnant patients will need prenatal care, it is appropriate to refer them for follow-up of both symptomatic *Trichomonas* infection and incidental identification of the organism on urinalysis.

Recurrent Infection

Recurrence is usually due to reinfection or noncompliance with therapy. There are resistant strains of *Trichomonas*. They usually respond to a 7-day course of

metronidazole, 1 to 2 g daily.

BACTERIAL VAGINOSIS

The most common cause of an abnormal vaginal discharge is a change in the vaginal flora, which has undergone several name changes as our understanding of the pathogenesis has evolved. High concentrations of anaerobic bacteria replace the normal lactobacilli, especially those species that produce hydrogen peroxide. Anaerobes increase tenfold, and *Gardnerella* species even more. The anaerobic vibrios from the *Mobiluncus* group are seen in about 50% of symptomatic patients. Therefore, bacterial vaginosis is best understood as a syndrome of bacterial synergism in which the vaginal flora become predominantly anaerobic. It does not produce inflammatory changes, hence the term, *vaginosis*, rather than vaginitis.

CLINICAL PRESENTATION

The most uniform complaint of women with this condition is an unpleasant vaginal odor, particularly noted after intercourse, when alkaline semen triggers the release of aromatic amines. The odor may be described as “fishy” or “musty.” The discharge is most often thin and adherent to the walls of the vagina. There is rarely any pruritus or erythema of the vulva or vagina unless concomitant *Trichomonas* infection is present. A wet mount of the discharge classically has “clue cells,” which are epithelial cells that have bacteria “studded” all over the surface, obscuring the cell wall. Few WBCs or lactobacilli are noted, but clumps of bacteria may be seen. The pH of the discharge is 5 to 6. When KOH is added to the slide, a fishy odor is released, a positive “whiff test.”

TREATMENT

Metronidazole 500 mg twice daily for 7 days is the treatment of choice. It results in 85% to 95% cure and a return of normal lactobacilli. Single-dose therapy is considerably less effective. Topical therapy with either metronidazole gel or clindamycin cream is also approved by the Food and Drug Administration and should have fewer side effects. Women who are allergic to metronidazole or who develop recurrence may be treated with clindamycin 300 mg every 12 hours for 7 days. Alternative therapy is listed in [Table 85.2](#).

Sexual Partners

Sexual transmission is probable but not certain, and there is no consensus on treatment of partners.⁶ The CDC does not recommend routine treatment, and no decrease in recurrence has been shown if partners are treated.

Pregnancy

Although there is an association between bacterial vaginosis and increased incidence of preterm labor, premature rupture of membranes, and endometritis, a causal etiology has not been established. If the patient is quite symptomatic and in the first trimester, 2% clindamycin vaginal cream daily for 7 days can be used. Minimally symptomatic patients may be referred to their obstetricians.¹²

Recurrence

Clindamycin 300 mg every 12 hours for 7 days is standard. Repeated regimens of metronidazole are not well accepted by patients. In one small study, recurrent infection was successfully (78%) treated with a 3-minute instillation of 3% hydrogen peroxide in the vagina.^{9,15}

COMMON PITFALLS

- The patient with a chief complaint of vaginal discharge is never a high priority in a busy ED. The most common pitfall is failure to do a good history and methodical examination.
- Misdiagnosing urinary tract infection in patients who complain of dysuria that is actually external and due to *Candida* vulvovaginitis or *Trichomonas*
- Overlooking noninfectious causes of vaginal symptoms, such as chemical irritants (bubble bath, topical contraceptive and feminine hygiene products, scents, deodorants, and soaps) or hormone depletion in postmenopausal women
- Failure to provide or refer for counseling regarding behavior risks and testing for HIV and other sexually transmitted diseases for patients with *Trichomonas* infection

Approximately 81,000 new invasive cancers of the female reproductive tract are diagnosed annually in the United States.¹⁴ These cancers eventually result in approximately 27,300 deaths each year.¹⁴ The yearly incidence of these diseases is increasing. As the baby boom cohort in the population ages, more ovarian, vulvar, and endometrial cancers will develop. An increased prevalence of human papillomavirus infection will result in an increase in cervical dysplasia and, possibly, cervical cancer, particularly if cytologic surveillance is not aggressively encouraged.¹⁰

With the advent of cytologic screening, and the consequent decrease in invasive cervical cancer, the most frequently diagnosed cancer of the female reproductive tract currently is endometrial.¹⁴ This condition is followed in incidence by ovarian, cervical, and vulvar cancer and, less frequently, gestational trophoblastic neoplasia and tubal and vaginal cancer. Although the most frequent cause of gynecologic cancer emergencies in the population at large is ovarian cancer, emergency physicians probably primarily see patients with cervical cancer. These patients typically belong to lower socioeconomic groups and are more likely to seek help in emergency department settings than from their primary physicians. This chapter's discussion of gynecologic cancer emergencies is organized according to their most frequent emergent clinical presentations, rather than according to the primary malignancies that cause these presentations.

VAGINAL BLEEDING

Patients who present to the emergency department with vaginal bleeding secondary to a gynecologic malignancy probably have either cervical or endometrial cancer.⁷ Occasionally, other corpus malignancies, such as sarcomas and gestational trophoblastic disease, are the cause. Rarely, the cause is advanced vulvar cancer.

Women who present with vaginal bleeding due to cervical cancer have a mean age between 40 and 45 years.²⁰ This mean age has recently decreased because younger women have been contracting cervical cancer secondary to an increased incidence of human papillomavirus infection, increased sexual contacts, and increased smoking.¹ Essential points in the history of patients who present with vaginal bleeding due to cervical cancer include the following:

- Painless vaginal bleeding, exacerbated or caused by coitus
- Lack of previous cytologic screening, or a history of prior abnormal findings on cytologic screening
- Lower socioeconomic status
- Multiple sexual partners

Although the physical examination should assess extrapelvic spread of disease, such as supraclavicular or inguinal adenopathy, the main focus of the examination should be the pelvis. In a patient whose lesion is so advanced that vaginal bleeding is the presenting complaint, the lesion should be visible on speculum examination. The speculum should be inserted gently to avoid further trauma to the bleeding site. A careful inspection of the vulva, vagina, and cervical os should be performed. If there is no visible lesion on the cervix and the bleeding is coming through the cervical os, then cervical cancer is an unlikely cause of bleeding. Bimanual examination as well as a rectovaginal examination should be performed to assess possible involvement of the parametrial tissues. Laboratory studies should include a pregnancy test and a complete blood count. If the bleeding is not severe, the patient can be discharged from the emergency department once appropriate referral and prompt follow-up by a qualified gynecologist have been obtained. If the bleeding is severe or life-threatening, then supportive measures should be instituted and consultation obtained. Measures that are effective in control of vaginal bleeding include packing the vagina, after insertion of a Foley catheter; use of Monsel's solution; and application of Oxycel. When all else fails, the packing material can be impregnated with a solution of epinephrine (1:500,000). If the bleeding is unremitting, the patient may need to be admitted for hypogastric artery ligation, embolization, or high-dose radiation therapy.⁵

In vaginal bleeding caused by endometrial or other corpus cancers, the bleeding is usually not as severe as that caused by cervical cancer. Patients tend to be in an older age group; the mean age for patients with this disease is 60.²¹ In approximately 5% of cases, endometrial cancers occur in women under age 40.⁷ Essential points of the history in the older patient include use of unopposed exogenous estrogens and obesity. In younger women, obesity, nulliparity, and infertility may be predisposing factors. Although vaginal bleeding is the most common presenting complaint for this disease, it is seldom of sufficient magnitude to cause an emergency department visit, unless the patient lacks a primary physician. In women who present with postmenopausal vaginal bleeding, the diagnosis should be endometrial cancer until proved otherwise.

Careful examination should be performed to assess the size of the uterus and the presence of extrauterine tumor. On speculum examination, the bleeding will be from the cervical os. Occasionally, endometrial cancer presents with a visible lesion on the cervix. The bleeding is seldom life-threatening, and the patient can be discharged from the emergency department as long as adequate provisions are made for prompt referral to a qualified gynecologist.

Vaginal bleeding caused by gestational trophoblastic neoplasia occurs in women in either early or late reproductive age. With increasing numbers of immigrants from Latin America and particularly from Asia, emergency physicians in inner-city situations may see this particular problem. Gestational trophoblastic neoplasia occurs in one out of 1200 pregnancies in the United States, but it is much more common in Asia and Latin America. In addition, as the pregnancy rate among inner-city teens burgeons, emergency physicians will see a steadily increasing incidence of this disease. Vaginal bleeding is the most common presentation for gestational trophoblastic neoplasia.¹² Salient points in the history include uterine enlargement greater than expected for gestational age, absence of fetal movements, repeated visits to medical facilities for bleeding (often the diagnosis is threatened abortion), and hypertension in early pregnancy.

Physical examination reveals a large-for-gestational-age fundal height; speculum examination shows bleeding coming from the os. Vesicular material also may be seen extruding through the os (Fig. 86.1). The definitive diagnosis is made by ultrasonography, which shows a distinctive multiechogenic pattern. The patient with gestational trophoblastic neoplasia should be admitted after a prompt obstetric consultation.

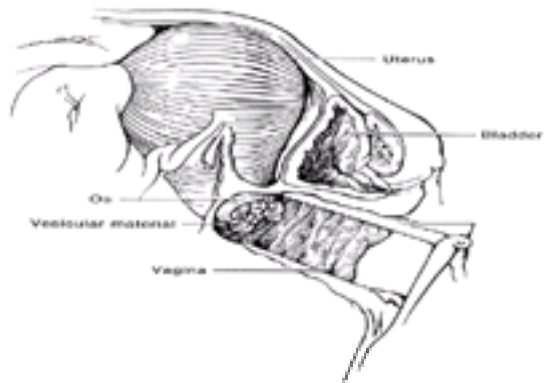

Figure 86.1. Gestational trophoblastic neoplasm.

Bleeding caused by vulvar cancer is rare.¹⁶ Women who present with this entity usually have an advanced lesion. Most are over age 60 and have other signs of neglect. Because of the possibility of either self- or institutional neglect, it is advisable to admit women who present with large, bleeding vulvar cancer lesions. Therapy can then be promptly instituted.

BOWEL EMERGENCIES

Bowel emergencies in patients with gynecologic malignancies are divided into two major subheadings: those that occur in nonradiated bowel and those with complications secondary to radiated bowel.

COMPLICATIONS OF NONRADIATED BOWEL

In the nonradiated bowel group, the most common bowel emergencies are bowel obstruction, colostomy problems, fistula formation, and perforation.

Bowel Obstruction

Small bowel obstruction, not in the perioperative period, is usually due to internal adhesions secondary to a previous surgical procedure or to gynecologic malignancy. In ovarian cancer, approximately 5% of patients have small bowel obstruction as the presenting complaint.²¹ Ovarian cancer spreads on the serosal surfaces of the bowel and can cause either adhesive or bulk obstruction (Fig. 86.2). The presentation of small bowel obstruction secondary to ovarian cancer is similar to that of bowel obstruction caused by nongynecologic causes. Consequently, the reader is referred to the appropriate chapters in this text for emergency department management. Two important points are unique to gynecologic cancer: (1) in elderly patients with no history of prior abdominal surgery, small bowel obstruction is a harbinger of ovarian cancer; and (2) in patients with a history of pelvic malignancy, small bowel obstruction may be the first sign of recurrence. In both situations, appropriate consultation should be obtained. Frequently, patients with obstruction secondary to long-standing ovarian cancer should not have surgical intervention immediately on presentation, but be managed conservatively.

Figure 86.2. Pattern of spread of ovarian cancer.

Large bowel obstruction can occur by direct extension of a cervical malignancy that blocks the rectum. It is also seen when a large tumor in the omentum causes compression at either the splenic or the hepatic flexure. The evaluation of the patient with large bowel obstruction secondary to gynecologic malignancy is the same as that in any other patient. However, emergency department management should include prompt consultation with a gynecologist. The most critical aspect of the evaluation is to rule out overdistention of the cecum; if in excess of 10 cm in diameter, prompt surgical decompression is necessary.²²

Colostomy Emergencies

Colostomy complications occur in approximately 30% of patients. These complications include stenosis of the stoma, peristomal hernia, wound infection, and prolapse.¹³ Most problems can be managed by a stomal therapist. However, some stomal complications require prompt initiation of care. Peristomal herniation of bowel requires admission for prompt surgical correction. Surgical or gynecologic consultation should be obtained, and the bowel should be kept moist in the emergency department. Mucosal prolapse of the stoma can be reduced by gentle digital pressure, but it should be done expeditiously to prevent infection and stomal damage.

Fistula Formation

Bowel fistulas in patients with gynecologic malignancies are usually enterocutaneous, enterovaginal, or rectovaginal. Rarely, these fistulas are the presenting sign of a gynecologic malignancy. More often they occur secondary to therapy. The patient with a new fistula should be admitted so that prompt evaluation can be done.

COMPLICATIONS OF RADIATED BOWEL

The role of radiation therapy in gynecologic malignancies is constantly changing. Radiation therapy is currently most frequently used for the primary treatment of advanced cervical cancer or cervical cancer in patients who are not operative candidates. It is also used with increasing frequency as adjuvant therapy for endometrial cancer and as adjuvant or consolidation therapy in ovarian cancer. Two stages of complications result from radiation therapy: early and late. An early bowel complication is radiation proctitis or enteritis with diarrhea. This injury can be seen during therapy (resulting in therapy interruption) or shortly after the completion of therapy. Patients with severe diarrhea secondary to radiation enteritis or proctitis can usually be treated conservatively and seldom need to be admitted. The diarrhea can be managed with diphenoxylate (Lomotil). Fluid resuscitation may be necessary secondary to severe diarrhea. The patient can be treated and discharged to her radiation oncologist or gynecologist for continuing care.

Late complications of radiation injury to the bowel are caused by endarteritis and progressive sclerosis of the smaller vessels.² This leads to several complications, including ulceration, infarction, enterofistulas, enteroenterofistulas, necrosis, and stenosis.⁶ Usually, the patient presents with either intestinal obstruction or severe intractable abdominal pain. In the emergency department, the patient must be managed with fluid resuscitation, nasogastric suction, prompt gynecologic or surgical

consultation, and admission.

Another common emergency presentation is rectal bleeding owing to radiation proctitis. If the bleeding is minimal, the patient can be discharged on Cort enemas (hydrocortisone) and a low-residue diet. Prompt arrangements should be made for follow-up with either the radiation therapist or the gynecologist. When the bleeding is severe or symptoms of shock exist, fluid resuscitation, transfusion, and prompt consultation should occur. When medical management fails, intervention may include angiographic embolization and colostomy.

UROLOGIC EMERGENCIES

Patients with genital tract cancer may present with urologic emergencies secondary to surgery, radiation therapy, or the malignancy itself.

URETERAL OBSTRUCTION

Ureteral obstruction may result from any of the three previously mentioned factors. It is seldom the presenting complaint in the emergency department, as most instances of this condition are diagnosed in nonacute settings. Ureteral obstruction most often presents as nonspecific flank pain, occasionally radiating to the pelvis and groin. Urinary infection is common, and may result in urosepsis. In rare cases in which there is bilateral obstruction, anemia and azotemia may result. Ureteral obstruction can occur at any time after surgery or radiation therapy, but it is usually seen during the first posttreatment year. It may be the first presenting sign of late recurrence of genital malignancy. It can also be an initial sign of cervical cancer (Fig. 86.3). The diagnosis is made on intravenous pyelography, computed tomography, renal nuclear scanning, or renal ultrasonography. Management depends on the severity of the obstruction. In patients with urosepsis, hospitalization should be arranged and antibiotics started after specimens for blood and urine cultures have been obtained. In patients who are stable and have insidious signs of ureteral obstruction, discharge may be contemplated once arrangements are made for continuing follow-up.

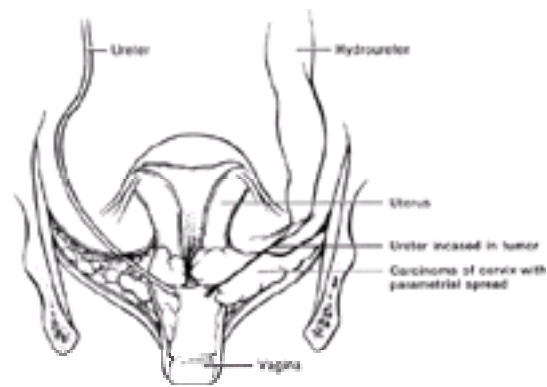

Figure 86.3. Cervical cancer: patterns of local spread.

UROLOGIC FISTULAS

Most patients with gynecologic malignancies do not present to the emergency department because of urinary fistulas. Urinary fistulas occur either because of extensive primary disease or secondary to radical hysterectomy for cervical or endometrial cancer. Surgical fistulas occur from 7 to 21 days after surgery.⁶ Occasionally, fistulas occur secondary to radiation therapy and are diagnosed 6 to 12 months after completion of treatment. The incidence of fistula formation after radical hysterectomy is approximately 1%.⁴ There is a three- to fourfold increase in this rate when radiation is given in conjunction with surgery. Fistulas that occur in patients after radical surgery are usually diagnosed by the patient's surgeon and seldom present to the emergency department. However, in inner-city situations, it is possible that the presenting sign of the malignancy may be vesicovaginal fistula secondary to spread of the disease into the trigone of the bladder.

Fistulas can be diagnosed either by direct observation of urine in the vagina or by injecting indigo carmine intravenously and placing a tampon in the vagina.

HEMORRHAGIC CYSTITIS

Hemorrhagic cystitis can be due to either radiation therapy or chemotherapy. Hemorrhagic cystitis secondary to cyclophosphamide or ifosfamide chemotherapy is seen infrequently because cyclophosphamide is now given in combination with cisplatin as a bolus with maximal hydration. Hemorrhagic cystitis is not uncommon after radiation, and the pathophysiology is similar to that of radiated bowel. Management can usually be done in the emergency department with a three-way catheter, irrigation, and, possibly, a hydrocortisone-containing solution. Once clots are removed and if the bleeding is not severe, the patient may be discharged with follow-up. In severe hemorrhage, the patient will need to be admitted and managed either with cautery by way of cystoscopy or by instillation of a sclerosing agent such as formalin. In all situations, urologic and gynecologic consultation are necessary.

URINARY CONDUIT COMPLICATIONS

Urinary conduits are either ileal or colon conduits. Complications include blockage of the ureteroconduit anastomotic site, with ureteral obstruction and possibly urosepsis; conduit necrosis; stomal necrosis secondary to avascularity; stomal problems, as described under the section on colostomy; and electrolyte imbalance owing to absorption of chloride in an overly long conduit, resulting in hyperchloremic acidosis.¹¹ Management in the emergency department is supportive. Admission considerations depend on the patient's overall electrolyte balance, the presence of urinary obstruction, and the patient's ability to return for follow-up care. Intravenous pyelography or ultrasonography usually defines the problem. If urinary obstruction has resulted in urosepsis, emergency percutaneous nephrostomy is necessary.⁹ Appropriate consultation with the radiologist and gynecologist needs to be obtained.

POSTOPERATIVE COMPLICATIONS

The emergency physician is most likely to be involved with three types of postoperative complications: (1) bowel obstruction secondary to surgery, (2) urologic fistula secondary to surgery, and (3) postoperative infection. The first two have already been discussed.

In the vast majority of cases, postoperative infections are diagnosed while the patient is still in the hospital. This is particularly the case with ovarian cancer, in which the first course of chemotherapy is initiated in the hospital in the absence of postoperative infection. The postoperative infections most likely to be seen by the emergency physician are wound infection, wound dehiscence, and wound evisceration. Wound dehiscence occurs 5 to 7 days after surgery; in some situations, it may occur after discharge. The patient can usually be managed with debridement and dressing changes. The patient's surgeon should be consulted. In situations in which home care is inadequate, the patient may need to be admitted. If signs of necrotizing fasciitis (skin discoloration, skin necrosis, and crepitus) are present, the patient needs to be admitted for surgical debridement.¹⁷ If there is fascial separation (evisceration), the patient must be admitted. The wound should be covered with sterile, moist towels and arrangements made for the patient to be taken to the operating room for fascial closure.

The other common postoperative infections in patients with gynecologic malignancies are vaginal cuff cellulitis and cuff abscess.¹⁷ Vaginal cuff cellulitis occurs in 8% of those who receive antibiotic prophylaxis before a hysterectomy. The most common cause is a mixed infection of anaerobes endogenous to the vagina. Occasionally, gram-negative aerobic bacteria may be involved. When this diagnosis is made, the patient should be admitted and broad-spectrum antibiotic coverage should be started. If the diagnosis is certain, the antibiotics can be started in the emergency department. Appropriate drugs for anaerobic bacteria are metronidazole, ampicillin-sulbactam, and ticarcillin-clavulanate. If an abscess is identified, gynecologic consultation should be obtained and arrangements made for drainage in the operating room.

The emergency physician may see patients with complications secondary to outpatient therapy such as colposcopy, conization, and laser therapy. The most common problem with these procedures is postoperative cervical bleeding. This can usually be managed by the application of Monsel's solution or packing the vagina with a Neo-Synephrine- or epinephrine-impregnated pack. Occasionally, the cervix needs to be sutured. In that situation, gynecologic consultation should be obtained. If the patient is not severely bleeding and the bleeding is controlled with the previously outlined procedures, the patient may be sent home and told to avoid intercourse and to follow up promptly with her primary physician.

COMPLICATIONS OF CHEMOTHERAPY

Chemotherapy is used primarily in ovarian cancer and gestational trophoblastic disease and as an adjuvant in endometrial cancer. The most commonly used drugs in gynecologic oncology are cisplatin, carboplatin, and paclitaxel. Complications caused by cisplatin are nausea and vomiting, which may be unremitting. In gynecologic oncology, cisplatin is given as a bolus medication. Most of the nausea and vomiting occur during the day of administration. Occasionally, the vomiting can be severe enough that the patient may come to the emergency department the day after chemotherapy instillation. Once fluid and electrolyte status are assured, the patient can often be managed by intravenous antiemetic medication as well as metoclopramide (Reglan). If nausea and vomiting are unremitting, the patient needs to be admitted for hydration. Elderly patients tend to have less nausea and vomiting on cisplatin.³ Other drugs that are commonly used in gynecologic oncology are cyclophosphamide, methotrexate, fluorouracil, doxorubicin, dactinomycin, vinblastine, etoposide, and ifosfamide. The most common complication with these medications is bone marrow suppression. It is unusual for these patients to present to the emergency department; however, if the patient presents with a neutropenia of less than 500 granulocytes and fever, she should be admitted for antibiotic therapy. Rarely, the patient presents with a very low platelet count. If the platelet count is less than 20,000 and there is spontaneous bleeding, the patient needs to be admitted for transfusion as well as platelet therapy. Bleomycin, another commonly used drug, may cause pulmonary fibrosis. The patient may present with dyspnea, cough, and bibasilar rales. A chest radiograph usually shows basilar infiltrates. The patient needs to be admitted, particularly if there is an upper respiratory tract infection in addition to the bleomycin toxicity.

Paclitaxel (Taxol) is now used in induction chemotherapy in ovarian cancer chemotherapy protocols. In addition to its bone marrow toxicity, it also can cause cardiac toxicity manifested by sinus bradycardia (30%), bradyarrhythmia with AV blockade, and short lived ventricular tachycardia.¹⁵ Although most of these side effects are noted while the patient is receiving chemotherapy, they can occasionally occur after discharge, particularly if the patient is given a 3-hour Taxol regimen.

COMPLICATIONS OF TOTAL PARENTERAL NUTRITION

In the past, the emergency physician seldom saw patients who presented with complications secondary to total parenteral nutrition (TPN). However, as home infusion services have increased, it is now more common to see extramural complications of TPN. The most likely complications secondary to home infusion TPN are infection and metabolic derangements.¹⁹ The patient with signs and symptoms of sepsis should be managed aggressively and promptly admitted. Metabolic complications include acid-base and electrolyte abnormalities and abnormalities in glucose metabolism as well as hypokalemia, hypomagnesemia, hypophosphatemia, and hypocalcemia. Patients may present with muscle weakness, hyporeflexia or hyperreflexia, lethargy, and mental status change. It is imperative for the emergency physician to obtain adequate screening laboratory studies before deciding whether the patient can be discharged.

ORGAN FAILURE

Patients with gynecologic malignancies may experience organ failure because of either the primary disease or therapy. A gynecologic organ failure should be managed the same as organ failure from any other cause.

As discussed, renal failure can occur from ureteral obstruction, conduit anastomosis problems, or urosepsis. It may represent a primary presentation of cervical cancer with bilateral ureterovesical junction obstruction. Liver failure is most frequently due to metastasis from ovarian cancer and less frequently from gestational trophoblastic neoplasia and endometrial, vulvar, or cervical cancer. Pulmonary metastasis is seen most frequently in endometrial cancer or cervical cancer; parenchymal pulmonary metastasis is seen somewhat less frequently in ovarian cancer.¹⁸ It is not infrequent, however, to see pleural effusions secondary to ovarian cancer in association with ascites. Brain metastasis is rare in gynecologic malignancies, except for gestational trophoblastic neoplasia. In the presence of gestational trophoblastic neoplasia, complaints of headache, seizure, visual disturbance, or mental status change should be evaluated with a computed tomographic scan of the head.⁸

COMMON PITFALLS

- In the presence of vaginal bleeding in a patient of reproductive age, pregnancy should be ruled out.
- If the cecum is dilated to 10 cm from large bowel obstruction, prompt decompression is mandatory.
- Necrotizing fasciitis requires prompt surgical debridement and admission.
- If any amount of ureteral obstruction is diagnosed, urosepsis must be ruled out before discharge from the emergency department.
- Febrile neutropenic patients must be admitted.

TABLE 87.2. Modified World Health Organization Comprehensive Classification of Ovarian Tumors

Despite the malignant potential of the ovary and the devastating outcome when malignancy occurs, benign neoplasms and functional cysts occur far more frequently. A benign cystic teratoma (dermoid) is the most commonly occurring neoplasm in the age range of 1 to 20 years.²² Serous and mucinous cystadenomas occur throughout the reproductive years as well as in the postmenopausal period. Mucinous cystadenomas may grow to more than 100 pounds.^{13,26} Physiologic cysts, such as follicle cysts, corpus luteum cysts, germinal inclusion cysts, endometriomas, theca-lutein cysts, and sclerocystic ovaries (polycystic ovary), occur throughout the reproductive years and may masquerade as pregnancy, inflammatory masses, and neoplastic growths.

Discussion of the adnexal mass is incomplete without consideration of pelvic inflammatory disease and ectopic pregnancy. Pelvic inflammatory disease may present without the classic acute symptom complex. An inflammatory mass may be as hard and discrete as an ovarian carcinoma. Ectopic pregnancies are usually tubal (98%) in location and present as an adnexal mass approximately 50% of the time. These are discussed in detail in [Chapter 74](#).

CLINICAL PRESENTATION

The presentation depends primarily on the cause of the adnexal mass. Initial signs and symptoms, which apply to all age groups, include pain, mass, and vaginal bleeding, or the patient may be asymptomatic. In children, ovarian enlargement presents as an abdominal mass, because the ovary does not become a pelvic organ until puberty. Pain is a variable symptom and depends on the rapidity of growth, capsular stretch, and complications such as torsion, rupture, infection, and infarction. A functioning ovarian tumor may result in signs of isosexual precocious puberty and vaginal bleeding. Menstrual disorders may be produced by most adnexal masses of gynecologic cause. Nongynecologic disorders are seldom associated with menstrual dysfunction unless there is a significant systemic manifestation of the disease. Myomas, specifically pedunculated myomas, are not associated with abnormal bleeding, but coexisting submucous or intramural myomas may be associated with menorrhagia or hypermenorrhea. Ectopic pregnancy is invariably associated with menstrual dysfunction. Parovarian cysts are nonfunctional and have no associated menstrual abnormalities. Ovarian functional cysts are often associated with menstrual irregularity manifested primarily by menstrual delay and subsequent hypermenorrhea. An ovarian carcinoma usually causes more menstrual dysfunction than a benign ovarian neoplasm. This may be manifested as amenorrhea, hypomenorrhea, or hypermenorrhea.

Ovarian neoplasms may be asymptomatic. A careful history may reveal nonspecific gastrointestinal symptoms such as anorexia, indigestion, belching, and dyspepsia. Pain and abdominal swelling are the most frequent signs of ovarian carcinoma. Pelvic fullness, abdominal swelling, ascites, bowel obstruction, and pain are indicative of advanced malignant disease.

The adnexal mass produced by gastrointestinal disease is usually associated with chronic symptom complex. Pain, alternating consistency of the stool, food intolerance, mucus and blood in the stool, and a left-sided mass are the most frequent signs and symptoms.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes those diseases listed in [Table 87.1](#). Age grouping and a careful history facilitate the evaluation. Chills and fever are associated with inflammatory disorders and seldom occur with ovarian neoplasms, benign or malignant. Ascites is usually a manifestation of ovarian malignancy, but it may be present¹⁵ in benign situations (Meigs syndrome) associated with pleural effusion.⁸ In evaluating the adnexal mass, signs that favor benignity are unilateral location, smooth surface, mobility, cystic consistency, and symmetric shape. Features of the mass that suggest malignancy are bilateral location, solid nodular and irregular surface, ascites, and nodular cul-de-sac. Extremely large masses that fill the entire abdomen are usually benign ovarian masses. A mass seen in a patient at either extreme of life must be considered malignant, and managed expeditiously. Tender masses associated with severe pain and peritoneal signs are usually of inflammatory origin. They may also represent complications of a noninflammatory process such as torsion, rupture, or hemorrhage. Masses that are located anterior to the uterus are most frequently benign cystic teratomas (dermoid) or endometriotic cysts.^{10,16} If a gynecologic cause of the mass is excluded, the other major source of an adnexal mass is the gastrointestinal tract. A rectovaginal examination with Hemoccult examination of the stool is mandatory.

EMERGENCY DEPARTMENT EVALUATION

History and physical examination should permit a refining of the differential diagnosis, but diagnostic studies usually are necessary. These are dictated by the patient's age, symptom complex, physical findings, and general condition.

LABORATORY STUDIES

Complete blood count, urinalysis, erythrocyte sedimentation rate, and b-hCG determination should be done in all cases. Serum electrolytes, renal function studies, and type and crossmatch are performed according to the clinical situation. Sensitive, rapid urinary b-hCG tests are now available and are valuable in the evaluation of pregnancy-related complications. Quantitative methods are not required for initial management or evaluation. Occasionally, serum markers will be positive (e.g., a-fetoprotein in embryonal carcinomas and endodermal sinus tumors; b-hCG in the presence of trophoblastic tissue).

RADIOLOGIC STUDIES

Ultrasonographic evaluation of the palpable adnexal mass is of limited immediate value if complications of pregnancy are not under consideration. The ultrasonographic features of the mass, although suggestive, are not diagnostic in malignancy, and false-positive results frequently occur.^{5,13,18} Ultrasonography may be helpful in the patient who is difficult to examine if a mass is thought to be present. Additional sonographic information, such as solid versus cystic, free peritoneal fluid, and additional masses, have little clinical value in the immediate management, although these findings are very helpful for later evaluation. Transvaginal (TV) ultrasonography, now readily available, is far superior to transabdominal (TA) ultrasound. TA ultrasound is diminished by poor spatial resolution, operator dependency, and patient body habitus. Although TV ultrasonography is considered superior in evaluating the adnexa for ectopic pregnancy,² this benefit does not extend to situations in nonpregnant patients. TV color Doppler sonography has become more readily available, but still has limited use. It does not appear to improve the diagnostic accuracy of TV ultrasonography in the areas of ovarian endometriomas¹ and is not as sensitive or nor as specific as TV ultrasonography in evaluating premenopausal patients.^{23,25} Furthermore, color and pulsed ultrasound measuring pulsatility index (PI) and resonance index (RI) cannot reliably differentiate benign from malignant lesions.⁶ Computed tomography (CT) and magnetic resonance imaging (MRI) offer similar advantages and disadvantages.²⁴ CT is far superior to ultrasonography in evaluating the pelvic retroperitoneum.^{27,28} TV ultrasound appears to be superior to MRI for assessment of suspected pelvic masses and is less expensive and more accessible.¹⁴ The role of MRI in evaluating pelvic masses remains to be determined, especially in differentiating between loops of bowel and masses.¹¹ Reports of the gynecologic applications of MRI suggest that MRI is of value in differentiating uterine from adnexal masses if unresolved by ultrasonography.¹² MRI is the preferred modality for confirming suspected endometriosis (endometrioma).^{14,19} Currently, MRI of the pelvis should be reserved for resolution of indeterminate findings of TV ultrasonography.²⁰ Plain films are often helpful in evaluating the mass. Information may be seen on plain films, such as free intraperitoneal air and intestinal obstruction. Calcifications are seen on plain films of benign cystic teratomas, but they may also be present in other ovarian neoplasms, such as fibroadenoma, papillary serous tumors (psammoma bodies), gonadoblastoma, and Brenner tumors. Contrast studies of the lower gastrointestinal tract are often helpful. Upper gastrointestinal studies are often warranted when metastatic lesions are considered, but they are probably not indicated emergently. In premenopausal women, gastric carcinomas may metastasize to the ovaries. Intravenous pyelography (IVP) is one of the most useful diagnostic studies. It provides information about the location of the kidneys and the pathway of the ureter. Upper urinary tract obstruction requires prompt management to minimize subsequent renal damage. Abnormalities in the normal course of the ureter may suggest the origin of the mass and provide essential information if retroperitoneal exploration is later required.

EMERGENCY DEPARTMENT MANAGEMENT

The history and physical examination determine the urgency of both subsequent evaluation and emergency department intervention. In the course of the initial evaluation, specific information must be recorded regarding size, location, consistency, and tenderness of the mass. This is especially important if subsequent

changes occur in the mass or clinical situation. Immediate emergency intervention is required primarily in the patient who presents with symptoms secondary to complications—specifically, ovarian rupture, torsion, infection, hemorrhagic shock, severe pain, gastrointestinal symptoms, peritoneal signs, and a febrile state. Vascular access should be established and intravascular volume expanded. In patients with peritoneal signs and vascular instability, culdocentesis should be considered. Ruptured structures with hemoperitoneum require immediate fluid resuscitation, blood therapy, supplemental oxygen, and cardiac monitoring. Intraperitoneal pus secondary to a ruptured pelvic abscess requires immediate fluid expansion along with intravenous antibiotics with activity against aerobic and anaerobic organisms. Although a number of antibiotics are known to be effective, the selection remains controversial among gynecologists. The emergency physician should discuss this with the consultant, if possible, before instituting therapy. Appropriate cultures should be taken from the blood, urine, cervix, and culdocentesis fluid before therapy is initiated.

DISPOSITION

Role of the Consultant

The urgency and type of consultation depend on the presenting situation. A ruptured ectopic pregnancy, tuboovarian abscess, or bleeding cyst requires hemodynamic stabilization and immediate evaluation by a gynecologist. Less acute situations require gynecologic evaluation, depending in part on patient reliability. Masses in children should be evaluated in the emergency department by a gynecologic oncologist or pediatric surgeon, as these masses are usually malignant ovarian neoplasms. Masses in postmenopausal women should be considered malignant, and consultation obtained from a gynecologic oncologist or gynecologist regarding further evaluation and management. In the menstruating woman, ectopic pregnancy should be ruled out. The size of the mass will influence subsequent management and timing of the consultation. Palpable masses found in individuals during the reproductive years that are between 5 cm and 10 cm in size may be managed expectantly, and consultation evaluation is not necessary in the emergency department.^{4,7} Appropriate telephone consultation with a gynecologist must be obtained and the patient counseled regarding the possible complications and the necessity for expeditious follow-up. In appropriate situations, in which malignancy is of minimal concern, operative laparoscopists should be consulted for definitive management.^{9,21} Pregnant women with adnexal masses not believed to be a simultaneous tubal ectopic pregnancy should be referred to operative laparoscopists who have advanced endoscopic skills.^{17,29} General surgical consultation should be obtained in older patients with gastrointestinal symptoms associated with left-side adnexal masses that may represent a diverticular abscess.

Indications for Admission

All patients who present with evidence of ovarian rupture, torsion, infection, or hemorrhage should be admitted to the hospital. Because of the probability of malignant changes in the prepubertal girl and the postmenopausal woman, these patients should also be admitted for definitive studies and prompt surgical exploration. Women in the menstruating age group generate the most controversy in management. If the physical findings suggest features of malignancy as described earlier, admission is indicated on an urgent basis. A patient with a mass less than 10 cm in size, with benign features, may be treated as an outpatient.

Transfer Considerations

Most adnexal masses are of gynecologic origin. If the treating facility has no gynecologic surgeon, the patient should be transferred after stabilization. Children should be transferred to a facility with a gynecologic oncologist or pediatric surgeon. The patient with a mass suggestive of malignancy should, ideally, be transferred to a gynecologic oncologist. With the exception of hemodynamically unstable patients, most complications of an adnexal mass may be treated with appropriate fluids, analgesics, and antibiotics, and then transferred.

COMMON PITFALLS

- Spurious masses created by retained urine and feces must be considered. The bladder and rectum must be emptied. This may require catheterization and low rectal enemas.
- Ectopic pregnancy must always be considered in a fertile female with an adnexal mass.
- Ruptured tubal or ovarian abscesses may present without systemic febrile response. Culdocentesis is often diagnostic.
- Ovarian carcinoma is commonly associated with gastrointestinal symptoms and ascites. If this complex is present, serious consideration should be given toward the diagnosis.
- Ovaries decrease in size with advancing age, and a palpable, normal-sized ovary (3.5 × 2.0 × 1.5 cm) in the postmenopausal woman is abnormal and must be evaluated.³ Functional cysts do not occur in postmenopausal women.
- Ovarian cysts are often thin-walled, and examination must be gentle to avoid rupture, with subsequent potentially serious complications.
- Ultrasonographic examination in a nonpregnant female with an adnexal mass is of little value and may delay or confuse diagnosis or therapy.
- The location, size, and consistency of the mass are helpful in diagnosis, but only histologic diagnosis is definitive. Care must be exercised to provide the patient with expeditious referral to the appropriate specialist. There are no noninvasive procedures that are totally reliable.

CHAPTER 88

Sexual Assault

Gwendolyn L. Hoffman

[Clinical Presentation](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

An emergency physician confronts a great variety of medical emergencies. One of the more complex is sexual assault or rape. The legal definition of *sexual assault*, which is the gender-neutral term, may vary from state to state, but most definitions of *rape*, which is the legal term, include genital, anal, or oral penetration by a part of the accused's body or by an object, using force or without the victim's consent.⁴ In 1996, the Bureau of Justice Statistics estimated there were 307,000 women who were the victims of rape, attempted rape, or sexual assault.^{12,15} It is estimated that less than one in three assaults is reported and that one in five American women will be victims of rape or sexual assault.⁵ The emergency physician must be adept at meeting the physical, emotional, and judicial needs of these patients.

CLINICAL PRESENTATION

The sexual assault victim may present to the emergency department immediately after the event. She is often accompanied by friends, family, or the police. She may have visible physical trauma and be emotionally distraught. On the other hand, it may be hours or days later before she presents. The victim may feel guilt, shame, humiliation, and embarrassment. She may not be immediately able to share her experience with anyone and may delay seeking treatment. The victim with physical trauma, such as airway compromise, severe laceration, or fracture, is most likely to obtain early medical intervention.

EMERGENCY DEPARTMENT EVALUATION

The emergency physician's first duty to the rape victim is to evaluate for any life threat. The ABCs—airway, breathing, and circulation—must be addressed appropriately. If specific treatment is administered, care must be taken not to destroy or alter any evidence on the patient's person or at the scene. If the patient herself calls the emergency department to say she has been sexually assaulted, she should be advised to come immediately for evaluation and treatment. She should be encouraged not to bathe, shower, douche, gargle, brush her teeth, eat, drink, urinate, defecate, take medicines, or change her clothing. If she has already changed clothes, she should be advised to place in a paper bag the clothes she took off and bring them to the hospital. If she has not notified the police, she should be advised to do so, or the emergency physician should offer to do it for her.

At the emergency department, the patient should be ushered into a private room where care can begin. Informed consent must be obtained in writing and witnessed before hospital personnel may perform the medical examination, collect and analyze specimens, take pictures, release information to legal authorities, or render treatment. If the hospital has a special sexual assault team, the team should initiate involvement with the victim at this point. An increasing number of institutions are associated with a sexual assault nurse examiner (SANE) program.⁷

Once consent has been obtained, the pertinent historical facts can be obtained if the patient is physically stable. The history need not be an exhaustive account of the details of the encounter. Information about minute details that the victim provides at a time of acute emotional strain may later prove confusing in court if any discrepancy is noted between the hospital and police reports. The history should include information necessary for medical treatment and for the collection of evidence, including time, date, and place of the event. This information may be important when trying to relate physical findings, such as a bruise, to the assault, or when looking for corroborating evidence, such as sand if the assault occurred at the beach. Threats of violence or reprisal made by the assailant should be noted. If any type of weapon, restraints, foreign bodies, alcohol, or drugs were involved, these facts should be noted, as well as the number of assailants; whether vaginal, oral, or anal penetration was attempted; and whether ejaculation occurred. If ejaculation occurred, seminal deposits must be carefully sought on clothing as well as on the patient's person. The patient should be asked if she has douched, bathed, urinated, or defecated since the assault. If she has, some evidence might have been destroyed.

A pertinent gynecologic history should include gravidity, parity, last menstrual period, contraceptive history, date of last consensual intercourse, history of recent sexually transmitted disease, and any recent gynecologic surgery. If the victim is taking birth control pills, she should be asked if she has missed taking any pills. All of this information will assist in deciding what type of medical treatment is necessary.

The medical history should include current medication, allergies, and tetanus immunization status. In some emergency departments, nurses take the history and collect specimens. It does not matter who gathers this evidence as long as it is done in a caring and professional manner. The important thing is that important information is not omitted and the chain of evidence is not broken. For this reason, most departments have specific protocols and prepared forms that should be used. The physician must be thoroughly familiar with department procedure.^{1,11}

It does not matter whether the physical examination is performed by a female or male physician. It is important that the physician be understanding, supportive, and caring. The purposes of the physical examination are to determine the need for medical treatment, to gather specimens for analysis, and to make and document observations for corroboration of the assault. If the police are present and if the victim is wearing the clothes she wore during the attack, the police may want to take photographs before she undresses. In this case, the patient should be asked to place her clothes in a paper bag, or to place each item in a separate bag, depending on protocol. Paper bags are used instead of plastic bags, because plastic bags do not "breathe" and may promote molding of blood and seminal stains. The patient should put the clothes in the bag herself to avoid possible cross-contamination from blood group antigens in the sweat of hospital personnel.

When the patient has donned a hospital gown and is ready, the physician should thoroughly explain what the physical examination will entail. The skin should be inspected for scratches, lacerations, abrasions, contusions, and bite marks; special attention should be paid to the neck, mouth, breasts, wrists, and thighs. When the mouth is being examined for trauma, a saliva sample should be obtained. The sample can be used to determine the patient's status as a blood group antigen secretor or nonsecretor. The teeth should be swabbed for acid phosphatase and sperm analysis. In addition to noting evidence of trauma, the presence of any foreign material, such as hair, blood, or semen, should also be noted. Foreign material should be scraped from under the fingernails and placed in the appropriate envelope. This material may reveal bits of the assailant's hair, blood, or skin, if the victim were able actively to resist. Semen may appear as lightly crusted areas. A Wood light can help to identify these areas because they fluoresce in ultraviolet light.⁹ Semen can be removed with a water-moistened swab. Fluorescence is not pathognomonic of semen because other stains and urine may fluoresce, but it may be helpful.

If photographs are not taken, the physician must be even more careful to document the findings completely and accurately. Documenting thoroughly at the time of the examination makes it easier to recall the examination accurately when called on in a court of law.

The pelvic examination should be performed next. The external genitalia should be checked for trauma and evidence of semen. If semen is present on the upper inner thighs, it can be swabbed as previously described. If it is present on pubic hair, the hairs should be trimmed. The patient's pubic hair should be combed to find strands of the assailant's hair, which can be analyzed to help identify the assailant's race and hair color.⁶ In order to differentiate it from the victim's hair, some of her pubic hair must be plucked for analysis also. Each specimen should be placed in the appropriate envelope.

Small vaginal lacerations can be identified with the use of toluidine blue.⁴ A small amount of the blue dye can be applied to the vaginal mucosa at the introitus. A positive test result is indicated by a linear blue stain, because the dye will be taken up by the nuclei of exposed submucosal cells. The dye is applied externally, not intravaginally. Therefore, it should not interfere with the collection of other evidence, but any excess should be wiped off before the speculum is inserted, just to be sure.

The hymen should be inspected to determine if it is present, intact, absent, or traumatized, with bleeding or fresh clots. In adolescent girls with an estrogenized

hymen, the examination is more difficult. A Foley catheter (14F) inserted through the hymen orifice and inflated, using 40 cc of air, has been used successfully to assess the redundant hymen.¹⁰ The speculum should be lubricated only with water; other lubricants may affect the acid phosphatase determination and sperm motility. The vaginal wall should be inspected for lacerations and for evidence of the penetration of any foreign objects. Any secretions that have pooled in the posterior fornix should be aspirated and placed in a sterile receptacle. These secretions can be used to determine the presence of sperm, acid phosphatase, and blood group antigens. If no secretions are present, the vagina should be washed with 5 to 10 mL of nonbacteriostatic sterile saline solution and followed with aspiration. If washing is not necessary, the posterior fornix should be swabbed with a cotton-tipped applicator and secretions smeared on two glass slides for later laboratory examination. One more swab should be obtained for wet mount examination. A Papanicolaou smear should be obtained from the cervix to help determine the presence of nonmotile sperm (the smear is useful up to several days after the assault). Cultures for gonorrhea, chlamydial infection, and herpes should be obtained, if indicated. A bimanual examination should be performed, and uterine size, adnexal masses, and tenderness noted. The rectal area should be examined carefully, especially if anal intercourse took place. Signs of trauma, semen stain, blood, and lubricant should be noted. Anal and rectal swabs can be obtained through the lumen of a water-lubricated anoscope; these are used to determine the presence of motile and nonmotile sperm and acid phosphatase. It is often difficult to document genital findings in sexual assault victims by gross visualization alone. Magnification with colposcopic examination and photography allows the examiner to document and characterize genital findings with more accuracy. Many emergency departments have a colposcope readily available.^{8,14}

Blood should also be drawn for ABO analysis, syphilis serology, drug and alcohol screen, and beta human chorionic gonadotropin (b-hCG). Routine testing for hepatitis B virus and human immunodeficiency virus must also be considered. This is especially true in an area of high seropositivity or if the assailant is known to be in a high-risk group.¹¹ Pregnancy may be detected as early as 1 week after implantation by using the radioimmunoassay beta subunit of hCG or the Tandem Icon II hCG urine assay. If the test result is negative initially and positive at a follow-up visit, the pregnancy probably originated at the time of the assault.

The oral, vaginal, and rectal swabs obtained for the identification of sperm must be examined microscopically for motile and nonmotile sperm. Sperm are not usually found motile after 12 hours. The presence of motile sperm is a reliable indication that the assault occurred at some point during the 12 hours preceding the examination, provided consensual intercourse did not also take place during that period. Nonmotile sperm may be present for 72 hours or longer.

The acid phosphatase enzyme may also indicate sexual contact. This enzyme is present in vaginal secretions but is found in much greater quantities in prostatic secretions. A high concentration of acid phosphatase is an excellent indicator of the presence of seminal fluid, even in the absence of sperm. The presence of acid phosphatase may be a more accurate indicator of the postcoital interval than the presence of nonmotile sperm.

A major seminal plasma glycoprotein produced in the prostate, p30, has been identified as another semen-specific marker. This protein is male-specific; therefore, the finding of any p30 in vaginal fluid establishes the presence of semen. p30 is present in men who have had vasectomies as well as in men who have not, and it can be found for approximately 48 hours after the assault.

The forensic laboratory will also develop a specific genetic profile of the assailant to compare with that of the victim. Genetic typing can determine the blood group and type of both parties. Three genetic markers found in semen are phosphoglucomutase (PGM), the peptidase-A (Pep-A) enzyme marker, and the ABO blood group antigens. With electrophoretic analysis, PGM and Pep-A can be further subdivided into a total of 40 possible combinations. Reference markers for the victim must be obtained at the initial evaluation; these markers are also in vaginal secretions but in lower concentrations.

DNA typing or fingerprinting is the newest method used to identify the assailant. This method involves the extraction of DNA from a small sample of blood, semen, or other DNA-bearing cells. Through various procedures, a specific "DNA fingerprint" is developed. This "fingerprint" can be analyzed and compared with the assailant's to establish a positive identification. The chance that two unrelated persons having the same DNA fingerprint is one in a quadrillion.^{3,14}

EMERGENCY DEPARTMENT MANAGEMENT

Physical trauma experienced by a sexual assault victim is treated like trauma in any other patient. In addition, the possibilities of psychological trauma, pregnancy, and venereal disease must be addressed.

Efforts to decrease the victim's distress can begin with her arrival at the emergency department. The staff must be attentive and encourage the victim to share her feelings. She has just experienced a threat to her life and must be helped to feel safe and secure. It is often helpful to have a rape crisis volunteer present to provide additional support and to make sure the patient understands the procedures explained to her by the physician and nurse. Her emotional trauma may be significant.

Rape is sudden and does not allow the victim to gather adequate defenses. Also, the victim feels trapped and often cannot fight back. The ability to trust is destroyed when the perpetrator is known.¹³ Rape also often involves intentional cruelty and physical injury. The victim will feel most comfortable with hospital personnel who are capable of projecting both professional objectivity and personal concern.

The possibility of pregnancy should be explained to the patient. It is estimated that the risk of pregnancy without contraception is 2% to 4%. If midcycle (days 14 to 16), the risk is higher.¹¹ Pregnancy should be ruled out before prophylactic treatment is considered. The "morning-after pill" can be administered if prophylaxis is desired. Diethylstilbestrol (DES; 25 mg by mouth twice daily for 5 days) must be administered within 72 hours of sexual contact to be effective. If conception occurs despite DES prophylaxis, a female fetus is at risk for vaginal adenosis and cancer and a male fetus is at risk for penile and testicular lesions.⁹ Birth control pills may be used instead of DES. A regimen that includes norgestrel plus oral ethinyl estradiol (two pills initially and two pills 12 hours later) is acceptable. Ethinyl estradiol (0.5 mg daily for 5 days) may also be used.¹¹ Premarin (25 mg), an oral conjugated estrogen, may be administered daily for 5 days. Good results and less nausea have been reported with the use of intravenous Premarin (50 mg for 2 days). One problem is ensuring that the patient return for the follow-up visit. All of the estrogen preparations may cause nausea and vomiting. To combat this problem, some physicians order an antiemetic to accompany the estrogen preparation. A history of pulmonary embolism, thrombophlebitis, estrogen-dependent tumor, or cardiovascular or liver disease is a contraindication to the administration of estrogens.

If the initial pregnancy test result is negative and a follow-up test result is positive, counseling is indicated, after which the patient may want to have a suction curettage or a therapeutic abortion.

The risk of contracting a sexually transmitted disease as the result of sexual assault is hard to estimate. Risk varies according to geographic area, the populations within that area, and whether the assault is reported. Some reports have indicated that the incidence of acquiring a sexually transmitted disease from a single sexual encounter is 5% to 10%.¹¹ Prophylaxis should be given if the patient requests it, if evidence of infection is present on examination, if follow-up is questionable, and if the assailant is suspected of being infected. The Centers for Disease Control and Prevention recommend prophylaxis for gonorrhea, chlamydia, and syphilis. Trichomoniasis should be treated with metronidazole 2 g po if seen on wet mount.²

Patients are usually treated by using one of the following regimens²:

Ceftriaxone 125 mg i.m.
Cefixime 400 mg PO once
Ciprofloxacin 500 mg PO once
Ofloxacin 400 mg PO once
Spectinomycin 2 g i.m.
Azithromycin 1 g PO once
Doxycycline 100 mg PO twice a day for 7 days

Ciprofloxacin and ofloxacin are contraindicated in pregnancy. Spectinomycin is recommended only for use during pregnancy in patients allergic to beta-lactams. Erythromycin, except for erythromycin estolate, (500 mg PO four times a day for 7 days) can be used in pregnancy. Both doxycycline and erythromycin will cover early syphilis, but the drug of choice remains penicillin G benzathine (2.4 million units i.m. once).² Hepatitis B virus vaccine should be considered if the patient was previously unimmunized. A dose of 1.0 mL i.m. should be given acutely and repeated 1 and 6 months later. Hepatitis B immune globulin should be reserved for a high-risk exposure, such as if the assailant is an intravenous drug user or if multiple assailants were involved.¹¹ Victims may be particularly concerned about the transmission of human immunodeficiency virus (HIV). The risk is felt to be very low but appropriate counseling should be arranged as well as pretesting if deemed necessary. At this time there is no proven prophylactic intervention.²

DISPOSITION

A gynecologist may be called during the initial examination if the emergency physician deems it necessary, especially if an operative intervention is needed. The emergency physician should strongly recommend that the victim seek follow-up care from a gynecologist or family physician.

Most hospitals have rape crisis volunteers available to consult with the victim during the first 24 hours after the assault. Encourage the patient to talk to the volunteers or to seek counseling with psychologists or psychiatrists, if indicated.

Admission to the hospital may be required in the case of significant physical trauma. As a rule, the sexual assault victim may be discharged from the emergency department in the company of relatives or friends. Follow-up care for the victim must be arranged before discharge. She will need to return after 2 weeks and after 6 weeks to be reevaluated for pregnancy and venereal disease. Any physical injury, such as a laceration, will need follow-up care. Psychological trauma may necessitate long-term treatment.¹ The short-term phase, characterized by disorganization, may last from a few days to a few weeks. During this time, the victim may exhibit a wide range of emotional behavior, from being quiet and subdued to demonstrating anger and fear. The long-term phase, characterized by reorganization, may last for months or years. Many victims experience depression, flashbacks, anxiety, and sexual dysfunction.⁴ These experiences may explain why 80% of rape victims end primary relationships within 1 year of the rape.⁴ Because the rape victim may have a large spectrum of psychological needs and concerns, the emergency physician must be certain that follow-up evaluation will address them. The patient should be reevaluated psychologically approximately 1 to 2 weeks after the initial medical evaluation. At that visit, the need for further counseling should be discussed.

COMMON PITFALLS

- When treating a sexual assault victim, the physician and other involved personnel must be certain that the collection, disposition, and transfer of all specimens are documented at every stage, from collection to introduction into the courtroom. This legal protocol is the chain of evidence and safeguards the rights of the accused during the judicial process. All specimens must be correctly collected and labeled. Documentation must be made of each person who takes possession of the evidence—the physician or nurse who gathers the evidence, the police officer who transfers it to the forensic laboratory, and laboratory technicians. No break must occur in this process, or the evidence will not be admissible in court.
- Each institution and state may have some variation in their requirements and protocol, so the emergency physician must be familiar with the sexual assault kit and the forms and procedures of his or her institution.
- Another pitfall is lack of follow-up. Up to 94% of rape victims do not return for their follow-up visits.⁴ Therefore, it is advisable that some member of the medical team, such as a social worker, contact the victim after discharge, to address concerns that arise later and to encourage follow-up care.

CHAPTER 89

General Principles of Trauma

Peter Rosen

[Trauma in Children](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Trauma is the leading cause of death in the first three decades of life.⁴ Many of the 100,000 fatalities resulting from accidents each year could be prevented by expeditious transfer of the multiply injured patient to a trauma center that can provide high-quality trauma care in the first hour after injury.

CLINICAL PRESENTATION

The appropriate care of the major trauma patient is best achieved in an institution that has a dedicated mission for trauma. Although there is no completely accurate field system for appraising the patient with subtle but serious trauma, and there are great economic concerns about overtriage of minor trauma, it is not the obvious case of major trauma that is the problem; rather, the problem is the patient with a moderate mechanism of injury who appears to have an isolated orthopedic injury, but who is harboring a ruptured liver or spleen. It is far better to overtriage the less serious injury than to undertriage the subtle serious injury.

In rural areas, it may well be impossible to have a trauma center as a destination; there are no trauma centers in Wyoming, Idaho, or Montana, for example. There are variations in capabilities of communities, and it may make sense to take a patient past the nearest hospital to reach one with a general surgeon or one that has computed tomography (CT) scan capacity. It is often necessary to attempt to stabilize a patient before transferring him or her to a tertiary care center or a trauma center in another state. It is therefore wise to have the transfer agreements and routes as well as the mechanics of evacuation worked out well in advance of the individual patient's need.

The trauma center can assemble a more efficient team and has the experience and resources to achieve timely response to reparable injury, which will definitely lower morbidity and mortality. Even if the emergency physician has been well trained in trauma, if the institution is not committed to the total care of the trauma patient, the effectiveness of the prehospital care or emergency department resuscitation will be lost.

Patients assessed by prehospital personnel as having a major mechanism of injury, or those arriving on their own who are recognized as having a potentially serious injury, should be triaged immediately to a suitable treatment area capable of major resuscitation. Appropriate management must coordinate not only the entire institution in which the patient will receive definitive care, but also the field care. There must be a total system commitment to ensure that the injured patient is taken to the correct facility where there are properly trained and skilled emergency physicians, surgeons, and technical personnel. Laboratory and special diagnostic equipment and technicians must be readily available, as well as anesthesia and operating rooms. There must be good intensive care unit support and the psychological and rehabilitative functions that will restore the patient toward full health.

Appropriate personnel should accompany the patient from the emergency department entrance to the resuscitation room to ensure that adequate life-support measures are being accomplished en route. Whether or not prehospital communication has taken place, details regarding the mechanism of injury are important clues in predicting potential injuries ([Table 89.1](#))

TABLE 89.1. Important Details about Mechanism of Injury

Triage must take into account the immediate threat to life or limb as well as patient discomfort and anxiety; the means to evaluation is an adequate history and physical examination. The triage officer must be capable of rapid decision making and must understand that the wrong decisions can have drastic consequences. Correct decisions require maturity, appropriate awareness, intelligence, and experience. In many hospitals, the triage function is fulfilled by an emergency department nurse. Larger centers may use a highly trained and experienced trauma nurse or a triage physician.

Seriously injured patients or those with a major mechanism of injury must be triaged to a major resuscitation room. Human nature is such that once a patient has been labeled "not serious," it is difficult to change that label and achieve appropriate care for the patient. Therefore, it is wise to overestimate the possible injuries. Fewer mistakes will be made by overresuscitation than by underresuscitation. Patients who are not overtly seriously injured may nevertheless be evaluated in the trauma resuscitation room if their injuries are potentially serious.

The trauma team must have a captain. The training and experience of this person may vary from place to place and should be appropriate to the specific hospital. Although the ideal may be impossible to achieve—a captain who is a physician with extensive experience in trauma management—an institution can no longer promote itself as a major trauma center without having that expertise. Increasingly, the captain is initially an emergency physician. In some settings, an emergency physician may be the only physician physically present in the emergency department (and, for that matter, in the hospital). Ideally, surgical support personnel are available within 10 to 15 minutes.

In trauma centers, surgical support is immediately available within the hospital. In this system, the emergency physician may assume the role of trauma captain for the initial assessment and resuscitation. When the attending trauma surgeon arrives, a defined transition of leadership should occur. The team concept must be maintained at all times.

If the responsibility for the major orchestration is formally handed over to the trauma surgeon, it does not relieve the emergency physician of responsibility for the patient. The emergency physician should stay and assist until the patient physically leaves for the operating room, intensive care unit, or special diagnostic study. On occasion, the emergency department may be busy with other seriously injured patients who demand immediate attention. In this situation, the emergency physician may have to leave the trauma patient, but this departure should always be made in coordination with the team and the team leader. The team may summon subspecialty consultations, as needed, for stabilization, but there must be a single person in charge of the orchestration of total patient needs. Too often, resuscitation becomes chaotic, with multiple subspecialists tunneled into the concerns of their own specialty. The trauma surgeon or emergency physician must stay in command of the overall care.

Nurses who care for trauma patients should have the special knowledge and skills to serve the patient adequately. In the large urban center, there is usually no

paucity of physicians to complete resuscitative procedures, but this is not the case in the rural emergency department, where the trauma nurse may need many technical skills ordinarily reserved for physicians. Field paramedics may need to stay in the emergency department so that their technical skills can be used, if they do not have to return to service or a field location immediately. Occasionally, they may be called on to initiate stabilization until a physician arrives. Protocols and guidelines should be available regarding expectations of nursing staff.

A coordinated, knowledgeable response from the blood bank, laboratory, respiratory therapy, and radiology department is key to an effective trauma system. Their direction and coordination for integral function with the trauma team are essential. Social workers, clergy, and lay support should be included in the team framework. The area of the radiology department designated for emergency patients should be located adjacent to the emergency department. Portable or built-in x-ray equipment in the trauma resuscitation room is also necessary for proper care of the seriously injured patient.

The radiologist must be considered a member of the trauma team; availability for consultation at all hours and adequate communication are essential. The radiology department should be integrated into the trauma team and should participate in planning.

The operating room must be immediately accessible to the emergency department for operative resuscitation of critically injured patients. Some centers have emphasized this relation by having an operating room as part of the emergency department or by reserving a single operating room for trauma use.

Ideally, potentially or obviously seriously injured patients are triaged either to a trauma resuscitation room or to an area where an appropriate history and physical examination can be carried out. Because of lack of space and personnel, sometimes triage must be consigned to the waiting room. Patients should not, however, be sent to a minor trauma room or the waiting room, to be forgotten. Adequate explanation of the need for delay and some show of concern and attention are required, for what the emergency department staff considers minor or nonurgent is almost never perceived as such by the patient.

EMERGENCY DEPARTMENT MANAGEMENT

The approach to the multiple-trauma patient begins with a rapid initial examination; this takes no longer than 1 minute and is done while vital signs are being assessed.⁶ The patient is stripped of all clothing. If there is any hint of vital sign instability, the clothes should be cut away. Too many patients have been thrown into severe shock when someone tries to sit them up to remove a T-shirt or some other trivial item of clothing.

Immediately ascertain the patency of the airway. Examine the neck for direct trauma, carotid pulsation, tracheal position, and character of neck veins. Quickly observe the chest for sucking wounds or paradoxical motion; palpate for crepitus, and auscultate for the absence of breath sounds or the presence of adventitious sounds.

Palpate the extremities. If they are cool, moist, or pale, shock must be presumed. In the absence of any contraindications, roll the patient from side to side to ensure that there are no wounds on the back. In the field, it may be impossible to auscultate the blood pressure because of extraneous noise, but in the emergency department, an attempt should be made to auscultate the systolic and diastolic pressures.

Locating a palpable pulse provides much information about the perfusion pressure. For example, if a radial pulse is present, the patient must have a systolic blood pressure of at least 80 mm Hg. A palpable femoral pulse indicates a systolic blood pressure of at least 70 mm Hg, and a carotid pulse, a systolic blood pressure of 60 mm Hg.

When intravenous lines are placed, blood is drawn for blood typing and other tests. If the field system can draw blood, having field staff draw samples will save time for blood typing, but not every hospital laboratory accepts field blood samples. It is more efficient to use a large, 50-mL syringe and simultaneously draw all needed blood samples, as well as measure arterial blood gas from the femoral artery. This site gives a quick indication of subtle malperfusion and provides quick access to a good blood source for obtaining the specimen quickly. It is the trauma captain's responsibility to ensure that blood is obtained in a timely manner.

The cervical spine must remain immobilized until it is radiographically cleared of injury. Hyperextension or flexion of the neck should be avoided if neck injury is suspected or if the patient is unconscious from a head injury.

Delivery of oxygen to the tissues is of primary importance, and clearing the airway is the initial step. In the unconscious patient, use a finger to sweep vomitus, blood, teeth, bone, or other debris from the oral cavity. A suction apparatus may be used to clear the upper airway. The patient who has facial but no neck injuries may be turned to a lateral or prone position, or placed in a sitting position, leaning forward, to allow rapid clearing of the airway. If the condition of the spine is unknown, it may be necessary to leave a suction catheter in the patient's mouth while the cervical spine is being cleared. A chin lift or jaw thrust will usually relieve upper airway obstruction.

If necessary, grasping the tongue with a towel clip or placing a suture in the tongue and drawing it forward will open a difficult airway. In some cases of severe maxillofacial trauma or direct tracheal injury, cricothyrotomy is needed. Supplemental oxygen should be given. If the patient needs active airway management because of secretions, the kinds of injuries present, or respiratory distress, do not take time to obtain arterial blood gas analysis; instead, secure the airway. Once the airway is patent, recheck breath sounds.

If the patient is not breathing spontaneously or adequately, ventilation must be controlled. Initial control may be by bag-valve-mask ventilation with high-flow oxygen. Once the patient is oxygenated and hypercapnia has been corrected, intubation is less hazardous, but undertaking it must always be weighed against the risk of distending an already full stomach.

Major trauma victims often need active airway management, even if they are breathing spontaneously. There is a tremendous metabolic cost to breathing, especially with thoracic or abdominal injuries, and this can be overcome by taking over the work of breathing for the patient. Moreover, many patients have injuries that potentially can distort their airways (e.g., a gunshot wound to the neck). It is far better to intubate these patients before the anatomy becomes so distorted that intubation is impossible to perform, even with a fiberoptic bronchoscope. It will also be much harder, if not disastrous, to attempt a surgical airway when the neck is filled with a massive hematoma.

There is almost always some degree of head injury in the patient with multiple trauma, and it is worthwhile to try to prevent or contain cerebral edema by hyperventilation. Finally, because few trauma patients have an empty stomach at the time of the injury, intubation can help prevent the risk of the patient's vomiting and aspirating the vomitus.

For many years it was believed unsafe to intubate the trauma patient unless there were radiologic clearance of the integrity and stability of the spinal column. For this reason, there were long delays during attempts to clear the cervical spine, and many cricothyrotomies were performed. We now have more data and experience with the management of the trauma patient's airway, and the preferred approach is to keep the neck immobilized to prevent hyperflexion, hyperextension, or hyperdistraction, and to proceed with a rapid-sequence intubation (RSI) using sedation, prophylactic lidocaine, muscle paralysis, and oral intubation ([Table 89.2](#)).

Crash intubation summary
Oxygenate the patient
Select appropriate endotracheal tube
Test the balloon
Insert stylette
Ensure suction is working
Apply tonsil tip to suction
Pretreat with lidocaine 1.5 mg/kg
In children, give atropine 0.01 mg/kg
Sedate the patient
Give succinylcholine 1.5 mg/kg
Perform Sellick's maneuver
Await fasciculations
Intubate quickly
Assess tube position
If correct, tie and tape in place
Assist ventilations
Obtain chest x-ray study

TABLE 89.2. Rapid-Sequence Induction

In the presence of head injury, nasal intubation should be avoided, if possible. Not every helicopter or ground system is set up to manage the airway in this fashion, and one must work within the agreed-on field protocols, but in the emergency department, the optimal approach to the airway is via the oral route.

While oral intubation using an RSI has been very successful and has virtually eliminated the need for cricothyrotomy, the technique is important. While a second pair of hands other than those of the intubator stabilizes the head and neck, it is necessary to open the anterior portion of the cervical collar. It is almost never possible to intubate orally with the anterior collar closed, and it is safer and preferable to open it before making any intubation attempt.

While RSI oral intubation has largely replaced cricothyrotomy, some patients with midface crunches and severe oral trauma are best managed by placement of a surgical airway. A surgical airway is also necessary if there is extensive damage to the patient's larynx or if there is complete tracheal separation. In the latter instance, the trachea may not separate because it is held together by the cervical fascia. Before making an incision in the neck of a patient with this possible injury (as seen in motorcyclists who have run into a chain strung across their paths), it is prudent to grasp the distal stump of the trachea with a towel clip. Then, when the incision is made, this distal stump will not retract into the anterior mediastinum, where it cannot be reached without splitting the sternum. If the damage to the larynx is too great or if the separation is distal to the larynx, a tracheostomy will have to be performed.

The need for active airway management is the most critical question in the patient with multiple trauma; universally accepted criteria for mandatory intubation, however, have never been established. [Table 89.3](#) lists mandatory and relative criteria that serve as guidelines for this decision.

MANDATORY
Massive facial injuries
Head injury with Glasgow Coma Scale <8
Penetrating injury to the cranial vault
Missile penetrating injury to the neck
Blunt injury to the neck, with expanding hematoma, painful phonation, or alteration of the voice
Bilateral missile penetrating injuries of the thorax
Multisystem trauma with persistent shock
RELATIVE INDICATIONS
Upper airway obstruction from any cause
Any patient with injuries impairing ventilation
Flail chest with increasing respiratory rate or deteriorating blood gases
Any patient with one or more rib fractures who is going to need a ventilator or a general anesthetic
Bilateral pneumothorax
Expanding hemothorax that recurs or does not respond to thoracostomy
Any patient developing severe hypotensive shock, extensive burns, pulmonary or facial or neck burns

TABLE 89.3. Criteria for Active Airway Management

Use direct pressure only to control external hemorrhage. Blind probing and clamping deep within a wound risk further injury to vessels and nerves.

Shock can be defined as inadequate perfusion of the tissues. Once oxygen has reached the alveolus and crossed into the blood, there must be a functional pump, adequate circulating volume, and an ample oxygen carrier before the oxygen can reach the tissues. Cool, pale, moist skin indicates shock.

In the treatment of shock, a Foley catheter is needed to monitor renal perfusion. A central venous catheter is also helpful in monitoring central volume. Vascular access is critical. Two large-bore (14- to 16-gauge) percutaneous catheters should be placed, avoiding, if possible, injured extremities. If veins are collapsed or sclerosed, cutdowns, either in the antecubital or saphenous veins, can be rapidly placed. A pediatric feeding tube or intravenous tubing works well as a large-bore catheter. Percutaneous central catheters inserted through the subclavian or internal jugular veins are more hazardous, particularly in the hypovolemic patient.

Percutaneous femoral lines may be useful, and, in the child under age 3, intraosseous needles may be the only available route. There is no single answer to intravenous access: Each patient must be evaluated individually, and the cost-benefit ratio of the chosen routes weighed. In general, it is best to insert a minimum of two large-bore peripheral lines, adding more as necessary. Sometimes, this scenario is impossible to achieve, however, and it is necessary to proceed immediately to a central line or peripheral cutdown to gain access.

While most traumatized adults can tolerate generous fluid infusions, because they are usually young and in previous good health, if there is any question about underlying diseases, it is wise to give intravenous fluids under control. An initial dose of 20 mL/kg is always safe. If the patient still shows signs of volume deficit after administration of 50 mL/kg, type-specific or O-negative blood should be started. In the patient who has an injury that obviously will produce a major volume deficit (e.g., shotgun blast with marked tissue destruction and loss), blood should be given immediately.

In the adult, crystalloid can be continued while progress is being made, but if there is no response or only a partial restoration toward a normal pulse or blood pressure, do not exceed a dose of 50 mL/kg before initiating blood or blood products. [1,2,5,6](#)

When massive transfusions are necessary, one must remember the need for additional platelets and other clotting factors. Blood should be warmed whenever possible.

In children, fluids should be given as aliquots rather than run wide open. An aliquot of 20 mL/kg is safe as an initial bolus. This dose can be repeated once and then halved, at a dose of 10 mL/kg. At this time, blood is started at 10 mL/kg. In addition to an aliquot dose, the time must be specified. The first volume should be administered in 30 minutes or less, the second volume over the course of an hour.

In all cases, the amount of fluids given depends on continued losses, which should be minimized as much as possible through proper splinting, bandaging, and avoidance of probing large soft-tissue wounds. We often forget how much a soft-tissue injury, especially to the scalp, can bleed, and the best treatment of hypovolemia is to locate the source of bleeding and stop the blood loss. The degree to which long-bone and pelvic fractures bleed is also not generally appreciated, and it is far more effective to begin giving blood as soon as these injuries are recognized than to wait.

Noting the character of the neck veins of the trauma patient is invaluable in identifying the cause of shock. If the neck veins are collapsed, hypovolemia must be presumed. If they are distended, then cardiogenic shock, tension pneumothorax, or pericardial tamponade must be excluded. Most trauma patients in shock are hypovolemic. Tension pneumothorax causes shock by increasing intrathoracic pressure, shifting the mediastinum, and compressing the great veins, thereby preventing venous return. The diagnosis is possible in any patient in shock who has distended neck veins and an increased resistance to bagging. An ipsilateral decrease in breath sounds may be noted, as well as a contralateral tracheal shift. Unfortunately, these physical findings are often not present in the acute trauma situation, and the only clues to the presence of a correctable cause of patient collapse may be a sudden rise in pulse, a drop in blood pressure, and an increased resistance to ventilation. The neck veins may not even be distended if the patient is concomitantly hypovolemic.

If tension pneumothorax is suspected in the field, it should be immediately decompressed with a large-bore over-the-needle catheter in the second intercostal space-midclavicular line. Many air ambulance personnel can perform tube thoracostomies. This route should be chosen in field cases if personnel have been trained to do the procedure, and in the emergency department. A tension pneumothorax is what kills patients, not a simple collapse of the lung.

Do not waste time obtaining radiographic confirmation of a suspected tension pneumothorax, as the patient may well arrest while the film is being obtained. Perform thoracostomy by inserting a large-bore chest tube in the fifth intercostal space, in the midaxillary line, to evacuate any blood present, as well as any air.

Cardiac causes of shock must not be overlooked. Pericardial tamponade is rare with closed-chest injuries, and another source of the shock should probably be sought. It must always be considered with penetrating injuries, even if the entrance wound appears anatomically remote. The physiologic response to tamponade is to compensate for the fall in cardiac output by raising the pulse rate. The classic physical findings in this disorder may also be absent in the acute situation. Thus, one

may not see distended neck veins if the patient is profoundly hypovolemic. Furthermore, heart sounds may be difficult to appreciate during a major resuscitation. If the patient still has vital signs, a pericardiocentesis can be performed. If, on the other hand, the patient has lost vital signs or has suddenly become bradycardic (an ominous sign in a patient with this potential pathology), an immediate thoracotomy should be performed.

Myocardial contusion, most commonly from blunt trauma, may cause dysrhythmias, often within the first hour after injury. An electrogram (ECG) should be obtained in patients with significant anterior blunt chest trauma. Continuous ECG monitoring is indicated. Myocardial infarction may occur as a result of the stress associated with blood loss and catecholamine release, or it may have preceded the traumatic injury. Coronary arterial air embolization occurs with penetrating neck and chest trauma or serious rib fractures after intubation and positive-pressure ventilation. Air passes from the airway into the pulmonary veins and embolizes to the arterial circulation, often involving the cerebral and coronary arteries. If air embolization is suspected, the patient should be immediately turned to the left lateral decubitus position (i.e., right side up); fluid infusion should be increased, and immediate thoracotomy with bypass arranged. It may be possible to salvage some of these patients with immediate femorofemoral bypass while preparing the operating room.

Possible sources of significant blood loss causing hypovolemic shock include the chest, abdomen (including the pelvis and retroperitoneum), and thighs. Head injuries seldom cause hypovolemia, even in children (except for extensive scalp lacerations), and other sites of occult blood loss must be excluded in a head-injured patient with shock. Spinal cord trauma with loss of sympathetic vascular tone can be assessed by rectal examination and examination of peripheral reflexes.

The diagnosis of intraabdominal hemorrhage is often difficult. Abdominal examination may be totally normal despite significant intraabdominal pathology. The pulse may not be rapid, especially if the bleeding has been sudden and profound, or if the patient has alcohol or other drugs in his or her system. Bowel sounds may be present, and no abdominal tenderness or guarding may be seen. Distention is a late finding that may be present even if there is no abdominal pathology, and does not predict the degree of blood loss.

The patient may also have other problems that interfere with an accurate diagnosis (e.g., intoxication, head injury, or competitive pain from another major injury). Few patients can perceive more than one major source of pain at a time. Unfortunately, the pain they may focus on may not be from the most serious injury.

The hemoglobin and hematocrit may not dilute, and may be normal right up to the time the patient arrests from hypovolemia.

One of the most important decisions in the management of the multiple-trauma patient is when to obtain an objective evaluation of the abdomen. With a major mechanism of injury (such as an automobile accident in which someone was killed), no matter how well a patient looks, it is wise to assess the abdomen for occult hemorrhage. The physical examination of the abdomen is extremely unreliable when there are multiple injuries, competing pain from skeletal (especially vertebral) trauma, or head injury, or if drugs or alcohol are involved. In the presence of any of these factors, objective evaluation must be obtained. Finally, in any patient who demonstrates vital sign instability without obvious source, it is important to evaluate the abdomen for hemorrhage.

The diagnostic peritoneal lavage (DPL) is one method to evaluate the abdomen. It is very accurate, being one of the few tests in medicine that has reliable significance when negative. It has largely been replaced by the CT scan as well as ultrasound (US), both of which are noninvasive. There are times, however, when performing DPL makes the most sense. If there is no institutional access to US or CT scanning, a DPL may provide information that will perhaps save a transfer to another institution or mandate a laparotomy prior to transfer. If the patient is unstable, the CT scan can accurately identify the intraperitoneal pathologies causing the hemorrhage, but the CT gantry is a very poor place to attempt to manage an unstable patient.

Ultrasonography can also be performed at the bedside, as is occurring with greater frequency in many institutions. It is reliable but may need to be performed more than once if the patient is seen very early after the trauma when there has been no time to produce visible bleeding. As with DPL, the US shows fluid in the abdomen, but not its source or the magnitude of injury.³ Another advantage of US is that the heart can be assessed for pericardial effusion.

The abdominal CT scan has become more useful with the advent of the very rapid spiral CT scanner. If the patient is too ill for oral contrast, intravenous (i.v.) contrast is useful. Moreover, a head CT scan can be obtained before any contrast is given, and the i.v. contrast can be administered and the abdomen evaluated. Rectal contrast is rarely needed without some indication of colonic injury.

Military antishock trousers have fallen into disuse, except to stabilize lower extremity fractures or attempt to minimize hemorrhage from pelvic fractures. Antishock trousers are dangerous to use in the instance of penetrating chest injury and do not appear to convey any advantage in the penetrating abdominal injury. Moreover, if a combative patient or an inexperienced physician removes them abruptly, there may be severe hypotension or lethal dysrhythmias.

Blood from a traumatic hemothorax can safely be collected and reinfused. After reinfusion of autologous blood, there is a transient coagulopathy that resolves after several days. Platelet function is also depressed. Because increased bleeding may result, this procedure should be reserved for more serious hemorrhage and when banked blood is not readily available.

If the patient has a cardiac arrest from hypovolemia or pericardial tamponade, or has evidence of coronary air embolization, immediate emergency thoracotomy is indicated. Thoracotomy offers the only chance for salvage. The best results are obtained in the presence of penetrating injury to the chest, particularly the heart. It is probably of no benefit to perform a thoracotomy unless the surgical expertise and institutional resources to render definitive care are readily available.

Surgery is part of the resuscitation of the unstable trauma victim. In the patient who cannot be resuscitated from shock and who has no obvious source of blood loss, immediate exploration is indicated. A chest film determines whether the chest or the abdomen is the site of initial exploration.

The priorities of definitive management are still vigorously debated, and it is often necessary to perform invasive procedures without the luxury of confirming diagnostic studies. In general, one should attempt to approach the pathology that poses the most immediate threat to the patient's life—usually in the abdomen. Any rule or protocol will at times have to be modified or abandoned to fit a given patient, but, fortunately, most patients are not in such an unstable life dilemma that they cannot be efficiently and effectively managed.

In the patient who stabilizes during resuscitation, the next priority is a complete head-to-toe examination, which includes performing repeat cardiopulmonary and maxillofacial, abdominal, neurologic, and orthopedic examinations, as well as checking for occult blood loss. A rectal examination is very important to reveal potential displacement of the prostate, any gross blood, and the neurologic assessment of the anal sphincter tone and sensation. The absence of tone or sensation can point to a spinal cord injury in a patient who has been assessed to have only head injury. If the patient is unconscious, determining the level of brainstem function and the presence of a herniation syndrome is paramount. Most trauma victims die of central nervous system–related injuries.

It is necessary to immobilize the spinal column until its status can be ascertained, but it is unnecessary to spend long periods of time trying to clear the cervical or other spinal column before dealing with more life-threatening injuries. The patient can be maintained on a backboard or hard cart with a hard collar while more immediate life threats are determined and prevented. Then, special imaging studies can be obtained to determine the limits of spinal injury.

Open fractures should be cultured, gently irrigated (realizing that this procedure will not substitute for more effective and complete irrigation and debridement under anesthesia), and splinted to prevent further injury and reduce pain and bleeding. Open fractures should be covered with clean dressings, and i.v. antibiotics commenced with an antistaphylococcal drug. Definitive care must await the diagnostic elimination or the surgical treatment of more serious, life-threatening injuries.

If the patient remains unstable, the single most useful diagnostic study is the chest film. Additional films are obtained depending on specific injuries encountered. Intravenous pyelography may be the only diagnostic modality available to some rural institutions, but elsewhere, the abdominal CT scan with i.v. contrast has replaced the i.v. pyelogram (IVP). The ease of obtaining an abdominal CT scan has somewhat liberalized the workup of the kidney. Prior to the high-speed scans, the indication for IVP was gross hematuria, penetrating injury that could involve kidney or ureter (e.g., gunshot wound of the flank), and decelerating flank trauma that might have produced an injury to the renal artery. With the abdominal CT scan, one obtains information about the other intraabdominal organs as well as the kidney. It does not replace a cystourethrogram, however, in those patients with straddle injuries or pelvic fractures.

Gross penile bleeding should be evaluated by retrograde urethrography before passage of a Foley catheter.

Aortography still has a role in the evaluation of the trauma patient, especially with some indication of blood vessel damage. For example, Doppler US may reveal a flow impairment in the carotid or vertebral vessels after a whiplash trauma to the neck. Most trauma surgeons will then wish to obtain an arteriogram to define the

injury. Another place for angiography is in the patient with a penetrating wound near a large vascular structure. If the patient is unstable, it is more prudent to take the patient to the operating room, obtain vascular control, and perform the angiography intraoperatively.

The CT aortogram has largely replaced aortography. It will accurately demonstrate aortic transection and may provide information about injuries to other intrathoracic or intraabdominal injuries.

A transesophageal echocardiogram is also very accurate in the diagnosis of aortic transection and has the added advantages that it can be performed at the bedside and requires no contrast material.

Unfortunately, not all of these modalities are available 24 hours a day, especially in rural institutions, and the patient will need to be transferred to an appropriate institution to obtain the diagnostic information.

The indications for arteriography include penetrating neck injuries, possible thoracic aortic tears, penetrating wounds of the extremities in proximity to major vessels (if exploration is not mandatory), dislocations of the knee, fractures associated with abnormal pulses, a kidney that is not visualized by IVP, and selected pelvic fractures.

The sequencing of radiologic studies should be prioritized in the same manner as the other components of the resuscitation. Because the patient's airway is the primary concern, the cervical spine should be assessed if active airway management is indicated and the patient is stable. If the airway has already been secured in the field, then the cervical spine can be immobilized while other, more pressing studies are obtained (e.g., chest and pelvic films). However, if the patient is unstable and an airway has not been secured in the field, immediate airway management is indicated without the delay of obtaining radiographic studies.

Once the airway has been addressed, other studies may be obtained. In victims of blunt trauma, chest and pelvic films should be obtained next and, if necessary, extremity films obtained thereafter. Patients with penetrating wounds of the chest (stab or gunshot wounds) should have chest radiographs taken either before resuscitative procedures are performed (if stable) or afterward (if unstable). Abdominal series are of low yield in the evaluation of stab wounds, but they are useful in localizing gunshot fragments.

While the ranking of priorities with head, chest, and abdominal injuries is still very difficult, there are some advantages from the modern spiral CT scan speed. In general, the critical ordering is still abdomen, head, and then chest, but, obviously, decisions must be colored by the actual pathologies present. A US or DPL that shows blood in the abdomen does not reveal the organ damaged or the amount of damage, and the patient's brain may have been the actual target. While the CT scan requires transfer to the radiology suite, the speed of the procedure may enable a quick assessment of the head en route to the operating room for laparotomy. It also adds a little time to the assessment to take cuts of the chest and abdomen.

While head injury alone rarely causes hypotension, it is critical to avoid hypotension in the head-injured patient, and thus it is critical to find and manage the sources of hypotension outside the head. An often overlooked source of shock in the patient who actually has only a head injury is an extensive scalp laceration. The bleeding is often hidden by the neck-stabilizing devices. It is helpful to control the scalp laceration until it can be safely repaired either by the use of Raney clips (the neurosurgical skin clips that can be quickly applied to the scalp laceration edges) or by placement of a 2-0 Ethilon running locked stitch to the laceration.

Finally, it is imperative to recognize that the trauma patient needs definitive care. Time wasted in the field, the emergency department, or the radiology suite may lead to death. Sometimes, the trauma surgeon must proceed to the operating room with a paucity of diagnostic information rather than have the patient continue to lose massive amounts of blood.

Trauma in Children

The pediatric trauma patient is not a miniature adult, and many important anatomic differences must be kept in mind when caring for injured children. Children under age 6 months are obligate nose breathers, so nasal obstruction in these infants may have serious consequences. The infant's oral cavity is small, and the tongue is relatively larger than the adult's. The larynx is located more cephalad in the infant, and the vocal cords are more distensible. Moreover, the vocal cords are anterior and inferior to their usual location in the adult. If these differences are not appreciated, an endotracheal tube may become lodged in the anterior commissure or passed into the esophagus.

The trachea is short: If this is not remembered, right mainstem bronchial intubation or perforation may result. The infant has a large occiput, so the neck is already flexed and the head is slightly extended, even in the "neutral" position. Oral intubation is easier than nasal intubation in infants and young children, and cricothyrotomy is virtually impossible in children under age 8. Needle jet insufflation by way of the cricothyroid membrane may be an appropriate temporizing technique if there is no upper airway obstruction.

The normal systolic blood pressure of a young child should be about 80 plus twice the age in years; diastolic pressure should be about two-thirds of the systolic pressure.

The high ratio of body surface area to body mass in young children greatly affects their ability to regulate core temperature. Their lack of substantial subcutaneous tissue and the presence of thin skin contribute to an increased evaporative heat loss and caloric expenditure. The resulting hypothermia leads to catecholamine secretion and shivering, resulting in a metabolic acidosis. The young child who is hypothermic may be refractory to therapy for shock. Therefore, the child's temperature should be maintained at 37°C by overhead heaters.

The child's chest wall is very compliant and allows energy to transfer to the intrathoracic structures, frequently without any evidence of injury to the ribs. The result is a higher frequency of pulmonary contusion and intrapulmonary hemorrhage than in adults. Injury to the great vessels is infrequent, however.

Almost all infants and young children who are stressed and crying swallow a large amount of air, and it is particularly important to decompress the stomach by inserting a small nasogastric tube. The tenseness of the abdominal wall often decreases as the gastric distention is relieved. Avoid deep palpation at the onset of the examination, as the child will voluntarily guard against subsequent abdominal compression. When performing a diagnostic peritoneal lavage, use a fluid volume of 10 to 15 mL/kg of warmed normal saline solution.

Blood loss associated with long-bone and pelvic fractures is proportionately greater in the child than in the adult. Injuries near joints in children will usually lead to a fracture through the growth plate, which will often be undetectable radiographically.

Head injuries are much more common in children than in adults. However, long episodes of unconsciousness in children do not necessarily correlate with a poorer prognosis. Conversely, children may sustain a significant concussion without any loss of consciousness being observed. Children are also prone to have apneic episodes at the time of injury.

DISPOSITION

The stable trauma patient may spend a number of hours between the emergency department and the radiology department during the completion of diagnostic tests. There is a finite period of time that it takes to completely exclude multiple occult injuries, and this period also allows an observation period to recognize the development of neurologic, cardiac, or pulmonary pathologies. Someone from either the trauma service or the emergency department must monitor the patient during these procedures to ensure that instability is not occurring and that a quick transfer to the operating room has not become necessary. While in the emergency department, this person is often the emergency physician, because the surgeon may be busy arranging for an operating team or consulting with the other subspecialty surgeons in regard to the timing of their repairs.

The patient is an emergency department responsibility until he or she is admitted to an operating room or an intensive care unit. Even if the trauma team monitors the patient in the radiology department, when the patient returns to the emergency department it again becomes the emergency physician's responsibility to become involved with the patient.

Not every patient will need to be admitted to the hospital after careful evaluation and some period of observation. However, any patient who has had a significant

mechanism of injury is likely to develop areas of pain and dysfunction that are not predictable in the emergency department. It is therefore prudent, although not mandatory, to provide 24 to 48 hours of observation and care in the hospital.

Transfer of the patient to another institution depends on multiple factors. If the patient is unstable, the only rationale for transfer is to achieve a level of care impossible at the original treating facility. It may be necessary to care for a threat to life (e.g., remove or salvage a torn spleen) and then transfer the patient for more sophisticated neurosurgical or thoracic observations and treatment.

COMMON PITFALLS

- Failing to ascertain details, or ignoring the severity of the mechanism of injury
- Ascribing positive physical findings to a benign cause
- Failing to set up for the patient before his or her arrival
- Failing to have a visible trauma captain throughout the resuscitation
- Failing to use a well-thought-out, systematic approach to the patient
- Chaotic and inefficient resuscitation because of poor use of team members or because too many physicians are trying to give orders
- Focusing on subspecialty need at the expense of real or potential life threats
- Overemphasizing diagnostic tests in an unstable patient.

[Chapter References](#)

Trauma scoring systems have been developed over the years to serve a multitude of purposes. In the prehospital setting, trauma scores are used to identify those patients requiring intervention and to aid in decisions regarding patient destination. In the emergency department, these same scoring systems are used to guide therapy, determine the level of response, and provide a means of monitoring changes in status.

Prehospital providers, emergency physicians, and inpatient trauma services use these scores for planning purposes and as a quality assurance screen to monitor performance of the system. Regional planners use these scoring systems to compare institutions and assess resource needs, and as a tool for performing research on the effects of intervention.

PREHOSPITAL SCORING SYSTEMS

Emergency physicians may be called on to choose trauma scores for their prehospital care systems. Several factors should be considered. First, the score that is chosen should be one that has been shown to be valid in a prehospital care system. Many trauma scores were developed by assessing their predictive value only for patients admitted to trauma services from the emergency department. Scores developed in this manner have a lower predictive value, as the patient population in which they were developed has a higher prevalence of serious injury than the general trauma population seen by an emergency medical services (EMS) system.

Second, the items that compose the score must be easily measurable by prehospital providers. For example, capillary refill may be easily assessed in the brightly lit emergency department but very difficult under field conditions.

Third, the components of the scale must have a high degree of interrater reliability. The observations must be easily made under field conditions and the criteria unambiguous. The score itself should be easily remembered and easily calculated.

Finally, scores are most useful when they can be used to assess changes in the patient's condition during the transition from prehospital care through the emergency department into the inpatient service. Ideally, the score that is chosen already has been demonstrated to be valid and reliable in several prehospital care systems. Consideration should also be made to prehospital scoring systems utilized by other EMS systems in the region. Use of a common scoring system would greatly facilitate quality monitoring among EMS agencies. Scores designed to determine the need for transport to a trauma center might also be employed to determine whether the surgery team needs to be present in the emergency department on the patient's arrival.

EMERGENCY DEPARTMENT SCORING SYSTEMS

Scores chosen for use in the emergency department will most likely be used to determine the patient's resource needs. For example, these scores may be chosen to assess the need for a trauma team response, the need for prophylactic intubation, the likelihood of occult injury, or the need for intensive care unit (ICU) admission.

A number of scores have been developed to assess injury severity. These scores use one or more of three predictive components: physiologic derangement, anatomic site of injury, or mechanism of injury. Many scoring systems use a combination of these factors. The comparison of these scores is complicated by the lack of an agreed upon "gold standard" against which the scores have been measured. These scores are commonly compared with regard to need for hospital admission, need for ICU admission, need for operative intervention, length of stay, injury severity score, or mortality.

Each of these end points has limitations. While it is clearly desirable to minimize death or missed injuries from trauma, the more subtle benefits of trauma center care, such as optimal resource use, low rate of missed injuries, and early return to functionality, are difficult to measure. The practicing physician considering the use of individual trauma scores should be aware of both the standard against which the score was developed and the setting in which it will be applied. A score that performs well in determining the need for trauma center transport by EMS may not be an appropriate score to use to assess the effects of new inpatient interventions. Similarly, a score developed in an urban environment with a high rate of serious injury may not be appropriate for another setting in which serious injuries are uncommon.

The advantages of using measures of physiologic derangement include the fact that these measures are part of routine clinical assessment, are unambiguous, and are easily measured. Additionally, these measures identify patients with substantial bleeding or major organ injury. Patients seen early after injury may not have indicators of physiologic derangement and may be mistriaged unless serial measurements are taken. Measures of anatomic injury are good predictors of the need for operative intervention. These measures are useful in retrospective reviews of trauma care, particularly when based on operative or autopsy information. Many of the factors that must be taken into account in these measures may not be available on initial clinical evaluation. Finally, mechanism of injury is generally sensitive in predicting the likelihood of injury. Experience has demonstrated, however, that reliance solely on mechanism of injury leads to a high rate of overtriaging.

The goal of a prehospital evaluation should be the timely transport of patients to appropriate hospitals. In doing so, two concepts conflict. Ideally, it is desirable to minimize the rate of undertriage, wherein patients who are seriously injured are transported to centers less prepared to care for them. Alternatively, it is also desirable to minimize overtriage, because it increases resource utilization, lengthens EMS transport times, and overloads trauma hospitals with patients with minor injuries. Unfortunately, as one increases the sensitivity of triage rules (thus minimizing undertriage), there is generally a concomitant fall in specificity (which increases overtriage). The best scores, therefore, are those that have a high sensitivity with an acceptable level of specificity. In general, one would expect an urban EMS system to consider approximately 5% to 10% of their trauma patients as having an injury serious enough to warrant transport to a trauma center.

Several studies have demonstrated that transport to designated centers has an effect on overall outcome. A study conducted in Orange County, California, reviewed 118 deaths from motor vehicle accidents, approximately half of which occurred prior to, and half of which occurred after, implementation of a regional trauma system.⁵ Following implementation of the system, the proportion of deaths from injuries that were potentially salvageable decreased from 34% to 15%.

Most of the apparently salvageable cases occurred in patients treated in nontrauma facilities. Further, when the authors of the study compared the death rates in the region prior to implementation of the system with those after implementation, they found that the death rates were lower than would have been projected using linear regression. In another study, 73% of deaths due to causes other than central nervous system injury were judged to be preventable prior to implementation of a trauma care system.²⁶ After implementation of the system, the percentage of deaths from causes other than central nervous system injury were reduced to 9%.

Abbreviated Injury Scale

Early efforts at categorizing trauma patients focused on quantifying the extent of injury. The Abbreviated Injury Scale (AIS) was developed as part of an attempt to assess automotive safety. In the AIS, injuries to various body areas were graded from 0 to 6, with 6 representing fatal injury.¹ The problem with the AIS was the difficulty in accounting for the effect of multiple injuries. Because the AIS is a summation, injuries in patients with multiple minor injuries may have a higher score than ones with single, life-threatening injuries. The AIS was last revised in 1990, with an emphasis on improving its accuracy with children.

Injury Severity Score

The Injury Severity Score (ISS) was developed as an extension of the AIS.¹ The original ISS was devised by summing the squares of the highest AIS grade in each of the three most severely injured areas. This modified scale was shown to correlate with fatality from trauma. Death from trauma begins to rise significantly with ISSs above 15. Unfortunately, both the AIS and the ISS can be calculated accurately only after the full extent of the patient's injuries is known. The ISS is now commonly used as a quality assurance tool, but it has no role in decision making either in the emergency department or in EMS systems.

Trauma Index

One of the earlier trauma scores intended for prehospital use was the Trauma Index. This index was developed from a retrospective review of trauma patients.⁴ Twenty-five variables were grouped under five categories related to site of anatomic injury, type of injury, and status of the cardiovascular, the central nervous, and the respiratory systems. The authors found that a high score (over 18) correlated with the occurrence of multiple injuries.

Triage Index

These concepts were further extended by Champion, in the development of the Triage Index.⁷ The Triage Index was derived from a series of 1,084 patients. It was initially composed of 12 variables found to correlate with death following initial hospitalization. Using statistical techniques, these variables were condensed into five variables that included respiratory expansion, capillary refill, eye opening, verbal response, and motor response.

Trauma Score

The Trauma Score was based on a retrospective analysis of 2,000 patients, using death from trauma as the end point. It included respiratory state and effort, blood pressure, capillary refill, and the Glasgow Coma Scale as variables.⁸ The Trauma Score was prospectively studied by Morris, who reviewed 1,106 patients admitted to the trauma center at San Francisco General Hospital. A trauma score less than 15 was significantly associated with mortality, the presence of closed head injuries, the need for immediate surgery, and length of both ICU and hospital stays. The trauma score predicted an ISS greater than 20 with a sensitivity of only 63%. More importantly, however, patients whose trauma score deteriorated from the initial value obtained in the field had a mortality rate of 26%, compared with a rate of 9% of those whose trauma scores improved and 4% of those whose trauma score remained the same.

Triage-Revised Trauma Score

The trauma score was revised in 1989, using data from the Washington Hospital Trauma Center and the Major Trauma Outcome Study. The revised trauma score was broken into three components: Glasgow Coma Scale, systolic blood pressure, and respiratory rate (Table 90.1). A Triage-Revised Trauma Score (T-RTS) less than 12 identified 97.2% of all fatally injured patients. As this score is based entirely on physiologic variables, there is the risk of inappropriate decision making when patients are seen early after injury. The authors recommended using a multistep approach in conjunction with the T-RTS. In another study, in which 4% (53 of 1,325) of patients were classified as having severe trauma using the ISS (ISS greater than 16), 11 of those 53 patients were missed using the T-RTS.

Glasgow Coma Scale	Systolic Blood Pressure	Respiratory Rate	Coded Value
13-15	>89	10-29	4
9-12	76-89	>29	3
6-8	50-75	6-9	2
4-5	1-49	1-5	1
3	0	0	0

TABLE 90.1. Revised Trauma Score Variable Breakpoints

Trauma and Injury Severity Score

While the ISS accounts for patients' injuries, prediction of mortality should take into account factors that affect likelihood of survival. Trauma and Injury Severity Score (TRISS) methodology incorporates the patient's age and ISS into a prediction of survival. Patients with outcomes different from those predicted by the formula may be candidates for quality assurance review. TRISSs are heavily weighted toward head injury. The W statistics, derived by comparison of a hospital's results to those from the Major Outcome Trauma Study, portray the number of excess survivors per 100 patients. The misclassification rate for TRISS is around 4%.

APACHE

The APACHE score takes into account acute vital signs, laboratory tests, age, and chronic health. Although it was intended for use in both medical and surgical patients, some communities use it for general hospital QA scoring. The APACHE II is limited by the relatively small number of trauma patients used for the derivation study. It tends to underestimate the risk of death for multiply injured patients with head trauma. APACHE III used a larger number of trauma patients and adjusts for head injury. Some studies have found that APACHE and TRISS perform in a similar, although limited, manner in predicting mortality in ICU patients.²⁵

ASCOT

A severity characterization of trauma system was developed based on analysis of the shortcomings of TRISS seen in the Major Trauma Outcome Study. In addition to the revised trauma score variables, ASCOT adds scoring assignments for injury to three body regions, including brain/spinal cord, thorax/neck, and abdomen/major vessel. ASCOT adjusts for patients with very good or poor expected outcomes in order to improve prognostic power for patients with less certain outcome. In comparison, ASCOT seems to perform superior to TRISS for bluntly injured adults. Both TRISS and ASCOT appear adequate for pediatric patients.⁶

CRAMS

The CRAMS Scale (Table 90.2) was developed through a review of 500 trauma transports, of which only 12 had major trauma defined as death in the emergency department or immediate transport to the operating room.¹⁴ The authors in the original study found that the CRAMS Scale has a higher sensitivity than the original Trauma Score. The CRAMS Scale was validated, with modifications, in 2,110 patients.¹¹ In the validation study, a score less than 7 identified all but one of the emergency department deaths.

CIRCULATION	
Normal capillary refill and BP > 100	2
Delayed capillary refill or BP < 90	1
Poor capillary refill or BP < 80	0
RESPIRATIONS	
Normal	2
Abnormal (labored or shallow)	1
Absent	0
ABDOMEN	
Abdomen and thorax nondistended	2
Abdomen or thorax tender	1
Abdomen rigid or flat chest*	0
NECK	
Normal	2
Requires only no pain (other than discomfort)	1
Poor response for discomfort	0
SPEECH	
Normal	2
Confused	1
No intelligible words	0
Score 0-3 = Major trauma	
Score 4-5 = Minor trauma	

Penetrating wounds to the abdomen or thorax Are taken into account since the study.

TABLE 90.2. Field Categorization of Trauma— CRAMS Scale

Prehospital Index

Another widely used trauma score is the Prehospital Index (PHI) (Table 90.3).¹⁵ The PHI was developed using 313 trauma patients, who were considered to have major trauma if they died within 72 hours of injury or required surgical intervention within 24 hours. As originally constituted, this trauma score utilized only physiologic parameters. The authors realized, however, that the addition of a measure of anatomic injury (penetrating injuries of the abdomen or chest) would improve the accuracy of their score. The PHI was validated in a multicenter study of 3581 patients.²⁰ In the validation study; the PHI had a positive predictive value of 52.1% and a negative predictive value of 99.4%.

Components	Value	Score
Blood pressure	>100	0
	86-100	1
	75-85	2
Pulse	0-74	5
	75-120	3
	51-119	0
Respirations	<50	5
	Normal	0
	Labored/shallow	3
Consciousness	<10min needs intubation	5
	Normal	0
	Confused/combatative	3
Total	No intelligible words	5
		0-20

*0 to 3, minor trauma; 4 to 5, major trauma.
 (Penetrating abdominal or chest injuries are given 4 points in addition to the calculated PHI.)

TABLE 90.3. Prehospital Index^a

Additional Methods

As mentioned previously, other authors have utilized mechanism of injury and anatomic injury as criteria for transport to trauma centers. A review of 2,057 patients compared various mechanisms and types of injuries with the ISS.¹² Combined with a trauma score greater than 12, the authors found that the likelihood of major injury was increased when the trauma score was combined with the presence of head, spine, chest, abdomen, or extremity injury. The prevalence of major trauma was also increased if it was caused by motor vehicle accident; a fall greater than 15 ft; penetrating injury to the head, chest, or abdomen; or Glasgow Coma Scale less than 10. In a similar vein, another study found that the addition of mechanism of injuries, including falls greater than 16 ft, motorcycle accidents greater than 20 mph, and automobile versus pedestrian accidents, increased the sensitivity of the various trauma scores.¹⁸

USE OF SCORING SYSTEMS

Scoring systems are among the many tools utilized to improve the quality and efficiency of care of the injured patient. Unfortunately, prehospital trauma rules, although they have been found to be good predictors of mortality, have not been found to be good predictors of other measures of major trauma.² The CRAMS Scale, Revised Trauma Score, and the PHI have been found to correlate poorly with ISSs.²¹ One study found that, using trauma prediction rules, 30% of patients initially classified as major trauma victims would be misclassified, while 30% of patients initially designated as having minor injuries would be later found to have major injuries.

These findings led Baxt and colleagues to utilize a different gold standard in designing a trauma score (Baxt Trauma Triage Rule) (Table 90.4).³ They classified major trauma patients as those who required operative intervention (other than orthopedic) within the first 48 hours, needed in-hospital fluid resuscitation of at least 1 L, had placement of invasive central nervous system monitoring, or died of their injuries. The score developed utilized systolic blood pressure less than 85 mm Hg, a motor component of the Glasgow Coma Scale less than 5, or penetrating injury of the head, neck, or trunk as indicators of major trauma.

<p>Patient meets the criteria for trauma center transport if any of the following are present:</p> <ol style="list-style-type: none"> 1. Systolic BP <85 mm Hg 2. Motor component of Glasgow Coma Scale <5 3. Penetrating injury of head, neck, or trunk

TABLE 90.4. Baxt Trauma Triage Rule

The American College of Surgeons has advocated a stepwise approach to trauma center triage (Fig. 90.1).²¹ In this classification scheme, patients are first assessed with the T-RTS, Glasgow Coma Score, Pediatric Trauma Score, or measurement of the blood pressure or respiratory rate. If none of those factors is abnormal, then anatomic injury and mechanism of injury are considered. Lastly, patients also meet the criteria for transport to a trauma center if they are at the extremes of age or if they have complicating medical factors. The authors of this system consider an undertriage rate of 5% to 10% to be unavoidable, with an overtriage rate up to 50% necessary to minimize missed patients.

Figure 90.1. American College of Surgeons Guidelines for Optimal Care of the Injured Patient. (Adapted from Krantz B. *Field triage in resources for optimal care of the injured patient*. Chicago: American College of Surgeons, 1993.)

This stepwise approach was assessed in a prospective study.⁴ The first step, involving physiologic parameters, was found to have a sensitivity of 46% and a specificity of 93%. The anatomic injury factors were found to have a sensitivity of 22% and a specificity of 98%. However, when mechanism of injury was added into the evaluation, the overtriage rate exceeded 92%.

Another study examined the individual American College of Surgeons trauma triage criteria and found that, individually, all criteria except speed greater than 20 mph or greater than 30-in. vehicle deformity had predictive value for hospital resource utilization.¹³

A few studies have been performed comparing the different scoring systems. One such study, performed in a rural population, found that the CRAMS Scale had a greater sensitivity than either the Trauma Score or the PHI.¹⁵ Another study, however, found that neither the CRAMS Scale nor the Trauma Score adequately identified major trauma patients in the field. A comparison of the CRAMS Scale, Baxt Trauma Triage Rule, PHI, and T-RTS found that all of the scores predicted mortality with a sensitivity of 100%. The T-RTS appeared to predict death, or the need for emergency operation, to a lesser degree than the Trauma Triage Rule, the CRAMS Scale, or the PHI.¹³ ASCOT performed better at predicting survival for adult blunt trauma when compared with TRISS.⁶

After reviewing the available scores and methodologies for triaging trauma patients, the practicing physician may wish to consider the role of clinical judgment. One study noted that inclusion of advanced emergency medicine technician (EMT) injury perception, in addition to standard out-of-hospital triage criteria, improved accuracy of field trauma triage.²⁴ In a large study evaluating the ability of urban EMTs to assess trauma, none of the scores were found to perform better than EMT judgment. Again, the physician considering the use of these scores will need to consider the setting in which the scores will be used. It would appear that most urban EMTs have the ability to recognize major trauma patients.⁵ In the prehospital setting, trauma scores can be used to guide trauma patient destination and to help educate EMTs on the importance of various anatomic, physiologic, and mechanism of injury factors that can identify the potentially seriously injured patient, as well as on their significant use in quality monitoring.

Prehospital trauma scores have also been used in stratifying the level of trauma team response. One study separated trauma patients into two classifications. Category 1 patients were felt to have a high likelihood of injury, while category 2 patients had a low likelihood of injury. Category 1 patients were treated by the full trauma team, consisting of both emergency medicine residents and staff and trauma surgery residents and staff. Category 2 patients were initially treated by emergency medicine personnel, with a member of the trauma surgery service responding within 30 minutes to provide consultation. This system effectively predicted the likelihood of serious injury, mortality, and need for emergency surgery. Over the 6-month study period, an estimated 578 physician-hours were saved using the two-tiered system.²³

New trauma-scoring systems continue to be devised. As discussed at the beginning of this chapter, until there is an agreement over a gold standard against which these scores can be measured, there is likely to be disagreement over the optimal scoring system. Hospital trauma services will likely continue to use both the T-RTS and the ISS because of their usefulness in assessing quality assurance through the TRISS methodology.

Depending on the purpose for which they are being used, emergency departments have a number of scoring systems available for their use. The T-RTS may be used to monitor changes in patient's condition during the course of the patient's initial resuscitation. Clearly, the use of mechanism of injury to activate the trauma team will lead to an overutilization of that resource, but, as mentioned earlier, a degree of overtriage is accepted in the effort to include all potentially injured trauma patients. EMS systems commonly use the PHI or the T-RTS. Medical directors may wish to consider the use of the Baxt Trauma Triage Rule because it has been demonstrated to be valid and easy to use.

[Chapter References](#)

The science of injury prevention is both one of the oldest and one of the newest areas of medicine. During the first year of life, we learn about different forms of energy and the harm they can cause. Thermal energy from hot water causes burns. Kinetic energy caused by the typical fall of a new walker elicits cries of pain. Thus, injury prevention becomes one of our most basic instincts.

Basic as it may be, injury prevention as a science has lagged behind the analysis of other illnesses, both in research output and funding support. As recently as 1989, Baker³ wrote of the “failure, until recently, of most health professionals and their institutions to give appropriate attention to the major cause of lost potential years of life before retirement.”

The foundation for the current practice of injury prevention was laid by a small group of true pioneers. Hugh DeHaven described the elements of effective crash protection after he was involved in a midair collision in World War I. ²² Carl Clark developed early prototypes of air bags, also using himself as a demonstration subject.³

Among others, William Haddon stands out as the developer of a framework for analysis and prevention of injury. His matrix, now known as the “Haddon Matrix,” allows for the placement of causative factors of injury into one of nine specific categories ([Table 91.1](#)).¹² This matrix, while originally designed for the analysis of motor vehicle crashes, can be easily applied to other types of injuries. Haddon also listed ten strategies available for reducing energy-damage losses (injuries) ([Table 91.2](#)).¹² Combinations of these strategies form the basis for injury prevention science as it is practiced today.

	Human	Vehicle	Environment
Pre-crash	Alcohol	Maintenance	Poor signage
Crash	Injury threshold (related to age, etc)	Energy- absorbing frame	Poles and trees near roadway
Post-crash	First-aid knowledge	Gas tank rupture	Access to EMS

TABLE 91.1. The Haddon Matrix (with examples)

1. To prevent the initial collection of the form of energy
2. To reduce the amount of energy collected
3. To prevent the release of energy
4. To modify the rate of spatial distribution of release of energy from its source.
5. To separate in space or time the energy being released from the susceptible structure.
6. To separate the energy being released from the susceptible structure by interposition of a material barrier.
7. To modify the contact surface, subsurface, or basic structure which can be impacted.
8. To strengthen the living or nonliving structure which might be damaged by the energy transfer.
9. To move rapidly in detection and evaluation of damage and to counter its continuation and extension.
10. All those measures which fall between the emergency period following the damaging energy exchange and the final stabilization of the process (including intermediate and long-term reparative and rehabilitative measures).

TABLE 91.2. Options for Reducing Injury Losses

Others describe injury in terms of performance and task demand. Performance relates to how an individual accomplishes an action. Task demand describes the skill required to complete that action. Injury occurs when energy is transmitted because an individual task demand exceeds performance. ²⁴ A toddler attempting to climb stairs may fall because she has not achieved the skills necessary to complete the climb. A driver may be able to operate a motor vehicle under normal circumstances, but may suffer from decreased performance with the same task demand while intoxicated.

Injury prevention professionals also speak of the three E's: Education, enforcement, and engineering, in various combinations, can be used to approach almost any injury problem. Education can include gun safety classes and public service announcements about the need for smoke detectors. Enforcement includes use of laws and regulations regarding fences around swimming pools (to prevent entrance of small children) to tougher drunk-driving standards. Engineering improvements range from roadside guardrails and antilock brakes to safety locks on guns. The “E's” must continue to be thought of as working together to reduce death and disability from injury.

COMPARATIVE EPIDEMIOLOGY

That injury is a major public health problem is well documented. In 1995, there were 37 million emergency department (ED) visits for injury and over 147,000 deaths due to injury. Injury accounted for 52% of all deaths among 5- to 14-year-olds and 77% of all deaths for 15- to 24-year-olds. Injury also accounted for 12% of all medical expenditures, with an estimated total cost of \$260 billion.¹⁵ Table 91.3 illustrates the leading causes of death by age group in the United States in 1995.²⁷ Deaths, while easiest to count, represent only a small part of the injury picture. Figure 91.1 illustrates the well-known injury pyramid, showing the relatively small number of deaths compared with the total number of injuries.⁹

TABLE 91.3. Leading Causes of Death in the United States by Age Group — 1995

Figure 91.1. The injury pyramid.

Injury must compete with other diseases, both in the United States and around the world, for attention and research funding. Unintentional injuries are the leading cause of death in the United States from age 1 to age 34. Intentional injuries, either homicide or suicide, also play a major role in this age group. The Centers for Disease Control and Prevention (CDC) reports these comparative statistics through the National Vital Statistics System.⁸ The World Health Organization estimates that injury will increase significantly as a cause of death throughout the world by the year 2020 in comparison to other illnesses. Traffic crashes are projected to move from ninth to third as a cause of loss of disability adjusted life years (DALYs) worldwide. Violence is projected to move from nineteenth to twelfth on the same list (Fig. 91.2).⁴³

Figure 91.2. Change in the rank order of disease burden for 15 leading causes, world, 1990–2020 (Disease burden measured in Disability-Adjusted Life Years [DALYs]). (From The Global Burden of Disease (Summary), the World Health Organization, with permission.)

As is shown by these statistics and the casual observation of a typical day in the ED, injury has a great impact on the practice of emergency medicine. The treatment model of medical practice places the role of emergency physician only in one box of the Haddon Matrix—postevent, environment. The prevention model expands the role of emergency medicine into all areas of the matrix, much in the way the medical community works to prevent heart disease, cancer, and acquired immunodeficiency syndrome (AIDS).

TERMINOLOGY

Injury is defined as “the result of a harmful event that arises from the release of specific forms of physical energy or barriers to normal flow of energy.”²⁴ The term *accident* has been a source of much consternation in the injury prevention field. While some, particularly investigators in the United Kingdom, continue to use the term, others feel that *accident* implies random events or “acts of God,” while *injuries* are caused by predictable and preventable events. A recent review of the issue by the Institute of Medicine (IOM) Committee on Injury Prevention and Control recommended against continued use of the word *accident*.¹⁵

The IOM also considered the terms *prevention*, *control*, and *treatment*. *Prevention* refers to preevent or event interventions that reduce the risk or severity of injury. *Treatment* refers to postevent measures (acute care and rehabilitation) that ameliorate the effects of injury. *Injury control* has gained common use as a term to encompass aspects of prevention and treatment. The IOM committee recommends against the term *injury control* as confusing, although it continues to be used extensively.¹⁵

DATA SOURCES

Adequate information about the injury problem and the effectiveness of interventions relies on adequate surveillance. How many injuries are happening, under what circumstances do they happen, and how are patterns changing, are all important questions to answer. Surveillance is basic to the planning and implementation of any public health intervention, including injury prevention.

Federal Sources

At the federal level, the National Center for Health Statistics maintains basic mortality data based on information from death certificates. This information is only as good as the quality of the death certificate information, which is influenced by the skill and interest of the person who completes the investigation. The National Hospital Discharge Survey collects and disseminates data on a probability sample of discharged patients. This data set can provide interesting information on patients injured enough to be hospitalized. The federal government also conducts periodic surveys on health behaviors and health-care expenditures.

The federal government also maintains data collection systems related to specific types of injuries. For motor vehicles, the Fatal Analysis Reporting System (FARS) collects data on nearly all crash fatalities. The National Automotive Sampling System (NASS) Crashworthiness Data System (CDS) provides for detailed analysis of a randomized area sample of tow-away crashes, which in many cases can be generalized to reflect national trends. The General Estimates System (GES) draws from a larger sample of police-reported crashes but also relies on police-reported injury data, which may not be sufficiently reliable for injury comparisons.

Injuries and deaths not related to motor vehicles are catalogued by multiple agencies. The Federal Bureau of Investigation (FBI) collects annual and frequently quoted data on homicides and assaults. The Bureau of Labor Statistics and the National Institute for Occupational Safety and Health collect data on occupational deaths and injuries, although reporting may be spotty. Emergency physicians may be familiar with a surveillance system maintained by the Consumer Product Safety Commission. This system is known as NEISS. The National Emergency Department Injury Surveillance System collects information on product-related injuries from a selected sample of EDs around the country. Rates and trends in product-related injuries (bicycles, tools, toys, childcare products, etc.) are obtained and disseminated from this system.¹

State and Local Sources

States, local jurisdictions, and hospitals maintain injury data in various forms. The most basic data collected by states are mortality data, in the form of medical examiner reports and death certificates. Deaths are coded using ICD-9-CM (International Classification of Diseases), N-codes (Nature of injury), and E-codes (external cause of injury).¹⁰ While in many cases medical examiners must investigate all unexpected deaths, specific information regarding the circumstances of the death and injuries sustained can be sketchy. This may be particularly true when death occurred at the scene, without the benefit of hospital data collection.

State and local morbidity data are usually based on hospital-acquired data. This information is available from discharge databases, trauma registries, ED surveillance, surveys, and specialized registries (burns, spinal cord injuries, etc.) Each of these systems has its own strengths and weaknesses, largely dependent on the purpose for which the method exists. For instance, if a discharge database was created to use ICD-9 codes to track financial and resource utilization information, it may not include important information necessary for epidemiologic research. Trauma registries, while highly specific, contain data on only the sickest patients. Improved ED surveillance systems hold promise for providing improved injury and cause of injury information on a broad subset of the population. The CDC has published initial guidelines for uniform ED injury data collection, which represents a first step toward improved ED injury surveillance.³³

UNINTENTIONAL INJURY

Motor Vehicles

The motor vehicle is ubiquitous in U.S. society and the most common factor related to unintentional injury. The first U.S. motor vehicle fatality was a pedestrian struck by a taxicab on the streets of New York in 1899.⁴⁵ Since then, millions have died on the road. Currently, approximately 42,000 people die in roadway crashes every year. Of these, approximately 32,000 are vehicle occupants. The rest are pedestrians, bicyclists, and motorcyclists. While the absolute number of deaths has remained relatively constant over the past two decades, the rate of death per 100 million miles traveled has dropped dramatically, from 7.6 in 1950 to 1.7 in 1997. Just between 1987 and 1997, the rate dropped 32%.³⁰ These decreases can be attributed to a complex combination of changes in vehicle and roadway engineering and changes in human behavior.

Several federal agencies play a role in traffic safety. The lead agency is the National Highway Transportation Safety Administration (NHTSA), charged with reducing death and disability on the highways. Other agencies, including the Federal Highway Administration and the CDC, have an impact. State efforts are most commonly led by Governors' Highway Safety Representatives, with close affiliations with law enforcement, medicine, and public health.

Kinetic energy is the agent that causes injury in motor vehicle occupants. Occupant restraint is the most important factor in reducing injury risk. Different types of impact cause different injury patterns. The biokinetics of impact stretch across all types of impact. A crash typically consists of three collisions. First, a vehicle strikes an object. The velocity, direction, mass, and rigidity of the involved objects govern the dynamics of the crash. The second collision occurs when the occupant strikes the interior of the vehicle. Proper restraint use will frequently allow the occupant to "ride down" this collision, reducing the impact force. The third collision causes direct injury to the organs involved. Complex linear and angular accelerations are involved in producing organ injuries.

The most common type of impact is frontal. Many safety systems, including air bags, laminated windshields, and collapsible steering columns, were created to reduce the severity of frontal crashes for occupants.²³ The second most common type of crash involves a side impact. Injury mechanisms can be complex. From the standpoint of prevention, it is interesting to note that drivers over age 55 experience a greater risk of side-impact crashes, suggesting numerous prevention strategies targeted at this age group.⁶ Rear impacts are very common, but typically less severe than other crashes. One area of particular interest to emergency physicians may be "whiplash," for which there is little consensus about diagnosis, treatment, or outcomes. Rollovers are complex random events that represent a very high injury risk, particularly in the absence of seat belt use. Patients should be aware that being thrown clear of the car is not the goal, and can lead to death or serious injury.

Motorcycles

In 1997, 2106 motorcyclists died in the United States, and another 54,000 were seriously injured.⁴⁰ The kinematics of motorcycle crash injuries are complex. Single-vehicle crashes may occur after loss of control of the vehicle, creating a random pattern of injuries that may include severe head, chest, and extremity injuries, along with the familiar abrasions (road rash). Motorcycle-to-vehicle impacts can also cause a constellation of injuries. First, the rider separates from the motorcycle, followed by significant contact with the other vehicle. The rider then strikes the road surface, causing a new set of major injuries.

There are numerous factors that contribute to effective injury prevention for motorcyclists. These include rider training programs, driver education about avoiding motorcycles, improved roadway design, and helmets and other safety equipment.

There is no doubt, however, that the most contentious and heavily researched area of motorcycle safety concerns helmets. Helmets work by absorbing energy that would otherwise be transmitted to the rider's head after a crash. Offner et al.³² reported that the use of helmets reduced severity of head injury and overall resource utilization in a group of riders matched for overall severity of injury. Sosin et al.³⁷ documented that motorcycle head injury-related death rates increased when state helmet laws were weakened and rates decreased where helmet laws were strengthened. Advocates use these findings and others when discussing motorcycle helmet requirements with state legislatures.

Bicycles

Injured bicyclists frequently present to EDs for care. In the United States, there are 800 deaths and 500,000 ED visits annually for bicycling-related injuries.³⁴ Bicyclists may not develop the speed of motorcyclists, but they benefit from some of the same equipment, including helmets.

The motion of the cyclist after a bicycle crash can be very random. Cyclists become large projectiles early in the crash sequence. The most common body region injured is the shoulder joint.³¹ Helmets clearly reduce the severity of the most potentially severe injury, brain injury.³⁹ Particularly among children, local programs to increase helmet use, combining education with enforcement, are having good results in reducing the incidence of bicycle-related brain injury.

Pedestrians

Approximately 6000 to 7000 pedestrians die annually in the United States.³⁴ Of the 500,000 annual worldwide traffic deaths, at least half are pedestrians.²² The young and the old are especially at risk. Children cross into streets unexpectedly, increasing the risk of a collision outside an intersection. Multiple factors may be contributing to recent declines in childhood pedestrian deaths. Traffic-calming measures may be working to reduce vehicle speeds through susceptible areas. A decrease in walking as a means of childhood transportation may also be a factor.

Among older adults, performance, manifested by walking speed, may not meet the task demand of crossing a street. Older adults are unable to clear intersections as quickly as younger adults,¹³ and may also perceive oncoming vehicle speeds differently. Younger adults have the added risk of alcohol consumption. In 1992, of fatally injured pedestrians over 14 years old, 43% had consumed alcohol. Of these, 55% had a blood alcohol concentration (BAC) of 20 g/dL or higher.⁵

The mechanism of injury of the pedestrian often relates to the relationship between the victim's center of gravity (CG) and the vehicle bumper height. Children with a lower CG may be "run over," sustaining a predictable pattern of head and torso injuries. Adults with a higher CG may be "run under," sustaining typical lower extremity fractures, followed by injuries to the pelvis, torso, and head.

Intervention strategies focus on at-risk populations. Neighborhood streets may be reengineered to calm traffic in areas frequented by children. Childhood education may focus on street-crossing technique. Areas populated by older adults may require retiming of crosswalk lights to allow for safe crossing.

Falls

While young people can suffer serious injury and death from falls, the most severe outcomes are concentrated in the older population. Emergency departments see typical patterns of children who fall from heights, and older persons who fall and suffer hip fractures and other debilitating injuries.

Pediatric falls are typically the result of a child falling down stairs or through windows where safety devices were not installed. The prime example of a pediatric fall prevention program is represented by "Kids Can't Fly" from New York in the early 1970s. Over a 4-year period, 123 children died in falls through windows in high-rise buildings. A citywide program to install window guards in at-risk buildings reduced these numbers dramatically, cutting the rate of falls by 50% in 2 years.³⁸

Falls in the elderly constitute a major burden for society and a principal focus for local injury prevention programs. Hip fractures are a common complication of these events. Death rates as high as 21.7% at 1 year after hip fractures, compared with 4.7% in a control group, have been reported.¹⁷ Local fall prevention programs include optimizing medical management of at-risk populations to prevent medical causes of falls, and direct examination of homes to look for loose throw rugs, poorly placed wires, and other tripping hazards and to install handles and railings to assist occupants. ED and emergency medical services (EMS) workers are ideally placed to identify those at risk for falls and to intervene.

Burns

One of the successes of injury prevention efforts has been in the area of burn prevention. Mortality from burns has decreased 80%, accompanied by a 74% decrease in injuries from residential fires. Smoke detectors and sprinkler systems have now become a standard part of building construction, both for reduction of property losses and for reduction of deaths and injuries. Burn deaths decreased from 6357 annually to 3700 annually from 1977 to 1997, respectively.³⁰ The most common cause of death in fires is not from burns, but from smoke inhalation and carbon monoxide poisoning. Unfortunately, scalding still remains a relatively common means of injury for children. Intervention programs have focused on public education aimed at reducing the set temperature for water heaters to 120°F.

Farm Injuries

In rural areas, agricultural injuries are frequent occurrences. In 1995, 679 deaths were reported related to farm work. As death certificates may not always include place of death, these numbers may be understated. Interestingly, each year approximately 50% of farm deaths are related to tractor overturns. While farm deaths and injuries have been dropping, the circumstances identified by available statistics may suggest educational and engineering interventions to make the farm a safer workplace.³⁰

General Occupational Injuries

The workplace, defined in many ways, can be very dangerous. Fortunately, working is much safer now than at the beginning of the twentieth century. In 1912, there were 21 unintentional work deaths per 100,000 population, while, in 1997, that rate was only two per 100,000 population. Occupational injury and death risk can be measured in a number of ways. The leading overall circumstance involved in occupational death is motor vehicle crashes (21.7%), followed by assaults (14.9%). Of the major occupation divisions, mining and agriculture carry the highest death rates. When analyzed by a measure known as index of relative risk by specific occupation, fishing and timber cutting are at least twice as dangerous as the third occupation in line, aircraft pilots.³⁰

Nonfatal occupational injuries can be generally divided into acute injuries and overuse (repetitive motion) injuries. Both of these categories are well known in the typical ED. While somewhat difficult to track, these injuries can be categorized using records of days lost from work or workers' compensation claims. Acute injuries are common in air and ground transportation, food service, and lumber and metal-related industries. Disorders associated with repeated trauma are most commonly reported in manufacturing industries. Leigh et al.¹⁹ estimated total overall cost of occupational injury in the United States in 1992 as \$171 billion. Intervention strategies in the workplace range include safe driving programs, equipment use in-service training, inspection of work sites by state and federal authorities, dispute resolution, and many others.³⁰

INTENTIONAL INJURY

Intentional injury, most often related to interpersonal violence, is a frequent cause of ED visits in all settings—from the most urban to the most rural. Intervention programs abound, with various levels of success. Injuries not involving guns have a clear impact. However gun-related violence, by virtue of volume and lethality of the weapon, is the focus of the vast majority of public interest and research efforts now, and will continue to be for the foreseeable future.

Injury from penetrating objects, particularly bullets, is also governed by the laws of physics. However, because the impact is very localized, a missile impact causes a much greater amount of energy transmission, and thus injury potential, per volume of tissue involved than does a vehicular impact. Bullets wound by causing permanent cavities of roughly the diameter of the bullet and temporary cavities caused by stretching of the tissue as the bullet passes through.

Firearms can be thought of in two categories: rifled firearms and shotguns. Rifled bullets, used in rifles and handguns, have smooth grooves to help with stability during flight. Lower velocity bullets, such as those in handguns, travel at speeds less than 274 mi/s, causing less tissue damage than higher velocity weapons because of their decreased capacity to create temporary cavitation. Higher velocity bullets, in the range of 600 to 900 mi/s, are fired from rifles.

Bullets may also come in two broad categories: nonexpanding and expanding. Nonexpanding bullets are jacketed to maintain the shape of their leading edge as they pass through tissue. Expanding bullets (also known as soft-point or hollow-point) begin to deform quickly on contact, potentially causing more tissue damage by creating a larger permanent cavity.

Shotguns have smooth barrels and typically fire multiple projectiles, distinguishing these weapons from rifled weapons. The multiple projectiles begin to expand quickly during flight, causing a wide but not deep area of tissue destruction. Beyond a range of about 7 m, shotgun blasts typically do not cause any massive tissue destruction.⁷

SPECIFIC INJURY ISSUES

Air Bags

Air bags came into wide use in the motor vehicle fleet in the late 1980s. These devices act as supplemental restraint systems, meant to fill space between occupant

and vehicle structure. Driver and passenger frontal air bags are now required to be present in every new car sold in the United States. In recent years, the benefits and risks have become a focus of interest of injury researchers and the public.

Air bags are rapidly inflating, multiple-component systems that deploy quickly after impact occurs above a preset threshold. For frontal bags, sensors are placed in various positions in the front portion of the car. Above a DV of between 12 and 18 mi/h, the sensor sends a signal to the inflator, which initiates a deployment, all within a period of milliseconds. The air bag vents hot inflation gases through specific vent holes, and then rapidly deflates. Optimal protection occurs when the occupant is properly restrained by a three-point seat belt.²⁰

Air bags are regulated by federal safety standards. As technology has changed and data have been acquired, standards have changed. Several specific issues hold interest for clinicians. Because deaths and injuries related to air bags were increasingly reported, public interest in air bag disconnection began to grow. Prior to 1997, air bag disconnection was the only option for concerned vehicle owners, and this option required specific approval by the federal government based on medical or other need. As of November 1997, on-off switches may be obtained under specific conditions certified by the vehicle owner. Among the potential reasons are medical conditions of concern. An extensive analysis of medical conditions of potential concern to patients was published in connection with release of the on-off switch rule.²⁸

Speed and power of air bag deployment may be directly related to injury potential. Occupants who are out of position may be killed or injured during deployment. Injuries to the upper extremities, face, eyes, and chest have been reported. In the cases resulting in death, there are three distinct patterns of injury. Adult drivers tend to be unbelted and suffer lethal chest injuries, including myocardial rupture. All infant deaths have occurred when the infants were placed rear-facing in infant seats in the front seat of vehicles with passenger-side air bags. These deaths occur when the deploying air bag creates a lethal brain injury. Older children killed have generally been unbelted or improperly belted in the front seat and have sustained lethal head and neck injuries after coming into close proximity to the air bag module. The NHTSA maintains a listing of investigations of air bag-related deaths on its World Wide Web site (<http://www.nhtsa.gov>).²⁰

Frontal air bags continue to evolve. There has been much interest in "smart" air bags. In theory, advanced-generation air bags would be able to sense various types of impacts, along with specific information, such as size, position, and restraint status of the occupant. After the system processes this information, the inflator would deliver very quickly a graded response appropriate for the situation. While theoretically optimal, the technical achievement of truly "smart" air bags will be very difficult, given the multiple permutations of potential crash dynamics. Air bags other than frontal air bags are now being introduced into the fleet. Side air bags may deploy from the door, from an area between the doors, from the side of the vehicle seat, or from above (in the roof header). These bags are designed to protect vulnerable occupants from the significant forces generated in a side impact. These devices differ from frontal bags in that they must fill a smaller space (between occupant and door) in much less time. The injury reduction benefits, and the risks, of these devices remain to be fully quantified.

Motorcycle Helmets

One of the ongoing battles in injury control is waged over the issue of mandatory use of motorcycle helmets. Three states have no helmet law, 24 states and the District of Columbia have comprehensive helmet laws, and 24 states have something in between. Until 1996, state helmet laws were common, based on federal law that gave states financial incentives to pass such laws. This incentive system was then repealed by Congress.¹⁶

The political battles over motorcycle helmets follow predictable lines. Advocates point out the known benefits of reduction in brain injury and death in states with mandatory helmet use.³⁷ These advocates also cite literature documenting the economic benefits of helmet laws from reduced direct and indirect costs.²⁶ In answer to anticipated concerns, advocates also cite directed studies that document the lack of significant loss of peripheral vision or hearing while wearing a properly fitting helmet.²¹

Those who oppose helmet laws challenge advocates on scientific and personal freedom grounds. The scientific arguments cite potential concerns about an increased risk of cervical spine injuries while wearing helmets. Those in opposition to helmet laws may argue that a decreased death rate after a passage of a helmet law actually reflects decreased motorcycle use by those who would prefer not to ride with a helmet. However, the discussion concerning motorcycle helmets most frequently centers around the conflict between individual freedoms and societal regulation of behavior for the greater societal good. While this general issue is not unique to injury prevention, it pervades many controversial discussions. Helmet laws will continue to be major areas of contention in many state legislatures for the foreseeable future.

Alcohol

Alcohol plays a role in many types of injury. Assaults, domestic violence, falls, drowning, and pedestrian crashes have all been related to injury risk. Nowhere is alcohol abuse more of a issue than in the case of drunk driving. Each year, approximately 17,000 people die on the highways in crashes caused by a drunk driver. As a percentage of total motor vehicle deaths, drunk driving deaths have now dropped to 38%, the lowest rate in years.²⁹ Improvements are related to a number of factors, including improved public awareness, lower blood alcohol levels constituting drunkenness, tougher sanctions, and technology-based sanction programs. Intervention efforts in drunk driving span the range of possibilities suggested by basic injury prevention theory. The "designated driver" message is now widely known in society. While education has not solved the problem, even the casual observer will note behavioral changes among the drinking public in the past 20 years. Frequent public service announcements reinforce the message.

Many efforts currently focus on enforcement. Drunkenness is defined by a combination of behavioral observations and serum alcohol levels. All of the complexities of drunk driving laws are beyond the scope of this text, but some of the key elements necessary for understanding the landscape are reviewed.

Most states recognize 0.10 mg/dL as a *per se* legal limit for defining *drunk driving*. In this case, *per se* in the law means that it is illegal to operate a car at that level, without any behavioral evidence being required. A growing number of states have revised this level to 0.08 mg/dL. In fact, one of the earliest levels set as law in the United States was 0.15 mg/dL. Many advocate lower standards because of the combination of the known physiologic effects of alcohol and the difficulty of operating a motor vehicle. Other countries in the developed world typically have lower *per se* limits than most of the United States³⁶ (Table 91.4).

BAC Limit	Countries
0.08	Austria, Canada, Denmark, France, Italy, New Zealand, Spain, Switzerland, United Kingdom, parts of Australia
0.05	Finland, Iceland, Japan, the Netherlands, Norway, parts of Australia
0.02	Sweden

TABLE 91.4. International BAC Limits

Other aspects of drunk driving laws can be confusing for those not regularly working in the field. For example driving under the influence (DUI) and driving while intoxicated (DWI) carry different connotations. DWI occurs when a driver operates a motor vehicle in an unsafe manner after consuming alcohol, regardless of the level. In some states, a driver is presumed not to be intoxicated (no DWI) if the level is less than 0.05. DUI requires levels (either 0.08 or 0.10) of BAC to provide physiologic evidence of the influence of alcohol.³⁶ Administrative license revocation (ALR) is allowed in many states to immediately remove driving privileges for someone found to be operating a motor vehicle under the influence of alcohol. Ignition interlock devices are used in many states as a form of punishment, usually for repeat offenders. These devices are essentially breath alcohol sensors with which a driver must test himself before starting the vehicle ignition. Zero tolerance is a relatively new concept supported by Congress. Because it is illegal in all states to drink before age 21, many states have decreed that any measurable level of alcohol

in an underage driver is evidence of drunk driving. These and other measures are in place to reduce drunk-driving incidence in the states. Optimal application of these countermeasures has yet to be achieved to reduce drunk-driving rates to levels set as national priorities.

Injuries in circumstances other than motor vehicle crashes are also commonly related to alcohol use. Two-thirds of partner abuse victims reported that alcohol was a factor in the abuse.¹¹ Other assaults are also strongly correlated with alcohol use by involved parties, either the victims or the perpetrators. In other areas of unintentional injury, alcohol also plays a major role. Pedestrians, while potentially victims of drunk drivers, are also likely to be intoxicated, as discussed previously.

Legislation aimed at reducing alcohol-related injury, particularly related to drunk driving, is not without controversy. The most recent major debate has concerned the 0.08 drunk-driving standard. Supporters of the standard note that several studies have shown or projected reductions in injuries because of this law, that other countries have even lower standards, and that the detrimental physiologic effects of alcohol are almost universally present at this level. Opponents question the methodology of the studies of this law, express concerns about the effects on the “social drinker,” and feel that enforcement efforts should be directed at drivers with higher BAC levels. Alcohol-related legislation continues to be a regular focus of debate in state legislative sessions and has the potential to affect ED practices.

Gun-Related Violence

Gun-related injuries and death are indisputably a major problem in the United States. In nearly constant dispute are the root causes and solutions. Approximately 39,000 firearm-related deaths occur each year in the United States. This number has trended generally upward each year since 1983¹⁴ (Fig. 91.3). Rates of firearm-related deaths in the United States are 20 to 30 times higher than those in Scotland, The Netherlands, and England and Wales, and two to seven times higher than those in other similarly developed nations. In the United States, 51% of firearm deaths are suicides, while 43% are homicides.⁸

Figure 91.3. Numbers of firearm-related mortality: United States 1980–1994.

Gun-related violence is clearly a disease of the young, and, quite disproportionately, a disease of young Black males¹⁴ (Fig. 91.4). In 1993, the rate of firearm homicide among White adolescents was 12.8 per 100,000, while the rate among Black adolescents was 131.5 per 100,000. A 1993 survey showed that more than 13% of male teenagers had carried a gun within a 30-day period; a similar survey of inner-city gun carrying revealed a rate of 22%, with rates as high as 83% among juvenile offenders.²

Figure 91.4. Rates of firearm-related mortality, by race and sex: United States 1980–1994.

Debates about guns and gun-related violence permeate political and social discussions. The IOM panel identified several priority areas for attention in gun discussions. Issues of personal freedom, issues of instrumentality and availability, and issues of child and adolescent vulnerability all warrant considerable attention as public health and politics collide over gun issues.

Issues of personal freedom are not unique to gun use in the injury prevention literature. However, in this case, the Second Amendment to the Constitution is specifically cited as pertaining to this issue. This amendment states, “A well-regulated militia, being necessary to the security of a free State, the right of the people to keep and bear Arms, shall not be infringed.” Although all Supreme Court decisions have held that the Constitution does not protect an individual’s right to private gun ownership, organizations such as the National Rifle Association (NRA) and a large proportion of the public feel otherwise. A 1991 poll showed that 60% of Americans thought that gun ownership was constitutionally protected, and a 1993 poll showed that 48% of Americans thought that stricter laws would violate the Constitution.⁴ The landscape of attitudes regarding private gun ownership changes very rapidly, and is significantly influenced by individual events, such as a 1998–1999 rash of school shootings, and changes in political realities.

Instrumentality and availability relate to the risk of firearm-related death and injury. Handguns and long guns (rifles, shotguns, etc.) are the two major types of weapons used in the United States. Handguns are generally divided into revolvers and semiautomatic pistols. Specific discussion of the mechanics of these types of weapons is beyond the scope of this text. Wintemute⁴² has reviewed the subject of handgun types in great detail. Handguns are more frequently associated with violent acts than are long guns for a number of reasons. Long guns are most commonly used in sport and hunting, for which handguns are less effective. Handguns are lighter, easier to handle, and easier to conceal, all factors that make them more likely to be used in both planned and impulsive illegal acts. The concealability of handguns raises specific public policy questions, as many states consider and enact laws that allow private citizens to carry concealed weapons.⁴² Public health and sociologic data are used on both sides of the thorny debate over concealed carry laws.

Specific issues of gun availability are raised by laws that attempt to introduce waiting periods and background checks for gun ownership, such as the “Brady Bill.” Weil and Knox⁴¹ determined that a law limiting handgun purchases in Virginia to one per month significantly disrupted the illegal interstate transfer of firearms. Wright et al.⁴⁴ found that among persons with felony convictions, denial of handgun purchases lowered the potential rate of violent and gun offenses. Those who favor this type of legislation feel that impulsive purchase of weapons leads to “crimes of passion” and that frequent and bulk purchases increase the risk of illegal transfer of weapons to criminals. Those who oppose restrictions on gun availability and purchase tend to argue that these restrictions are ineffective and impede the rights of law-abiding citizens. Restrictions on the frequency and volume of individual gun purchases will continue to be a focus of public debate.

Child and adolescent vulnerability to gun-related injury, both intentional and unintentional, is a specific area of increased concern. Highly publicized cases of children causing injury with guns taken from their own homes have raised the profile of this issue. Equally as alarming are concerns about suicide. One case-control study by Kellermann et al.¹⁸ documented an increased risk for suicide across all age groups in homes where weapons were readily available. Data from the NEISS was used to calculate a rate of 2.6 per 100,000 unintentional, nonfatal firearm-related injuries annually in those under age 14. The rate of similar injuries for those ages 15 to 24

rises to 16.2 per 100,000.³⁵ News reports of deaths related to children playing with guns found in the home are particularly poignant. Educational programs that teach children to avoid guns and report their presence to adults, combined with legislation proposing mandatory child-safety devices, are in use to reduce the incidence of unintentional gun injury among children. Patient education materials related to gun safety are available from numerous sources for distribution in EDs.

Knives are also commonly used in assaults. While clearly dangerous and potentially deadly, knives do not pose the risk associated with guns. Mock et al.²⁵ reported reduced hospital charges and public costs associated with reduced severity of illness in a population of stabbing victims, compared with victims of gunshot wounds in the same institution. The authors calculated an annual savings of \$981,000 in public funds in their institution if all of their gun assaults had taken place with knives instead.

Gun-related violence continues to occur at alarming rates. Politics will continue to play a major role in all facets of public discussion of this issue. The recent IOM report "recommends the development of a national policy on the prevention of firearm injuries directed toward reduction of morbidity and mortality associated with unintended or unlawful uses of firearms. An immediate priority should be a strategic focus on reduction of firearm injuries caused by children and adolescents." Public education about gun safety and proper storage, engineering of solutions directed at children, and enforcement of current and future laws will all work in concert to reduce the incidence of gun-related death and injury.

SUMMARY

Injury is a broad field about which volumes can and have been written. EDs are the point of presentation for many victims of injury, both intentional and unintentional. Many parts of this and other texts focus on methods for improving the acute and continuing care of those who are injured. Just as in other diseases, prevention is a major part of treating injury as a disease. Through understanding of the principles of surveillance, biomechanics, public policy, and patient education, the emergency physician can quickly develop skill and expertise in the field of injury prevention.

CHAPTER 92

Out-of-Hospital Care and Transport of the Trauma Patient

Juan A. March and C. Crawford Mechem

[Advances in Out-of-Hospital Therapy](#)
[Patient Transport](#)
[Patient Destination](#)
[Chapter References](#)

Out-of-hospital care for the trauma patient has evolved tremendously over the past two centuries. During the Napoleonic Wars, wounded soldiers in Europe were transported from the front line to the hospital in light, two-wheeled wagons called “flying ambulances.”² In contrast, today highly trained medical personnel transport patients in fully equipped air and ground ambulances.

Emergency medical services (EMS) in its current form arose from the realization that the quality of medical care administered to wounded soldiers in Vietnam far surpassed that administered to civilians injured in automobile accidents back home. To help address this, the National Highway Safety Act of 1966 established an EMS division of the National Highway Traffic Safety Administration. It also set aside funds for training of hospital care providers and for ambulances and communication systems.¹⁴ The Emergency Medical Systems Act of 1973 led to the establishment of 300 regional EMS systems across the United States and made the Department of Transportation (DOT) responsible for creating a formal training curriculum for emergency medical technicians (EMTs).⁹ Since 1981, funding and oversight of the EMS system has shifted from the federal level to state and local levels.²²

ADVANCES IN OUT-OF-HOSPITAL THERAPY

In 1995 the National Highway Traffic Safety Administration implemented a revised, national, standard EMT-Basic curriculum.²⁶ Adoption and implementation of the new curriculum is the choice of the lead EMS agency in each state. In some states, legislative changes will be required before full adoption of the new curriculum is possible. As a consequence, even today, individual state and local EMS systems continue to have levels of certification varying from EMT-Basic to EMT-Paramedic.¹⁵

Appropriate airway management is critical to the out-of-hospital care of the trauma patient. The new standards for the EMT-Basic curriculum include an optional session for endotracheal intubation, thus allowing for advanced airway intervention in EMS systems that otherwise might not be able to afford personnel trained to the paramedic level. While orotracheal intubation is the preferred method for ventilation and prevention of aspiration in patients with respiratory compromise, skills maintenance may be difficult in EMT-Basic systems or in smaller EMS systems with low call volumes.^{11,20} The traditional alternative to intubation has been bag-valve-mask ventilation with an oral airway in place. Bag-valve-mask ventilation can be technically difficult, often resulting in inadequate tidal volumes, and may lead to aspiration of gastric contents. Other airway adjuncts that have proven successful in lower volume EMS systems include the Pharyngeal Tracheal Lumen Airway (PTL), the Laryngeal Mask Airway, and the Combitube. However, there are no data available regarding the morbidity or mortality associated with the use of these devices in the trauma patient.¹⁹

The role of out-of-hospital fluid resuscitation has been an area of controversy for numerous years. Whether fluids improve outcome and, if so, which fluid is best are questions that have been hotly contested. Deliberately delaying fluid resuscitation in hypotensive trauma patients until bleeding is surgically controlled has been referred to as “permissive hypotension.” The rationale behind this practice is that giving fluids increases hemorrhage by increasing intravascular hydrostatic pressure. In addition, soft clots may be dislodged and clotting factors diluted.^{8,16}

Clinical support for this comes from a prospective study of 598 hypotensive adults with penetrating thoracic trauma who were randomized to either receive intravenous fluids in the out-of-hospital setting or have a heplock placed but not given fluids. Those not given fluids had a higher survival rate.⁵ However, it is unclear whether these results can be generalized to blunt trauma victims, to those with closed-head injuries, or to EMS systems with long transport times. Ultimately, the extent of out-of-hospital fluid resuscitation may be dictated by the specific injuries involved and the EMS location.²¹

The Pneumatic Anti Shock Garment (PASG), a modification of the jet aviator's G-suit, was in widespread use in the late 1970s and early 1980s to restore blood pressure in hypotensive trauma patients. Its mechanism of action was thought to involve increased preload and increased systemic vascular resistance.¹² This device has fallen into disfavor following the publication of studies questioning its theoretical mechanism of action and suggesting a lack of efficacy. In fact, a study of 911 hypotensive blunt and penetrating trauma victims who were randomized to PASG or no-PASG therapy demonstrated a worse outcome in the PASG group in patients with cardiac and thoracic vascular injuries.^{4,13}

A position paper developed by the National Association of EMS Physicians reviewed the available clinical data on use of the PASG.⁷ In the trauma setting, scenarios in which use of the PASG was acceptable, and probably helpful, included hypotension due to suspected pelvic fracture, uncontrollable lower extremity hemorrhage, and severe traumatic hypotension with a pulse but no obtainable blood pressure. The PASG was possibly helpful in the setting of penetrating abdominal trauma, pelvic fracture without hypotension, and spinal shock. The use of the PASG was felt to be inappropriate in case of diaphragmatic rupture, penetrating thoracic injury, abdominal evisceration, and as a splint of extremity fractures.

PATIENT TRANSPORT

Options for transport of trauma victims from the scene to definitive care include both ground and air ambulances. Air transport involves both helicopters and fixed-wing aircraft. In most cases, trauma victims will be transported by helicopter from the scene to definitive care. One distinct advantage of air ambulances over ground transport is the speed of transfer between two points. In addition, highly trained flight crews can perform life-saving interventions en route, such as rapid-sequence intubation, needle decompression of a tension pneumothorax, and cricothyroidotomy. Air travel is ideal in the rural setting, where there are often great distances to cover and transport time becomes a crucial factor.¹⁰

The first helicopter aeromedical program in the United States went into service in 1972 at St. Anthony's Hospital in Denver, Colorado.²³ In 1998 approximately 275 helicopter air medical programs were operating in the United States.¹ Helicopter staffing includes the pilot and generally two medical members, often two flight nurses or a nurse and a paramedic. However, physicians and respiratory therapists may also be used, as dictated by the nature of the mission.²⁴ In the wake of a series of air medical tragedies, the Commission on Accreditation of Medical Transport Systems in 1991 established accreditation standards to ensure patient and flight crew safety. These address such issues as pilot and crew training and equipment maintenance. As of 1998 there were 62 accredited transport services.⁶

When applied appropriately, air medical transport can have a profound impact on trauma patient survival. A large study of 1273 blunt trauma victims transported by helicopter found a 21% reduction in predicted mortality.³ Data involving air transport of traumatic cardiac arrest patients are less promising. In a study of 67 trauma patients in cardiac arrest at the scene, 47 were transported to hospital. None survived to hospital discharge.²⁵ Therefore, the benefits of air transport must be weighed against potential risks on a case-by-case basis.

Although helicopters attain much greater speeds than ground transport, flight team preparation usually requires 3 to 8 minutes prior to lift-off from the base, and patient loading in the vehicle may require more time than it would in a routine ground transport. In addition, helicopters may be limited by inclement weather and the need for a safe landing zone, which can often be difficult to find in an urban setting.¹⁸ Thus, air transport is not appropriate in all cases. Guidelines developed by the National Association of Emergency Medical Services Physicians (NAEMSP) for trauma patient transport via helicopter are outlined in detail in [Table 92.1](#).

A. SPECIFIC	
1.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
2.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
3.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
4.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
5.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
6.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
7.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
8.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
9.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
10.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
11.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
12.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
13.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
14.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
15.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
16.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
17.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
18.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
19.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
20.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
21.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
22.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
23.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
24.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
25.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
26.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
27.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
28.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
29.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
30.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.

49.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.
50.	Establish a critical incident response consisting of personnel who are trained in the use of the equipment and procedures for the transport of patients in a vehicle capable of a minimum speed of 100 mph and equipped with appropriate safety features to allow for the safe transport of patients.

TABLE 92.1. NAEMSP Guidelines for Transport of Trauma Patients

PATIENT DESTINATION

Direct transport from the scene to a regional trauma center has obvious advantages. These include the immediate availability of highly trained medical staff, including but not limited to emergency physicians, trauma surgeons, neurosurgeons, and cardiovascular surgeons. In addition, the necessary ancillary equipment and personnel for such as blood bank, x-ray, computed tomography scanners, cardiopulmonary bypass, and surgery are readily available. The American College of Surgeons' Committee on Trauma (Table 92.2) has developed guidelines for transfer directly to a trauma center.

TABLE 92.2. ACS Trauma Center Transfer Guidelines

Frequently, for logistic reasons, victims of major trauma are initially transported to hospitals that are not trauma centers. The decision to transfer these patients to a regional trauma center must be based on the capabilities and limitations of the local institution. Guidelines provided by the American College of Surgeons recommend that patients identified as having a high risk of dying of their injuries should be transferred. Such injuries include but are not limited to major head and chest trauma, pelvic fractures, multisystem injury, or the presence of comorbid conditions. Table 92.3 provides a complete listing.

TABLE 92.3. Interhospital Triage Criteria

Patients not initially brought to a regional trauma center, but identified as requiring a trauma center referral, should be transferred as soon as possible following initial assessment and resuscitation. Early contact with the referral facility is necessary to optimize patient management en route and to facilitate the transport process, whether by ground or air ambulance. The Consolidated Omnibus Budget Reconciliation Act of 1985 (COBRA), also known as the Emergency Medical Treatment and Active Labor Act (EMTALA), requires that the physician at the receiving hospital be contacted and accept the patient prior to transport.

The receiving hospital must have the necessary facilities to care for the patient. The referring and receiving physicians share the medical and legal responsibilities of transferring a patient. Direct communication should occur between these physicians as frequently as necessary to ensure appropriate patient care en route. This initial contact should be made as soon as criteria indicating the transfer are identified. Communication should remain open to inform the receiving physician of details of the physical examination, pertinent diagnostic test results, or any changes in the patient's condition.

Recently, there has been some controversy over air medical transport and the COBRA requirement for an emergency department evaluation of each patient by a physician. Is an evaluation at the local community hospital by a physician required, when the trauma patient is transported by ground ambulance from the scene directly to the helipad at the local community hospital and the patient never enters the emergency department doors at the local community hospital? Even when the sole purpose for ground transport to the local community hospital is to facilitate rendezvous with the flight team, is the local hospital required to perform a screening evaluation, which might include x-rays of the chest, pelvis, and cervical spine? This evaluation would only delay the patient's transport to definitive care at a regional trauma center, particularly since flight teams are capable of performing most of any critical emergency interventions required. No literature is currently available regarding this aspect of COBRA. Local policies should determine how these cases should be handled.

In conclusion, management of the trauma patient by out-of-hospital care providers has changed tremendously over the past two centuries. This change has been even more dramatic in the past three decades, as new advances in emergency medicine research have continued to change out-of-hospital care.

Expert management of the airway is the single most important skill that must be acquired and maintained by the emergency physician. Because of the potential diversity of patient population and presentations, acquisition of the skills and knowledge base necessary for optimal management of acute airway emergencies calls for multidisciplinary training unique to emergency medicine that includes anesthesia, critical care, pediatrics, surgery, and emergency medical services training. This chapter discusses the unique aspects of airway management in patients with multisystem trauma in the setting where the emergency physician may be the sole physician provider of resuscitative care.

PROBLEMS UNIQUE TO TRAUMA AIRWAY MANAGEMENT

Many victims of trauma will benefit from early control of the airway to ensure adequate oxygenation and ventilation, and to protect against aspiration. Contrary to popular belief, most trauma patients are not initially managed in the sophisticated environment of the trauma center, where ample expert assistance is readily available. Instead, these patients are managed by the community emergency physician who has little or no surgical, anesthesia, or additional emergency medicine assistance. Therefore, the chosen approaches must result in very rapid and safe acquisition of the airway in the majority of clinical scenarios.

Airway management in trauma victims is problematic for many reasons. The five most immediate concerns are listed in [Table 93.1](#). It is wise to assume the presence of cervical spine (c-spine) injury in most blunt trauma victims. Because of altered mental or hemodynamic status, and difficulty in obtaining adequate c-spine radiographs rapidly, c-spine injury cannot be excluded in most patients requiring emergent intubation.

- 1) Inability to position airway optimally for intubation secondary to possibility of C-spine injury.
- 2) Presence of hypovolemic shock or occult hypovolemia
- 3) Presence of full stomach and risk of aspiration
- 4) Possibility of concomitant head injury
- 5) Known or unknown pre-existing disease states

TABLE 93.1. Factors Complicating Trauma Airway Management

All well-known methods used to predict the difficulty of intubation, including the Mallampati classification, or measuring distances between various landmarks, require a cooperative patient or one who is able to fully extend his or her neck. The inability to optimally position the airway can be problematic in obtaining an adequate laryngeal view during intubation. Coexisting facial and penetrating neck trauma add to this problem. Therefore, the ability to predict the difficulty of intubation in the setting of trauma is minimal.

Hypovolemia complicates airway management because secondary hemodynamic deterioration can be caused by the drugs given to facilitate airway management. Occult hypovolemia or compensated shock is especially hazardous if not considered. Not until the patient has lost 30% to 40% of his or her blood volume does shock uniformly manifest itself. Occult myocardial dysfunction has also been found to exist in trauma victims.¹²

Because the timing of traumatic injuries is unpredictable, all trauma patients must be presumed to have a full stomach. The response to pain from injury and resuscitative maneuvers frequently causes nausea and vomiting, resulting in an increased risk of aspiration.

Concomitant head injury also alters the approach to airway management in the multiply injured patient. Issues of cerebral blood flow and intracranial pressure (ICP) must be considered together with volume status and cardiovascular function so that neither is compromised. The presence of a drug or alcohol-induced altered mental status further complicates the determination of the potential presence of closed-head injury requiring emergent airway management.

All of these concerns are aggravated by the presence of preexisting disease. Elderly patients, for example, may be taking cardioactive medications that adversely affect the hemodynamic response to injury or intervention. All of these issues must be considered when selecting approaches to trauma airway management.

TECHNIQUES OF AIRWAY MANAGEMENT

Intubation of the trachea with a cuffed endotracheal tube is the standard of care when it is clear that the patient cannot protect his or her airway or is at the point of respiratory failure. Orotracheal intubation (OTI), blind nasotracheal intubation (NTI), and surgical cricothyrotomy are the major choices for definitive airway management. The act of intubation is not benign and may cause severe stress to the patient. The routine use of awake intubation is too stressful in all but the most severely injured patients who are deeply comatose and hypotensive.

Laryngoscopy and intubation result in circulatory responses that can cause bradycardia, tachycardia, hypertension, increased ICP, and disturbances in cerebral blood flow. Intubation in an awake patient that causes struggling may result in gagging, with profound spikes in ICP, vomiting and aspiration, and significant movement of the c-spine. Regardless of technique, proper preparation is essential. The use of the mnemonic SOAPME is helpful to ensure readiness ([Table 93.2](#)).³²

-
- S. Suction should be readily available with Yankauer or tonsil tip apparatus.
 - O. High-flow oxygen (15 l/min) with appropriate methods of delivery such as bag-valve-mask device and nonrebreathing masks should be available.
 - A. Airway supplies should be present in various sizes. These include nasal and oropharyngeal airways, endotracheal tubes with stylets and 10-mL syringes, and functioning straight and curved-blade laryngoscopes. Consider having other airway adjuncts available for difficult airways. Adequate assistance to keep the airway positioned and to provide cricoid pressure is essential.
 - P. Pharmacology in the form of induction, sedative, analgesic and neuromuscular blocking agents, as well as local anesthetics should be available for immediate administration.
 - ME. Monitoring equipment such as ECG, pulse oximetry, end-tidal CO₂ monitoring, and stethoscopes should be applied and in working condition.
-

TABLE 93.2. Preparation for Airway Management: Mnemonic

Orotracheal Intubation and Rapid-Sequence Induction

OTI may be performed in several modes, ranging from having the patient totally awake to performing it in conjunction with rapid-sequence induction (RSI). RSI is a technique by which the physician quickly prepares the patient for intubation: Oxygen and various induction and paralytic agents are used to perform intubation in a manner that reduces the chance of aspiration and hemodynamic disturbances.

OTI with RSI has become the procedure of choice in managing the trauma airway. It is also meeting with a great deal of success in the prehospital setting. Although different pharmacologic agents may be chosen, the major components of this technique remain the same: preoxygenation, administration of agents that cause loss of consciousness, administration of paralytics, and administration of postintubation analgesia and sedation.

Preoxygenation is performed to prevent hypoxemia during the intubation process. It is achieved either actively, such as with use of a bag-valve-mask (BVM), or by letting the patient with spontaneous respiration (and adequate minute ventilation) inhale 100% oxygen. Active preoxygenation should be avoided, if possible, to reduce the risk of gastric insufflation, although arguments exist that a brief attempt should be made to assist the patient with a BVM to ensure the patient can be adequately ventilated prior to inducing paralysis. Regardless, application of cricoid pressure (Sellick maneuver) is essential during RSI, or any other active ventilation technique, to prevent gastric insufflation and regurgitation. This maneuver is applied until the endotracheal tube cuff is inflated and tube position is confirmed.

Unless lung or chest trauma exists, it should be possible to significantly denitrogenate the lungs within 30 seconds if the patient receiving 100% oxygen can take four maximally deep breaths or if the equivalent can be delivered actively with a BVM.¹⁰ This reservoir of oxygen will last several minutes before desaturation of hemoglobin occurs. Although pulse oximetry should be used to detect desaturation, it should be remembered that it is essentially insensitive to PaO₂ levels above 90 mm Hg. In addition, pulse oximetry readings may lag behind true oxyhemoglobin changes by 1 to 2 minutes.

Induction refers to a rapid and controlled drug-induced loss of consciousness. Producing a state of controlled unconsciousness before intubation has many advantages. Even hypotensive trauma patients are often conscious and aware of their surroundings, making intubation both mechanically difficult and stressful for the patient. Induction is most commonly produced by such drugs as the sedative-hypnotics.^{26,27 and 28,32}

Paralysis is performed during RSI for a number of reasons. It reduces the chance of regurgitation and aspiration by eliminating the efferent gagging and coughing response to the stimulus of laryngoscopy. Paralysis also totally relaxes the upper airway musculature to allow the physician an optimal view of the larynx. It also prevents spontaneous movements by the at-risk patient that might produce spinal cord injury during the periintubation period.

Because of the problem in predicting the degree of difficulty in intubating the trauma patient who has facial and neck injuries, inhalation injuries, or potential c-spine injuries, care must be taken in using paralytic agents if there is likely to be a problem in providing other forms of artificial ventilation.

Airway adjuncts, as well as cricothyrotomy equipment, must be immediately available at all times during RSI. In such cases, RSI may be modified to provide adequate sedation: An appropriate sedative-hypnotic is used in conjunction with topical or intravenous anesthesia, but the paralysis component is deleted. This combination may be the best alternative to reduce patient stress and to partially blunt the physiologic response to laryngoscopy and intubation. Paralytic agents may then be given immediately after proper endotracheal tube position is confirmed.

Although advocated by some, placement of a nasogastric tube prior to intubation can be extremely problematic, depending on the patient's level of consciousness at the time. Although gastric emptying prior to RSI would appear to offer advantages, many patients in distress will not tolerate its placement. The result is sometimes dangerous movement of the c-spine as well as gagging and vomiting, which may lead to aspiration or deleterious changes in cerebral hemodynamics.

Blind Nasotracheal Intubation

NTI has long been advocated as the method of choice for intubating patients with suspected c-spine injury and patients in whom sedation is contraindicated. It requires a patient who is spontaneously breathing and in whom the operator can recognize inspiration and expiration. Patients with significant midface trauma have not been considered candidates for NTI, although clinical studies demonstrate its safety in patients with demonstrated cribriform plate fractures.¹⁶

Although popular, NTI has drawbacks. Because optimal performance requires proper preparation of the nasal mucosa, it can be time consuming, taking several minutes to complete. NTI often requires multiple attempts. Even after mucosal preparation, significant epistaxis may occur, placing the patient at risk for aspiration and possibly making subsequent OTI more difficult. NTI is capable of causing intense cardiovascular stimulation, which along with any patient struggling may result in increasing ICP. In addition, struggling may cause significant c-spine movement in those at risk for cord injuries.

NTI has a place if time and circumstances do not permit preparation for OTI. If it is performed, oxygen should be given by high-flow delivery throughout the procedure to prevent desaturation. The largest nares should be chosen. The nasal mucosa should be prepared, using a topical anesthetic and vasoconstrictive agent (i.e., 4% lidocaine and 1% phenylephrine) if possible. Adequate sedation, as well as adjuncts such as intravenous lidocaine, may decrease the incidence of the previously discussed side effects. Attention should be paid to maintaining c-spine immobilization if indicated, as well as to the application of cricoid pressure.

Special endotracheal tubes have been designed in which the tip of the tube can be manipulated by a proximal trigger, thus enhancing the success of blind placement in the trachea (Endotrol, Mallinckrodt Medical Inc.). In addition, a technique has been described in which the endotracheal tube cuff is inflated in the oropharynx using 15 cc of air.³¹ In patients with normal pharyngeal anatomy, this technique centers the tip of the tube and directs it anteriorly toward the larynx. When resistance is felt on advancement, this signifies contact with the vocal cords (breath sounds should still be heard). The cuff is then deflated and the tube is advanced into the trachea.

This technique has actually been demonstrated to have a high degree of success in nonbreathing, paralyzed patients. It has also been demonstrated to be as successful as the use of fiberoptic assistance in patients who require c-spine immobilization.³¹ Still, in patients in whom secretions are minimum, fiberoptic assistance may be valuable but requires a higher degree of skill maintenance. In patients with shallow breathing, the use of capnography may be helpful in determining the exact onset of inspiration and expiration.

Surgical Airway Management

Surgical airway management, in the form of cricothyrotomy, was previously recommended as the procedure of choice in patients in whom a c-spine injury was suspected and NTI had failed or was impossible because of massive facial or upper airway injury. Despite the high success rates of RSI/OTI and NTI, cricothyrotomy continues to serve a role. Cricothyrotomy equipment must always be immediately available in any patient undergoing RSI. Even with the development of percutaneous kits, experience remains essential. Cricothyrotomy is often better performed after successful use of an airway adjunct (discussion follows) to allow for more control of

the procedure while avoiding any intervening hypoxemia.

SPECIAL MANEUVERS AND INTUBATION ADJUNCTS

Displacement of the thyroid cartilage backward against the cervical vertebrae, upward or as superiorly as possible, and laterally to the right—the BURP maneuver (Fig. 93.1)—has been described and found to significantly improve the view of the glottis during laryngoscopy.³⁰ It is finding widespread acceptance as an aid in management of the difficult airway. The mechanism by which BURP improves visibility may lie in the ability to move the glottis back into the line of vision, as laryngoscopy itself tends to push the tongue and possibly the larynx toward the left.

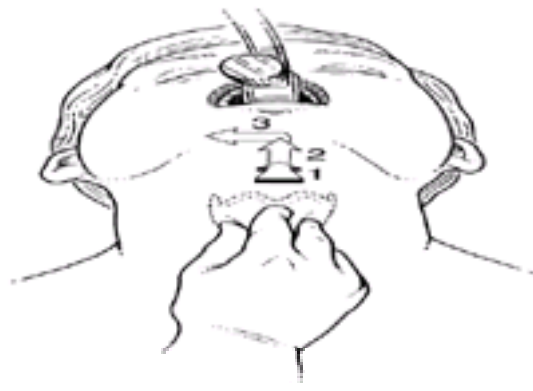

Figure 93.1. Diagram of application of the BURP maneuver in improving the glottic view during laryngoscopy. The thyroid cartilage is moved backward against the cervical vertebrae, upward or as superiorly as possible, and laterally to the right. See text for further explanation.

The use of BURP in the setting of potential c-spine injury in which in-line immobilization of the neck is necessary has not been studied. It is, therefore, unknown if the laryngeal view in this setting is significantly improved. It is also unknown how displacement of the thyroid cartilage might effect an unstable c-spine injury. However, its use in patients without suspected cervical spine injuries would seem to be advantageous and without contraindications. It should be remembered that BURP does not replace the need for cricoid pressure in any patient undergoing intubation.

Several airway adjuncts either aid in the intubation process or are designed to temporarily replace intubation if it cannot be performed (Table 93.3). As an adjunct is likely to be used after unsuccessful intubation in the most desperate of circumstances, the chosen adjunct would ideally provide adequate ventilation with some degree of airway protection when blindly placed, while resulting in little movement of the c-spine.

Nasal	
Use with audio assist device or capnography, or use with fiberoptic assistance.	
Oral	
1)	Blind with tactile (digital) technique
2)	Blind with use of lighted stylet
3)	Use with fiberoptic assistance: fiberoptic apparatus or Bullard laryngoscope
4)	Use with other special laryngoscopes or blades: McCoy laryngoscope, Belscope blade
5)	Blind with use of retrograde technique through trachea
Surgical	
1)	Needle cricothyrotomy and percutaneous translaryngeal jet ventilation
2)	Cricothyrotomy using various cricotomy and percutaneous devices
Nondefinitive management alternatives	
1)	Esophageal tracheal Combitube
2)	Pharyngotracheal lumen airway
3)	Laryngeal mask airway
4)	Intubating laryngeal mask airway

TABLE 93.3. Intubation Alternatives and Adjuncts

The esophageal tracheal Combitube (ETC) and the laryngeal mask airway (LMA) deserve comment. Each of these devices is gaining in popularity and each has its advantages and disadvantages. Both, however, require little training for proper use. Major advantages of the ETC include its double-lumen design (ability to ventilate regardless of esophageal or tracheal placement), ability to be placed blindly, the upper airway protection afforded by its pharyngeal balloon, and the ability to aspirate gastric contents from one of its lumens.³ Once placed, other approaches to the airway (fiberoptic, surgical, etc.) may be attempted while avoiding hypoxemia. The LMA was originally designed for the outpatient surgery setting, but its use as a rescue airway device has become popular. Although more attention is required for specific placement, recent modifications of the device have resulted in an intubating version that allows passage of specially designed endotracheal tubes.¹⁷

The major disadvantage is that until an endotracheal tube is placed via the LMA, little airway protection is afforded, and decreases in chest wall compliance or increases in airway pressure may prevent adequate ventilation. Application of cricoid pressure has also been demonstrated to impede placement and ventilation through the LMA. Placement of both devices can be greatly enhanced by lubrication of the devices, use of paralytic agents, and use of a laryngoscope to reduce obstruction from the tongue. Use of these adjuncts earlier rather than later in the course of managing an airway may greatly reduce the incidence of hypoxemia or other complications.

Several new laryngoscopes and laryngoscopic blades have been marketed in an attempt to help improve the glottic view, especially during difficult intubation in which minimal or no movement of the c-spine is desired. These include the Bullard and McCoy laryngoscope and the Belscope blade.^{8,9,34} The Bullard laryngoscope is rigid and uses fiberoptic technology to obtain an indirect view of the larynx. The McCoy laryngoscope has a blade with a hinged tip, allowing elevation of the epiglottis from a fulcrum deep within the pharynx. The Belscope blade is specially angulated, with a detachable prism allowing indirect visualization of the larynx. All have advantages and disadvantages; the Bullard and Belscope apparatus take more time to use and master. A large emergency department experience has not been reported with any of these devices.

PHARMACOLOGIC ADJUNCTS

Pharmacologic agents may be chosen to accomplish several goals, including topical anesthesia, sedation, analgesia, amnesia, and paralysis. Judicious use of these agents may facilitate rapid intubation, while avoiding such complications as increased ICP and regurgitation. Selecting the wrong agent can cause life-threatening complications such as prolonged paralysis with an inability to ventilate or cardiovascular collapse. Unfortunately, there are no agents that are rapid acting, of short duration, and totally void of complications in all situations. Current suggestions are based on a combination of practical and theoretical considerations.

Local Anesthetics

Lidocaine is an amide that can be used topically, locally, or intravenously to aid in airway management. Maximum doses are 3 to 4 mg/kg. When applied topically in a 4% solution, lidocaine may be used with topical vasoconstrictors to aid in NTI. Nebulization of a 4% solution into a spontaneously breathing patient can produce complete topical anesthesia of the oro- and nasopharynx and the vocal cords in 5 to 7 minutes.⁴ Although somewhat controversial, when given intravenously in a dose of 1.5 to 2.0 mg/kg 2 to 3 minutes before intubation, lidocaine may attenuate much of the hemodynamic and cough reflex-mediated rise in ICP.²⁴ As lidocaine is, for the most part, hemodynamically inert, its use in intubation as an aid in modulating the response to laryngoscopy, especially in cases of head injury, seems reasonable.

Induction Agents

Sedatives and hypnotics, as well as potent narcotic analgesics can be used as pharmacologic adjuncts to achieve states ranging from light sedation to loss of consciousness. There is a risk-to-benefit ratio for each of these agents in the trauma setting. Although adverse effects on respiration can be countered in most instances with artificial ventilation, there is no simple maneuver to counteract the cardiac dysfunction that may be produced by these agents in the trauma victim. The choice of agent should be based on the following:

- The agent's reliability of induction
- The need to maintain spontaneous respiration
- The patient's level of consciousness and risk of head injury
- The patient's hemodynamic or suspected hemodynamic status
- The patient's preexisting physiologic state, if known

The barbiturates thiopental and methohexital are very short-acting sedative and hypnotic agents that provide no analgesia. Their onset of action is within 1 minute; their duration of action is between 5 and 10 minutes.²⁶ The benefits of these agents are their induction reliability and rapidity of onset. The major disadvantage is that they can result in myocardial and respiratory depression.²⁶ Their use may cause sudden and profound hypotension in the presence of preexisting myocardial dysfunction or hypovolemia, although this is not a major factor in the normal host. Even in "normal" subjects, mild-to-moderate decreases in blood pressure and increases in heart rate may result. Thiopental doses, ranging from 3 to 5 mg/kg in the setting of normal hemodynamics, and 0.5 to 1.0 mg/kg in the unstable patient, have been recommended for induction.²⁶

Barbiturates reduce ICP by reducing cerebral blood flow in a dose-dependent fashion. Concomitant matched reductions in the cerebral metabolic rate must also occur to prevent cerebral ischemia. Whether matched reductions occur after a single bolus or lower titrated doses in the injured area of brain is unclear. Although barbiturates may be safely used in victims of isolated head trauma in whom preexisting disease states are known, their widespread use in the multiply injured patient in whom volume status and history are unknown may be risky because of potential side effects.

Propofol is a substituted isopropylphenol; it is highly lipophilic and capable of producing profound sedation, hypnosis, and amnesia but is without innate analgesic properties.²⁸ Propofol's major unique characteristic is its rapid metabolic clearance and redistribution, which is approximately ten times faster than that of thiopental. Clinical recovery is extremely rapid (4 to 8 minutes), with little residual sedation apparent, even after prolonged administration. A large experience with the use of propofol as an induction agent in the initial resuscitation of the critically ill or injured patient is lacking. Its major drawbacks (due to its potency) are those of respiratory and cardiovascular depression even in healthy normovolemic individuals.²⁸ Extreme caution must, therefore, be exercised if propofol is used in the undifferentiated trauma patient. Favorable cerebral hemodynamics can be produced, similar to those seen with the barbiturates if decreases in mean arterial pressure can be minimized. Again, it is unclear if this extends to injured brain areas after single-dose use. Because trauma patients remain intubated for prolonged periods for resuscitation and diagnostic purposes, the advantages of propofol's rapid redistribution is limited in this setting. If used, slowly administered doses ranging from 1.5 to 2.5 mg/kg are recommended.

Etomidate is a nonbarbiturate, nonnarcotic sedative-hypnotic induction agent that exhibits no analgesic properties.²⁸ In doses of 0.2 to 0.3 mg/kg, induction is reliably produced in less than 1 minute, and the duration of action is between 4 and 6 minutes. This drug has several properties that make it attractive for use in the multisystem trauma victim. When given in single induction boluses, it evokes minimal changes in heart rate and cardiac output compared with equipotent doses of thiopental.²⁸ This advantage may be particularly useful in patients with hypotension or compensated shock, as well as in those patients with preexisting myocardial dysfunction.

Etomidate also causes significantly less respiratory depression than do barbiturate agents, although, when given rapidly, transient apnea, may induce.²⁸ Etomidate may in fact stimulate ventilation independent of action on the medullary respiratory centers. For this reason, it may be advantageous to choose etomidate when maintenance of respiration is desirable, such as during sedation with NTI or modified RSI. Like the barbiturates, etomidate can reduce ICP by causing a dose-dependent reduction in cerebral blood flow and cerebral metabolic rate. Whether consistent improvements in cerebral hemodynamics are obtained after a single induction bolus of etomidate remains to be determined.

Etomidate occasionally causes side effects, but none should contraindicate its use as a single injection in the unstable or potentially unstable patient (with or without head injury). Side effects include transient burning on injection, transient but potentially significant myoclonus after administration, and transient suppression of endogenous cortisol production.²⁸ Although a concern, this occasional temporary suppression of cortisol production has not been shown to affect outcome. Supplemental cortisol can be given if needed. The relatively inert hemodynamic profile of etomidate in the trauma setting outweighs these potential problems.

Ketamine is a phencyclidine derivative that produces dissociative anesthesia. It is the only agent that possesses sedative, hypnotic, analgesic, and amnestic properties.²⁸ It provides the most cardiovascular and respiratory support of any agent. Although it is a direct myocardial depressant, heart rate and blood pressure are usually maintained or increased because of centrally mediated sympathetic stimulation. Central sympathetic stimulation also results in transient bronchodilation. Unless it is given rapidly, apnea does not occur.

The major advantage of ketamine lies in the setting of the overtly hypovolemic patient, especially when the heart is directly involved, such as in pericardial tamponade.²⁸ Its onset of action is within 1 minute when given intravenously (1 to 2 mg/kg), and its duration of action ranges from 5 to 15 minutes. It may also be given intramuscularly (4 mg/kg), with the onset of action delayed by several minutes. This is advantageous when rapid control of the patient without venous access is needed.

The disadvantages of ketamine are few. Its use may result in worsening hypotension if given to patients who are either sympathetically depleted or who have severe coronary artery disease and may not tolerate increased myocardial oxygen demand. However, administration of any induction agent in this setting is hazardous. Use in hypertensive patients with suspected traumatic aortic injuries may also be problematic. Because it is a phencyclidine derivative, ketamine can cause an emergence delirium. While this is a concern during conscious sedation, this should never prohibit its use as an intubation adjunct in a critically ill trauma patient. Intubated trauma patients are usually kept sedated and paralyzed for many hours after their initial presentation, and emergence delirium at this time is rare.²⁸ Continued sedation with benzodiazepines virtually eliminates the occurrence of emergence delirium.

An additional concern regarding the use of ketamine is its potential to affect ICP, secondary to its ability to increase cerebral blood flow by 30% to 60%.²⁸ Even though the cerebral metabolic rate is increased with ketamine, cerebral blood flow is probably sufficient to meet demand. Evidence is accumulating that this increase in cerebral blood flow does not increase ICP.^{14,15} In fact, there is evidence that ketamine is neuroprotective in the setting of head trauma.²² Despite this evidence, there is still reluctance to use ketamine in the presence of potential head injury. Its use may still be warranted in the setting of head injury, however, when induction is needed in a hypotensive patient: Any reduction in mean arterial pressure has more potential to worsen cerebral ischemia than will a transient rise in ICP.

Benzodiazepines (diazepam and midazolam) have been used alone, and in combination with narcotics, as induction agents. They provide good anxiolysis and amnesia, but large doses are usually needed to produce states of induction that are equivalent to and similarly predictable as the previously discussed agents.²⁷ No analgesia is provided.

Midazolam is currently the most commonly used benzodiazepine for airway management. It is two to four times as potent as diazepam. An induction dose of midazolam (0.3 mg/kg) takes effect within 1 to 2 minutes and has a duration of action of between 30 and 60 minutes. Even at doses of 0.3 mg/kg, induction is not always predictable. This dose can be accompanied by side effects such as severe respiratory depression (even more so than equivalent doses of thiopental). Significant decreases in mean arterial pressure and cardiac contractility can also occur, especially in patients with hypovolemia or heart disease.¹ All of these effects are more pronounced when opioids are given simultaneously. Subinduction doses (0.03 to 0.05 mg/kg) of midazolam are not commonly associated with these complications and can serve as valuable adjuncts in providing continued sedation for patients after intubation, but they do not provide sufficient induction conditions.

The newer synthetic opioid agonists (fentanyl family), which include fentanyl, sufentanil, and alfentanil, are 100, 500 to 1000, and 20 times more potent than morphine, respectively.²⁵ They are fast acting, having an onset of action of less than 1 minute, and their duration of action is between 15 and 60 minutes. Fentanyl has gained widespread popularity in emergency medicine as a fast-acting analgesic used in conscious sedation. For reasons not entirely clear, it has also become

used as an induction agent in emergency medicine. Although not an ideal induction agent in the trauma setting, fentanyl can induce states of unconsciousness. However, the doses required to induce it are extremely variable and if high enough may cause unwanted side effects in the critically ill patient. Depending on the existing state of consciousness and the presence of drugs such as alcohol, the dose necessary to produce unconsciousness can range from 2 to 20 µg/kg or more.

The effect of fentanyl on ventilation varies, but doses above 2 µg/kg result in a high incidence of respiratory depression in “normal” subjects.² This incidence is even higher when used with other agents. Fentanyl results in little or no histamine release, and its cardiovascular effects in the normal host are minimal. At higher doses, however, small but potentially significant decreases in blood pressure may occur.²⁵ Fentanyl has been touted as a valuable preinduction adjunct in intubation of the head-injured patient because of its ability to attenuate the hemodynamic response to intubation. Although effective, when given in sufficient doses to achieve this (at least 3 µg/kg, 2 to 3 minutes before laryngoscopy), increases in ICP result that possibly negate any advantage to its use in the setting of traumatic brain injury.²³

This increase in ICP has also been shown with sufentanil and alfentanil administration. Coupled with their potential for producing premature hypoventilation and apnea, their routine use as induction or preinduction agents in this setting is controversial. The best roles for fentanyl in trauma airway management may be to provide postintubation titrated sedation and analgesia to attenuate hyperdynamic responses from pain and intubation and to make continued intubation and ventilation more tolerable.

The use of morphine in the management of the trauma airway is discouraged because of its effect on histamine release, which may result in hypotension. If used, carefully administered test doses should be given first.

Despite the most careful of evaluations and precautions, occasionally, the use of any induction agent may result in sudden and profound hypotension not responsive to simple fluid boluses. In cases of head injury, even transient hypotension can result in prolonged cerebral hypoperfusion whether or not blood pressure and oxygen delivery are restored to normal levels.¹⁹ For this reason, it may be advisable to have an agent such as phenylephrine available for administration in bolus form (50 to 200 µg) to help immediately restore mean arterial pressure until the offending induction agent is sufficiently redistributed or metabolized. Phenylephrine is a synthetic noncatecholamine that stimulates principally alpha-1 adrenergic receptors by a direct effect. Its onset is very rapid and relatively short-lived when given in bolus form.

Neuromuscular Blocking Agents

The use of neuromuscular blocking agents (NMBAs) to facilitate intubation has become widespread in emergency airway management. They help provide ideal intubating conditions in many circumstances, as well as help to facilitate and control other aspects of patient management. They have no analgesic or sedative properties; their sole use without analgesia and sedation, except in the most hemodynamically tenuous or deeply comatose patients, is never indicated. These agents are classified as depolarizing and nondepolarizing.

The only depolarizing NMBA in use in the United States is succinylcholine. Succinylcholine (1.0 to 2.0 mg/kg) is the agent of choice during emergent RSI. No agent has a faster onset (less than 1 minute) or is of shorter duration (4 to 6 minutes). The disadvantages of succinylcholine are relatively minor and should never prohibit its use in the acutely injured patient. These include fasciculations, hyperkalemia, and transient rises in intragastric, intraocular, and intracranial pressure.²⁶ These side effects have caused some to disapprove of its use in patients with burns, crush injuries, and eye and head injuries. Succinylcholine-induced hyperkalemia in burns and crush injuries does not occur in the acute setting. If fasciculations and elevated intraocular, intragastric, and intracranial pressure are major concerns, administration of a defasciculating dose of a nondepolarizing agent (i.e., vecuronium 0.01 mg/kg) 2 to 3 minutes before succinylcholine administration may help prevent these occurrences.²⁹ If a defasciculating dose of a nondepolarizing agent is used, the dose of succinylcholine should be increased to 1.5 to 2.0 mg/kg to maintain its rapidity of onset. Unpredictably, a few patients may develop vagally mediated bradycardia, histamine-induced hypotension, and malignant hyperthermia with succinylcholine administration. Succinylcholine can also be given intramuscularly (4 mg/kg), but its onset is delayed by 2 to 4 minutes.

There are several nondepolarizing NMBAs in current use, with vecuronium and rocuronium the major agents in use in trauma airway management. The advantages of these agents are that they are longer acting, cause no fasciculations, and cause no reported increase in intraocular, intragastric, or intracranial pressure. They also have little effect on the cardiovascular system.^{7,29} The major disadvantage of vecuronium is that it may take up to 2 to 3 minutes to take full effect. Time to onset can be reduced with the priming principle, in which an initial smaller subparalyzing dose is given 1 to 2 minutes before the paralyzing dose.²⁹ This method would appear to have no advantage in managing an emergent trauma airway, wherein time is the issue.

Priming and defasciculating doses of nondepolarizing agents may produce significant respiratory impairment in elderly patients, so meticulous care of the airway is necessary.¹³ Large doses of vecuronium (0.25 mg/kg), used as an initial bolus, can achieve paralysis within 90 seconds but may last as long as 90 minutes. The onset of action of rocuronium (0.6 mg/kg) is similar to that of succinylcholine, although its duration of action is similar to that of vecuronium (25 to 40 minutes).²⁹ Nondepolarizing agents can be reversed to some extent by drugs that block cholinesterases, such as neostigmine, edrophonium, and pyridostigmine. Their routine use is not advised because of potential cardiovascular complications.

Because the peak onset of both succinylcholine and rocuronium approaches 1 minute and the onset of action of induction agents such as etomidate, thiopental, and ketamine essentially occurs in a one-arm-to-brain circulation time (less than 1 minute), it may be advantageous to administer the paralytic agent first, followed by the induction agent (timing principle).²¹ Because clinical weakness will occur at approximately 30 seconds with both agents, administration of an induction agent such as etomidate 10 to 20 seconds after administration of either succinylcholine or rocuronium will produce adequate intubating conditions in approximately 1 minute after paralytic administration.

For patients who are not being actively oxygenated with a BVM prior to RSI, this helps to guard against premature apnea/hypoventilation (thus preserving the functional residual capacity of oxygen) while ensuring adequate induction at the time of laryngoscopy. Patients intubated with the timing principle do not demonstrate restlessness prior to loss of consciousness and do not report any dissatisfaction postoperatively.²¹

SPECIAL CONSIDERATIONS

Cervical Spine Injury

In most urgent situations, a detailed neurologic examination cannot be performed before the need to intubate is addressed. Even in the face of normal radiographs, the patient would need to be able to fully cooperate with a physical examination to exclude c-spine injury. The patient with a blunt trauma or penetrating neck injury requiring intubation is unlikely to be able to meet this criterion. The role of c-spine radiography before intubation is, therefore, controversial. Lateral c-spine radiography can miss up to 20% to 30% of c-spine injuries.

It has been estimated that a small but significant percentage (1.2%) of all blunt trauma victims will have an occult c-spine injury, given a 6% total incidence of injury and a 20% miss rate on lateral c-spine radiography.³³ If time permits, a lateral c-spine radiograph that reveals an unstable injury may cause the operator to choose a particular intubation technique. It is imperative to remember, however, that a negative radiograph does not exclude injury. Of interest, recent studies have indicated that certain populations traditionally intubated with c-spine precautions may not require such precautions, including victims of penetrating head trauma.¹¹

Cadaveric studies of unstable c-spine injuries demonstrate no superiority of one method over the other when meticulous c-spine immobilization is practiced. However, even maneuvers such as jaw thrust, BVM ventilation, and cricoid pressure have been demonstrated to induce significant movement of unstable c-spine injuries if extreme care is not taken.⁵

OTI utilizing RSI is now the procedure of choice in achieving definitive airway control in patients with suspected c-spine injury.¹⁹ Because the ability to position the airway in this setting is limited, it may be preferable to use a straight laryngoscope blade rather than a curved blade; the straight blade will lift the epiglottis directly.

Perhaps counterintuitive, removal of the front of the cervical collar while maintaining in-line immobilization (not traction) significantly improves the view of the larynx during intubation.⁶ When manual immobilization is present, an intact c-collar offers no additional advantage. Regardless of approach, airway management in the setting of potential c-spine injury is optimally performed with at least three people: One is the intubator, one provides in-line immobilization of the c-spine, and one applies cricoid pressure (Fig. 93.2).

Figure 93.2. Demonstration of RSI OTI in victim of multisystem trauma. Note that three persons are participating. One is intubating, one is maintaining c-spine immobilization, and one is applying cricoid pressure. Also note that the front of the c-collar is removed to aid in viewing the larynx.

In cases of penetrating neck trauma with possible altered upper airway anatomy or signs of airway obstruction, OTI with RSI is still the procedure of choice in most circumstances.²⁰ Administration of paralytic agents may be strategically deleted if proper sedation and upper airway anesthesia are provided. Use of induction agents with less effect on ventilation (etomidate and ketamine), along with intravenous and/or nebulized lidocaine, will aid in reduction of gagging and further hemorrhage or distortion. Concomitant use of the lighted stylet or fiberoptic assistance may be helpful.

Head Injury

The pathophysiology of traumatic brain injury is complex and involves a combination of mechanical and biochemical events initiated by the trauma itself, followed by the potential of secondary injury in the form of ischemia. Traditional approaches to the head trauma victim who required intubation assumed that the brain had lost some degree of its ability to autoregulate its blood flow. Cerebral blood flow in this setting is determined by the mean arterial pressure minus the ICP. Emphasis has been placed on reducing ICP during intubation with the use of agents such as barbiturates, but little emphasis has been placed on ensuring maintenance of the mean arterial pressure during this critical time. Because ICP is not known at the time of initial resuscitation, a mean systemic arterial pressure between 80 mm Hg and 100 mm Hg should be maintained. Although an attempt to reduce ICP during intubation is of theoretical benefit, it has never been demonstrated to affect outcome. Because reductions in ICP are caused by reductions in cerebral blood flow, and must be matched by similar reductions in cerebral metabolic rate to avoid ischemia, it would appear that achieving this goal with the use of a single dose of an induction agent would be of very transient, if any, benefit.

More important, any advantage gained in reducing ICP would be lost if the mean arterial pressure were not maintained. Restoration of mean arterial pressure after transient hypotension does not ensure restoration of prehypotensive cerebral blood flow.¹⁸ Titration of various cardioactive medications (barbiturates, beta blockers, and nitrates) for induction of head-injured patients to reduce ICP and blunt the cardiovascular effects of laryngoscopy has been suggested, but this strategy is unlikely to result in the desired effect of decreasing ICP and may still lower blood pressure, thus jeopardizing cerebral oxygen delivery.

In reality, probably no airway drug affects ICP more than the struggles of the patient or the procedures (many of them painful) performed during the initial examination and resuscitation. Because most head injuries occur in association with multisystem trauma, a more reasonable approach would be to administer agents that cause a predictable loss of consciousness, cause no increase in ICP, and maximize the chance to maintain mean arterial pressure. Use of paralytic agents and adjuncts such as lidocaine prevents the largest and most harmful increases in ICP caused by gagging and coughing during laryngoscopy. Cerebral hemodynamics are probably best managed immediately after intubation with limited hyperventilation and continued paralysis, along with concomitant sedation and analgesia guided by heart rate and blood pressure. An earnest attempt should be made to document the patient's Glasgow Coma Score and mental status prior to intubation.

PRESENTATIONS AND SUGGESTED APPROACHES

Despite the deluge of suggested techniques and approaches, the final decision on airway management depends primarily on the urgency of the situation and how comfortable the physician feels with a particular approach. In the end, the most immediate causes of mortality and morbidity are hypoxemia and hypotension that are not quickly reversed. In the most urgent of situations, use of rapid-acting paralytic agents followed by laryngoscopy with c-spine control, if needed, may be the best approach. Follow with sedation and analgesics as tolerated.

Assuming that the emergency physician is the sole physician provider of initial trauma care, examination and resuscitation roles cannot be split. It is difficult to spend long periods of time securing an airway by titrating therapy when other resuscitative maneuvers are also rapidly needed. Although each patient is unique, several assumptions should be made to prevent iatrogenic harm when faced with a patient who needs aggressive airway control. In trauma victims at risk for internal thoracic and abdominal injuries, one should assume that the patient is occultly hypovolemic, even if no signs of shock are present. In victims of blunt trauma or penetrating head injuries who require intubation, one should assume that intracranial injury exists until proven otherwise. In victims of blunt multisystem trauma or victims with penetrating neck trauma, one should assume that a c-spine injury exists.

Trauma patients can be grouped into three categories based on the possibility of their having head and neck injuries and hypovolemia. This grouping is helpful in choosing the approach to airway management ([Table 93.4](#)). Bearing these groups in mind, the following goals should be achieved during both the preparation period and during intubation:

<p>1) Blunt trauma with suspected head, maxillofacial, neck, and multisystem injury involvement at risk for hypovolemic shock</p> <p>2) Isolated blunt or penetrating head or neck trauma requiring c-spine control but not at risk for hypovolemia</p> <p>3) Penetrating injury below the head and neck not at risk for c-spine and head injury but at risk for hypovolemia.</p>

TABLE 93.4. Major Presentations of Trauma Patients

1. The patient does not experience further decreases in mean arterial pressure secondary to administration of medications or maneuvers.
2. The patient does not develop premature apnea or hypoventilation.
3. The patient does not develop large increases in ICP.

If these assumptions and goals are addressed, and airway and pharmacologic interventions are chosen accordingly, rapid and safe acquisition of an airway should be possible, and the physician will rarely be caught off guard by hemodynamic changes or neurologic deficits. [Table 93.5](#) and [Table 93.6](#) demonstrate intubation sequences that should meet the needs of the majority of severely injured patients and result in few complications.

- 1) Prepare and preoxygenate passively or actively with BVM. Use Sellick maneuver if using BVM. Manually immobilize c-spine but remove front of c-collar.
 - 2) Lidocaine 1.5-2.0 mg/kg IV (2-3 minutes prior to laryngoscopy)
 - 3) Sellick maneuver, and a defasciculating dose of nondepolarizing agent if using succinylcholine in step four. Give at least two minutes prior to succinylcholine administration. May be given simultaneously with lidocaine.
 - 4) Succinylcholine 1.5-2.0 mg/kg IV
 - 5) Etomidate 0.2-0.3 mg/kg IV (reduce to 0.1-0.2 mg/kg if hypotensive) 10-20 seconds after paralytic administration.
 - 6) Intubate trachea, inflate cuff, confirm placement with auscultation and end-tidal CO₂. After placement is confirmed, release cricoid pressure.
 - 7) Continue paralysis with nondepolarizing agent if desired. Provide appropriate sedation and analgesic as allowed.
- If using rocuronium step 3 may be deleted (with exception of Sellick maneuver). Rocuronium administered in place of succinylcholine in step 4 at dose of 0.6 mg/kg followed by induction agent (step 5) 10-20 seconds later.

TABLE 93.5. Example of RSI Protocol for Multiply Injured Patient with Suspected Hypovolemia and Head and Neck Injuries

- 1) Prepare and preoxygenate passively or actively if required. Apply Sellick maneuver if using BVM. Optimally position airway.
- 2) Ensure Sellick maneuver and give succinylcholine (1-2 mg/kg) or rocuronium (0.6 mg/kg) IV.
- 3) 10-20 seconds later administer etomidate 0.2-0.3 mg/kg (0.1 to 0.2 mg/kg if hypotensive) or ketamine 1-2 mg/kg (0.5-1.0 mg/kg if hypotensive).
- 4) Intubate trachea, inflate cuff, confirm placement with auscultation and end-tidal CO₂. Release Sellick maneuver after placement confirmed.
- 5) Continue paralysis if desired along with appropriate sedation and analgesia.

TABLE 93.6. Example of RSI Protocol for Patient at Risk for Shock but Not Head or Neck Injuries

After intubation, most patients benefit from continued sedation and analgesia. Small and frequent aliquots of midazolam (1 to 3 mg) and fentanyl (50 to 100 µg), guided by cardiac monitoring, blood pressure monitoring, and movement (if the patient is not paralyzed), are appropriate and devoid of major side effects.¹² After loading, carefully titrated, continuous infusions of the same may also be considered. Longer acting agents such as lorazepam and morphine may also be carefully used.

Continued or newly initiated paralysis simultaneous with provision of analgesia and sedation may be required to optimize resuscitation and diagnostics. It does little good to perform a meticulous neuroinduction for a brain-injured patient only to have the patient fight and buck the ventilator during the ensuing resuscitation. Early removal of patients from backboards, proper splinting of fractures, and application of local anesthetics to wounds will significantly decrease patient discomfort.

COMMON PITFALLS

- Failure to consider occult hypovolemia and shock and preexisting disease states when choosing induction agents
- Failure to provide cricoid pressure (Sellick maneuver) during intubation until proper endotracheal tube placement is confirmed
- Failure to maintain meticulous control of the c-spine during intubation in patients with suspected c-spine injuries
- Failure to have airway rescue adjuncts available for cannot intubate—cannot ventilate situations.
- Failure to provide adequate ongoing postintubation sedation and analgesia

[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Shock generally refers to inadequate tissue perfusion manifested clinically by hemodynamic disturbances and organ dysfunction. At the cellular level, shock indicates the insufficient delivery of required metabolic substrates, principally oxygen, to sustain cellular homeostasis. In the setting of trauma, shock is most often related to loss of circulating blood volume due to hemorrhage, although inadequate oxygenation, mechanical vascular obstruction, neurologic dysfunction, and cardiac dysfunction may be either primary or contributing factors.^{3,6}

Traumatic shock may result from either blunt trauma (e.g., motor vehicle collisions, falls, assault) or penetrating trauma (e.g., gunshot wounds, stab wounds, impalements). Traumatic shock usually results from one or more of the following conditions: hemorrhage from solid-organ injury, major vascular injury, pelvic fracture, or multiple long-bone fractures; tension pneumothorax; hemothorax; pericardial tamponade; pulmonary contusion or hemorrhage; myocardial contusion and dysfunction; and neurologic injury that adversely affects ventilation or hemodynamics.

PATHOPHYSIOLOGY

The pathophysiology of traumatic shock relates largely to an imbalance in oxygen supply and demand. In the early phase of acute trauma, this imbalance is usually due to hypoperfusion, although low arterial blood oxygen saturation may be a significant contributing or even a predominant factor. Aggressive resuscitation with fluids having low oxygen-carrying capacity in the setting of severe and ongoing hemorrhage may lead to a critically low hemoglobin concentration that further contributes to tissue oxygen debt.

Acute blood loss elicits compensatory hemodynamic changes that serve to maintain vital organ perfusion. They include increased heart rate and vasoconstriction primarily in splanchnic vascular beds and the peripheral circulation. Compensated shock generally indicates varying degrees of tachycardia and peripheral vasoconstriction that maintain adequate vital organ perfusion. Arterial blood pressure in compensated shock states may be moderately low to within normal range. Uncompensated shock generally indicates significant hypotension with inadequate vital organ perfusion. It is important to recognize that “compensated shock” and “uncompensated shock” are imprecise designations along a continuum of progressive physiologic derangement.

Vasoconstriction in response to hemorrhage and hypovolemia is a protective response that preserves perfusion to the vital organs at the expense of peripheral and abdominal organ perfusion. In the hypoperfused tissues, however, oxygen demand exceeds oxygen delivery, and the numerous cellular processes that depend on oxidative metabolism and adenosine triphosphate (ATP) begin to fail. If the pathologic processes are not stabilized or corrected, cellular metabolism is depressed, resulting in loss of transmembrane ion gradients, membrane integrity, and enzyme activity. These processes lead to total cellular dysfunction and organ failure.

There are four general pathophysiologic types of shock: (1) hemorrhagic or hypovolemic, (2) cardiogenic, (3) neurogenic or vasogenic, and (4) septic.³ *Hemorrhagic* or *hypovolemic shock* involves the loss of circulating intravascular volume caused by blood loss internally, externally, or both. *Cardiogenic shock* indicates a process that prevents the normal pumping of the heart and can be caused by pericardial tamponade that prevents normal ventricular filling, tension pneumothorax with vena caval compression and reduction in venous return to the heart, or direct cardiac damage with loss of contractile force (myocardial contusion).

Neurogenic or *vasogenic shock* may be caused by severe brain injury with loss of autonomic regulatory function or spinal cord injury with loss of peripheral vascular resistance. Major spinal cord injury results in acute vasodilatation but generally does not cause impaired tissue perfusion unless other injuries are present. *Septic shock* refers to the hyperdynamic responses (elevated cardiac output, tachycardia, and low systemic vascular resistance), followed by decreased cardiac output, increased systemic vascular resistance, and organ function deterioration associated with the metabolic demands and toxic mediators accompanying infection.

Although septic shock is seldom an emergency department concern in the trauma patient, traumatic shock may be caused by more than one of these pathophysiologic mechanisms. A complex, confusing clinical picture results in which important pathologic processes may be difficult to detect. If the acute stress of the traumatic shock state is sufficiently severe or prolonged, organ dysfunction may subsequently develop, including acute tubular necrosis (ATN), adult respiratory distress syndrome (ARDS), systemic inflammatory distress syndrome (SIRS), and multiple organ failure (MOF). These entities can develop within a few hours to several days after the acute injury.

CLINICAL PRESENTATION

The most common initial findings in a patient with traumatic shock are tachycardia, hypotension, signs of poor peripheral perfusion, and alteration in mental status. Loss of circulating blood volume eventually results in a decrease in blood pressure. In response to this blood pressure drop, heart rate increases to sustain normal cardiac output. Peripheral vasoconstriction and central venoconstriction shunt blood centrally and result in a narrowed pulse pressure. Decreases in peripheral perfusion are manifested by cool, pale, diaphoretic extremities, with prolongation of capillary refill.

The skin commonly becomes mottled in appearance, but cyanosis is relatively rare. The narrowed pulse pressure makes the pulse quality weak or thready. Alterations in mental status caused by hypoperfusion may be subtle initially and can be difficult to distinguish from associated head injury or intoxication. Therefore, altered mental status on presentation or a subsequent decline in mental status, especially in patients with no evidence of head trauma, should raise concern of systemic hypoperfusion and impending circulatory collapse.

Not all patients present with tachycardia, hypotension, and poor peripheral perfusion. Young, healthy patients with substantial blood loss may maintain a blood pressure within the normal range by compensatory vasoconstriction and increases in heart rate. Heart rate can even occasionally be in the upper normal range. In such patients, signs of peripheral hypoperfusion and subtle changes in mental status may be the only warning signs preceding rapid hemodynamic decompensation. Elderly patients may not develop a tachycardic response to blood loss because of heart disease or medications. A bradycardic response to abdominal trauma that may be vagally mediated has been described.¹⁸ Conversely, hypotension and tachycardia may be exacerbated in a pregnant trauma patient for a given degree of blood loss due to compression of the inferior vena cava by the gravid uterus, resulting in decreased venous return.¹²

Decline in urine output due to renal hypoperfusion and renal fluid reabsorption is an important manifestation of shock physiology. Monitoring urine output may be useful in the emergency department and, later, it is a critical parameter for the trauma surgeon and intensivist. Therefore, a urinary catheter should be placed in patients who exhibit evidence of shock, and the bladder should be drained to begin urine output monitoring as well as to search for hematuria.

DIFFERENTIAL DIAGNOSIS

As stated, the most common cause of traumatic shock is hemorrhage-induced hypovolemia. However, several pathologic entities must be considered as either potential contributors or primary causes of shock (Table 94.1). These include cardiac tamponade, tension pneumothorax, pulmonary contusion or hemorrhage affecting oxygenation, myocardial contusion with dysfunction, myocardial infarction associated with trauma, autonomic dysfunction or spinal cord shock, and effects of toxicologic or pharmacologic agents. Other less common entities include pneumothorax, hemothorax, flail chest, air or fat embolism, and diaphragmatic rupture

extensive enough to significantly affect oxygen saturation.

TABLE 94.1. Differential Diagnosis and Treatment

Pericardial tamponade is classically described as exhibiting Beck's Triad of hypotension, distended neck veins, and muffled heart sounds. A pulsus paradoxus of greater than 10 mm Hg may also be seen. All of these markers may not be present. In a hypovolemic patient, the neck veins may be flat. Muffled heart sounds may be difficult to distinguish in the busy trauma resuscitation arena, and detection of a pulsus paradoxus is not reliable. Thus, pericardial tamponade must be considered whenever a penetrating object might have reached the heart or there are rib fractures near the heart. The immediate availability of ultrasonography or echocardiography offers the best potential for rapid and accurate diagnosis.

A large pneumothorax or hemothorax can usually be detected by diminished breath sounds. Confirmation with a chest radiograph is usually prudent if the patient is not hypotensive. A tension pneumothorax may also result in deviation of the trachea away from the affected side, cardiac displacement, and hypotension related to inferior vena caval compression that limits venous return to the heart. However, tracheal deviation and cardiac displacement may be difficult to detect by physical examination, and hypotension associated with a pneumothorax may be caused by hemorrhage elsewhere. A chest radiograph usually demonstrates a tension pneumothorax well. Ultrasonography may also be beneficial. However, if a patient is hypotensive and has clinical evidence of a pneumothorax, placement of a chest tube or needle thoracostomy before diagnostic imaging is appropriate.

Myocardial contusion resulting in significant contractile dysfunction is a difficult diagnosis to ascertain during the emergency department phase of trauma evaluation, unless echocardiography is immediately available. Myocardial contusion should be suspected when blunt trauma involves the sternum and anterior left chest. Evidence of cardiogenic shock (hypotension, tachycardia, elevated central venous pressure) should be sought, although it may be difficult to distinguish when there is multisystem trauma. Myocardial contusion should be suspected in the presence of ventricular ectopy, dysrhythmias, or electrocardiographic demonstration of ST segment elevations (especially in the anterior precordial leads).

Head trauma with severe brain injury may result in autonomic dysfunction that manifests hypotension in the absence of significant hemorrhage, although this event usually does not occur acutely. Spinal cord trauma with neurogenic shock may present with hypotension due to loss of peripheral vascular resistance. In this setting, presence of neurologic deficits and lack of signs of peripheral vasoconstriction should arouse suspicion for this entity. Such patients generally have warm extremities and good urine output. Volume status must be carefully monitored, because excess fluid administration in patients with spinal shock may be detrimental.

Signs of shock in a trauma patient may not be a direct consequence of the injury. For example, a myocardial infarction in a patient may cause a motor vehicle collision, or the physiologic stress associated with trauma may cause a myocardial ischemic event in a patient with coronary artery disease. A history, examination, or electrocardiographic findings consistent with myocardial infarction arouse suspicion of combined medical and surgical processes. Pharmacologic agents such as beta-adrenergic blockers and recreational agents such as ethanol and cocaine may significantly affect the clinical picture in the setting of acute trauma.

EMERGENCY DEPARTMENT EVALUATION

Effective management of the acute trauma victim exhibiting shock requires that initial assessment and treatment begin simultaneously. ¹ Assessment of airway patency, adequacy of ventilation (respiratory excursion and lung auscultation), hemodynamic status (pulse rate, central and peripheral pulse quality, blood pressure), and evidence of controllable hemorrhage should be immediately linked with interventions to (1) secure the airway while protecting the cervical spine, (2) enhance oxygenation, (3) provide ventilatory assistance, (4) limit further hemorrhage, (5) gain intravenous access, (6) initiate volume replacement, and (7) obtain blood for laboratory and blood bank testing ([Fig. 94.1](#)).

Figure 94.1. Treatment algorithm for traumatic shock.

After the primary assessment and initiation of treatment, a thorough secondary assessment should be initiated to identify potential injuries to the head, neck, chest, abdomen, pelvis, back, extremities, and neurologic system. The patient's temperature should be determined and the patient should be kept normothermic. Hypothermia can markedly depress hemodynamics and should be aggressively treated. The potential for the presence of any of the entities listed under "Differential Diagnosis" should be considered, and clinical signs of these conditions should be sought. Acute trauma is a highly dynamic disease process that requires frequent and careful reassessment of ventilation and hemodynamic status, and physical examination, to optimally adjust therapeutic interventions and identify evolving pathologic processes.

Initial laboratory studies in patients with major trauma should include (1) CBC: white blood cell count, hemoglobin, hematocrit, platelets; (2) arterial blood gases: pH, PO₂, PCO₂, HCO₃, base balance, oxygen saturation; (3) electrolytes: Na, K, Cl, HCO₃, blood urea nitrogen (BUN), creatinine, glucose; (4) coagulation studies: prothrombin time (PT), partial thromboplastin time (PTT); (5) type and crossmatch for 4 to 8 U of blood; and (6) toxicologic studies ([Table 94.2](#)). Urine should be obtained and checked for blood. Lactate and ketone levels may be useful when there is metabolic acidosis. Initial radiographs should include the lateral view cervical spine, chest, and pelvis. Completion of the cervical spine series and other radiographs should be done after hemodynamics have stabilized and after determination that immediate surgery is not required.

LABORATORY

Complete blood count
Arterial blood gases
Electrolytes (including BUN, creatinine, glucose)
Coagulation studies (PT, PTT)
Type and crossmatch for 4-8 U of blood
Toxicologic studies (as indicated)
Urinalysis

Cross-table lateral cervical spine
Pelvis x-ray, AP view

TABLE 94.2. Initial Laboratory and Radiographic Studies in Major Trauma

Monitoring of heart rate, respiratory rate, blood pressure, temperature, and pulse oximetry are important. Placement of arterial pressure catheters and central venous pressure lines may be considered in patients who do not rapidly stabilize or are suspected of having cardiogenic or neurogenic shock components. Placement of a nasogastric or orogastric tube for decompression reduces the chances of aspiration and may improve ventilation if the stomach is distended with air. A urinary drainage catheter should be placed after a search for potential urethral injury has been performed.

Urethral injury should be suspected in patients with pelvic fractures in the area of the symphysis, anterior lacerations on rectal or vaginal examination, or abnormal position of the prostate gland. As noted, urine output becomes an important indicator of the adequacy of organ perfusion. Quantitative end-tidal carbon dioxide (ETCO₂) monitoring, if available, is useful in intubated patients. ETCO₂ can help avoid hypoventilation, prevent excessive therapeutic hyperventilation, and detect decreases in cardiac output. Pulmonary artery catheterization is useful in complex critical cases, but this is seldom performed in the emergency department phase of trauma care. Sequential assessment of hemoglobin/hematocrit and arterial blood gases during therapy for traumatic shock may be useful. These should be interpreted together in terms of oxygen-carrying capacity and blood oxygen content. For example, an O₂ saturation of 90% with a hematocrit of 35% may be more favorable than an O₂ saturation of 100% with a hematocrit of 20% in terms of actual tissue oxygen delivery. Serial lactate levels or base deficit assessments have been advocated.^{13,14} In the trauma patient, the presence of metabolic acidosis in the early phase of resuscitation indicates poor tissue perfusion and should be considered an indicator of inadequate volume resuscitation or ongoing hemorrhage.

Constant reassessment of ventilation and oxygenation, hemodynamic response to volume replacement therapy, and physical examination findings is crucial to detect clinical deterioration, adjust therapy, and identify previously missed injuries. Trauma resuscitations involve multiple individuals performing numerous tasks. During the process of this activity, tubes and catheters can become dislodged or disconnected, pneumothoraces can develop or enlarge, external or internal injuries may bleed again as blood pressure increases, pulmonary congestion may develop in response to volume therapy, core temperature may drop substantially in an exposed patient receiving large amounts of intravenous fluids, or the previously unremarkable abdomen may become distended or rigid. These are examples of significant changes that can occur rapidly during the trauma resuscitation. Careful and constant attention with frequent reassessment is crucial to ensure optimal outcome.

EMERGENCY DEPARTMENT MANAGEMENT

As discussed, initial treatment in traumatic shock occurs concurrently with initial evaluation. Insertion of oral or nasal airways, assisted ventilation, endotracheal intubation, hemorrhage control, and vascular access are all essential components of the initial trauma resuscitation. Early control of the airway in the patient with traumatic shock may be lifesaving and should take priority over all other interventions.

Gaining intravenous access rapidly is essential to begin volume replacement and support the hemodynamics of the patient in traumatic shock. In the presence of obvious shock and impending circulatory collapse, establishing adequate intravenous access and initiating volume replacement is a higher priority than performing the secondary survey or obtaining such parameters as a blood pressure or pulse oximetry measurement. If a patient appears to be in profound shock, knowing the exact blood pressure does not change initial decision making regarding rapid volume replacement.

The antecubital fossa is an excellent site to initiate intravenous access. Large-bore catheters and high-flow intravenous tubing should be used to maximize delivery rate of fluids. At least two intravenous sites should be secured, and, if adequate intravenous access cannot be established within a few minutes, percutaneous femoral venous access, ankle venous cutdown, greater saphenous venous cutdown at the proximal thigh, or subclavian/jugular venous access should be considered. The intravenous sites should be above the diaphragm if a major vascular injury in the abdomen is suspected, as may occur with penetrating abdominal trauma and less commonly with blunt abdominal trauma.

Fluid therapy in trauma is an area of emerging controversy.¹¹ Intravascular volume replacement to compensate for blood loss and restore tissue perfusion has been accepted standard therapy for many years. Research, mostly laboratory investigations, has raised questions regarding the appropriate end point of fluid therapy. Briefly, these studies suggest that normalizing blood pressure with intravenous crystalloid solutions may be detrimental by increasing bleeding at sites of tissue injury.^{4,16} These studies suggest that limited volume replacement, termed *hypotensive resuscitation*, that maintains minimally adequate organ perfusion may result in improved outcome. Although these studies raise very important questions, there are presently insufficient clinical data to support deviation from the guidelines for fluid therapy presently recommended by *Advanced Trauma Life Support* (American College of Surgeons Committee on Trauma).¹

Volume replacement should initially begin with crystalloid solutions, such as normal saline or lactated Ringer's solution. Warmed fluids should be used to work against hypothermia. Fluids may be warmed ahead of time or administered through a fluid warmer. In an average-sized adult showing signs of shock, infusion of 2 L of crystalloid and immediate reassessment of hemodynamics is a reasonable course of action. The point in volume resuscitation at which blood transfusion is initiated is not defined. Factors that influence the decision to start blood transfusion include severity of shock, initial response to crystalloid, initial hemoglobin/hematocrit, and general health of the patient. In general, if hemodynamics do not respond adequately to 3 to 4 L of crystalloid (or about 40 to 50 mL/kg) given rapidly, further volume replacement with blood is indicated.

The value of colloids in the treatment of traumatic shock is uncertain. Colloids, such as albumin, hetastarch, and dextran, can effectively increase intravascular volume and maintain plasma oncotic pressure at more normal levels than can crystalloids. Substantial data, however, demonstrate that crystalloid and colloids are equally effective in resuscitation from hemorrhagic shock.^{15,17} Because the cost of colloids is high and because their effectiveness is in doubt, use of colloids in this setting is not endorsed. Furthermore, evidence suggests that colloids may have deleterious effects in patients with hemorrhagic shock. Hypertonic saline has been extensively studied but has not become an accepted resuscitation fluid in clinical trauma care.

Typed and crossmatched blood is the best choice for blood transfusion. If the need for transfusion does not permit the time required for crossmatching, however, type-specific blood is an appropriate alternative. If traumatic shock is severe and immediate transfusion is critical, low-titer O-negative blood should be used until type-specific or typed and crossmatched blood is available.

If several units of blood are required to manage profound hypovolemia or ongoing hemorrhage, fresh-frozen plasma (FFP) and platelets may be needed to stabilize the coagulation system and limit further "nonmechanical" hemorrhage. In otherwise healthy individuals, FFP is rarely required until blood transfusion approaches 10 U. Empiric administration of FFP and platelets is not indicated.⁸ Coagulation studies and platelet counts should be used to help guide such decisions.

Calcium therapy is controversial and is generally indicated only in the presence of documented hypocalcemia or cardiac dysfunction that is unresponsive to inotropic agents. Bicarbonate therapy in patients with traumatic shock should, in general, be avoided. Restoration of circulating volume and control of hemorrhage are the mainstays of therapy. When metabolic acidosis is profound, however, bicarbonate therapy might be considered as a temporary measure until hemodynamic stability can be obtained. As a general guideline, a pH of less than 7.10, despite aggressive volume replacement, has been suggested as an indicator of the need for bicarbonate therapy. Bicarbonate should not be administered if adequate ventilation has not been established.⁷

Pneumothorax or hemothorax should be managed by the placement of a large chest tube (32F or 36F) in the lateral chest with the tubes oriented toward the

apicoposterior chest wall. If a tension pneumothorax is suspected and the patient is hypotensive, needle thoracostomy using a long, large-gauge angiocatheter or needle inserted at the second intercostal space in the midclavicular line is an appropriate measure until a chest tube can be inserted.

If pericardial tamponade is suspected and the patient is hypotensive and worsening despite volume resuscitation, pericardiocentesis is an appropriate intervention. A pericardiocentesis needle is inserted in the left subxiphoid area and directed 45 degrees toward the left shoulder or sternal notch while suction is maintained on an attached syringe. If possible, the needle should be hooked to an electrocardiographic lead to show evidence of needle contact with the myocardium. Blood in the pericardium often forms clots, thus precluding the value of pericardiocentesis. If the patient is profoundly hypotensive or has lost discernible blood pressure for only a few minutes, an emergency left lateral thoracotomy may be considered to open the pericardium. Patients who have not shown signs of life after sustaining blunt trauma are poor candidates for emergency department thoracotomy.²

Traumatic shock due to hemorrhage is most often caused by intraabdominal injury. The clinical presentation and response to initial therapy dictate the subsequent assessment of the abdomen. Hemodynamically unstable patients with physical examination evidence of abdominal injury should immediately undergo exploratory laparotomy. Patients with suspected abdominal trauma who have exhibited transient hemodynamic instability or patients with other injuries causing hemodynamic instability should undergo diagnostic peritoneal lavage (DPL) to rule out an intraabdominal source of bleeding. Focused abdominal (or assessment) sonography for trauma (FAST) is an acceptable alternative to DPL and will reliably identify free intraabdominal fluid, provided that the person performing the examination is adequately proficient.^{5,9} Hemodynamically stable patients with potential abdominal trauma are reasonable candidates for abdominal computed tomography (CT) scanning.

The role of a pneumatic antishock garment (PASG) or military antishock trousers (MAST) is controversial.¹⁰ The use of these devices is not a substitute for volume replacement, and their value in the emergency department and in the prehospital setting with short transport times is questionable. One generally accepted indication for the use of these devices is in the patient with pelvic fractures in whom these garments provide fracture stability and pelvic compression that limits further blood loss until the patient is surgically stabilized.

In general, vasopressors and inotropic agents are not used in the emergency department management of traumatic shock. In cases of neurogenic or vasogenic shock (e.g., spinal cord injury) in which peripheral vasodilatation causes or contributes to hemodynamic instability, however, vasopressors such as dopamine, phenylephrine, or norepinephrine may be useful. In cases of myocardial infarction associated with trauma or significant myocardial contusion, inotropic support with dobutamine, for example, may be appropriate.

Emergency Department Thoracotomy

Performing a thoracotomy in the emergency department is appropriate when it is unlikely that the patient will survive long enough to reach the operating room. Indications for an emergency department thoracotomy are (1) cardiac arrest in or just before arrival at the emergency department, (2) suspected pericardial tamponade with profound hypotension (extremis), and (3) uncontrollable, exsanguinating hemorrhage below the diaphragm.

The technique involves a left lateral chest incision at the level of the lower margin of pectoralis major muscle, extending from the costochondral junction to the posterior axillary line, curving in the general path of the ribs. The chest cavity is entered in the fourth or fifth intercostal space, using a scalpel or scissors to divide the intercostal muscles over the top of one of the exposed ribs. A rib spreader should be used to give adequate exposure. The pericardium should be examined for signs of tamponade. A dull reddish appearance of the heart without visible epicardial blood vessels indicates pericardial tamponade.

To avoid injury to the phrenic nerve, the pericardium should be opened in a cephalad-to-caudal direction, using the fingers after a small opening is made with scissors or a scalpel. Internal manual cardiac compression can be done with one hand pressing the heart upward against the sternum or with two hands cupped around the heart. The aorta can be identified by running the hand posteriorly along the ribs toward the spine. The aorta has a more rubbery texture than the esophagus. (A nasogastric tube in place greatly aids in distinguishing between the two.) The aorta should be cross-clamped with a vascular clamp after incising the pleura. Penetrating cardiac injuries can be temporarily managed with finger pressure over the defect. Insertion and inflation of Foley catheters and temporary sutures have also been advocated.

DISPOSITION

Definitive management of the patient with traumatic shock often requires emergency surgery. Consultation with a surgeon (preferably a trauma surgeon) should be initiated as soon as possible in all victims of significant trauma who might require operative or critical care interventions. If information from prehospital care providers indicates potentially serious injury, the surgeon (or trauma team) should be notified before the patient arrives at the emergency department. If transfer to another hospital is required, early mobilization of resources (ambulance, staff, or air medical transport service) should be initiated concurrently with assessment and stabilization.

The criteria for transfer to a trauma center include lack of an experienced trauma surgeon, lack of adequate critical care or support services, and lack of adequate resources to manage a patient's injuries. The use of scoring systems such as the Trauma Score (TS), Revised Trauma Score (RTS), and the Glasgow Coma Score (GCS) for triage may be useful in identifying patients with severe injury. Patients with a TS less than 12, an RTS of 8 or less, or a GCS less than 10 generally have serious injuries and should be managed within an organized trauma system.

Criteria for emergency surgical intervention include evidence of internal abdominal hemorrhage (liver, spleen, vascular, bowel), intracranial hemorrhage (subdural hematoma, epidural hematoma), open skull fracture, penetrating cardiac injury, traumatic aortic disruption, complex pelvic fractures, or multiple trauma. Criteria for intensive care unit monitoring include neurologic injury, ventilatory support, hemodynamic instability, and potential for serious complications.

COMMON PITFALLS

- A common error in traumatic shock is not recognizing the severity of trauma. Vital signs, such as a relatively normal blood pressure or absence of tachycardia, can be misleading. Failure to recognize signs of decreased peripheral perfusion can lead to suboptimal management. An initial favorable response to volume replacement should not lull the emergency physician to be less vigilant in trauma management. Adequate resuscitation can temporarily mask ongoing significant hemorrhage. Careful monitoring and repeated examinations are important to detect changes in clinical status and to respond with appropriate interventions.
- Delays in surgical consultation or transfer to a trauma center can have adverse effects, especially when transfer is required. The emergency physician must determine which interventions and diagnostic studies are essential before transfer. These decisions are affected by mode of transport, distance to the trauma center, and the capabilities of the referring hospital. For example, delaying transfer to obtain a head CT scan, abdominal CT scan, or plain radiograph is of no benefit if there is no neurosurgeon, general surgeon, or orthopedist available or if no immediate intervention will take place at the referring hospital. On the other hand, if a head CT scan is indicated and can be obtained while waiting for transfer transport to arrive, and will not cause a delay in transport, it is optimal to proceed with the head CT scan.
- Missed injuries, especially in patients with severe multiple trauma, can have devastating effects. Frequently, repeated examinations can minimize such missed injuries.

Nearly 12 million patients with traumatic wounds are treated annually in emergency departments (EDs) in the United States.³⁶ The ultimate goals are to restore the physical integrity and function of the injured tissue in a cosmetically pleasing manner and to reduce the risk of infection. Treatment of these wounds involves a series of decisions that determine the methods of evaluation, wound preparation, wound closure, and postoperative care most likely to help attain these goals.

Experimental studies provided the basis for previous wound care recommendations. Over the last 5 years, clinical studies have helped refine and better delineate appropriate wound management strategies.

CLINICAL PRESENTATION

Evaluation of the patient with a traumatic wound begins with an expeditious, comprehensive assessment of the patient. This assessment can be divided into primary and secondary surveys, following Advanced Trauma Life Support Algorithms (see [Chapter 89](#)). Unless the wound compromises the ABCs, formal wound evaluation and management occurs during the secondary survey and management phase of the trauma evaluation.

Lacerations occur predominantly in young adults, although they span the spectrum from childhood until older adulthood; the majority of patients with lacerations are males.²¹ Most wounds are located on either the head or neck (50%) or the upper extremity (35%), usually involving the fingers or hands. The most common mechanism of injury is application of a blunt force, such as bumping the head against a coffee table. Such contact crushes the skin against an underlying bone, causing the skin to split. Other causes of injury include sharp instruments, glass, and wooden objects.²¹ While mammalian bites continue to receive much attention, they are a relatively infrequent cause of puncture wounds and lacerations.²¹

Most patients present within several hours of the injury and they may have already attempted to cleanse or care for their wounds. The emergency physician should identify conditions that place the patient at risk for infection or delayed healing after wound closure. Patients with diabetes mellitus, obesity, malnutrition, chronic renal failure, advanced age, and steroid use are at increased risk for wound infection.¹⁰ Chemotherapeutic or other immunosuppressive agents may delay wound healing by affecting inflammation and the synthesis of new wound matrix and collagen.

Because anesthetic agents and antibiotics may be used, a detailed history of any allergies to these agents is essential. With the increased incidence of severe reactions to latex products, it is also vital to review any prior allergy to latex. Tetanus immunization status should be verified.

External bleeding can usually be controlled by applying direct pressure over the site of bleeding. When possible, skin flaps should be returned to their original position prior to application of pressure, to prevent vascular compromise of the injured area. Amputated parts should be cared for as outlined in the chapter on orthopedic emergencies ([Chapter 120](#)). Digits should be covered with a protective dressing, placed within a waterproof bag, and then placed in a container of ice water for preservation and consideration of future reattachment.

Most other aspects of wound management are not emergent and are addressed in the following sections.

EMERGENCY DEPARTMENT EVALUATION

Proper wound management begins with a thorough patient history. Particular emphasis should be placed on the various factors that can have adverse effects on wound healing. Host factors such as the extremes of age, diabetes mellitus, chronic renal failure, obesity, malnutrition, and the use of immunosuppressive medications such as steroids and chemotherapeutic agents all increase the risk of wound infection and can impair wound healing.¹⁰ Wound healing can also be impaired in the presence of inherited and acquired connective-tissue disorders such as Ehlers-Danlos syndrome, Marfan syndrome, osteogenesis imperfecta, and protein and vitamin C deficiencies. The tendency of patients to form keloids should be ascertained; the formation of keloids can result in a scar with less than acceptable cosmesis. Black and Asian populations are more prone to keloid formation.³⁶

Identification of the mechanism of injury is essential to help ascertain the presence of potential wound contaminants and foreign bodies that might result in chronic infection and delayed healing.³⁶ Failure to diagnose foreign bodies in wounds is the fifth leading cause of litigation against emergency physicians. Missed tendon and nerve injuries and failure to prevent infection are other common wound-related causes of litigation.

A careful history can also predict the likelihood of foreign bodies. Organic and inorganic components of soil can potentiate infection. Wounds contaminated by these fractions will become infected with lower doses of bacterial inoculum. The major inorganic particles that potentiate infection are the clay fractions, which reside in heaviest concentration in the subsoil rather than in the topsoil. Injuries that occur in swamps or excavations are at high risk of being contaminated by these fractions. Other soil contaminants, such as sand grains, are relatively innocuous. The black dirt on the surface of highways appears to have minimal chemical reactivity.

Knowledge of the types of forces applied at the time of injury also helps predict the likelihood of infection. Thus, crush injuries that tend to cause greater devitalization of tissue are more susceptible to infection than are wounds resulting from the more commonly seen shearing forces.⁹ Impact injuries with low energy levels may not result in division of the skin; they can, however, disrupt vessels and produce an ecchymosis.

Disruption of vessels in the underlying tissue results in hematoma formation. Some hematomas spontaneously resorb. Those that become encapsulated usually require treatment to prevent permanent subcutaneous deformity. When still gelatinous, a hematoma may be treated by incision and drainage. As further liquefaction occurs, aspiration with a large-bore needle (18-gauge or larger) may be possible.

Adequate wound examination should always be conducted under optimal lighting conditions in a field where bleeding has been controlled. cursory examination under

poor lighting conditions or when the depths of the wound are obscured by blood will ultimately result in underdetection of embedded foreign bodies and damage to important structures such as tendons, nerves, or arteries. One way to minimize the possibility of missing an injury to a vital structure is to start the wound examination with a careful neurovascular assessment of pulses, motor function, and sensation distal to the laceration. Finger tourniquets may then be used to obtain a bloodless field, but they should not be used for more than 30 to 60 minutes.

The anatomic location of the injury helps to predict the likelihood of infection. In general, the composition of the skin microflora allows subdivision of the body into separate anatomic areas. The first area comprises the torso, upper arms, and legs, in which the density of the bacterial population is low. Moist areas of the body, such as the axillae, perineum, toe webs, and intertriginous areas, harbor millions of bacteria per square centimeter. The exposed anatomic areas of the body constitute the third anatomic region, with a bacterial density in the millions per square centimeter. Organisms are normally sparse on the palms and dorsa of the hands, in the hundreds per square centimeter. The majority of organisms (10,000 to 100,000/cm²) on the hands reside beneath the distal end of the fingernail plate or adjacent to the proximal or lateral fingernail folds. Lacerations of the oral cavity are usually heavily contaminated with facultative species and obligate anaerobes. Obviously, wounds with human or animal fecal contaminants run a high risk of infection despite therapeutic intervention.

Anatomic variation in regional blood flow also plays a role in determining the likelihood of infection. Wounds located on highly vascular areas, such as the face and scalp, are less likely to be infected than are wounds located in less vascular areas.²¹ The increased vascularity of the scalp more than offsets the high bacterial inoculum found in this area. As a result, lacerations of the scalp and face have a very low infection rate regardless of the intensity of cleansing.²²

Wound location also contributes to the cosmetic appearance of the scar by affecting static and dynamic skin tensions (Fig. 95.1). Lacerations over joints are subject to large, dynamic skin tensions and will have a wider scar than will similar lacerations subject to less tension. Wounds that run perpendicular to the lines of minimal skin tension will also be prone to the development of wider and more visible scars.

Figure 95.1. Langer's lines of least skin tension. Lacerations parallel to these lines will have less evident scarring.

Finally, the presence of allergies to local anesthetics, latex, and antibiotics should be determined. The tetanus status of all patients should be assessed, and patients should receive immunization in accordance with current Centers for Disease Control and Prevention recommendations (Table 95.1). Before inspecting the wound, the emergency physician must carefully question the patient regarding the time and mechanism of injury. The amount of time elapsed since the accident has considerable influence on treatment decisions.

	Clean Minor Wounds		All Other Wounds ^a	
	Td	TIG	Td	TIG
History of tetanus immunization				
<3 or uncertain doses	Yes	No	Yes	Yes
≥3 doses				
Last dose within 5 years	No	No	No	No
Last dose within 5–10 years	No	No	Yes	No
Last dose : 10 years	Yes	No	Yes	No

^aFor example, contaminated wounds, puncture wounds, avulsions, burns, crush injuries.
Td, tetanus-diphtheria toxoid; TIG, tetanus immune globulin.

TABLE 95.1. Recommendations for Tetanus Prophylaxis³⁶

EMERGENCY DEPARTMENT MANAGEMENT

Aseptic Technique

Practitioners should probably use sterile gloves for examination and repair of routine lacerations in the ED, despite the fact that their use has not been clearly demonstrated to reduce infection rates. Caps and gowns may be worn to for the protection of the practitioner, although they have not been shown to decrease the development of infection following laceration repair.³³ Likewise, the use of full sterile technique has not been shown to effect a lower infection rate than laceration repair using a surgically clean technique.⁴⁰ Nonetheless, the use of some type of gloves is necessary to comply with universal precautions.

The use of sterile gloves makes common sense, despite the lack of clinical evidence supporting their use. While more costly, use of powder-free gloves may reduce the risk of foreign-body reaction or infection that can theoretically occur from the introduction of talc particles into the wound. While the practice of universal precautions is recommended in all patients, double-gloving is recommended when caring for patients who can transmit serious infections to the health-care provider. Patients who harbor the human immunodeficiency virus or hepatitis are among those for whom the health-care provider may wish to take extra precautions, such as double-gloving.

Latex Allergy

Concerns have been raised about the safety of latex. Absorption of water-soluble proteins through intact mucosa or the surgical wound is believed to elicit an immunoglobulin-E (IgE)-mediated anaphylactic response in sensitive individuals. Severe reactions have resulted in fatalities. Populations that appear to be at increased risk for allergic reactions to latex include patients who have undergone multiple operations, patients with atopic disease, children with spina bifida, and medical personnel with frequent latex exposures.²⁸ Careful screening should identify patients who may be at increased risk for latex hypersensitivity.

Wound Examination

Wound examination should always be conducted under optimal lighting conditions and with bleeding in the field controlled. Wound examination should begin with a neurovascular assessment of pulses, motor function, and sensation distal to the laceration.

Bleeding should be controlled with direct pressure. When lacerations continue to bleed despite reasonable pressure, placement of a sphygmomanometer cuff proximal to the injury, with inflation to a pressure greater than the patient's systolic blood pressure, will help contain bleeding to allow proper examination. Palpation of the bones adjacent to the injured site may detect tenderness, a defect, or instability consistent with an underlying injury. Liberal use of radiography should be used to

detect fractures. Detection of an open fracture will dictate a change from usual management. Carefully evaluate wounds occurring adjacent to a joint for joint violation. This condition requires meticulous cleaning and possibly debridement, usually in the operating room.

Complicated injuries involving most open fractures, joint penetration, flexor tendon injuries, nerve injuries, or arterial injuries are usually treated in the operating room. In most other cases, wound repair will occur in the ED.

The ultimate appearance and function of a scar can be predicted by the static and dynamic skin tensions on the surrounding skin. The static skin tensions are the forces that stretch the skin over the underlying bony framework when the body is motionless. The clinical relevance of these tensions can be ascertained by visualization of the gap between wound edges. The static skin tensions vary between different anatomic body sites. In some regions of the body, static skin tensions possess a directional orientation that has an effect on the ultimate cosmetic outcome (see [Fig. 95.1](#)). The most aesthetically pleasing scar occurs when the long axis of the scar is parallel to the direction of maximal skin tension, because the static skin tensions continually pull on the wound edges even after wound closure. The ultimate width of the scar is proportional to the magnitude of the static skin tensions. This information can be used to help answer the ubiquitous question, "Will I have a scar?"

The magnitude of static skin tension per unit length of wound is also considerably influenced by configuration of the wound. In uneven, jagged-edged wounds, the perimeter of the wound is considerably longer than that of linear incisions. Consequently, the magnitude of static tensions per unit length of a jagged-edged wound is less than that for a straight laceration. Meticulous reapproximation of the jagged edges of the wound yields a narrow scar. When jagged wound edges are converted into smoother edges, the potential benefits of the long wound perimeter are eliminated and a lenticular defect that is considerably wider than the initial wound may result. Knowledge of static tensions might alert the practitioner that certain unfavorable lacerations would benefit from the use of absorbable sutures beneath the surface of the skin. They may help reduce the tendency of the scar to widen as wound remodeling occurs.

Dynamic skin tensions may have considerable impact on the magnitude and extent of scar formation. These changing tensions are caused by a combination of forces that are associated with joint movement or mimetic muscle contraction. The clinical significance of dynamic tensions is particularly apparent in skin of changing dimensions in which elasticity is needed for normal function. In general, a linear scar intersecting the transverse axis of a joint or running perpendicular to the wrinkle lines can result in a serious contracture because the scar does not stretch or recoil like uninjured tissue. The patient should be warned that an unattractive scar may result. An appreciation of the effects of various dynamic tensions can be used to determine the need for absorbable sutures in addition to the nonabsorbable skin closure.

Wound Anesthesia

Most lacerations will require some form of anesthesia prior to wound closure. The administration of anesthesia prior to wound cleansing will enable more vigorous wound cleansing and possibly surgical debridement. All visibly contaminated wounds and wounds that will require anesthesia for closure should receive anesthesia prior to cleansing so that adequate mechanical removal of bacteria, soil, and other debris can be more readily accomplished.

Local Infiltration

The most common form of anesthesia for traumatic injuries is local infiltration. Unfortunately, local anesthesia is painful. In order to reduce the pain associated with local infiltration, several strategies can be employed. The addition of sodium bicarbonate to lidocaine (pK_a , 7.9) in a 1:9 ratio increases the ratio of uncharged to charged ions and results in more rapid diffusion of anesthetic agent into nerve endings. It reduces the pain associated with local infiltration without altering the ability of host defenses to prevent infection.³ The use of warm anesthetic solutions, small needles, slow rates of infiltration, injection through the wound edges in noncontaminated wounds, and pretreatment with topical 1% tetracaine or LET are additional strategies that can be used to decrease the pain of infiltration.^{4,7,23,25,18}

For injection of local anesthesia, use a 27- to 30-gauge needle attached to a 10-mL syringe. The needle should be passed into the subdermal tissue rather than the intradermal tissue because subdermal injections are less painful. Full anesthesia to pinprick is present 5 to 6 minutes after subdermal injection. The local anesthetic agent should be instilled slowly to decrease the pain that accompanies tissue infiltration.²⁵ The needle should be passed through the dermal tissue initially; then the anesthetic agent can be injected as the needle is slowly withdrawn. This technique minimizes distention and pain by providing a potential space for the anesthetic solution. Aspiration of the syringe before injection is recommended to prevent inadvertent intravascular injection.

The two major classes of local anesthetics are the esters and amides ([Table 95.2](#)). Because the amides cause less sensitivity and allergic reactions than the esters, lidocaine and bupivacaine are most commonly used for local anesthesia. These anesthetic agents do not damage tissue defenses, nor do they increase the risk of infection. Both classes of agents are similar with respect to the degree of pain upon subdermal injection, time to onset of anesthesia, and frequency of satisfactory anesthesia. Because the duration of local anesthesia induced by bupivacaine is nearly four times longer than that of lidocaine, bupivacaine (0.25%) should be used when longer durations of anesthesia are desirable ([Table 95.3](#)).

Amides	Esters
Lidocaine	Procaine
Bupivacaine	Cocaine
Etidocaine	Tetracaine
Mepivacaine	Benzocaine
	Chlorprocaine

TABLE 95.2. Classification of Local Anesthetics

Agent	Trade Name	Local Anesthetic Class	Concentration	Usual Sub-Dose	Onset	Duration
Procaine	Novocain	Ester	0.5%-1.0%	7mg/kg	10min	5-6min
Bupivacaine				9mg/kg	15min	30-100min
Lidocaine	Xylocaine	Amide	0.5%-2.0%	4-7mg/kg	15min	1-2h
Bupivacaine				7mg/kg	15min	3-6h
Bupivacaine	Narcaine	Amide	0.25%-0.5%	2mg/kg	15min	4-6h
Bupivacaine				3mg/kg	15min	4-6h

TABLE 95.3. Properties of Commonly Used Local Anesthetics

Vasoconstrictors such as epinephrine can be used as adjuncts to the local anesthetic agents. They will reduce bleeding and oozing within the laceration, which will make exploration and closure easier to accomplish. Clinical studies have not found that the vasoconstriction associated with epinephrine use results in differences in

infection rates. The use of vasoconstrictors is generally discouraged in areas with end-organ blood supply, such as the fingers and toes.

Although patients may state that they have had an allergic reaction to local anesthetic agents in the past, careful review of this reaction will usually indicate the presence of either a vasovagal response associated with painful injection or evidence of minor toxicity from the anesthetic agent.²³ Rarely, patients may report a true allergy to one of the local anesthetics. Because there is little cross-reactivity between agents of the two classes, use of an agent from the other class should be considered (see [Table 95.2](#)). Some patients with “allergies” to lidocaine are really allergic to methylparaben, the preservative used in multidose vials. This preservative is similar in molecular structure to one of the ester anesthetic degradation products. As a result, the use of an ester in place of an amide may be problematic. Cardiac lidocaine is a single-use preparation that does not contain this preservative. As such, it represents a therapeutic alternative. Another option is to use an anesthetic agent unrelated to the “caines,” such as diphenhydramine or benzyl alcohol.^{5,14} Diphenhydramine is an effective local anesthetic, but its infiltration is more painful than with lidocaine. If diphenhydramine is used, it must be diluted to 1% in order to avoid risk of tissue necrosis. Benzyl alcohol is as effective as lidocaine and is less painful to inject than diphenhydramine.

Regional Anesthesia

When the nerve supply to a wound is easily accessible, a regional nerve block is a valuable alternative to local anesthesia. The use of regional nerve blocks will prevent distortion of the wound edges, facilitating approximation and increasing the likelihood of an excellent cosmetic result. Additionally, it is more useful than local anesthesia in areas with abundant sensory nerve supplies, such as the fingers, palms, and soles. Regional nerve blocks can be accomplished by only one or two needle passages through skin proximal to the injury site. Often these areas have a considerably higher threshold of pain. Regional nerve blocks of the supraorbital, infraorbital, and mental nerves are useful for facial lacerations. Median, radial, and ulnar nerve blocks may be useful for lacerations of the hand. Digital or metacarpal nerve blocks can be used for finger lacerations. Regional nerve blocks can also be used for lacerations of the feet. Field blocks can be considered for more proximal extremity injuries.

A 27- or 25-gauge needle is preferred to a 30-gauge needle for a regional nerve block, because either one is more resistant to deflection during passage through tissue. The duration of sensory analgesia can be significantly prolonged when epinephrine (1%) is added to the anesthetic solution. When the needle puncture site is the mucous membrane, anesthetizing the mucous membrane with a topical anesthetic agent makes the introduction of the needle painless.

Topical Anesthesia

Topical anesthesia eliminates needle use and the risk of inadvertent needle sticks while allowing the application of painless anesthesia. A combination of tetracaine, adrenaline, and cocaine (TAC) is an effective topical anesthetic in children and on the face and scalp.¹⁹ However, improper use can result in serious adverse events (e.g., seizures and death).^{19,36} Better alternatives include various combinations of lidocaine (1% to 4%), adrenaline (1:1,000 to 1:2,000), and tetracaine (0.5% to 2.0%).^{17,18} EMLA cream (eutectic mixture of local anesthetics) can be used to decrease the pain associated with local infiltration, but it takes more than 30 minutes to develop significant anesthesia. Novel methods for enhancing the topical absorption of local anesthetics, such as iontophoresis and sonophoresis, are currently being studied. Their role has not yet been defined.

Preparation of Skin

Removal of the hair surrounding a laceration may facilitate meticulous wound closure. Because many bacteria normally reside in hair follicles, shaving the hair prior to repair may increase wound infection rates.³⁴ Reduced damage to hair follicles may be achieved by using hair clippers instead of a razor. Removal of the eyebrow hair should be avoided because it does not always grow back. Additionally, the presence of hair serves as a guide to approximation of wound edges during laceration repair.

The skin surrounding the wound should be disinfected; avoid contacting the wound itself with disinfectant. The ideal agent for disinfection must be a safe, fast-acting, broad-spectrum antimicrobial preparation that significantly reduces the number of microorganisms on intact skin, usually after a single application. Two groups of antiseptic agents, containing either an iodophor or chlorhexidine, may be used for preparation of the intact skin around the wound. Both agents have a long shelf life and no significant inactivation. Both exhibit a substantive effect on the skin microflora, suppressing the proliferation of a broad spectrum of microorganisms. Although these agents can reduce the bacterial concentration on intact skin, they appear to damage wound defenses, making it more susceptible to development of infection. Consequently, any contact of these agents with the wound should be avoided. Also take care to avoid antiseptic contact with the eyes.

Debridement

Appropriate debridement is an important factor in the management of contaminated wounds.²⁰ Retained devitalized soft tissue, fat, muscle, and skin can damage wound defenses and increase the likelihood of infection through the promotion of bacterial growth and the inhibition of phagocytosis. Identification of the exact limit of devitalized tissue in wounds may be difficult. Evaluation of the color, consistency, contraction, and circulation is useful.

In some anatomic sites, such as the trunk, debridement is best accomplished by complete excision of the skin and deep tissues. Heavily contaminated wounds with serpiginous defects in these regions can be converted to clean wounds by more generous tissue excision. When a heavily contaminated wound contains specialized tissues, such as the nerves for tendons, that perform important physical functions, complete excision often is not feasible. In such instances, mechanical wound cleansing followed by excision of all fragments of tissue that are not clearly viable is indicated.

The benefits of debridement must be weighed against the consequences of excision of the tissue. Debridement of skin and underlying tissue leaves a significant soft-tissue defect that makes reapproximation more difficult. The increased static skin tensions produced may result in a wider scar. In some cases, debridement may be best performed in the operating room, where sterile conditions, lighting, and assistants may offer an advantage.

Cleansing the Wound

Using Mechanical Forces

Mechanical forces are typically used to cleanse the wound of bacteria and other particulate matter retained on the wound surface by adhesive forces. For such forces to be successful, they must exceed the adhesive forces of the contaminant. The two basic methods of wound cleansing are hydraulic forces (irrigation) and direct contact (scrubbing).

Irrigation. Some debate exists over both the optimal method of irrigation and the preferred solution. The efficacy of wound irrigation can be correlated with the pressure at which the irrigant is delivered to the wound.¹⁶ In irrigation, the hydraulic forces of the irrigating stream act on particulate matter in the wound. The magnitude of the hydraulic force is a function of the relative velocities and the configuration of the particle. When subjected to the same velocity of irrigating stream, particles with a smaller frontal surface area experience less force than particles with a similar configuration but with a greater surface area. Consequently, it takes significantly less hydraulic pressure to rid the wound of large foreign bodies than it does to remove bacteria.

In an experimental model involving a contaminated animal wound, high-pressure irrigation was more effective than low-pressure irrigation in reducing both bacterial wound counts and wound infection rates.³⁸ High-pressure irrigation successfully cleans wounds of small particulate matter, such as bacteria and soil. Such cleansing has reduced the infection rate of experimentally contaminated wounds. In contrast, low-pressure syringe irrigation, even with large volumes of fluid, demonstrates negligible capability for removing small particles (bacteria), but removes large particulate matter, such as detached devitalized tissue.

Wound impact pressures of more than 8 psi can be easily obtained using a 30- to 60-mL syringe and a 19-gauge needle³⁸ or Zerowet splash shield. However, it must be noted that sustained high-pressure irrigation can result in tissue damage. As a result, at very high pressures, infection rates actually increase.¹⁶ Thus, the optimal irrigation pressure lies somewhere in between.

For individual wounds, the benefits of high-pressure irrigation should be weighed against the potential risks. Thus, for noncontaminated wounds in highly vascularized areas containing loose areolar tissue, such as the eyelid, high pressures should be avoided. In fact, high-pressure irrigation has not been found to offer any advantages for cleansing clean, noncontaminated facial lacerations. Infection rates and cosmetic appearance at the time of suture removal demonstrated comparable

results when facial wounds were repaired with and without prior irrigation.²² Conversely, high-pressure irrigation is clearly indicated for contaminated wounds of the lower extremity.

The choice of irrigation solution is relatively straightforward. Normal saline is the most cost-effective and readily available choice. It has compared favorably with more expensive, less easily available alternatives.¹³ Because of their tissue toxicity, detergents, hydrogen peroxide, and concentrated forms of povidone-iodine should not be used to irrigate wounds.¹⁶ Irrigation volume should be individualized based on patient and wound characteristics such as location and etiology. Use of a device designed to reduce splatter will minimize the health-care provider's risk of exposure to potentially infectious materials.

Scrubbing. Direct scrubbing of the wound with a sterile surgical brush helps remove both bacteria and particulate matter, which potentiate the risk of wound infection. However, scrubbing also contributes to the tissue damage and reduces the ability of the wound to resist infection. The magnitude of the damage to the local tissue resistance is correlated with the porosity of the sponge. Sponges with a low porosity (45 pores per inch [ppi]) are more abrasive and exert more damage to the wound than do sponges with a higher porosity (90 ppi). The addition of a nontoxic surfactant to a sponge minimizes the tissue damage it inflicts while maintaining the bacterial removal efficiency of mechanical cleansing. Because the use of high-porosity sponges and surfactant adds to the cost of wound care, their use is probably justified only for highly contaminated wounds.

Use of Drains

The potential benefits of the use of surgical drainage in a clinical setting must be weighed against its harmful effects. Drainage evacuates potentially harmful collections of pus and blood from wounds. When no definite localized fluid exists, drainage must be considered prophylactic, and its potentially harmful effects become more important. Drains act as retrograde conduits through which skin contaminants gain entrance into the wound. Placement of both Silastic and Penrose drains within experimental wounds exposed to subinfective inoculations of bacteria greatly enhanced the rate of infection compared with that observed in undrained controls.²⁶

Open Wound Management

After wound cleansing, the physical integrity and function of the injured tissue must be restored. The technique of wound closure largely depends on whether the wound has lost tissue. If not, primary closure usually can be accomplished. For wounds with associated significant tissue loss, grafts or flaps are often required to close the defect. These procedures are usually performed in the operating room. They are relatively infrequent occurrences in the ED.

The timing of laceration closure is critical. Most wounds should be closed primarily in order to reduce patient discomfort and speed healing. While there is a direct relationship between the time interval from injury to laceration closure and the risk of subsequent infection, the length of this "golden period" is highly variable.³⁶ A study of forearm lacerations found that closure within 4 hours had a lower infection rate than later closure.²⁹ A large series of pediatric patients (2,834 patients) with lacerations did not find a difference in infection rate for lacerations closed within or greater than 6 hours from the time of injury.² Facial lacerations healed well regardless of the time to closure. In contrast, trunk and extremity lacerations exhibited lower rates of healing if they were closed more than 19 hours from the time of injury (63% to 75%) as compared to earlier (75% to 91%).⁶

On the basis of these data, it seems appropriate to consider each individual laceration separately, taking the time from injury until presentation into account, along with laceration location, degree of contamination, risk of infection, and importance of cosmetic appearance, before deciding whether to perform primary wound closure. For example, a 19-hour-old laceration on the face of a healthy 5-year-old child may be closed primarily, while a deep laceration from a puncture in the dirty foot of a diabetic patient will be at very high risk of infection and should not be closed primarily. Thus, the timing during which wound closure is deemed safe must be individualized.³⁶ Wounds that are not closed primarily due to a high risk of infection should be considered for delayed primary closure after 3 to 5 days, when the risk of infection decreases.

Wound Closure

The ideal wound closure technique should allow a meticulous closure, be accomplished rapidly with ease, be painless, pose a low risk to the health-care provider, be inexpensive, result in minimal scarring, and involve a low infection rate. The optimal wound closure technique varies with the clinical situation. Sutures are the most commonly employed wound-closure technique. Tissue adhesives can be used in up to one-third of ED laceration repairs.³² Staples and surgical tapes can be used in selected situations. The advantages and disadvantages of various wound-closure techniques are summarized in [Table 95.4](#).

	Advantages	Disadvantages
Sutures	Time honored Meticulous closure Greatest tensile strength Lowest dehiscence rate	Requires removal Requires anesthesia Greatest tissue reactivity Highest cost
Staples	Rapid application Low tissue reactivity Low cost	Less meticulous closure May interfere with some older generation imaging techniques (CT, MRI)
Tissue adhesives	Rapid application Patient comfort Resistant to bacterial growth No need for removal Low cost	Lower tensile strength than sutures Dehiscence over high-tension areas (joints) Not useful on hands Cannot bathe or swim
Surgical tapes	No risk of needlestick Least expensive Rapid application Patient comfort Low cost No risk of needlestick	Frequently falls off Lower tensile strength than sutures Highest rate of dehiscence Requires use of thick subjects Cannot be used on areas of hair Cannot get wet

TABLE 95.4. Advantages and Disadvantages of the Common Wound-Closure Techniques

Sutures

The choice of suture technique should be determined by the configuration and biomechanical properties of the wound, in combination with an assessment of its risk of infection. Percutaneous sutures pass through the epidermal and dermal layers of the skin. They are used alone for low-tension lacerations and in combination with dermal (subcuticular) sutures for higher tension lacerations. The dermal suture reapproximates the divided edges of the dermis without penetrating the epidermis. Often, dermal and percutaneous sutures are used together.

Most often, percutaneous sutures are performed with nonabsorbable sutures ([Table 95.5](#)), such as nylon and polypropylene. Both nylon and polypropylene retain most of their tensile strength for more than 60 days and are relatively nonreactive.³⁶ Removal of nonabsorbable sutures is required. Percutaneous sutures of either monofilament nylon or polypropylene exert the least damage to the wound defenses. Polybutester suture has greater elasticity than other sutures, allowing the suture to return to its original length once tension is removed. Polybutester sutures are useful when sutures are subject to wound edema and may be expected to stretch. Nylon, polypropylene, and silk resist extension under low forces, thereby lacerating encircled tissue and creating unsightly marks on the skin.

Suture	Knot Security	Tensile Strength	Tissue Reactivity	Workability
Nylon (Ethilon)	Good	Good	Minimal	Good
Polypropylene (Prolene)	Least	Best	Least	Fair
Silk	Best	Least	Most	Best

TABLE 95.5. Characteristics of Nonabsorbable Sutures

Nonabsorbable sutures made from natural fibers potentiate infection more than synthetic nonabsorbable sutures, correlating with the reaction of tissue to these sutures in clean wounds. The use of silk and cotton should be avoided in wounds that have significant bacterial contamination. The incidence of infection in contaminated tissue containing monofilament sutures is lower than in those containing multifilament sutures. Although use of absorbable sutures is generally reserved for dermal closures, more rapidly absorbing forms can be used to close skin in children and avoid the discomfort and inconvenience of suture removal.

Dermal closures are generally accomplished with absorbable sutures ([Table 95.6](#)). They increase the duration of time the wound retains 50% of its tensile strength from 1 week until as many as 8 weeks. Chromic gut lasts for up to 2 weeks, but it is associated with increased tissue reactivity. Polyglactin (Vicryl) and polyglycolic acid (Dexon) maintain tensile strength for 20 to 28 days and have less tissue reactivity. Some synthetic absorbable sutures, such as polydioxanone (PDS) and polyglyconate (Maxon), retain their tensile strength for as long as 2 months. They are particularly useful in areas with high static and dynamic tensions. These sutures should be used only in the deeper areas, because they can become extruded after long periods of time.

Suture	Knot Security	Tensile Strength	Wound Security (60% Tensile Strength)	Tissue Reactivity
Surgical gut	Poor	Fair	5-7 d	Most
Chromic gut	Fair	Fair	10-14 d	Most
Polyglactin (Vicryl)	Good	Good	30 d	Minimal
Polyglycolic acid (Dexon)	Best	Good	30 d	Minimal
Polydioxanone (PDS)	Fair	Best	45-60 d	Least
Polyglyconate (Maxon)	Fair	Best	45-60 d	Least

TABLE 95.6. Characteristics of Absorbable Sutures

The use of dermal sutures relieves skin tension, decreases dead space and hematoma formation, and, theoretically, should improve cosmetic outcome. Research in experimental animal models has found that deep sutures increase the risk of infection in highly contaminated wounds, but they do not do so in clean, noncontaminated lacerations.^{1,27} Sutures placed through adipose tissue do not reduce tension and they increase the infection rate. Deep sutures should not be placed in adipose tissue and should not be used in contaminated wounds.¹²

Undermining the wound margin decreases the forces required for wound closure. Theoretically, it should limit the width of the ultimate scar. However, this benefit must be weighed against its potential damage to the skin blood supply, which may limit the patient's defenses, increasing the likelihood of infection. Consequently, undermining should be reserved for clean, noncontaminated wounds subjected to strong static and dynamic tensions.

The magnitude of the suture's damage to the local tissue defenses is related to the quantity of the suture within the wound. As a result, the narrowest diameter suture (50 or 60) that is strong enough to resist disruption of the skin should be used ([Table 95.7](#)). Approximation of the midportion of the laceration first, with subsequent bisection of the remaining portion, will enable the use of least amount of suture. Interrupted dermal sutures placed in each quadrant of the wound subjected to strong static and dynamic skin tensions provide sufficient strength to permit early suture removal.

Location	Suture Size ^a
Face	6-0 or 7-0
Scalp	5-0
Chest	3-0 or 4-0
Back	3-0 or 4-0
Forearm	4-0 or 5-0
Fingers	4-0 or 5-0
Hand	4-0 or 5-0
Lower extremity	4-0 or 5-0
Foot	4-0 or 5-0

^aLarger suture sizes may need to be used for wounds with higher tension.

TABLE 95.7. Suture Selection Based on Anatomic Location

Tissue Adhesives

Tissue adhesives are cyanoacrylate polymers. Shorter alkyl chain molecules (methyl, ethyl) are more reactive and have greater histotoxicity and weaker tissue binding than longer alkyl chain cyanoacrylates. In large quantities, the shorter chain molecules result in tissue toxicity. The *n*-butyl-cyanoacrylates are less toxic than shorter chain cyanoacrylates and maintain a stronger bond. 2-Octylcyanoacrylate (Dermabond) is even more stable, has greater flexibility, and maintains a stronger bond. It has a breaking strength three to four times greater than the butylcyanoacrylates, and degrades much more slowly. It is considered nontoxic.

Observational studies of children with small scalp, face, or limb lacerations treated with Histoacryl Blue (Braun, Germany), a butyl-2-cyanoacrylate, found low infection rates (less than 2%) and low dehiscence rates (0.6% to 1.8%). Histoacryl Blue results in similar long-term cosmetic outcomes to 5-0 or 6-0 sutures when used for repair of small facial lacerations.^{32,41}

Several clinical studies have compared the use of 2-octylcyanoacrylate to 5-0 and 6-0 sutures. Quinn et al.⁴² found the long-term cosmetic outcomes to be equivalent. The use of 2-octylcyanoacrylate was faster and less painful than the use of sutures. The clinical trial that led to Food and Drug Administration approval of Dermabond enrolled 818 patients from a variety of office-based and ED sites. Patients were randomized to receive skin closure with either 5-0 or 6-0 sutures or

2-octylcyanoacrylate. Of the 818 patients enrolled, 333 had subcuticular or subcutaneous sutures placed prior to laceration closure.

Comparing the group of patients who received 2-octylcyanoacrylate with the group of patients who received skin closure with sutures, the 3-month cosmetic outcomes, short-term infection rates, and wound dehiscence rates were all similar. Again, the time to wound closure was reduced by more than 50% in the group treated with 2-octylcyanoacrylate. Results of the study in the ED patient subpopulation were analogous to the findings of the group as a whole.³⁷ Likewise, subgroup analysis of patients from the pediatric ED found equivalent 3-month cosmetic outcomes.⁸ The use of octylcyanoacrylates for skin closure following elective facial plastic surgical procedures produced better long-term results than did the use of sutures.³⁹

Although *in vitro* and *in vivo* studies have found that cyanoacrylate tissue adhesives possess gram-positive antimicrobial properties, it is imperative that clinicians adhere to standard wound preparation and wound-cleansing procedures. When tissue adhesives have been used without anesthesia, and wound cleansing is not performed in a thorough manner, an increased rate of wound infections has been observed.

The application of tissue adhesives is rapid and relatively painless. Adhesives also have the advantage that they do not require later removal, as do sutures. They will usually slough off in 7 to 10 days as the keratinized layer of epithelium sloughs. They should be used only topically. Tissue adhesives should not be placed within the wound or between wound margins. Octylcyanoacrylate tissue adhesives provide greater three-dimensional tensile strength than do butylcyanoacrylates. Both polymers are a needleless alternative to sutures for the closure of most facial lacerations, providing an excellent cosmetic appearance, comparable to that provided by sutures.

2-Octylcyanoacrylate is packaged in a sterile, single-use ampule and is colored with violet dye. After the inner glass portion of the ampule is manually crushed, the polymerization process begins. The adhesive should be painted on top of the skin as the laceration edges are manually approximated. If lacerations cannot be manually approximated and the skin edges cannot be held together without tension, the use of tissue adhesives is inappropriate. When 2-octylcyanoacrylate is painted on the laceration, the clinician should apply at least three to four coats to provide adequate strength to the wound closure. Take care to avoid applying too much tissue adhesive, because polymerization is associated with an exothermic reaction (heat release). Increased rates and amounts of polymerization may be associated with the perception of increased heat sensation by the patient.

2-Octylcyanoacrylates can be used in locations that could otherwise be closed with 5-0 or 6-0 nonabsorbable sutures. 2-Octylcyanoacrylates should be used in higher-tension areas only if subcutaneous or subcuticular absorbable sutures are placed to relieve tension on the skin. They should not be used over high-tension areas or areas with repetitive movement, such as joints. When tissue adhesive application leads to a suboptimal wound closure, antibiotic ointment, petroleum jelly, or bathing can be used to accelerate removal. Acetone can be used when more rapid removal is necessary.

The butylcyanoacrylates possess less tensile strength than 5-0 sutures and only approximately one-third the tensile strength of the octylcyanoacrylates.³⁶ They are not currently available in the United States, although clinical trials are ongoing. Studies have found that for the repair of very small facial lacerations, the butylcyanoacrylates are equivalent to 5-0 and 6-0 sutures or octylcyanoacrylates. They are packaged in nonsterile, multiuse vials and are applied in beads across the laceration. In general, the butylcyanoacrylates are more brittle and friable than octylcyanoacrylates and do not allow the same degree of movement and flexibility of the skin.

When 2-octylcyanoacrylate is used, take care to avoid picking or scrubbing of the area. For patients on whose skin tissue adhesives remain for prolonged periods, antibiotic ointment, petroleum jelly, or bathing may accelerate removal.

Staples

Staples can be applied more rapidly than sutures. Staples are associated with a lower rate of foreign-body reaction and a lower infection rate.³⁰ In general, staples are considered particularly useful for scalp, trunk, and extremity wounds.³⁶ They can also be used when time is limited, such as in situations of mass casualties or multiple trauma.³⁶ On the other hand, they do not allow as meticulous a skin closure as sutures, and their use is limited when cosmetic appearance is of utmost importance. They are slightly more painful to remove than sutures. In experimental animal models, staples have shown lower rates of bacterial growth and lower infection rates than sutures,²⁴ although these effects appear to have limited clinical significance.

Adhesive Tapes

The ideal adhesive tape should have the following performance characteristics.³¹ It should be strong enough, even when wet, to withstand the forces disrupting the wound. Its adhesive should be sufficiently aggressive to securely adhere to the skin and maintain approximation of the wound edges. Although a secure bond to skin is necessary for wound security, it also appears to be beneficial for the tape to stretch slightly under constant stress. This ability to elongate under moderate loads reduces the shear forces on the underlying edematous skin, thereby preventing blister formation. The tape construction should provide an environment on the skin surface that is resistant to bacterial growth.

The ease with which wounds can be closed by tape varies according to the anatomic and biomechanical properties of the wound site. Linear wounds in skin subjected to minimal static and dynamic tensions are easily approximated by tape. The relatively lax skin of the face and abdomen is amenable to wound closure by tape. With tape closures, patients are spared the discomfort of suture removal and the development of suture puncture scars. An additional benefit of this technique is that patients need not be subjected to the painful injection of the local anesthetic agent required for suturing.

Surgical tapes are intrinsically less reactive than staples.²⁴ However, adhesive tapes require the use of adhesive adjuncts (e.g., tincture of benzoin), which are tissue toxic and increase local induration and wound infection rates. Adhesive adjuncts are toxic to wounds, and care should be taken so that they do not enter the wound. Although the various surgical tapes have different degrees of adhesion, porosity, breaking strength, and elasticity,³¹ tapes alone will not maintain wound integrity in areas subject to tension.³⁶ They are seldom recommended for primary wound closure in the ED, but are often used after suture removal to decrease tension on the wound until they fall off.

Postoperative Wound Care

Postoperative wound care should optimize healing. It must be tailored to both the type of wound and method of wound closure. Sutured or stapled lacerations should be covered with a protective nonadherent dressing for 24 to 48 hours until enough epithelization takes place to protect the wound from gross contamination. Maintenance of a moist wound environment increases the rate of reepithelization. Additionally, pressure dressings minimize the accumulation of the intercellular fluid dead space. When possible, the site of injury should be elevated above the patient's heart to limit the accumulation of fluid in the wound interstitial spaces. The wound with little edema heals more rapidly than one with marked edema.

Topical antibiotic ointments may help reduce infection rates and prevent scab formation. Although white petrolatum may be as effective as bacitracin in ambulatory surgery patients, topical antibiotics result in lower infection rates than white petrolatum in traumatic lacerations.¹⁵ Patients whose lacerations are closed with tissue adhesives should not have topical ointments applied. They will loosen the adhesive and result in dehiscence.

Prophylactic antibiotic administration should not be used as a regular adjunct to wound care. Several studies and a metaanalysis have found no benefit to prophylactic antibiotics for routine laceration repair.¹¹ Use of antibiotics should be individualized on the basis of the degree of bacterial contamination, the presence of infection-potentiating factors (e.g., soil), the mechanism of injury, and presence or absence of host predisposition to infection. In general, decontamination is far more important than antibiotics. Antibiotics should be used in most human, dog, and cat bites; intraoral lacerations; open fractures; and exposed joints or tendons.³⁶ Additionally, patients with soft-tissue lacerations who are prone to the development of infective endocarditis, patients with prosthetic joints and other permanent "hardware," and patients with lymphedema should receive antimicrobial therapy. Intravenous antibiotics should be given prior to wound care in patients at high risk for systemic complications of infected soft-tissue injuries.

Sutured or stapled wounds should be kept clean and gently cleansed after 24 to 48 hours. Patients with tissue adhesives may shower, but they should avoid bathing and swimming: Prolonged moisture will loosen the adhesive bond. Gentle blotting should be used to dry the area, as wiping could result in dehiscence. Elevation of the injured area decreases edema formation. Splinting may prove helpful in areas subject to high tension (e.g., in lacerations across joints). Patients should be instructed to observe the wound for erythema, warmth, swelling, and drainage, as these findings may indicate infection. Use of standardized wound-care instructions

improves patient compliance and understanding.

Sutures or staples in most locations should be removed after approximately 7 days ([Table 95.8](#)). Facial sutures should be removed sooner (within 3 to 5 days) to avoid the formation of unsightly sinus tracts. Sutures subject to high tension (e.g., in joints, hands) should be left in for 10 to 14 days. When 2-octylcyanoacrylate is used, take care to avoid picking or scrubbing the area or exposure to water for more than brief periods until the previously noted times. When tissue adhesives remain on the skin for prolonged periods, antibiotic ointment, petroleum jelly, or bathing can accelerate removal. Acetone can be used when more rapid removal is required. Patients should be told when and with whom to follow up for suture removal or wound examinations.

Location	No. of Days
Face	3-5
Scalp	7
Chest	8-10
Back	10-14
Forearm	10-14
Fingers	8-10
Hand	8-10
Lower extremity	8-12
Foot	10-12

TABLE 95.8. Optimal Time from Placement of Sutures until Suture Removal

Abraded skin may develop permanent hyperpigmentation after exposure to the sun.³⁵ Consequently, abraded skin should be protected with a sun-blocking agent for at least 6 to 12 months after injury.

Prevention of Tetanus

Two-thirds of the recent tetanus cases in the United States have followed lacerations, puncture wounds, and crush injuries. For every wounded patient, information about the mechanism of injury, the characteristics of the wound and its age, previous active immunization status, history of a neurologic or severe hypersensitivity reaction after a previous immunization treatment, and plans for follow-up should be recorded in a permanent medical record.

Proper immunization plays the most important role in tetanus prophylaxis. Recommendations on tetanus prophylaxis are based on the condition of the wound and the patient's immunization history. A summary guide to tetanus prophylaxis of the wounded patient, as recommended by the CDC, is outlined in [Table 95.1](#). As noted, passive immunization with TIG is indicated only under specific conditions.

The only contraindication to tetanus and diphtheria toxoids is a history of neurologic or severe hypersensitivity reaction after a previous dose. Local side effects do not preclude repeated use. Local reactions, generally erythema and induration with or without tenderness, are common after the administration of vaccines containing diphtheria, tetanus, and pertussis antigens. These reactions are usually self-limited and require no therapy. If a systemic reaction is suspected to represent allergic hypersensitivity, immunization should be postponed until appropriate skin testing is undertaken. If the use of a tetanus toxoid is contraindicated, passive immunization against tetanus should be considered in a tetanus-prone wound. In those patients who have not completed a primary tetanus immunization series, appropriate follow-up should include referral to a physician who can complete active immunization.

DISPOSITION

Role of the Consultant

The appropriate surgical specialist should be consulted for patients with open fractures of long bones, nerve or vascular injuries, flexor tendon disruptions, repair of specialized structures such as the parotid or lacrimal duct, replacement of skin loss by a flap or graft, or extensive debridement.

Indications for Admission

Few patients with lacerations will require admission to the hospital. Even those patients requiring surgical intervention can often be discharged with appropriate follow-up arrangements. Often, definitive repair can be accomplished via same-day surgery.

Transfer Considerations

If the initial receiving hospital does not have the appropriate emergency or surgical specialist, transfer is necessary. The patient should be transferred in the most expeditious manner possible.

COMMON PITFALLS

- Failure to detect sensory, motor, and vascular complications or injuries to specialized tissues
- Failure to detect and remove foreign bodies
- Vasoconstrictors in anesthetic agents should not be used in areas with terminal end-arteriole blood supply.
- Removal of hair by a razor may increase the infection rate.
- Antiseptic agents should not contact the wound.
- Drain placement should not be used as a replacement for meticulous hemostasis, but should be reserved for removal of harmful collections of fluid.
- Tetanus toxoid adsorbed should not be administered indiscriminately to all patients with traumatic wounds, but should be considered part of the recommended tetanus prophylaxis regimens for the patient with traumatic wounds.
- The use of tissue adhesives should not preclude appropriate cleansing and exploration.
- Tissue adhesives should not be used in high-tension wounds or over joints.
- Not understanding the different indications for the use of butyl- and cyanoacrylate tissue adhesives.

APPENDIX

BALLISTICS

A collision between a missile and the human body represents a considerably higher level of energy absorption per unit volume of tissue than that encountered in an automobile accident. As tissues are struck by a missile, a combination of shear, tensile, and compressive forces interact to produce a relatively reproducible amount of destruction.²⁴ The two mechanisms of tissue disruption caused by a penetrating missile are the permanent and the temporary cavities. The penetrating missile or fragment destroys tissue by crushing it during penetration and punching a hole through the tissue. This hole, or missile track, is the permanent cavity. The cross-sectional area of the missile track is similar to the presenting area of the missile, and its dimensions are comparable for all soft tissues tested.

After passage of the missile, the walls of the permanent cavity are stretched outward radially. The maximum lateral tissue displacement delineates the temporary cavity. Tissue stretch is responsible for the damage of temporary cavitation. The resistance of tissue to stretch depends on tissue elasticity. The same stretch that causes moderate contusion and functional changes in relatively elastic muscle, skin, lung, and bowel wall can cause catastrophic disruption of the liver, heart, and

brain. Muscle, skin, lung, and bowel wall are flexible and elastic, having the physical characteristics of good energy absorbers.

These permanent and temporary cavities are the sole wounding mechanisms of missiles. The sonic shock wave generated by supersonic missiles does not cause either tissue displacement or detectable damage. In general, based on missile velocity in projectile–tissue interactions, there are a minimum of five variables: projectile mass, projectile shape, projectile construction, projectile fragmentation, and target tissue type. Projectile fragmentation can greatly enhance the effects of the temporary cavity by providing points of weakness on which the stretching effects of cavitation are focused, rather than being absorbed evenly by the tissue mass. A muscle, which tolerates a temporary cavity stretch from a nonfragmenting bullet with little gross disruption, is severely damaged when the stretch follows its penetration by a fragmenting bullet.

Firearms include two basic types: rifled firearms and shotguns. A rifled firearm (pistol and rifle) has spiral grooves in its barrel and discharges hot gases, soot, powder grains, and bullet. Rifled bullets are rotated around their long axes by the rifling of the barrel to give them a sufficient gyroscopic stability to maintain the point-forward position while traveling through air. Bullets fired from a properly designed rifle barrel yaw (the yaw angle is the angle between the long axis of the bullet and the line of flight) no more than a few degrees during flight. However, this gyroscopic rotation may be insufficient to stabilize bullet point-forward travel in tissue; the development of bullet yaw in tissue can be an important determinant of injury.

Most handgun projectiles strike tissue at a speed less than 274 m/s. At this velocity, the predominant mechanism of tissue injury is the permanent cavity. There is some temporary cavitation, but tissue displacement is so small that there is no clinically detectable damage. Bullet shape, construction, and yaw make little difference at this velocity.

Rifle bullets are available in nonexpanding and expanding types. The nonexpanding rifle bullets are designed primarily for military use and strike tissue at speeds between 610 and 914 m/s. No deformation of the bullet occurs unless bone is struck. Nonexpanding bullets make a 180-degree rotation around their short axes (yaw) and terminate by traveling in a base-forward position. The distance traveled by a particular bullet in tissue before it begins rotation around its short axis is a relatively constant characteristic. The increase in size of the permanent cavity caused by the yawing bullet is determined by how much tissue the bullet strikes while traveling sideways. As the bullet yaws, there is also a marked increase in the temporary cavitation.

Most bullets of the expanding variety (soft-point or hollow-point) that are used for hunting are designed to deform on striking the tissue. They produce a marked increase in the size of the permanent cavity that occurs at a shallower depth. The expanding bullet also causes a large temporary cavity for the same reason that the yawing bullet does. For expanding bullets striking at more than 762 m/s, bullet fragmentation causes the major part of the permanent tissue destruction. As pieces of the bullet break off, they are flung radially outward by the centrifugal force of bullet rotation. Each fragment crushes its own path through tissue, ending up as far as 8 cm from the original path. This tissue, perforated a number of times, is stretched by temporary cavitation. The synergy between fragmentation and the temporary cavity causes massive tissue destruction.

Shotguns differ from rifles and pistols in that they have a smooth barrel that discharges hot gases, wad, and either multiple projectiles or a single projectile (rifled slug). Shot charges containing multiple projectiles spread out from the muzzle in a conelike pattern. The distance from the muzzle of the shotgun to the point of impact of the projectiles is a key determinant of the magnitude of injury. At short range (less than 6 m), the shot charge containing multiple projectiles results predominantly in a single-hole inshoot wound (diameter of less than or equal to 6 cm) that communicates with a deep underlying wound with massive tissue destruction. At this short range, soft-tissue impact deforms the individual pellets, increasing their original cross section with a concomitant increase in tissue crush or hole size. The multiple pellets result in severe disruption between the multiple wound channels. A gradual decrease in the amount of pellet deformation and tissue destruction occurs as the distance of the impact range increases. When the impact range exceeds 7 m, the multiple projectiles result in numerous discrete wounds that are not associated with underlying massive tissue destruction.

Shotguns also can discharge rifled slugs that are designed for killing larger animals. The muzzle velocity of rifled slugs (487 m/s) is approximately half that of nonexpanding, fully jacketed rifle projectiles. The rifled slug does not hold the point orientation that it has as it is propelled from the muzzle of the gun, but drifts toward a sideways orientation as it moves toward the target. The rifled slugs experience a 25% decrease in velocity as the impact range increases from 5 to 45 m. At short range (less than or equal to 45 m), the slug deforms on striking the tissue, thereby enhancing the size of the permanent and temporary cavities.

ACKNOWLEDGMENT

Dr. Richard Edlich is acknowledged for his excellent contribution to *The Clinical Practice of Emergency Medicine*, Second Edition.

Data from the National Institute of Neurologic Disorders and Stroke estimate that there are 2,000,000 cases of traumatic brain injury (TBI) in the United States per year, with approximately 500,000 patients requiring hospitalization. There are many more patients who do not seek any medical attention after mild head trauma. A review of U.S. mortality data reveals that head injury is responsible for 26% of trauma-related deaths. TBI deaths are bimodal, with a peak in the 15- to 24-year age group due to motor vehicle collisions and a second peak due mostly to falls in the 75 year and older group.¹⁵ The economic impact of head injury in the United States is estimated to exceed \$25 billion annually.¹⁵

The nature of crucial interventions in the emergency department (ED) depends on the severity of the head injury. In patients with a moderate TBI (Glasgow Coma Scale [GCS] score of 9 to 12) ([Table 96.1](#)) and a severe TBI (GCS less than or equal to 8), the goal is to adequately resuscitate the patient to prevent further brain injury. In patients with mild head trauma (GCS 13 to 15), the initial challenge is to identify which patients harbor a significant intracranial lesion that may lead to neurologic deterioration and require neurosurgical intervention.¹

TABLE 96.1. Glasgow Coma Scale

CLINICAL PRESENTATION

The clinical presentation of patients with head trauma has been arbitrarily divided into mild, moderate, and severe categories based on the GCS. Over 80% of patients seen by emergency physicians will have a GCS of 13 to 15. Alcohol and other drugs are the most common causes of a loss in a GCS speech point. Patients may complain of headache, nausea, or vomiting; have a history of loss of consciousness or amnesia; or have external signs of head trauma. The possibility of a coexisting cervical spine injury should be considered, and the patient should be placed in spine precautions until injury has been ruled out. In addition, the patient with an altered sensorium from TBI may require radiologic imaging and observation to determine whether there is coexisting intraabdominal injury. Concurrent medical conditions may need prompt identification and treatment.

DIFFERENTIAL DIAGNOSIS

The dramatic presentation of the trauma patient should not detract the physician from considering other medical conditions that could have contributed to the trauma or that may be causing a change in mental status. Myocardial infarction, arrhythmia, a cerebrovascular event, or a seizure may have been the primary insult that precipitated the head trauma. Causes of hypotension, including infection and sepsis, and gastrointestinal bleeding should also be considered. Secondary factors should especially be considered in patients involved in single automobile collisions or falls. The etiology of an altered sensorium in a patient with TBI may also be multifactorial. One should consider metabolic causes, including hypo- and hyperthermia and hypo- and hyperglycemia. Drugs, both legal and illicit, may also play a role in the patient with a change in mental status, with alcohol the most common ingestion noted. Frequently, a complete and reliable history cannot be obtained, and proper management by the clinician requires maintenance of a broad differential diagnosis and systematic exclusion of medical conditions through objective testing.

EMERGENCY DEPARTMENT EVALUATION

The general goal in the management of patients with head trauma is to minimize further brain injury from secondary insults such as hypotension, hypoxia, herniation, seizures, and infection.⁵ Prehospital information such as mechanism of injury, speed of vehicle, airbag deployment, height of a fall, loss of consciousness, posttraumatic seizure(s), or alterations in neurologic function since the accident will determine the need for urgent neuroimaging and for neurosurgical consultation. Other important historical components include preexistent history of cardiac disease or stroke, diabetes mellitus, as well as conditions that suggest the patient may be coagulopathic (cirrhosis, hemophilia, or, more commonly, warfarin anticoagulation).

The crucial initial intervention will be based on the patient's general appearance and vital signs. All resuscitations begin with the ABCs. Both hypotension (systolic blood pressure less than 90) and hypoxia (PaO₂ less than 60) have been shown to be independent predictors of poor outcome. Hypotension has been associated with a doubling of mortality, even when controlled for trauma to extracranial organ systems.⁴ As many as one-fourth of patients with severe brain injury are hypoxic and hypotensive. The emergency physician needs to be aggressive at volume resuscitating hypotensive head injury patients, without the fear that excess fluids will lead to brain swelling and herniation.

After the initial ABCs, the clinician will complete the primary and secondary surveys, with focus on pupillary size, symmetry, and motor function. Intervention will be necessary if there is evidence of increased intracranial pressure (ICP) or signs of herniation, or if the patient demonstrates seizure activity. Seizures increase the metabolic requirements of the brain and produce hypoxia and hypercarbia, which promote secondary injury. Herniation from a laterally based intracranial hematoma causes downward pressure on the uncus, which in turn causes compression of the ipsilateral third cranial nerve, and therefore produces pupillary dilation on the same side as the hematoma ([Fig. 96.1](#)). The presence of a palpable cranial defect, which may be depressed; a fracture near the middle meningeal artery groove; "raccoon" eyes; hemotympanum; or a penetrating object suggests the presence of more severe intracranial pathology. Open skull fractures serve as an entry site for bacteria, with the associated risk of secondary infection. The same risk applies to patients who exhibit leaks of cerebrospinal fluid (CSF) from the ears or nose, suggesting injury to the basilar skull or cribriform plate, respectively.

Figure 96.1. The intracranial cavity depicted as a funnel and subdivided by the tentorium into the supratentorial and the infratentorial compartments. Note herniation of the ipsilateral uncus with compression of the adjacent third cranial nerve and the posterior cerebral artery. Note also cerebellar tonsillar herniation with compression against the medulla.

In patients with mild head injury, ED evaluation focuses on the selection of those patients who need urgent cranial computed tomography (CT) scans, as well as the evaluation of any other medical conditions that might have led to the trauma. The prevalence of positive a CT scan in the GCS 13 to 15 group is in the 7% to 18% range, while the prevalence of neurosurgical lesions is approximately 1%.¹⁵ A subgroup of patients, called “talk and deteriorate,” present to the ED with GCS speech scores of 4 and 5, but, within 24 hours, have a total GCS less than or equal to 8. In this group, mortality is high, and the remaining survivors tend to be severely disabled. The most common CT finding is a subdural hematoma (SDH), which causes a greater than 10-mm midline shift ([Fig. 96.2](#)).⁹

Figure 96.2. A male presents 3 weeks after a fall, with increased sleepiness and change in personality. Cranial CT scan demonstrates a chronic subdural hematoma.

Many investigators have tried to elucidate risk factors that identify those of these apparently low-risk patients who harbor significant intracranial pathology; however, an adequate triage algorithm that addresses those who need CT scans remains elusive. Some clinicians use the presence of loss of consciousness or amnesia as a marker to screen patients for urgent cranial CT scan.^{16,11,16} The alcoholic patient who experiences head trauma is a frequent visitor to the ED. A strategy of serial observation until sobriety is achieved is a common one, although, as previously stated, once the patient has undergone deterioration, the outcome is significantly worse. Elderly patients also compose a high-risk subgroup for acute intracranial pathology. The anticoagulated patient is also likely to be in a high-risk subgroup, although this has not been studied in a prospective fashion.

Skull films should not be used to rule out intracranial injury, as they can have a false-negative rate as high as 80%.¹⁰ Skull fractures, however, should raise the suspicion for further intracranial injury; the range of associated injury is between 7% and 50%, depending on the study reviewed.

Specific Lesions

Epidural hematomas (EDHs) usually result from a blow to the head that fractures the skull immediately adjacent to the middle meningeal artery ([Fig. 96.3](#)). The arterial pressure is able to dissect the dura away from the inner skull table. This occurs less commonly in elderly patients, as the dura is more closely attached to the periosteum. The classic history of a blow to the head, loss of consciousness, lucid interval, and subsequent deterioration is seen in less than 30% of patients. EDH is an operative emergency: Prompt neurosurgical intervention is important, as operative patients who exhibit intact neurologic examinations have a mortality of close to 0. Mortality in unconscious operative patients is approximately 20%.¹³ EDHs can also involve lower pressure dural structures, and these can develop over longer periods of time.

Figure 96.3. A case of an epidural hematoma. Note the classic biconvex, hyperdense lesion on the CT scan. This patient underwent urgent clot evacuation in the emergency department.

SDHs are more common than EDHs, and they can be present in as many as 70% of patients with moderate and severe head trauma. Individuals with brain atrophy (i.e., elderly and chronic alcoholic patients) are more susceptible to damage to bridging veins in the increased subdural space produced by rotational or acceleration–deceleration mechanisms. An SDH can be characterized by the time it takes for patients to become symptomatic after injury ([Fig. 96.5](#)). Acute SDH appears as a crescent-shaped, hyperdense (whiter than brain tissue) mass on CT scan. As the time to presentation increases, the SDH becomes less dense and can appear isodense when compared with brain tissue. Chronic SDHs are hypodense and become symptomatic more than 2 weeks after injury. In elderly patients, there may be no history of trauma, and patients may present with a more subtle change in cognition and mental status ([Fig. 96.2](#)). SDHs exhibit a higher mortality than do EDHs, which can approach 70%. Patients with signs of neurologic dysfunction usually require clot evacuation.

Figure 96.4. A self-inflicted wound from a handgun. CT scan reveals injury to the bilateral hemispheres and intracranial fragments of bone, bullet, and air.

Figure 96.5. An elderly woman with change of mental status after a fall. Note the bilateral, subacute subdural hematoma, with varying densities and layering.

Cerebral contusions are the most common lesions seen on cranial CT scans in patients with mild head trauma. They are found in frontal, temporal, and occipital distributions and can frequently be seen on the inferior surfaces of these lobes (because the skull base has a rough interior). Contusions can vary from punctate (millimeters in size) to several centimeter collections of blood, necrotic brain tissue, and edema. Complications include worsening edema and rebleeding from injured vessels. Patients may exhibit focal neurologic deficits if contusions occur in the sensorimotor strip.

Penetrating Trauma

Penetrating head trauma most commonly results from firearm injuries. The projectile may traverse the skull or may ricochet intracranially, making anatomic prediction of injury clinically difficult. The overall mortality of patients who arrive in the ED is in excess of 60%. Cranial CT can demonstrate bleeding, skull fragments, bullet fragments, and intracranial air (pneumocephalus). Impaled objects should be left in place in the ED and removed in the operating room.

EMERGENCY DEPARTMENT MANAGEMENT

Prehospital

The prehospital phase begins secondary injury prevention. Airway management, intravenous (i.v.) access, and fluid resuscitation, as well as spinal immobilization, are initiated by trained paramedics. Determination of a scene GCS, detection and treatment of hypoglycemia, control of seizures, and “coma cocktail” administration can also begin in the prehospital phase. Prehospital personnel are frequently the sole source of information from scene witnesses regarding trauma mechanism or details regarding loss of consciousness.

Hospital

ED management begins with the primary survey and the ABCs. Managing the airway includes familiarity with rapid-sequence techniques.¹⁷ Patients with an initial GCS less than or equal to 8 or a decreasing level of consciousness will be unable to protect their airway and will need intubation. As laryngeal stimulation can reflexively increase ICP, blood pressure, and heart rate, one should utilize drugs that blunt those increases (e.g., thiopental, fentanyl, and lidocaine) prior to intubation. One should be aware that the use of these drugs can also produce hypotension, especially in the patient who is hypovolemic from blood loss. The F_{iO_2} should be set to 100%. A patient should not be hyperventilated unless signs of herniation exist. Shock needs to be treated aggressively with crystalloids and blood. Those studies that have suggested that patients with penetrating trauma have a better prognosis when managed with controlled hypotension did not include patients with head trauma. Patients must undergo frequent hemodynamic monitoring, cardiac monitoring, and pulse oximetry. Initial blood analysis, depending on both the degree of head injury and coexistent injury, may include complete blood count, including a platelet count, rapid glucose determination, blood urea nitrogen and creatinine, type and screen or cross, a coagulation profile, and a serum ethanol level. Urine screening for drugs of abuse may also be appropriate.

If the patient exhibits signs of intracranial hypertension, several therapeutic options are available.⁴ Hyperventilation can decrease cerebral blood flow and decrease intracranial hypertension, as cerebral arteries constrict when there is a decrease in hydrogen ions in the CSF. A PCO_2 of 30 is the hyperventilation target. Because of regional imbalances in cerebral perfusion and loss of autoregulation in the early postinjury period, hyperventilation can worsen an ischemic insult. A growing body of evidence indicates that prophylactic hyperventilation in patients with TBI has been shown to be detrimental at 3 and 6 months postinjury.¹² Sedation, mannitol, and ICP bolt placement with direct drainage of CSF (if possible) demonstrate a lower risk-to-benefit ratio than hyperventilation.³

Osmotic diuresis is another modality used to reduce ICP.³ Recommended doses of mannitol range from 0.25 to 1.0 g/kg. The duration of action of mannitol ranges from 90 minutes to more than 6 hours. Repeated mannitol use may allow it to concentrate within brain tissue, causing a reverse effect and a worsening of ICP. Like hyperventilation, mannitol should be used only in patients who exhibit signs of increased ICP. The patient's fluid status should be carefully monitored to avoid osmotic dehydration. When given as a rapid bolus, mannitol serves as a small-volume resuscitation fluid and will expand intravascular volume and cause an increase in cerebral blood flow.

While steroids can decrease edema in patients with intracerebral malignancies, they have no utility in head injury; this finding is supported by prospective randomized trials.² Active seizures are treated with either diazepam (0.1 mg/kg up to 5-mg bolus i.v. every 5 minutes) or lorazepam (0.05 mg/kg up to 2-mg bolus every 5 minutes), followed by i.v. phenytoin (13- to 18-mg/kg load). Seizure prophylaxis with phenytoin is also commonly used to prevent secondary injury in individuals with intracranial hematomas.

Once the patient's vital signs and neurologic function have been stabilized, the ED physician needs to complete the primary and secondary surveys. Patients with severe and moderate head injuries will require urgent cranial CT scanning. Any patient with a suspicion of significant intracranial injury will require prompt neurosurgical consultation. Severely compromised patients may go from the CT scanner directly to the operating room for hematoma evacuation. Emergency burr holes may be indicated in the patient who rapidly deteriorates despite the use of conventional ICP-lowering treatments. Neurologic intensive care management of patients with severe intracranial injury is based on the optimization of cerebral perfusion pressure (CPP). ICP and mean arterial blood pressure (MAP) are directly measured; then, using the relationship $CPP = ICP - MAP$, CPP is maintained at a minimum of 70 mmHg.

Magnetic resonance imaging (MRI) scans are generally more difficult to obtain and take longer to perform than cranial CT scans. They are useful in those instances when posterior fossa injuries, or nonhemorrhagic injuries, especially diffuse axonal injury, are suspected. Cranial CT scans are much better than MRI scans, however,

for the detection of skull fractures.¹⁴

In the mild head trauma patient, the moderate risk factors listed in [Table 96.2](#) may prompt the physician to order a cranial CT scan. Patients with cerebral contusions and nonoperative SDHs are generally admitted for observation with serial examinations, seizure prophylaxis, and follow-up imaging. Mild head trauma patients with negative CT scans who have a GCS of 15 and normal neurologic examinations are said to have suffered a concussion. Concussion is very common and ranks third highest in incidence among all neurologic diseases, behind migraine headache and herpes zoster. Symptoms include headache, nausea, blurry vision, unsteadiness, vertigo, and difficulty with concentration. The duration of symptoms noted after a head injury is related to the patient's age and the length of posttraumatic amnesia. Young patients with no loss of consciousness may have symptoms for days to weeks, while those who are 55 years old and older who exhibit prolonged posttraumatic amnesia may require months to clear, if they ever have a full recovery. Treatment options include analgesics, antiemetics, amitriptyline, as well as psychotherapy and neurorehabilitation.¹⁸

LOW-RISK GROUP Asymptomatic Headache Elevated ICP Seizure prophylaxis, lactation, confusion
MODERATE-RISK GROUP History of altered consciousness History of progressive headache Alcohol or drug intoxication Unreliable or inadequate history of injury Age <2 or >65 years old Possible skull fracture Possible facial fracture Possible posttraumatic amnesia Multiple trauma Serious facial injury Signs of basilar skull penetration or depressed fracture Possible skull penetration or depressed fracture Possible physical child abuse
HIGH-RISK GROUP Depressed level of consciousness not clearly caused by alcohol or drug use or other causes Focal neurologic signs Decreasing level of consciousness Penetrating skull injury or palpable depressed fracture

TABLE 96.2. Categorizations for Imaging Head Trauma Patients

DISPOSITION

Patients who have documented intracranial pathology and depressed neurologic function (GCS less than or equal to 8) need to be managed in a facility with immediately available neurosurgical capability and an intensive care unit that can monitor ICP and CPP. This may require safe and expeditious transfer from facilities that lack these capabilities.

A negative cranial CT scan in patients with mild head trauma is useful in deciding who can be safely discharged home, even if a home observer is not available.⁸ A patient with mild head trauma, in whom a cranial CT scan was not obtained, and who has a lack of risk factors for significant injury (e.g., minor mechanism, no loss of consciousness or amnesia), may be discharged home as long as the patient and a competent observer can understand and execute post-head injury discharge instructions. Patients with mild head injury, for whom a CT scan cannot be obtained, may be either transferred to an institution with CT capability or admitted for observation and frequent neurologic checks.

Protocols have been designed to help manage the patient with a sports-related head injury.⁷ These management recommendations incorporate the concept and risk of the second impact (reports of severe neurologic sequelae after multiple minor concussions). Concussions are graded on the basis of duration of confusion (15 minutes is the threshold) or loss of consciousness (even if seconds). Depending on the number and grade of concussion, the physician may recommend that the athlete remain inactive for a day, a week, or the entire season.

COMMON PITFALLS

- Being concerned that fluid resuscitation in the hypotensive head-injured patient will worsen brain injury by increasing the risk for swelling. Persistent hypotension (systolic blood pressure less than or equal to 90) or hypoxia (PO_2 less than 60) is the greatest contributor to posttraumatic morbidity and mortality.
- Failing to consider that other conditions that contribute to changes in mental status, including stroke, hypoglycemia, or other drugs and toxins (including alcohol), may be present in the head-injured patient.
- Failing to remember that the use of hyperventilation and mannitol should be limited to patients with signs of intracranial hypertension. Prophylactic use of hyperventilation has been shown to be detrimental.
- Failing to remember that patients with mild head trauma may have an intracranial injury that can cause neurologic deterioration. Patient outcome is enhanced if these lesions can be identified before clinical decompensation.
- Failing to remember that skull films are not a substitute for a cranial CT scan, as skull films can have a false-negative rate of up to 80% for the detection of intracranial pathology.

[Common Pitfalls](#)
[Chapter References](#)

Blunt and penetrating facial trauma are commonly seen in the emergency department. About 54% to 70% of all motor vehicle collision victims sustain facial injuries, accounting for an estimated 300,000 to 3 million maxillofacial injuries per year from this mechanism alone.²¹ Blunt maxillofacial injuries have also been reported to occur with significant frequency in other settings, such as athletic events. Penetrating maxillofacial trauma is becoming increasingly common in the urban setting.^{5,14} Unfortunately, up to one-fourth of women who sustain facial trauma do so in the setting of domestic violence.

The variety of mechanisms of injury and the complexity of the facial structures result in multiple potential injuries when the face is traumatized. In large series, the most frequently fractured facial bones are the zygoma, maxilla, and mandible; orbital, ethmoidal, and frontal injuries are less common.^{4,9,21,23} As might be expected, the relative frequency of specific bony injuries is dependent on the setting of the injury and the likely destination of hospital: For example, community hospitals, where more minor vehicle crash victims and sporting and recreational injuries are more commonly seen, most frequently see blunt nose and mandible injuries; and urban trauma centers more commonly see midfacial and zygomatic injuries. These findings are generally consistent with the relative strength of individual bones of the face (Fig. 97.1).²²

Figure 97.1. Relative strength of facial bones.

In the multiple trauma patient, the maxillofacial region is only one of many potential areas of injury, and the emergency physician must not allow the easily visible and often remarkable appearance of maxillofacial injuries to distract attention from more critical injuries. Maxillofacial injuries are rarely a proximate cause of death, and standard trauma priorities must not be altered because of an obvious facial abnormality. Underscoring the need to follow standard trauma care is the significant association of maxillofacial fractures with injuries to other body regions, most notably the head and neck.^{3,4,9,22,23}

Both short- and long-term considerations are pertinent to the management of facial trauma. Facial injuries may require prompt attention early in the trauma resuscitation if disruption of bony integrity or hemorrhage results in airway compromise. Blood loss in the patient with maxillofacial trauma is rarely life-threatening, but the vascularity of the facial region can result, in some instances, in substantial hemorrhage. Timely planning of further evaluation and management of individual fractures is best discussed with the appropriate consultant. Cosmesis is likely to be a major concern of the patient and family, but discussion of further management and prognosis is best done by the surgical specialist in a more controlled setting.

CLINICAL PRESENTATION

The presentation of patients with significant maxillofacial trauma depends largely on the mechanism of injury. Patients who have sustained facial injuries as part of a significant blunt traumatic event (e.g., motor vehicle collision) are likely to present with multiple potentially injured body systems. The initial evaluation and stabilization of these patients should follow a standard multiple trauma resuscitation: Neglect of potentially serious chest or abdominal/pelvic injuries in the multiple trauma patient with distracting facial deformities is a dangerous error.

Victims of penetrating maxillofacial trauma are less likely to have sustained serious injuries to other organ systems (except the globe, head, and neck) but have a high likelihood (33%) of requiring urgent airway control.¹⁴ In addition, the emergency physician must be particularly attuned to the possibility of central nervous system (CNS) injury, which has been reported to occur in about 20% of victims of penetrating facial trauma.^{4,5,8,19} A patient who presents with decreased visual activity, visual field limitation, eye pain, limitation of extraocular movements, subconjunctival hemorrhage or lid laceration, diplopia, or infraorbital anesthesia should prompt a careful examination of the globe and periorbital area. Blindness occurs in 0.5% to 3.0% of patients who sustain facial fracture(s), particularly zygomatic, LeFort II, and LeFort III (2.2%).

Maxillofacial injury becomes a treatment priority during evaluation of the multiple trauma patient primarily due to airway compromise. Airway problems may result from dislodged teeth or intraluminal hemorrhage, or from facial fractures, causing loss of structural support for the soft tissues surrounding the airway. Foreign bodies such as teeth, denture fragments, or other soft-tissue fragments may be aspirated, with resulting respiratory embarrassment.¹¹ In addition to the immediate risks of hemorrhage into the airway, edema and hematoma formation may compromise airway patency 24 to 48 hours after the injury.¹⁷ This delayed risk of airway compromise has prompted some authors to recommend intubating patients who present with significant intraoral blood or moderate-size hematomas in the neck or face.⁵

The significant vascularity of facial structures may result in substantial blood loss with maxillofacial trauma, producing hypotension and, rarely, exsanguination. However, the tamponading effect of the facial musculature combined with the relative ease of application of direct pressure on most bleeding sites makes life-threatening hemorrhage relatively unlikely.²²

DIFFERENTIAL DIAGNOSIS

The remarkable appearance of the patient with facial trauma sometimes distracts the examining physician from more serious injuries, but it also ensures that the diagnosis of severe facial trauma is rarely missed. The primary diagnostic goals in evaluating the facial trauma patient, once life-threatening injuries have been addressed, concern delineation of all bony and soft-tissue facial injuries.

Due to neurologic dysfunction from associated injuries or intoxication, the patient with facial trauma often cannot provide an adequate history. When confronted with the patient presenting with altered mental status and facial swelling, the physician should use the history provided by family or prehospital care providers, the initial physical examination, and screening laboratory tests to rule out other causative processes, including infection (e.g., cellulitis), immunologic reaction (e.g., angioedema, anaphylaxis), and atraumatic structural pathology (e.g., superior vena cava syndrome). The history should include the time of injury, the mechanism of injury, and possible loss of consciousness. Ocular complaints should be sought, in order not to miss important globe injuries and orbital fractures (see [Chapter 99](#), "Eye Trauma"). The examining physician must always maintain a high index of suspicion for domestic violence and pediatric and elder abuse.

EMERGENCY DEPARTMENT MANAGEMENT

The initial evaluation of the patient with maxillofacial trauma should follow standard trauma resuscitation. The need for meticulous trauma evaluation in patients with facial fractures has been underscored by multiple series describing serious associated thoracic, abdominal, orthopedic, and neurologic injuries. [4,7,9,14](#) Maxillofacial injuries are seldom life-threatening, but other organ system injuries occur frequently and are associated with significant morbidity and potential mortality. [4,5,7,9,14,23](#)

Head injury is the most prevalent associated injury. This association has prompted the recommendation that routine head computed tomography (CT) be performed in all patients with blunt or penetrating maxillofacial injuries who have a suspicious mechanism of injury or neurologic deficit. [5,23](#) Studies have cast significant doubt on the classical association of maxillofacial trauma with cervical spine (c-spine) injury. [5,23](#) Until this issue is resolved, liberal use of plain c-spine radiography is recommended, in keeping with both routine trauma management and the need to clear the c-spine before performing certain facial imaging techniques.

The airway is the first consideration in patients with maxillofacial trauma. The potential for respiratory embarrassment in a patient with facial trauma is significant; many mechanisms and treatment strategies for airway compromise have been described.¹¹ Any portion of the airway may be blocked by hemorrhage or soft-tissue swelling or edema. Soft-tissue swelling and edema usually do not cause airway compromise until hours after the patient's initial presentation to the emergency department, but the significant risk of airway impingement by progressive swelling is one reason for the liberal use of early prophylactic airway control. In patients who exhibit continued blood loss from accessible vessels despite direct pressure, hemorrhage control may be achieved by packing open wounds or the nose. Major vessel embolization or ligation is sometimes needed to provide definitive control of facial bleeding.

Maxillofacial trauma can result in airway compromise at the nasal, oropharyngeal, or laryngeal level. Collapse of the nasal airway can result from posteroinferior displacement of maxillary fractures. In this instance, definitive control of the airway and hemorrhage may be achieved by correcting fracture fragment alignment by anterior traction on the maxilla.⁸ The oropharyngeal airway may also be occluded by a prolapsing tongue, the anterior attachments of which have been disrupted by central mandibular fracture. Anterior traction on the tongue with a traction suture or towel clip should reestablish airway patency in these patients. Maxillofacial trauma may also be associated with direct trauma to the neck, causing airway collapse at the level of the larynx. Cricothyrotomy is possible if the level of injury is above the larynx. In patients with injuries at or inferior to the level of the larynx, endotracheal intubation may be attempted, but tracheostomy is often necessary. If tracheal injury is inferior to a level at which tracheostomy will provide an adequate airway, emergent consultation by a thoracic surgeon is warranted. [11,24](#)

Urgent airway control by oral endotracheal intubation or the creation of a surgical airway is reportedly needed in one-third of patients sustaining gunshot wounds to the face.¹⁴ As such, early intubation is recommended for all patients who exhibit hemodynamic instability or who have significant intraoral bleeding or facial hematomas.⁵ The justification for aggressive airway intervention in victims of penetrating trauma lies primarily in the potential for airway lumen compromise by expanding hematoma, intraluminal bleeding, or collapse of surrounding soft tissues.

Other factors support early, aggressive airway control in patients with significant blunt or penetrating facial trauma. Significant technical difficulties may be encountered in patients who deteriorate and require airway intervention on an emergent basis. In addition, stability of the airway should always be ensured in patients who will have a prolonged stay in the radiology suite. Anatomic distortion and the risk of tube misplacement preclude nasal endotracheal intubation in the patient with significant midface trauma. If there is any question concerning the ability to perform bag-valve-mask ventilation or rapid-sequence orotracheal intubation easily, jet insufflation or cricothyrotomy equipment should be immediately available. The intubating physician should first assess the degree of potential difficulty for both intubation and mask-valve ventilation (Mallinpati criteria). One alternative may be awake intubation. Fiberoptic intubation may provide another choice, depending on the injuries sustained and the comfort level of the operator. The c-spine should be cleared or adequately immobilized until clearance is possible. Certain diagnostic imaging, due to required patient positioning, may need to wait until c-spine immobilization is discontinued.

In the patient with facial trauma, the "B" of the trauma ABCs is much less of a problem than airway maintenance. Breathing is rarely problematic in patients with isolated maxillofacial injury. Patients with severe injury are usually intubated and mechanically ventilated. CNS injury is the most likely explanation for hypoventilation in the setting of facial trauma. Continuous pulse oximetry, which is indicated for any severely injured patient, is a helpful monitor of ventilatory adequacy in patients with facial trauma.

Circulation problems in the patient with maxillofacial trauma may be due to bleeding from traumatized vascular structures of the face. However, hypovolemic shock in such patients should be assumed to be due to other injuries until proven otherwise. Standard trauma resuscitation should identify and address hemorrhage from intrathoracic, abdominopelvic, or extremity trauma.

The general approach to hemorrhage should include direct pressure both externally and internally (such as with anterior and posterior nasal packing) where indicated. A steady flow of blood from the nasal or oral cavities, accompanied by bleeding into the soft tissues of the face, may be produced by closed fractures of the maxilla, nose, and ethmoids. If blood loss is not expeditiously addressed, ongoing hemorrhage may be sufficient to cause hypotension and coagulopathy. Blind vessel clamping is contradicted due to possible inadvertent damage to other major structures, such as the facial nerve or parotid duct. Manual reduction of fracture fragments may cease hemorrhage; this is especially helpful in some Le Fort fractures or dislocations. Urgent surgical consultation is indicated if the preceding steps do not control hemorrhage.

The initial examination should include assessment for basilar skull fracture and cerebrospinal fluid (CSF) leakage. Basilar skull fracture may be indicated by hemotympanum, or later by periorbital (raccoon eyes) or retroauricular ecchymosis (Battle's sign). CSF rhinorrhea may be found in patients with naso-orbito-ethmoid, frontal sinus, Le Fort, or orbital roof fractures. The CSF leak is created when a bony fracture (accompanied by interruption of the periosteum and mucosa) of the anterior cranial fossa causes disruption of the arachnoid and dural layers. Identification of CSF rhinorrhea is important as a diagnostic clue to underlying fractures and, depending on individual neurosurgical preferences, serves as an indication for prophylactic antibiotics. The filter paper ring sign and assessment of rhinorrhea fluid for glucose and protein may help determine whether CSF is present in nasal drainage. Definitive treatment for CSF rhinorrhea associated with facial fractures is open reduction and fixation of the bony injury.⁶

After the ABCs of trauma and any injuries to other organ systems are addressed, the emergency physician should perform a thorough and directed examination of the maxillofacial region. Performing an optimal physical examination of the face is challenging due to anatomic complexity, swelling, lacerations, pain, and altered level of consciousness. These difficulties, in addition to the often significant distraction produced by the impressive appearance of facial trauma, underline the importance of proceeding with an orderly physical examination.

Some general comments regarding the traumatized facial region should help organize the approach to physical examination. The first steps in evaluating patients with maxillofacial trauma are inspection and palpation; improved imaging techniques have not relegated physical examination to a minor role. Asymmetry, loss of contour, ecchymosis, and hemorrhage are important visual clues to soft-tissue and underlying bony injuries ([Fig. 97.2](#)). Remember to view the face from the superior, lateral, and inferior positions, as each may reveal injury not obvious from other views. Also examine for facial function; for example, have the patient smile. Palpation may reveal step-off, tenderness, crepitation, or bony mobility in patients with fractures. Subcutaneous crepitus is usually present in patients with fractures involving the sinuses.

Figure 97.2. Superficial facial injuries provide important visual clues to underlying soft-tissue and bony injuries.

Mandible Fractures

In several series, the mandible has been described as the most commonly fractured facial bone. ^{2,9,23} Figure 97.3 illustrates sites and incidence of mandible fractures.

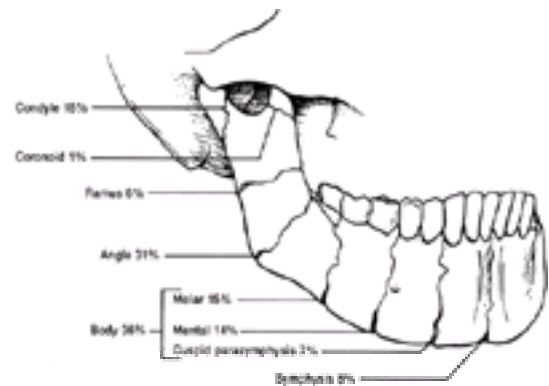

Figure 97.3. Mandible fractures: sites and incidence.

Evaluation

Inspection of the patient's jaw for asymmetry is the first step in the evaluation of possible mandibular fracture. When a fracture is present, the jaw is often deviated toward the injured side; with a unilateral dislocation, the mandible is deviated toward the contralateral side. Preauricular swelling or bleeding from the external auditory canal may indicate a condylar fracture, which can be notoriously difficult to identify on plain radiographs. ¹

The patient is asked whether occlusion feels normal, as bite discrepancy suggests mandibular or maxillary fracture. The sensitivity of the proprioceptive receptors of the teeth allows for detection of as little as 1 to 2 mm of bite discrepancy. ²² After inspection and palpation of the mandible, normal condylar excursion is assessed: The examiner's finger is inserted into the external ear canal and the patient is instructed to open and close the mouth. In the patient with pain and without obvious fracture, the tongue depressor test may prove useful. A positive test, suggestive of possible fracture, is elicited when the patient reflexly opens his mouth when a tongue depressor clenched between the teeth on the suspect side is twisted by the examiner. ²² Finally, the lower lip and mandibular dentition are assessed for sensory function. Abnormalities of sensation in these regions indicate mental nerve injury, possibly secondary to mandibular fracture.

If mandibular fracture is suggested by the history or physical examination, plain radiographs are indicated (Fig. 97.4). The posteroanterior view provides information on the symphysis and body of the mandible, and the lateral oblique view adds delineation of the mandibular rami. Towne's projection demonstrates the mandibular rami and condyles. The 180-degree panoramic view provides good visualization and definition of most of the mandible, except the symphysis.

Figure 97.4. Plain PA radiograph of the mandible shows displaced fractures of the mandible. Illustrated are fractures near the right angle, one within the body, and one just to the left of the symphysis. There are also bilateral fractures of the maxillary antra, involving the lateral walls and anterior walls. There is a slightly displaced fracture involving the lateral wall of the right orbit at the zygomaticofrontal suture.

The most frequently missed mandibular fracture is the condylar fracture. This is sometimes inadequately imaged with plain films. A facial CT scan is indicated when clinical suspicion of condylar fracture persists despite negative plain radiography. ¹⁴ Advanced imaging sometimes provides the surgeon with additional information to help plan the operative management of the fracture (Fig. 97.5).

Figure 97.5. Facial CT image. There are multiple eggshell-like fractures involving the wall of both maxillary antra. Both maxillary antra are opacified with blood. The nasal passages are filled with soft-tissue density, suggesting blood and contused tissues.

Management

Open mandibular fractures require admission for surgical therapy and intravenous antibiotic coverage of oral pathogens. Penicillin is the drug of choice, with clindamycin and first-generation cephalosporins serving as alternatives. Mandible fractures secondary to penetrating trauma are, by definition, open fractures, and thereby also merit hospital admission. These fractures should probably undergo open reduction, because of the high rate of associated complications.¹⁴ Many closed mandibular fractures can be treated on an outpatient basis with a Barton's bandage, pain medication, and a liquid diet. The specific treatment plan should be formulated with the appropriate consultant.

Maxillary Fractures

Maxillary fracture is the most common finding in patients sustaining penetrating facial trauma. These also occur quite frequently in victims of blunt trauma.^{14,23}

Evaluation

Fractures of the maxilla may be detected by inspection but are usually more easily identified by palpation. Anterior and lateral inspection for symmetric contour of the midface may be the best means of identifying impacted (i.e., immobile) maxillary fractures, which are relatively common due to the large forces required to produce midface fractures.²²

Palpation of the maxillary structures follows inspection. Special attention is given to crepitus, which indicates possible maxillary sinus fracture. Next, the examiner firmly grasps and exerts pressure on the upper alveolar ridge (not the teeth), checking for abnormal midface mobility (Fig. 97.6). In patients with facial mobility on maxillary manipulation, the fracture is further characterized by delineating the mobile portions of the midface.

Figure 97.6. Checking for abnormal midface mobility.

In the patient with a Le Fort I fracture, the nose does not move with the abnormally mobile alveolar ridge. The Le Fort I fracture line is a transverse separation of the hard palate from the lower portion of the pterygoid plate and nasal septum (Fig. 97.7). The Le Fort II, or pyramidal, fracture is associated with mobility of the nose and the alveolar ridge of the maxilla. This fracture line separates the central maxilla and palate from the rest of the face. Craniofacial dysjunction (Le Fort III fracture) is associated with separation of the entire facial skeleton from the cranium; maxillary excursion reveals mobility of the entire face (including the inferior and lateral orbital rim). In actual practice, pure Le Fort fractures are much less common than unilateral or bilaterally mixed (e.g., left Le Fort I with right Le Fort II) maxillary fractures.

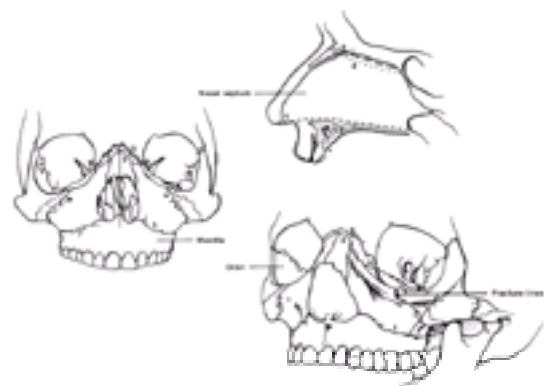

Figure 97.7. Lines of fracture in Le Fort I, Le Fort II, and Le Fort III. Fractures are shown from different views.

Physical findings with maxillary fractures are tenderness, loss of contour, and crepitus (with involvement of maxillary sinuses). Maxillary (or zygomatic) fracture may result in damage to the infraorbital nerve, manifested by paresthesias of the upper lip and central incisors. Facial nerve injury may also accompany maxillary fractures, with resultant facial muscle paralysis. When there is trauma to the lateral midface, especially if there is clinical suggestion of facial nerve injury, the physician should carefully examine cheek wounds for clear or pink fluid leakage, representing possible parotid duct damage.¹¹

Management

Assuming the ABCs are assessed and stable, the clinician's next step is to order appropriate imaging of the face. In the patient with trauma sufficient to warrant cranial CT scanning, the answer is simple: Coronal scan the facial bones simultaneously.¹⁶ For patients with physical findings consistent with facial trauma and no indication for cranial CT, the decision is more difficult, but specialists still recommend beginning the radiographic workup with coronal cut facial CT scanning and proceeding to three-dimensional CT scanning if needed.²⁰ The rationale for the direct use of facial CT scanning is that it delineates fractures clearly and is thus a prerequisite to preoperative surgical planning; also, plain films are time consuming to perform and usually add no additional information. This relatively recent change in the choice of radiographic imaging for patients with midface trauma is a result of evolution in the surgical therapy of these fractures. Closed reduction techniques required only plain radiographs to identify the presence of fractures. Current optimal surgical therapies require careful delineation of facial architecture, which can be achieved only with CT scanning.¹

If the patient's condition permits, optimal management of maxillary fractures dictates that the midface should be imaged in the coronal plane.¹ This approach has the added benefit of allowing subsequent three-dimensional reconstruction of the image. Three-dimensional CT scanning offers superior fracture delineation and preoperative planning, and may reduce the time spent in the operating room. However, this procedure is currently too expensive to be used in every patient.^{18,20} MRI has little role in the emergency department evaluation of the patient with suspected maxillary (or other facial) injuries, as CT scanning is more readily available and provides better information in a shorter period of time.⁷ For patients whose history suggests significant facial trauma but who have no findings consistent with

maxillofacial fracture, plain radiography provides a reasonable, cost-conscious screening examination. ^{13,22}

Surgical specialists should be consulted early when fractures are identified, as an increasing number of facial surgeons have correlated early management with improved outcome.^{6,16,20} For patients with midface injuries secondary to penetrating injury, the need for early surgical consultation remains, but early open reduction is probably contraindicated due to the high risk of complications. ¹⁴

Orbital Fractures

Trauma to the orbital regions may result in a number of injury patterns. Almost always, direct ocular trauma results in traumatic iritis. Injury to virtually any part of the eye may occur when the globe is impacted with sufficient force.¹² Injuries occurring as a result of trauma to the globe are discussed in detail in [Chapter 99](#), "Eye Trauma." Relevant to the current discussion is the blowout fracture ([Fig. 97.8](#)). Orbital floor fractures, which may result in development of entrapment when intraorbital soft tissues herniate into the maxillary sinus, account for as many as one-fifth of facial fractures. ²¹

Figure 97.8. Blowout fracture.

Evaluation

Inspection of the patient's orbital region sometimes provides clues to the presence of fracture. Eyelid edema or ecchymosis, enophthalmos or hypophthalmos, or obvious inability of the patient to deviate the involved eye are pertinent findings on visual examination of the patient with orbital region fractures. ^{12,19}

Palpation of the orbital rims often reveals any fracture(s) present. The medial orbital rim may be palpated from both sides with the aid of a padded hemostat or alligator forceps very gently placed in the nares as the external orbital rim is palpated with the fingers; any movement elicited is abnormal.

Orbital blowout fracture associated with entrapment syndrome may also be identified by a patient complaint of diplopia or inability to deviate the eye upward. Infraorbital anesthesia or crepitus may be present in orbital fractures involving the infraorbital nerve or sinuses, respectively.

When there are findings consistent with fracture in the orbital region, the emergency physician's first step is a meticulous evaluation of the globe. The ocular examination takes precedence because certain injuries (e.g., globe rupture) benefit from early diagnosis and management, and because an adequate examination may be impossible to perform after a few hours of swelling and edema formation.

Once ocular injuries have been ruled out, or identified and appropriately managed, attention shifts to radiographic evaluation of the orbital region.

Blowout fractures most commonly involve the orbital floor, but the medial, lateral, and superior walls may also fracture (in that order). ¹⁷ The blowout fracture is said to be "pure" if the central area of the orbital wall is the only portion fractured; impure blowout fractures extend to the orbital rim. Impure fractures are often found in association with maxillary, naso-orbital, and frontal bone fractures. ¹⁷ The emergency physician identifying one of these injuries should carefully search for an associated blowout fracture and entrapment syndrome. The orbital wall defect created by a blowout fracture may be filled with a variety of soft tissues; orbital fat is most commonly entrapped. However, the extraocular muscles may become involved, resulting in the entrapment syndrome. This syndrome, which almost always involves the inferior rectus muscle, is characterized by diplopia or failure of conjugate gaze. Muscle function is impaired, but the entrapment syndrome is usually caused by herniation, not of the muscles, but of fibrous septae that provide positional support for the extraocular muscles. ¹⁷

Management

When a low index of suspicion exists, plain radiographs provide a cost-conscious screening examination for fractures in the orbital region. When there is significant question about the presence of a blowout fracture, CT scanning in the horizontal and coronal planes is the optimal imaging study. ¹⁷

Management of orbital blowout fractures has been controversial, but guidelines for therapy provide a reasonable basis for decision making in the emergency department. ¹⁷ In cases associated with minimal displacement, no entrapment, and no diplopia, the patient may be treated as an outpatient with next-day surgical follow-up. Absolute indications for surgery include acute enophthalmos or hypophthalmos or muscular entrapment with mechanical gaze restriction. Contraindications for surgery include hyphema, retinal tears, and globe perforation, as soft-tissue injuries of the eye may be aggravated by surgery for blowout fractures. Patients with a single eye should not undergo surgical exploration and repair for blowout injuries, as the small but real risk of visual loss from the operation outweighs the potential benefits of the procedure. Timing of surgery for orbital blowout injuries is critical. If repair is attempted too soon, the outcome can be compromised by incomplete diagnosis, localized swelling, excess hemorrhage in tissues in the inflammatory phase of healing, or problems resulting from associated traumatic injuries. If surgery is delayed too long, however, bones will have fused and scarring may be established. A period of 7 to 10 days appears optimal. This decision is left to the consultant, who should see the patient the next day if the fracture is to be managed on an outpatient basis. ¹⁷

Nasal Fractures

Many (if not most) significant fractures of the midface are associated with fractures of the nasal bones. Other than prompting evaluation for airway, hemorrhage, and septal hematoma, these fractures do not play a significant role in the emergent management of patients with significant facial trauma. Isolated nasal fractures are very common, however, and the emergency physician should be able to manage most patients with these injuries.

Evaluation

Inspection is the primary means to make the diagnosis of nasal fractures, which require no immediate treatment other than ice packs and analgesia if alignment is satisfactory. If radiography is required to make the diagnosis of nasal fracture, the fracture is unlikely to require significant therapy in the emergency department; x-rays are, therefore, not recommended in the initial evaluation of patients with suspected nondisplaced nasal fractures. Depression of nasal contour, with or without lateral deviation, usually indicates a fracture or dislocation of the nasal cartilage or bone.

After inspection, the most important part of the physical examination of the patient with nasal trauma is careful speculum examination of each naris to identify lacerations or septal hematomas and ability to breathe through each naris. A septal hematoma may appear as a bulging blue mass inside the septum, or it may be identified during palpation as a doughy area of the septum.

Management

If a fracture with malalignment is identified, the emergency physician can anesthetize the nose with cocaine or tetracaine-soaked pledgets and perform closed reduction. Some ear, nose, and throat (ENT) surgeons prefer to reduce the fracture themselves, however, either acutely or after swelling has subsided. The emergency physician and consulting plastic or ENT surgeon should prospectively discuss the management plan for their practice area. Those patients with significant swelling or deformity should be seen by the consultant in 5 to 7 days when swelling has resolved, in order to optimally time further reduction.

Septal hematomas, if not drained in the emergency department, can lead to abscess formation or necrosis of the nasal cartilage, with resultant saddle nose deformity. Drainage is performed through a mucosal incision. The area is subsequently packed with gauze, which is removed on next-day follow-up.²² Patients who have difficulty breathing through the nose should be seen by the consultant in follow-up in the outpatient setting.

Ethmoid Fractures

Naso-orbito-ethmoid (NOE) fractures are produced by trauma to the bridge of the nose and involve the central portion of the midface (the nasal bones, frontal processes of the maxilla, and ethmoid bones) (Fig. 97.9). These often prove difficult to diagnose. The diagnostic challenge is emphasized by the fact that these fractures are fairly common, accounting for almost 40% of midface fractures in one series.⁴

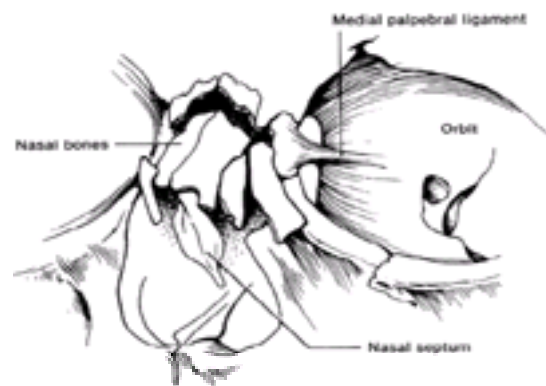

Figure 97.9. Nasoethmoidal fractures.

Evaluation

A thorough history, especially regarding the mechanism of injury, combined with careful physical examination will help the emergency physician make the diagnosis of NOE fracture. If performed before the development of significant swelling and edema, inspection of the face may aid in the evaluation of patients for NOE injury. In the patient with NOE fracture, the intercanthal distance, normally about half the interpupillary distance, is usually widened enough to require open surgical repair. An intercanthal distance of 35 mm suggests a displaced NOE fracture; a distance of 40 mm is diagnostic.⁶ Also characteristic of NOE fractures are a short and retruded nasal bridge, enophthalmos, shortened and blunted medial palpebral fissure, and epiphora. These findings are increasingly difficult to detect as swelling progresses. Palpation of the medial orbital rim may reveal crepitus or movement of bony fragments.⁶

Management

Because of the difficulty in detecting NOE fractures by physical examination or plain radiographic assessment, this diagnosis is usually made by facial CT scan. CT scanning should be the initial imaging modality for any patient with suspected NOE injury. Both axial and coronal sections are desirable, as reconstructed coronal sections are usually of insufficient quality to visualize properly the middle third of the orbit and the anterior cranial fossa.⁶

The emergency physician's role in management of the patient with NOE fracture is to make the diagnosis and to rule out associated lacrimal system injury or dural tear. These tasks may prove difficult but are very important: NOE fractures are difficult to repair if the diagnosis is delayed by more than 2 weeks.⁶ The emergency physician must carefully search for NOE fractures. The consultant should be contacted regarding admission of the patient if NOE injury is identified.

Zygomatic Fractures

Zygomatic fractures, reported in some series^{4,21} as the most common facial bony injury, are infrequently missed in the emergency department evaluation. The zygoma may fracture through its arch or body, or at one of its many attachments to the frontal, maxillary, or temporal bones. Fracture at the suture lines with the three adjacent bones is termed a *tripartite* or *tripod fracture* (Fig. 97.10).

Figure 97.10. Zygomaticomaxillary complex fractures.

Evaluation

Physical examination reliably detects most zygomatic fractures. Inspection of patients with zygomatic injuries may reveal flattening of the lateral facial contour, depression and tenderness of the orbital rim at the zygomaticomaxillary or zygomaticofrontal sutures, lateral orbital droop secondary to disruption of the lateral canthal ligament, lateral subcleral hemorrhage, or trismus. Further examination may reveal horizontal diplopia (damage to the lateral rectus muscle), vertical diplopia (damage to the inferior rectus or oblique muscle), or hypesthesia in the infraorbital nerve distribution.²² Simultaneous palpation of both zygomatic arches allows easy detection of flattening due to fractures of these bones. Displacement of zygomatic fractures may interfere with excursion of the mandibular condyle, producing resultant occlusal impairment or trismus.^{20,22}

Radiographic evaluation of patients with zygomatic fractures is managed in much the same way as for other facial injuries. If the index of suspicion is low based on history and physical examination, evaluation should be initially limited to plain radiographs. Standard x-rays (e.g., the submentovertex view or "bucket handle" for simple arch fractures) detect many zygomatic injuries. Facial CT scanning is necessary to determine the status of surrounding soft tissues (e.g., orbital contents) and sinuses and the existence of tripod fractures in patients with zygomatic body fractures.

Management

The presence of a zygomatic fracture does not necessarily prompt further evaluation with CT scanning, as some nondisplaced fractures can be managed nonoperatively.¹⁷ When tripod or other complex fractures are identified or suggested by plain radiography, CT scanning and surgical consultation are obtained. In patients with uncomplicated, nondisplaced fractures (e.g., the zygomatic arch), emergency department management is limited to providing antibiotics in patients with sinus disruption, analgesia, and surgical follow-up within 2 to 3 days.

Frontal Fractures

[Figure 97.1](#), depicting the forces required to fracture the facial bones, shows why the frontal bones are relatively rarely fractured.^{21,23} Due to the proximity of the frontal bone and sinus to the brain, and the significant forces required to fracture these bones, fractures in this area are associated with a high risk of intracranial injury.^{22,23} The large forces required to produce frontal fractures usually cause other facial bony injuries as well; thus, any patient with a frontal bone fracture should undergo head CT scanning and meticulous evaluation for associated facial injury.

Evaluation

Frontal bone fractures may be apparent on inspection, which may reveal depression of the involved region of the forehead. Glabellar depression indicates fracture of the anterior wall of the frontal sinus.²² Palpation of the frontal region may reveal crepitus if the sinus is involved, or tenderness or step-off due to other fractures.

Injuries involving the frontal sinus or nasal region, especially displaced nasofrontal fractures, may be clearly imaged with plain radiography.¹⁵ If cranial CT scanning is performed on all patients with significant frontal injury, most frontal fractures will be identified on simultaneous frontal bone imaging. The improved delineation of soft tissues and sinus walls provided by CT imaging allows more accurate management. Assessment of the integrity of the posterior wall of the frontal sinus is particularly important, as fracture of this structure may be associated with frontal lobe contusions and lacerations, dural tears, and CSF rhinorrhea.²²

Management

Antibiotic prophylaxis is indicated when the walls of the frontal sinus are fractured. The rest of the emergency department management of patients with frontal bone injuries includes evaluation of other parts of the face and the intracranial contents. Early consultation with neurosurgical and facial surgery specialists, in addition to the ophthalmologist, as necessary, is indicated in patients with frontal bone fractures.¹⁵

Soft-Tissue Injuries

Almost all patients with facial fractures have associated cutaneous injuries. These should not be closed in the patient who will undergo surgical evaluation in the emergency department, as the opening may be used for examination or repair. Laceration repair is discussed in [Chapter 95](#). In addition to lacerations, oral, ocular, salivary, lacrimal, or neurologic injuries may also be associated with maxillofacial trauma ([Fig. 97.11](#)).

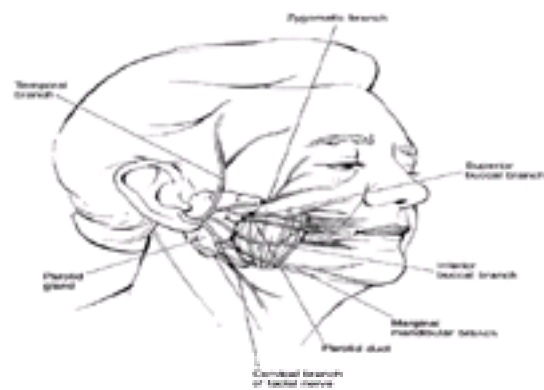

Figure 97.11. Important soft-tissue structures of the face.

Evaluation and Management

Careful intraoral examination should be part of the evaluation of all patients with facial trauma. Attention should be given to airway and bleeding considerations; tongue, frenulum, and gingival lacerations; identification of alveolar or palatal fracture; and dentition. Any dental appliances present should be removed to prevent their aspiration from compromising the airway. These appliances should be saved: They are expensive and may provide important guides to pretraumatic oral alignment.

The significant incidence of ocular injuries associated with various facial fractures necessitates meticulous ophthalmologic evaluation in all patients sustaining maxillofacial trauma. Injuries to the lacrimal system, with associated findings such as epiphora, may be present in patients with midface fractures. Lacrimal disruption is rare, however, even in patients with significant craniofacial trauma.²⁰ These injuries are discussed more fully in [Chapter 99](#).

Maxillofacial trauma may damage the parotid gland or duct. Clear or pink-tinged fluid in a wound over the course of Stensen's duct or the parotid gland should prompt the examiner to evaluate the patient for these injuries. Glandular laceration does not require repair, as commonly occurring salivary fistulas resolve spontaneously in less than a month. Stensen's duct may be repaired by suturing the ends together over a stent; this is most appropriately performed by an oral and maxillofacial, ENT, or plastic surgery consultant.

Except for mandibular fractures, the classically emphasized risk of c-spine fractures occurring in association with facial injuries has been greatly overstated. However, there is sufficient risk to warrant c-spine imaging as the initial radiographic evaluation in patients with significant facial trauma.^{4,9,10,22,23} If the incidence of c-spine injury occurring concurrently with facial fracture has been overstated, the significant association between maxillofacial trauma and brain injury merits special emphasis. As many as 85% of patients sustaining significant facial fractures have associated intracranial injury. Certain trends have been illustrated in published series (e.g., the high risk of intracranial injury with frontal bony injury), but no definite set of clinical parameters currently allows prediction of intracranial pathology based on fracture location.²³ As a result, all patients with significant facial fractures require cranial CT scanning.

DISPOSITION

Role of the Consultant

In the vast majority of patients with maxillofacial trauma, the emergency physician can perform the initial trauma resuscitation and stabilization without the need for consultation with maxillofacial specialists. The role of emergent surgical consultation in patients with airway compromise or refractory facial hemorrhage has been discussed.

Involvement of the appropriate surgical specialist is now recommended at an earlier time than had been standard in the past. Delays in treatment have been shown to result in suboptimal outcome in some facial injuries.^{6,15,19} In patients with severe multisystem trauma, the maxillofacial surgeon should be consulted early for brief examination, wound closure, debridement of avulsive dentoalveolar injuries, and temporary stabilization of grossly unstable dentoalveolar or mandible fractures.¹⁵

Indications for Admission

Indications for admission of patients sustaining maxillofacial trauma may be related to concomitant injuries in adjacent or remote regions, or for management of the facial trauma itself. Patients with nondisplaced simple facial fractures can often be managed as outpatients after telephone consultation with the appropriate surgical specialist provides for disposition and follow-up planning. Any patient with significant airway compromise, hemorrhage, or complex facial trauma requires admission. In the patient with isolated facial fractures, a regular-floor bed should suffice; however, any patient with injuries prompting concern for airway compromise or hemorrhage should be observed in a monitored setting.

Patients with CSF leak must be evaluated by a neurosurgeon in addition to the specialist consulted for accompanying facial fractures. Many neurosurgeons consider CSF rhinorrhea an indication for prophylactic antibiotics, but this decision is left to the consultant.

Transfer Considerations

The surgical therapy of maxillofacial trauma is a rapidly evolving field. Patients with significant injuries should be transferred to referral centers if local consultants lack expertise in treating the injury in question. Before transfer, the patient who requires definitive care of maxillofacial injuries must be evaluated for other more potentially life- or limb-threatening injuries. Even in the setting of isolated maxillofacial trauma, the potential for airway deterioration is real, and pretransfer stabilization in these instances may reasonably include intubation. The potential for airway compromise, as well as the high frequency of significant associated injuries, dictates a high level of training for personnel involved in the prehospital or interhospital transport of the patient with significant maxillofacial trauma.

COMMON PITFALLS

- Failure to manage the airway aggressively with intubation or cricothyrotomy where indicated. Do not wait for swelling or hemorrhage to convert an elective procedure into an urgent one.
- Failure to consider the presence of injuries other than ones that are obvious. Pay particular attention to the neurologic and ophthalmologic examinations.
- Failure to order CT views where the index of suspicion is high, even if plain radiographs are negative.
- The historical emphasis on searching for c-spine injuries in patients with facial fractures is probably relevant only in patients with mandible fractures. Because of the potential need for endotracheal intubation for airway management and the patient positioning required for many facial imaging modalities, plain radiography of the c-spine remains the initial radiologic study.
- Frontal bone injuries are particularly likely to be associated with intracranial injury, but investigators have been unable to define rules allowing correlation of specific facial fractures with intracranial injury. All patients with significant facial fractures require cranial CT scanning.

Injuries to the teeth and their supporting structures occasionally present the emergency physician with a challenge in both diagnosis and treatment, in part because of the limited training physicians receive in dentistry and oral emergencies. Another problem is that in patients with multiple injuries, oral injuries are often overlooked once the airway is secured and more life-threatening injuries are addressed. Teeth have the lowest potential of any tissue for returning to a normal healthy state after injury; because the prognosis of some dental injuries is greatly enhanced by prompt initial treatment, rapid care is imperative. ¹⁵

Dental trauma is best categorized as either intentional or unintentional, with injuries caused by domestic violence or assaults considered intentional and those caused by sporting events, motor vehicle crashes, falls, or collisions categorized as unintentional. Over 50% of all physical trauma from child abuse is inflicted on the child's head and neck region, with soft-tissue injuries predominating. ^{1,8,15} These types of injuries should alert the physician, and a complete physical examination must be undertaken to ascertain other injuries. In adult abuse (inflicted typically on women and the elderly), lip lacerations, fractured teeth and jaws, missing teeth, and bruises and burns of the palate, gingivae, and face predominate. ^{1,8,15}

Of the unintentional injuries, sporting injuries are most prevalent in teen-age males, and account for 13% to 39% of all dental trauma. ² Motor vehicle crashes account for 11%, and motorcycle or bicycle crashes account for another 10% of dental trauma. ² Finally, falls account for 17% to 69% of injuries, and occur most frequently in young children, the elderly, and the intoxicated. ^{2,8}

Predisposition to dental trauma involves the extremes of age (children and the elderly), patients prone to risk-taking behavior (teen-age males), and the debilitated. In children, predisposing anatomic factors for traumatic tooth injuries include postnormal occlusion, an overbite exceeding 4 mm, short upper lip, incompetent lips, and mouth breathing.

INITIAL EVALUATION

As with other injuries, the examiner should attempt to determine the exact time and mechanism of the injury. Any missing teeth or dental prostheses must be accounted for, to prevent them from compromising the airway or being retained in soft-tissue wounds. A comprehensive medical history helps determine if tetanus immunizations are up to date and whether antibiotics are indicated as a prophylaxis before any dental manipulation or as an aid to wound healing (e.g., if the patient has a history of rheumatic heart fever or diabetes). ^{1,11}

EXTRAORAL EVALUATION

The extraoral evaluation should assess for lacerations, abrasions, and contusions. In wounds under the chin, jaw fractures and condylar injuries must be excluded. If the patient has difficulty opening or closing the jaw or if there is asymmetry to these movements, fractures of the mandible or facial bones should be suspected. Assess midface stability by placing two fingers along the hard palate and pulling the alveolar process forward and backward gently. If there is crepitus or motion, the patient has, at minimum, a LeFort I fracture. ¹

INTRAORAL EXAMINATION

Next, evaluate intraoral bleeding sites and lacerations of the mucosa and gingival tissues. Contaminated or bleeding areas should be cleansed with dampened gauze or irrigated. Hemorrhage in the gingival crevice of the tooth may indicate subluxation, and the presence of traumatized gingivae or mucosa suggest underlying dentoalveolar injuries. This examination and the remainder of the intraoral examination is best performed with two tongue blades and a bright light. Once this examination is complete, bimanually palpate the cheeks and floor of the mouth for foreign bodies or tooth fragments.

Evaluate the dentition for cracks, chips, abnormal alignment, and missing or abnormally occluding teeth. If teeth are missing or chipped, look for fragments in soft-tissue wounds. ^{1,11} Changes in tooth coloration (red or greyish hue) may occur with pulpal necrosis or congestion. The horizontal and vertical mobility of teeth should be assessed using tongue blades rather than fingers, because the fingers can miss subtle findings.

Remember that deciduous teeth near the time of exfoliation normally exhibit mobility. If teeth move en bloc, a fracture of the alveolar process may be present. ^{1,11} Percussion of the occlusal edge of teeth may elicit extreme sensitivity or tenderness if periodontal tissues are traumatized. This sensitivity also supports the diagnosis of subluxation. ¹⁰

Finally, if a partial denture or missing tooth cannot be located, it may be imbedded in soft-tissue wounds or the patient may have swallowed or aspirated it. The examiner should document all damaged or missing teeth (Fig. 98.1). Finally, injuries to the orofacial region are often not limited to the teeth and supporting soft tissues. In trauma patients, one must always suspect other bony injuries to the face as well as neurologic injury (discussed in depth in [Chapter 96](#) and [Chapter 97](#)).

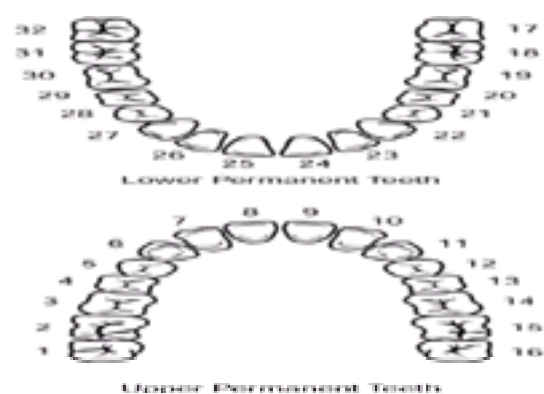

Figure 98.1. Upper and lower permanent teeth.

RADIOGRAPHIC EXAMINATION

Dental radiographs, such as panoramic, occlusal, or periapical films, are helpful in further diagnosis. Because most emergency departments are poorly equipped in this regard, standard mandible or facial films may be useful in certain circumstances to aid diagnosis.

TREATMENT OF DENTAL INJURIES

The treatment of dental injuries in the emergency department varies according to the facilities available and the examiner's expertise.

Concussed Teeth

Concussed teeth are those that, when examined, have no obvious injury other than a sensitivity to percussion.^{5,18} These teeth may have sustained an injury sufficient to cause later pulpal (nerve) death and necrosis. Treatment consists of a soft diet and follow-up care.

Tooth Displacement

Subluxation

Subluxated teeth appear undamaged but demonstrate abnormal mobility on examination. Teeth may be sensitive to extremes of temperature and there may be some gingival bleeding. The patient may complain of not being able to bite all the way into his or her normal occlusion. This slight extrusion is due to edema at the apex of the root. Treatment consists of minor adjustment of occlusion or splinting.

Displaced Teeth

There may be intrusive, extrusive, buccal, or lingual displacement of the tooth; the tooth is in an abnormal position. For buccal, labial, and lingual displacements, the tooth is repositioned in its alveolar socket with the aid of a gloved hand and a gauze pad. Extruded teeth may be repositioned by having the patient gently bite down on a folded gauze pad. If gentle attempts at these maneuvers are too painful, dental anesthesia by infiltration or a nerve block may be necessary. Once reduced, the tooth should be splinted.

Occasionally, teeth sustain a blow sufficient to intrude or embed them into the alveolar bone.⁵ These teeth are usually not mobile and present no interference to the patient's occlusion. These patients must be referred to a dentist as soon as possible. Primary teeth are allowed to reerupt or are extracted. Permanent teeth may reerupt on their own, but often require orthodontic or surgical eruption with stabilization. Subsequent root canal therapy is often necessary. All patients with displaced teeth should be prescribed analgesia and a soft diet. The use of straws should be avoided. Warm saline rinses three times a day may help promote gingival healing. Dental follow-up is required in 24 hours.^{5,6,18}

Avulsed Teeth

Complete displacement of a tooth from its alveolar socket constitutes an avulsion. A permanent tooth that has been avulsed is a true dental emergency, with the prognosis for recovery greatly enhanced by prompt intervention.^{5,20} Primary teeth are usually not replanted: Replanted teeth fuse to the alveolar bone and interfere with the eruption of the underlying permanent teeth. Most anterior primary teeth are present until age 6 or 7.

Avulsed permanent teeth must be replanted for both aesthetic and functional reasons. In adults, the open space is unaesthetic, and it is often difficult to match a false tooth to the remaining teeth. Functionally, the adult teeth will shift if the tooth is not replaced. This malalignment can lead to periodontal disease and temporomandibular joint pain and dysfunction.

The object of initial care is to ensure immediate replantation of the tooth to prevent or lessen the process of root resorption, which may cause loss of the tooth. Although early replantation is viewed as a temporary measure, it has been shown that teeth replanted within 30 minutes have a 90% retention rate without significant root resorption for up to 5 to 10 years. Conversely, 95% of the teeth replanted after 2 hours show root resorption.^{5,11,18,19}

Proper handling of the tooth is equally important to ensure the long-term survival of the tooth and the periodontal ligament remnants attached to the root. These remnants are sensitive to damage by drying, and successful replantation depends on their survival.^{1,5}

When the patient, parents, or emergency medical technicians contact the emergency department concerning treatment for an avulsed tooth, they should be told the following^{1,5,18,19 and 20}:

- The root of the tooth may not be touched. Only the crown may be handled.
- If the caller is able to replace the tooth in its exact location, have him or her do so after thoroughly rinsing the tooth with tap water (advise the caller to stopper or close off the drain first). Debris *should not* be scrubbed from the root surface.
- If replantation in the field is unsuccessful or impractical, have the caller transport the tooth by placing it under the patient's tongue, if the patient is a coherent, responsible adult. Alternatively, the tooth may be wrapped in moist gauze or placed in a cup of saline solution, saliva, milk, or Hanks balanced salt solution¹³ for immediate replantation by a physician or dentist.

If replantation was successful in the field, the physician must check for proper alignment and degree of mobility. Most teeth require some form of stabilization (see the later discussion on [stabilization of traumatized teeth](#)).

If replantation is done in the emergency department, follow these guidelines:

- Replantation should be questioned in patients with grossly neglected oral hygiene and severe periodontal disease. There is minimal chance of successful replantation.
- If the alveolus or socket is intact, replantation should be attempted.
- The tooth should be handled by the crown only. Saline solution is used to irrigate debris from the root.
- The socket should then be gently irrigated or swabbed free of clot. The socket should not be subjected to curetting, which damages the remaining periodontal ligaments.
- The tooth is reinserted using gentle pressure with the aid of gauze to provide a firm grip on the crown. Once the tooth is inserted, have the patient slowly bite down on folded gauze and seat the tooth into its proper position.
- If possible, the position of the tooth should be checked radiographically.
- Reimplanted teeth should be splinted.
- Tetanus immunization should be updated.
- Penicillin or clindamycin are prescribed for antibiotic coverage.
- Follow-up care is required within 24 hours.

Fractured Teeth

Fractures of the Enamel (Ellis Class I)

Fractured teeth may show minor chipping of superficial enamel surfaces, causing sharp edges that may be irritating. Referral to a dentist for follow-up care and smoothing of rough edges should be arranged.

Fractures of the Enamel and Dentin (Ellis Class II)

Fractures through enamel (white) and the underlying dentin (pale yellow) expose dentinal processes that communicate directly with the central nerve or pulp and make them susceptible to necrosis and abscess formation. The patient experiences pain to touch or percussion, and frequently the exposed free nerve endings cause exquisite pain when air passes over them.^{1,11,18}

The dentist will cover the exposed dentin with a layer of calcium hydroxide, an inert substance that seals the dentinal tubules, commonly eliminating the pain.^{1,2,5} This layer is then covered by a composite dental material by acid-etching the surrounding enamel to provide microscopic undercuts that aid in retention of the material on the tooth surface.⁵ Emergency department treatment is limited to providing dental consultation or follow-up as soon as possible. A soft diet is prescribed, and the patient should avoid hot or cold foods.

Fractures of the Enamel and Dentin with Pulp (Nerve) Exposure (Ellis Class III)

When a pink or red color or fleshy substance is noted within the surrounding dentin (pale yellow) on inspection of a fractured tooth, a fracture involving the pulp (nerve) should be suspected. The relative size of the pulp chamber in an adult central incisor is shown in [Fig. 98.2](#). The patient usually has pain with manipulation of the tooth, exposure to air, or exposure to hot or cold fluids. Most fractures that involve pulp exposure require root canal therapy by removing the remaining vital pulp as soon as possible to prevent later abscess formation.⁵ However, more conservative measures of pulp capping, or covering the exposure with calcium hydroxide, followed by restoration, may be indicated in small exposures of healthy teeth.

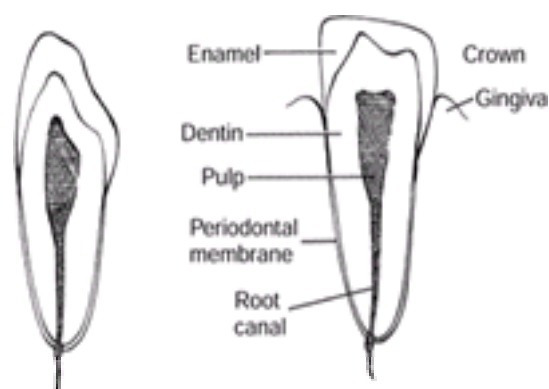

Figure 98.2. An adult central incisor.

Ideally, a dental consultant should see the patient in the emergency department. If unavailable, dental follow-up should be provided as soon as possible.

Root Fractures

Teeth with root fractures are difficult to diagnose by clinical examination alone. The only outward sign may be abnormal mobility or sensitivity to percussion. Dental films are mandatory to confirm the diagnosis, so immediate dental consultation is advisable.

In the acute setting, significantly displaced teeth must be reduced to their proper position and stabilized with a splint. Early intervention allows retention of the teeth without the need for root canal therapy in up to 80% of cases.¹

Crown Root Fractures

While similar in appearance to crown fractures (described earlier), crown root fractures start above the gingival margin of the tooth and continue subgingivally within the tooth's alveolar socket. If the fracture fragments are nondisplaced, they are difficult to detect clinically. Management rests on determining the extent of damage to permanent teeth by removing the coronal portion of the tooth. Primary teeth generally require extraction. Immediate dental consultation is warranted.¹⁸

Dentoalveolar Fractures

Fractures that involve the alveolus or tooth-bearing portion of the maxilla and mandible vary in their degree of displacement, mobility, and comminution and in the number of teeth affected. The patient usually complains of malocclusion, mobile teeth or alveolar segments, and local pain when biting. The examiner usually notes a displaced alveolar segment or group of teeth, a mobile segment on palpation, and malocclusion. Dental radiographs or facial films should be ordered. They may show fracture lines running between or just apical to the roots of the teeth.

Treatment of dentoalveolar fractures usually involves repositioning the displaced segment, possibly under local anesthesia or intravenous sedation, stabilization of the segment with rigid splinting, and follow-up care. Often these fractures require care that is unavailable in the emergency department. Therefore, urgent consultation should be sought from a qualified general dentist or oral and maxillofacial surgeon.⁵

Oral Soft-Tissue Injuries

Most soft-tissue injuries of the mouth can be managed by an emergency physician. Rapid closure in the emergency department results in decreased risk of infection, decreased healing time, and improved hemostasis and future cosmetic result. Final cosmetic result, however, depends on the rapidity of closure after injury (ideally within 12 hours), the degree of contamination, and the orientation of the injury to Langer's lines of skin tension. Favorable lacerations parallel Langer's lines. Unfavorable ones cross Langer's lines, and patients must be advised that they have a greater risk of contraction and scar formation. Scars can be revised by a plastic surgeon when they are mature (when fibrous elements dominate over vascular elements), 1 year after repair.

General Approach

All soft-tissue wounds require copious irrigation, assessment of retained foreign bodies, and, if grossly contaminated or devitalized, minimal debridement. A patient's tetanus immunization status must be assessed and updated if necessary. Penicillin is advocated for intraoral and puncture wounds, while clindamycin is utilized in patients who cannot tolerate penicillin. Through-and-through wounds require the addition of an antistaphylococcal antibiotic (dicloxacillin or cephalexin) for 5 days.¹⁵ A soft diet and warm saline rinses four times a day are prescribed, and patients should see a dentist within 24 to 48 hours. Immediate medical attention must be sought in the case of fever, increasing edema, or erythema at a wound site, or if pus is noted.

Puncture Wounds

Animal bites, particularly dog bites, are the most common bites of the face in children. Wounds must be meticulously examined for foreign bodies, especially in cat bites, where the small, relatively brittle teeth can remain in the wound. Lacerations smaller than 2 cm and all puncture wounds should be left to heal by secondary

intention. If the patient presents within 12 hours and the wound is minimally contaminated, however, it may be closed with as few interrupted sutures as possible to achieve approximation of wound edges.

Closure should be undertaken only if the defect is so great that secondary healing will result in a deformity. A drain may be placed for 24 to 48 hours in the setting of a deep laceration. Prophylactic and empiric therapy of bites is best achieved with amoxicillin–clavulanic acid for 5 days.^{3,7} In addition to antibiotic coverage, all animal bites should be considered for rabies prophylaxis.

Human bites are highly prone to infection. As some *Bacteroides* species are resistant to penicillin because of their b-lactamase activity, penicillin and a penicillinase-resistant penicillin or amoxicillin–clavulanic acid are advocated.^{3,7}

Tongue Lacerations

In treating tongue lacerations, anesthesia is achieved by using a 25-gauge needle filled with 1% lidocaine and inserting the needle posterior and medial to the most distal molar on the side of the tongue laceration. In children, advance the needle approximately 0.5 cm in depth, and in adults approximately 1 cm in depth; aspirate to check for intravascular needle placement; and then inject 0.5 to 1.0 mL of anesthetic agent. If the laceration is bleeding, local anesthesia with 1:100,000 epinephrine can be used to decrease the rate of bleeding. The only disadvantage to this mode of anesthesia is that the tissues may be distorted by the anesthetic bolus.

Interrupted absorbable sutures (3-0 or 4-0 chromic or Vicryl) approximate deep muscle, then submucosa, and finally the dorsal or ventral surface (or both). All knots are buried (inverted). Occasionally, placement of sutures is difficult because of the floppy nature of the tongue. Grasp the tongue between folded gauze or place a single suture at the tip, with the two long ends wrapped about your nondominant hand, and exert gentle outward traction; this technique generally provides adequate visualization.^{16,19}

Buccal Mucosa

Anesthesia of the buccal mucosa is most easily achieved by local infiltration of 1% lidocaine with 1:100,000 epinephrine. Through-and-through lacerations should be closed in layers from the inside out. The inner layer should be approximated with an inverted 3-0 or 4-0 absorbable suture. If irrigation was difficult to achieve when both margins were open, the closure of the inner layer will now allow the irrigation solution to flow outward and not fill the mouth. The muscle layer is then closed with absorbable inverted sutures, and the skin is closed with interrupted sutures of 5-0 or 6-0 nylon.

Remove these sutures in 4 to 5 days. If there is any injury to Stensen's duct, the patient should be referred to an oral surgeon to avoid complications of fistula or mucocele formation and infection.¹⁹ Lacerations or injury to Stensen's duct can be diagnosed in the following ways:

- Dry the inside of the cheek and exert gentle pressure on the parotid gland. If it is intact, a globule of saliva should appear at the ductal opening.
- On occasion, the severed ends of the duct can be localized in the wound.
- If the upper lip on the side of the injury is drooping: The buccal branch of the facial nerve runs slightly superior to the duct as it crosses anterior to the masseter. Injury to this nerve suggests injury to the duct as well.
- The patient complains of swelling of the cheek, particularly after meals. The swelling is the accumulation of saliva in the buccal tissues.

Injury to the parotid gland is repaired by closing the skin over the cut gland. Warn the patient that fluid may escape through the margins of the wound. This seepage should cease once scar tissue forms in the wound. If a fistula develops, the duct was either severed or obstructed and needs to be reexplored and repaired.¹⁹

Gingiva

Gingival lacerations are sometimes noted at the site of mandibular or maxillary fracture locations or at the site of avulsed teeth.¹⁴ Rarely, patients present with gingival degloving, but treatment is the same.² The gingiva are repositioned and sutured in place with fine silk sutures. Given the friability of the gingiva, suturing may be best accomplished with an anchoring stitch on the opposite side of the tooth. Sutures are removed in 4 to 5 days.

Lip Lacerations

In lip lacerations, it is best to use nerve blocks rather than local infiltration in order to prevent distortion of the vermilion border. If local infiltration is used, the addition of epinephrine to the anesthetic solution decreases the amount of agent needed for anesthesia and will help maintain hemostasis. Blanching of the mucosa may occur, however, obliterating the vermilion border.

For injuries of the upper lip, an infraorbital block is used. In injuries of the lower lip, a mental block will provide anesthesia from the midline to the labial commissure. An inferior alveolar block will encompass the area of a mental block and also anesthetize the buccal mucosa, the lingual gingiva, the anterior two-thirds of the tongue, and the dentition on the side of the injection.

After anesthesia is achieved, minimal debridement of devitalized tissue and damaged minor salivary glands is undertaken. If salivary glands are incorporated in the repair, there is risk of mucocele formation.

Proper closure rests on first approximating the vermilion border. Place a stitch that aligns the two edges of the wound and then continue with local anesthetic infiltration or the closure itself. Needle scratches or marking the edges with a surgical marker are not recommended: The scratch or pen mark may be obliterated once the wound is prepped with Betadine, and the marker tips are often not fine enough to clearly demarcate the border.

Closure of a through-and-through laceration begins at the inner fibro-fatty layer. Using a 3-0 or 4-0 absorbable suture, place inverted, interrupted sutures starting inferiorly and continue upwards, stopping at the apex of the wound. Suture the outer fibro-fatty layer in a similar fashion, working inferiorly to the wound apex. Reapproximate the two fibro-fatty layers once the outer closure meets the inner closure at the apex of the wound. Close the epidermal–dermal layer last. Using the vermilion border as a starting point, place interrupted, 5-0 nonresorbable sutures (nylon) to the apex of the wound. If the laceration extends to the mucosa (wet inner surface) of the lip, 4-0 or 5-0 chromic is used to close this layer. Another option in this setting is to close both inner fibro-fatty layer and mucosa as a unit and to suture from the base to the apex.¹⁶

Another option is the use of isobutyl cyanoacrylate in the repair of both superficial and deep lip lacerations. In one case report, a deep wound that included the orbicular muscle was repaired by inserting isobutyl cyanoacrylate from the bottom of the wound toward the lip surface, while continuously approximating the margins of the wound. After application, the patient was asked to slowly open his mouth to control bonding and orbicular muscle position. Excess material was removed with wet gauze.⁴

Penetrating Intraoral Trauma

The incidence of intraoral trauma in children is unknown, but it is likely that most cases heal spontaneously without complications.¹² However, there is a sizable literature documenting complications from these injuries, including retropharyngeal and mediastinal abscesses, mediastinitis, widespread emphysema, internal carotid artery thrombosis, and airway obstruction.^{9,12}

Most commonly, children sustain injuries after falling with sharp objects in their mouths.^{9,17} The injuries tend to be on the posterolateral oropharynx, and initial symptoms are limited to mild erythema or slight bleeding at the site of injury.^{9,17}

Management of these patients is controversial. Patients with obvious symptoms need hospital admission and aggressive management of the airway and infection. There is no consensus on the management of symptom-free patients.

Some authors advocate admission and observation for those with lateral or retropharyngeal injuries. Others recommend discharging patients with detailed instructions

for prompt return.^{9,17} Patients should return immediately if they have difficulty breathing, difficulty handling secretions, fever, change in mental status, or any change or worsening in condition. Finally, there is no consensus on the use of antibiotics for surgical exploration. However, the suturing of minor wounds should be resisted.^{9,12,17}

STABILIZATION OF TRAUMATIZED TEETH

In teeth that are concussed, there is typically no displacement of the tooth; therefore, splinting is generally not required. In teeth that are subluxated a flexible splint should be placed if one or more teeth are mobile. However, if only one tooth is slightly mobile, a splint is not required. The splint stabilizes teeth during the healing phase and can be safely removed in 7 to 10 days,⁶ ample time for healing of the periodontal ligament.

In both extrusive and buccal luxation, teeth are splinted and joined together by a wire or nylon line.¹³ Intrusive luxation is the most severe form of luxation injury and the tooth frequently undergoes external root resorption. Treatment is difficult and may involve either repositioning and splinting or watchful waiting. Because most teeth that are repositioned have a greater likelihood of external root absorption, watchful waiting is now recommended.¹³ Teeth that have been displaced long enough for blood to thoroughly clot should not be forced back into position because of the induction of root resorption.⁴ As with intrusive luxation, better results are achieved with orthodontic therapy.

An avulsed tooth should also be splinted once reimplanted into the socket. This splint may be removed in 7 to 10 days as well. However, with a concurrent alveolar fracture, the splint is left in place for 4 to 8 weeks.¹⁸

Temporary stabilization can be achieved by crimping a piece of aluminum foil around the teeth or using cotton rolls placed between the lip and teeth. Another means of stabilization if a formal dental examination is imminent is by having the patient bite down on a piece of folded gauze. A periodontal dressing, such as Coe-Pak (COE Laboratories, Chicago, Illinois) can also be used. The teeth are first cleaned and dried. Equal lengths of two pastes are mixed on a paper pad and then the material is folded over and crimped around the teeth and soft tissues.¹⁸

Two other means of stabilization include splinting with wire or nylon fishing line (flexible fixation) and Erich arch bars (rigid fixation). Light ligature wire (28-gauge) or fishing line can be used with isolated avulsed teeth or multiple mobile teeth, as long as there is no concomitant dentoalveolar fracture. For rigid fixation in severe injuries, Erich bars are utilized.

In the case of a single maxillary subluxated tooth, the tooth is first brought back into position, as outlined earlier. Stabilization is achieved by including both teeth distal and mesial (lateral and medial) to the injured tooth. A large loop of wire is first placed, encompassing all three teeth and gently crimped on the labial surface at the posterior tooth. Smaller pieces of wire are then placed interdentally, passing over the original loop of wire superiorly on both labial and lingual surfaces. This second wire passes back inferiorly between the teeth, sandwiching the original loop of wire between it. It is then twisted and crimped on the labial side.

This process continues until all interdental areas are secured. Care must be taken not to break the wire at any point. If it does break, the entire procedure must be redone.^{1,6} If available, the wire can be further stabilized by bonding it to individual teeth with acid etching. Small beads are placed on individual teeth and the wire is embedded in the material. If nylon fishing line is used, multiple ties are used instead of twisting and crimping.

An Erich arch bar is a semirigid wire, which is placed along the labial surface of the teeth and held in place with loops of wire, in a fashion similar to the previously described interdental technique. A similar splint, considered to be the splint of choice, is the acid-etched resin and arch wire splint. An arch wire is conformed to the labial surface of the teeth to be splinted. The middle third of each tooth is etched and the wire is attached with resin. At least two uninjured teeth are included in this splint, with the injured teeth sandwiched between them, and the arch is applied to these uninjured teeth first.^{1,6,13,18} Because Erich arch bars require advanced dental techniques, the emergency physician should master ligature wire–nylon splinting. In all cases, patients should be advised to eat a soft diet and use oral rinses in place of brushing until dental follow-up can be obtained.

COMMON PITFALLS

- Improper handling and transport of avulsed teeth
- Delaying reimplantation of avulsed teeth
- Failure to radiographically rule out aspirated teeth in the comatose patient
- Failure to splint teeth that are subluxated, avulsed, or have root fractures
- Failure to first approximate the vermilion border in lip lacerations

Eye trauma is common, accounting for up to 10% of emergency department visits. In general, it is associated with 12 to 29% of facial fractures. Each year, over 2 million eye injuries occur at home, work, and play. Sixty thousand are admitted. Visual impairment occurs in 50,000. Children under 17 have a higher percentage of serious injuries. It is estimated that wearing protective lenses could prevent 90% of all eye injuries. ⁵

The emergency physician (EP) is in an ideal position to diagnose, manage, and refer eye injuries. It is important that the EP be aware of conditions that threaten vision and perform a systematic examination to exclude those conditions. Many conditions that would have impaired vision in the past can now be preserved through advances in ophthalmologic therapy. Injuries to the eye occur by four mechanisms: abrasion, blunt force, penetrating object, and burns. This chapter presents an overview of the EP's approach to and management of eye trauma.

EMERGENCY DEPARTMENT EVALUATION

When confronted with eye trauma, the EP must conduct a systematic and comprehensive eye evaluation. Therapy is usually reserved until the evaluation is completed; however, there are two instances in which immediate action is imperative: the chemical burn and traumatic endophthalmitis. On arrival to the emergency department, the chemically burned eye must be irrigated immediately and continuously for at least 30 minutes with saline or another neutral solution (usually several liters), and preferentially until the measured pH reaches physiologic neutrality. This must happen before the completion of triage or any other portion of the evaluation. Traumatic endophthalmitis usually presents as pain and inflammation out of proportion to the penetrating injury that has led to the infection. It demands immediate ophthalmologic consultation to inject the eye with intravitreal antibiotics.

History

The history should establish four basic pieces of information: mechanism of injury, symptoms, eye history, and scene of the injury. The mechanism may involve an object striking the eye, a fall, a motor vehicle crash, an explosion, or a fire. Was the globe ruptured by blunt trauma or penetrated by an object? Symptoms referable to the globe include blepharospasm (involuntary lid closure), blurred vision, diplopia, eye pain, discharge from the eye, flashes of light, floaters, foreign-body (FB) sensation, halos, photophobia, redness of the eye, and tearing. The history includes visual acuity prior to the injury, eye disease, and past injury.

Visual Acuity

Visual acuity should be documented as soon as possible after the patient arrives, because it is the single most important predictor of visual outcome. Test one eye at a time, covering the opposite eye. Begin with the worst eye. Corrective lenses should be worn when possible; if they are missing, try using a piece of paper with multiple pinholes. Do not put contact lenses into an injured eye. The order of preference for testing acuity is as follows: far vision (20 ft from a Snellen chart), near vision (14 in. from a Rosenbaum card), reading print (note distance), counting fingers, hand motion, light perception, and no light perception. Children require some special consideration. From age 6 months to 3 years, fixing on a moving light source corresponds to 20/40 vision. From age 3 to 6 years, use Allen pictures. For those who cannot read, use the "E" chart.

Lids and Other Periorbital Structures

Examine the lids and periorbital structures. When there is any suspicion of an open globe secondary to blunt or penetrating trauma, *no pressure* should be applied to the globe thereafter for *any* part of the examination (see [Emergency Department Management](#)). Inspect for swelling, ecchymosis, proptosis, enophthalmos, ptosis, lacerations, and FBs. If the eye is swollen shut, lid retraction is necessary to view the globe and underlying structures. Ptosis suggests contusion or laceration of the levator palpebrae, Horner syndrome, or third-nerve palsy. Upper lid lacerations should be explored enough to note penetration of the tarsal plate, the muscle, or the entire lid (through-and-through). All three indicate significant force and raise the concern for injury to the globe. Any surface FBs that are noted should be removed. Penetrating FBs are always left for the surgeon to remove. Palpate the orbital rim and soft tissues and the zygomatic arch area, noting point tenderness, step-off, and subcutaneous emphysema.

Anterior Segment

The anterior segment of the eye includes the sclera, conjunctiva, cornea, anterior chamber, iris, and lens. To examine this part of the eye requires the use of a topical anesthetic, usually a minimum of 2 drops of anesthetic followed by 2 or more drops 20 seconds or more later. Inspect for globe laceration, FBs, subconjunctival hemorrhage (note extent), chemosis, limbal edema, lid laceration, and contact lens (remove when identified). Remove nonadherent FBs as soon as identified (see [Emergency Department Management](#)). Perform a slit-lamp examination to evaluate the globe (FBs, lacerations, and leaking vitreous), lid margins (lacerations), the cornea (FBs and abrasions), the anterior chamber (cell, flare, FBs, hyphema, and hypopyon), the iris (any disruption), and the lens (may be displaced partially or completely). Under a cobalt light, fluorescein dye is used to highlight abrasions on the cornea and to perform Seidel's test for leaking vitreous.

Pupils

The pupils provide information through size, shape, and reaction. Inspect the pupils, looking for anisocoria and distortion in the pupil. *Anisocoria* has been defined as a disparity in size greater than 0.3 to 1.0 mm. If the pupils react briskly and the degree of anisocoria is unchanged with and without bright light, the anisocoria is physiologic. A distorted pupil suggests globe rupture, iridectomy, or synechiae. In a ruptured globe, the pupil is tear-shaped, with the apex of the teardrop pointing toward the rupture. Test for relative afferent pupillary defect (RAPD) suggesting any of the following: efferent third-nerve damage, glaucoma, iris incarceration, massive internal derangement of the eye, optic chiasm or tract damage, optic nerve damage, retinal detachment, traumatic mydriasis, or vitreous hemorrhage. Observe the pupil symmetry and size in ambient light. Swing a bright light from eye to eye. When the light strikes the *unaffected* eye, both pupils constrict. When the light strikes the *affected* eye, both pupils paradoxically dilate. Verify the findings by swinging the light from eye to eye a few times.

Extraocular Muscles

Test the extraocular muscles in the six cardinal positions of gaze. With infants, use keys, a light, or toys. Binocular diplopia can be seen with an abscess, cellulitis, cranial nerve palsy, hematoma, orbital edema, orbital floor fracture with muscle entrapment, orbital wall fracture with muscle entrapment, or retrobulbar hemorrhage. Monocular diplopia can be seen with corneal irregularity, a dislocated lens (natural or implant), iridodialysis, or retinal detachment.

Posterior Segment

The posterior segment consists of the optic nerve, retina, and vitreous. The direct ophthalmoscopic examination yields limited but important information. It is not necessary to dilate the pupils. Absence of the red reflex or inability to visualize the fundus suggests cataract, hyphema, lens rupture, retinal detachment, or vitreous hemorrhage.⁴ Visual field testing by confrontation is sufficient for the EP. Optic nerve function is assessed by testing for RAPD (see previous section on [pupils](#)). If the pupils are nonreactive or irregular, red desaturation testing is a suitable substitute. To test red desaturation, ask the patient to view a bright red object with each eye separately and compare the two images. If the optic nerve is damaged in one eye, the image coming from that eye will appear gray or washed out in comparison to the good eye.

Intraocular Pressure

The intraocular pressure (IOP) may be elevated above 22 mm Hg in several conditions: acute glaucoma (from angle recession), globe rupture, hyphema, lens dislocation, lens swelling, suprachoroidal hemorrhage, and retrobulbar hemorrhage. Normal pressure ranges from 10 to 20.¹⁰ When the pressure is less than 5 mm Hg, penetration of the globe should be considered.

Imaging the Eye

When there is suspicion of injury to the orbit or globe, spiral computed tomographic (CT) scanning with axial and coronal cuts is the preferred study. Choroidal detachment, endophthalmitis, fractures, FBs, extraocular hemorrhage or hematoma (less than 3 days old), lens luxation or subluxation, globe rupture, orbital cellulitis, subperiosteal hematoma, vitreous hemorrhage (less than 3 days old), and, probably, retinal detachment can be identified. It can detect FBs as small as 0.6 to 1.5 mm, depending on the composition. Although ultrasound can detect FBs as small as 0.2 mm, operator dependence and the necessity of applying pressure to the globe limit its use.⁹

EMERGENCY DEPARTMENT MANAGEMENT

Blowout Fractures and Other Facial Fractures

When a ball, fist, or another object larger than the orbital rim strikes the eye, a blowout or other fracture may result. It is important to maintain a high index of suspicion, because the signs and symptoms can be minor. Suggestive signs and symptoms are diplopia, enophthalmos, epistaxis (medial orbital wall involvement), inferior displacement of the globe, ipsilateral numbness of the cheek and the upper lip (damage to the infraorbital nerve), periorbital ecchymosis, periorbital swelling, periorbital subcutaneous emphysema (sinus involvement), point tenderness of the orbital rim or maxilla, and palpable step-off.¹¹ Plain films have been used for diagnosis, but can be falsely negative (less than or equal to 60%) or falsely positive (less than or equal to 46%)²; therefore, a spiral CAT scan with coronal cuts is preferred for diagnosis. Most blowout fractures involve the inferior or medial walls of the orbit. Involvement of the roof of the orbit signals that considerably more force (about seven times) occurred and suggests violation of the cranial vault with associated injury to the brain.

LeFort fractures (I to III), tripod fractures, nasal fractures, and other fractures about the head and face may or may not have an associated eye injury, but it should be sought, given the forces involved. At the minimum for an apparently uninvolved eye, the visual acuity, extraocular movement, absence of obvious trauma, and absence of visual symptoms should be documented. See [Chapter 97](#), "Maxillofacial Injuries," for further discussion of facial trauma.

Management consists of oromaxillofacial referral, ophthalmologic referral, antibiotics (cover *Staphylococcus* and *Streptococcus*) for 10 to 14 days, avoidance of blowing the nose, ice packs, and nasal decongestant spray (oxymetazoline). Surgical repair can be delayed for up to 14 days. Eighty-five percent of blowout fractures (even symptomatic) will resolve without necessitating surgical intervention.¹

Burns

Five types of burns are considered here: chemical, electrical, infrared (IF), thermal and ultraviolet (UV). All eyes with chemical burns must be irrigated immediately with saline for at least 30 minutes. Check the pH 5 minutes after completing the irrigation. Repeat the irrigation until the pH is 7.0 to 7.4. Irrigation must not be held up for triage or registration. Time is sight. Irrigation at the scene is not an adequate substitute, because it is often inadequate. Contact the local poison control center for assistance in identifying the chemical in question, its pH, and its potential to cause damage to the eye. It is always a good idea to notify poison control so they can add the information to their record of exposures. After the irrigation is completed, the eye examination is conducted. *Alkali burns* are particularly devastating, because alkalis destroy and penetrate (liquefaction necrosis). Alkali damage is classified as four grades:

1. Corneal epithelial damage similar to a corneal abrasion with a good prognosis
2. Cornea is hazy, but the details of the iris are seen and up to one-third of the limbus is ischemic (whitened); the prognosis is still good.
3. Corneal epithelium is destroyed and the details of the iris are blurred; one-third to one-half of the limbus is ischemic; the prognosis is guarded.
4. Cornea is opaque, with the details of the iris and pupil obscured; more than half of the limbus is ischemic; the prognosis is poor.

Acid burns are classified in the same manner, but less often produce severe damage, because strong acids precipitate proteins, forming a barrier to further penetration (coagulation necrosis).

For severe chemical burns, the symptoms are dramatic. Pain is severe. The eye is reddened or white. The signs include anterior chamber reaction, chemosis, corneal edema or opacification, and vessel loss or ischemia (conjunctiva, limbus, and episclera). Prior to irrigation, remove all foreign matter by sweeping the fornices with a moistened cotton-tipped applicator. *Calcium hydroxide* tends to cake and may be easier to remove if the applicator is moistened with 10% EDTA. Minimal irritation and no symptoms after irrigation require no further follow-up. Moderate irritation with symptoms requires instillation of antibiotic ointment, and referral to an ophthalmologist in 24 hours. Any injury producing more than moderate irritation and significant change in vision mandates immediate consultation with an ophthalmologist.

Electrical burns are rare; however, the injury may be indirect. Nine percent of patients experiencing electrical injuries about the head develop cataracts 6 to 12 months after the injury. *Infrared radiation* can produce keratitis and "glassblower cataract" after prolonged exposure to heat. It can also result in macular damage or cataract formation. *Thermal burns* are rare. The light of a heat flash reaches the eye faster, producing the upward rotation reflex of the globe (Bell's phenomenon), which protects the cornea from damage. Thermal corneal injury occurs when hot objects, such as lighted matches, spitting grease, and car radiator steam, are propelled into the eye. These burns rarely involve more than the corneal epithelium and heal in a few days. Treatment involves the application of cold compresses (just cold enough to eliminate the pain) for up to 2 hours. Then, for partial thickness burns of the lids and surrounding skin, ophthalmic antibiotic ointment is applied. Minor burns of the

cornea are managed similarly to a corneal abrasion. For more severe burns, an ophthalmologist should be consulted immediately. *Ultraviolet radiation* from the sun, tanning salons, and welder's arc produces acute, diffuse, superficial punctate keratitis (SPK) of the corneal epithelium about 6 to 12 hours after exposure. The amount of radiation is enhanced by reflection (water, rocks, snow) and altitude above 8000 ft. If the exposure is prolonged, damage may occur to the retina, particularly the fovea, and vision is affected 1 to 2 days later.¹⁴ This injury is managed similarly to that of a corneal abrasion. A nonsteroidal antiinflammatory medication and a narcotic-containing analgesic are prescribed. Ophthalmologic follow-up for all burns of the eye is essential unless the injury is minimal.

Corneal and Conjunctival Injuries

The corneal epithelium is four to six cells thick, and abrasions thereof usually heal in 12 to 36 hours, and sometimes longer, depending on the injury. Wounds that extend through the basement membrane of the epithelium, and deeper, require surgical approximation. Infection is a risk with any wound, and a retained FB heightens that risk. Iron-containing FBs will leave a rust ring deposit after being in place for a couple of hours. Rust rings extrude to the surface over 2 days, where they are easily removed with an ophthalmic burr, similarly to an FB.

Corneal abrasions usually present with an FB sensation, whether or not there is an FB present on the cornea. Often, there is a history of something striking the eye. High-speed particles raise the suspicion for a penetrating eye injury. In addition to an FB sensation, symptoms include blepharospasm, blurred vision, eye pain, halos around lights, photophobia, red eye, and tearing. Occasionally, there is no report of pain. Visual acuity is mildly decreased. The eye is hyperemic, the eyelids are mildly swollen, and an anterior chamber reaction (cells and/or flare) is sometimes noted. Abrasions are highlighted by fluorescein and easily seen on slit-lamp examination or in a darkened room, using a hand-held cobalt light. Because fluorescein permanently stains a soft contact lens, remove the lens prior to fluorescein instillation. Low-mass, low-speed particles produce insignificant trauma without anterior chamber reaction; therefore, the IOP need not be measured. When larger objects, such as a finger, fist, or ball, strike the eye, the IOP should be measured. Treatment begins with instilling anesthetic ophthalmic drops (1 to 2 drops, followed in 20 seconds by 1 to 2 more drops). Removal of an FB is accomplished by using gentle irrigation; a saline-moistened, cotton-tipped applicator (brush off); an ophthalmic burr; or a 25-gauge needle held tangential to the corneal surface (pick off). Rust ring removal is accomplished with an ophthalmic burr. Instill a cycloplegic (homatropine 2% or cyclopentolate 2%, 1 to 2 drops) to reduce synechiae formation secondary to inflammation. Although controversial, some ophthalmologists would advocate patching the eye if there is considerable pain caused by blinking or the abrasion is greater than 2 mm in size. Antibiotic ointment is instilled and the patch (use two eye pads) is applied lightly, but firmly enough to keep the lids from opening under the patch. Patches are removed and the eye reexamined in 12 to 24 hours. Do not keep a patch in place for more than 24 hours because of increased risk of infection. If the eye is not patched, an ophthalmic antibiotic (drops q.i.d. or ointment b.i.d. or t.i.d.) is prescribed. Analgesics prescribed include a nonsteroidal antiinflammatory (daily dosing for 3 days) and a narcotic as needed. All corneal abrasions are followed closely, usually at a 1-day interval, until healed. EPs can manage corneal abrasions, but referral to an ophthalmologist the next day is a suitable option.

Contact lens usage can lead to numerous corneal problems. The symptom complex is similar to that of corneal abrasions. Contact lens–related corneal abrasions result from hypoxic injury (improper fit or overwear), toxic deposits under the lens, and trauma related to insertions or removal of the lens. Infectious keratitis can occur secondary to gram-negative bacterial organisms, particularly *Pseudomonas*, and protozoa, specifically, *Acanthamoeba* (soft contact lens wear, nonsterile saline rinsing solution made from salt tablets, and swimming while wearing the lenses). Chemical irritation occurs secondary to preservatives (thimerosal and chlorhexidine) and inadequate rinsing of lens after enzyme use. Tight lens syndrome occurs within 2 days of the fitting of the offending lens (usually a soft lens). The lens appears “sucked-on” and leaves a conjunctival imprint of the lens after lens removal. Other findings that may be seen with soft contact lens use include corneal ulceration, SPK, anterior uveitis, and hypopyon (infrequent).¹⁴ Treatment begins with removal of the contact lens. Remember that fluorescein permanently stains the lens. The eye is not patched. An antipseudomonal ophthalmic antibiotic preparation is prescribed. A cycloplegic is instilled (see [corneal abrasion management](#) in previous paragraph). Refer to an ophthalmologist the next day.

Conjunctival and *subconjunctival* injuries are minor if the underlying sclera remains intact, because the conjunctiva do not provide any structural support to the eye. Often, there is no history of anything striking the eye. The visual acuity is usually unaffected. There may be an associated corneal injury, exhibiting the usual corneal symptoms. All conjunctival wounds, with or without an associated FB, must be examined under magnification for indications of scleral penetration. The eye is anesthetized in the usual manner (as noted under [corneal abrasion management](#)) and the wound is teased with a cotton-tipped applicator, while observing for white scleral tissue. Seidel's test can provide additional information. If there is any doubt about wound penetration of the sclera, the injury should be managed as though there has been violation of the globe, and an ophthalmologist should be consulted immediately. FBs are removed from the fornices by hand-held irrigation or forniceal sweeping with a saline-moistened, cotton-tipped applicator (eye must be anesthetized in the usual manner). If the wound solely involves the conjunctiva and there is no associated corneal injury, an ophthalmic antibiotic is prescribed, as noted with corneal abrasions. There is no need to patch the eye. Refer the patient to follow-up with an ophthalmologist the next day.

Eyelid Lacerations (Complex) and Other Penetrating Trauma

As soon as there is any evidence of globe penetration, either overt or suggestive, the visual acuity must be documented grossly, the eye shielded immediately from any further pressure, and an ophthalmologist consulted. All protruding objects penetrating the eye must be left alone and protected from manipulation until an ophthalmologic surgeon takes over the management of the injury. Any penetrating wound near the eye is assumed to have penetrated the globe until proven otherwise. Isolated lacerations of the conjunctiva are benign. Lacerations of the sclera, or the full thickness of the cornea, are considered a penetrating injury. When the cornea is penetrated, the iris plugs the wound and distorts the pupil into a teardrop shape, with the apex of the drop pointing at the wound ([Fig. 99.1](#)). When there is doubt regarding a penetrating wound, Seidel's test should be performed. Parenteral antibiotics (gentamicin plus vancomycin or clindamycin) should be administered prophylactically (see section on [Endophthalmitis](#)). All penetrating eye wounds demand an emergent ophthalmologic consultation.

Figure 99.1. Penetrating corneal foreign body with entrapment of the iris, forming a teardrop pupil. This was a metallic chip projectile that resulted from hammering metal on metal.

An ophthalmologic surgeon should repair complex eyelid lacerations. These wounds are characterized by any of the following: exposed orbital fat, globe penetration, muscle laceration, nasolacrimal system damage, significant force involved, tarsal plate laceration, or through-and-through laceration. With any wound of the eyelid or near the eye, it is imperative that the lids be retracted to rule out globe penetration. The nasolacrimal duct system is located in the medial eyelids, extending laterally 5 to 7 mm from the medial canthus. Medial to the canthus, the system runs vertically to empty into the nose. A parenteral antibiotic (cover *Staphylococcus* and *Streptococcus*) should be administered prophylactically. All wounds should be covered with a sterile saline dressing to keep the tissues moist until the ophthalmologist arrives.

Eyelid Laceration (Simple) and Periorbital Contusion

Either an eyelid laceration or a periorbital contusion, isolated or in combination, mandates a thorough evaluation (as outlined under Emergency Department Evaluation) to eliminate involvement of the globe or other underlying structures. Periorbital contusion is managed with ice packs, concurrent intracranial injury must be evaluated, and instructions are given for the ensuing 48 hours. Resolution of a simple contusion can take 2 to 3 weeks, while hemorrhage into the levator palpebrae may produce ptosis that can last for months. A simple laceration of the eyelid involves neither underlying structures (see [Complex Eyelid Lacerations](#)) nor the lid margin. Simple eyelid lacerations can be repaired readily by an EP. Contaminated wounds must be irrigated without directing the force against the underlying globe.

No tissue should be debrided, because of the excellent blood supply to the eyelid. Wound closure is accomplished with single interrupted 6-0 or 7-0 unabsorbable suture, which should be removed in 5 days. If the wound was contaminated, parenteral antibiotics (cover *Staphylococcus* and *Streptococcus*) are administered in the emergency department and oral antibiotics prescribed for the following 7 to 10 days. Unless the trauma was minimal, refer the patient to an ophthalmologist for follow-up evaluation.

Globe Luxation or Subluxation

This is rare. The visual acuity in the involved eye may vary from mildly reduced to no light perception. Reduction must be effected immediately, before the onset of orbital edema prevents reduction and to decrease tension on the optic nerve. If an ophthalmologist cannot be present within 20 minutes to reduce the globe, the EP should attempt reduction by applying gentle pressure to the globe while retracting the eyelids. Admission is mandatory for further ophthalmologic management.

Globe Rupture Secondary to Blunt Trauma

As soon as a ruptured globe is suspected, it is imperative to shield the globe, using a Fox shield, paper cup, Styrofoam cup, or similar device; and then to consult an ophthalmologist immediately (Fig. 99.2). Parenteral antibiotics (gentamicin plus vancomycin or clindamycin) should be administered prophylactically (see the section on [Endophthalmitis](#)). Additionally, bedrest, with the head of the bed elevated, and antiemetics are indicated to lessen the occurrence of stresses that might increase IOP. The globe is ruptured up to 3.5% of the time in blunt trauma.^{3,7} Ruptures typically occur at the weakest areas of the globe: the equator, the limbus, or muscle insertions. Another site of rupture is that opposite to the point of impact. The conjunctiva often remain intact after rupture, and bleeding occurring beneath the conjunctiva produces circumferential bloody chemosis (Fig. 99.3). When severe eye hemorrhage (hemorrhagic chemosis, hyphema, vitreous hemorrhage) or severe periorbital hemorrhage has occurred, the presence of one of four signs predicts rupture with a sensitivity of 100% and a specificity of 98.5%. Those signs are (1) a visual acuity that demonstrates light perception or less, (2) an anterior chamber that is abnormally deep or shallow, (3) an IOP of less than or equal to 5 mm Hg, and/or (4) a media opacity that prevents fundus visualization.⁷ If intubation is necessary, the use of succinylcholine should be avoided, if possible, because it raises extraocular muscle tone.

Figure 99.2. Ruptured globe from blunt trauma with prolapse of choroid, easily mistaken for clotted blood.

Figure 99.3. Large subconjunctival hemorrhage with bloody chemosis associated with occult ruptured globe, subsequent to blunt trauma.

Hyphema and Other Anterior Segment Injuries

The forces of blunt and penetrating trauma contuse, cut, rupture, stretch, and tear the tissues of the anterior segment of the eye, resulting in hyphema, glaucoma, lens displacement, and cataracts. When any of these conditions are diagnosed or suspected, an ophthalmologist should be consulted immediately. *Hyphema* may be microscopic (cells visualized by slit lamp) or gross (gauged by the percentage of the anterior chamber that is filled). If blood fills the chamber entirely, it is called an "eight ball" hyphema (Fig. 99.4). Symptoms include pain, red eye, and blurred vision. Treatment begins by shielding the eye and elevating the head to 30 degrees. Medications, other than those for pain and nausea, are administered only at the direction of an ophthalmologist. Some microhyphemas are managed on an outpatient basis. When there is a history of sickle cell disease or trait and the IOP is greater than 25 mm Hg, the anterior chamber may need to be washed out. In general, rebleeding will occur in up to 37% of the cases.⁶

Figure 99.4. Traumatic hyphema (25%) with blood layering in the anterior chamber, subsequent to impact from a racquetball.

Traumatic glaucoma occurs if the trabecular meshwork is obstructed by blood and inflammatory products or is disrupted. Glaucoma may develop acutely over hours or be delayed for months or years, depending on the injury. Medications employed acutely include topical b-blockers, acetazolamide, mannitol, and, sometimes, miotics. Lens displacement varies in degree, as do its associated symptoms, which include myopia, monocular diplopia, and, most commonly, blurred vision. Several signs suggest this diagnosis, including decreased visual acuity, anterior chamber asymmetry, a displaced lens, quivering of the iris (iridodonesis) or the lens (phacodonesis) after rapid eye movement, visibility of the lens edge, and the presence of vitreous in the anterior chamber. *Traumatic cataracts* can occur secondary to blunt trauma alone (contusion cataracts) or secondary to penetrating trauma, irrespective of direct injury of the lens capsule. Violation of the lens capsule tends to accelerate the process. Traumatic cataracts also may occur after lightning injuries. They develop in hours to months. Symptoms include blurred vision, glare from

lights (particularly headlights), and reduced color vision. Signs include decreased visual acuity, an indistinct retina, lens opacity, and a reduced red reflex. In acute trauma, the eye should be shielded as soon as any of these conditions are identified or suspected.

Intraocular Foreign Bodies

Eighty percent of all intraocular FBs enter the eye through the cornea. The obvious penetrating FB of the eye is easy to diagnose. When not evident, they should be suspected in certain circumstances, including a history of hammering metal on metal (grinding usually does not lead to penetration), a child with eye pain and a history of something sharp being near the eye, and a history of head trauma with the eye(s) swollen shut. Metal splinters produced by hammering metal on metal and glass splinters produced by shattering glass can penetrate the eye painlessly.⁸ Plain films can be helpful but do not differentiate intraocular from extraocular FBs. Some FBs are not intraocular but intraorbital. In this circumstance, damage to the globe must be ruled out. The imaging study of choice for detecting intraocular FBs is spiral CT.

Intraocular FBs that remain in the eye can produce varying degrees of inflammatory reaction. Copper, iron, steel, vegetable matter, and wood produce severe reactions. Aluminum, nickel, mercury, and zinc produce mild reactions. Carbon, coal, glass, gold, lead, plaster, plastic, platinum, porcelain, rubber, silver, and stone are inert. Iron, nickel, and steel are magnetic. Inflammatory reactions put the eye at risk for endophthalmitis.

Posterior Segment Injuries

The posterior segment consists of choroid, optic nerve, retina, and vitreous, and any indication of injury to it mandates an immediate ophthalmologic consultation. The choroid, retina, or vitreous may be detached, hemorrhagic, ruptured, or torn. The optic nerve may be injured along its course by direct or indirect mechanisms.

Symptoms are often lacking. When they occur, they are nonspecific: blurred vision, curtain of darkness, flashes of light, floaters, pain, and red eye. Important signs are blurring of fundus detail, decreased acuity, and RAPD. Anatomic findings are not necessarily apparent on direct funduscopy performed in the emergency department, even with dilatation. They are best identified by an ophthalmologist using dilated indirect funduscopy.

Retrobulbar Hematoma

This is a very rare condition. It is associated with intraoperative retrobulbar injections and occurs postoperatively. It is less often associated with trauma. Signs and symptoms include severe eye pain, nausea, vomiting, decreasing vision, diplopia, RAPD, decreased ocular motility, hemorrhagic chemosis, and proptosis. If it develops over minutes, the eye must be decompressed immediately by lateral canthotomy (Fig. 99.5). If it develops over hours, conservative management is appropriate and involves head elevation, ice packs, acetazolamide, mannitol, timolol, and serial measurements of IOP and pupillary responses. An ophthalmologist must be consulted as soon as this condition is suspected.

Figure 99.5. Retrobulbar hemorrhage demonstrating dramatic proptosis and subconjunctival hemorrhage after a fist strike in a man on warfarin.

Subconjunctival Hemorrhage (Isolated)

Typically, an isolated subconjunctival hemorrhage is flat and involves a small portion of the bulbar conjunctiva without any break in the membrane. The history may reveal a related Valsalva maneuver or rubbing the eye, but often there is no history to explain the event. In addition, there is no history of anticoagulant use, blood dyscrasia, or recurrent subconjunctival hemorrhage. No treatment is necessary. The condition is not threatening to the eye and will resolve over approximately 14 days.

Traumatic Iritis

Any trauma to the eye may produce inflammation in the anterior segment of the eye, with symptoms of blurred vision, pain, photophobia, redness of the eye, and tearing. Other names for this condition are *anterior chamber reaction*, *anterior uveitis*, *uveitis*, and *iridocyclitis*. Iritis occurs in up to 18% of eye trauma.¹² Symptoms vary from mild to severe and include blurred vision, pain, photophobia, redness of the eye, and tearing. Visual acuity is usually mildly decreased, but can be significantly reduced. The pain of ciliary spasm is exacerbated by light shining in the eye, which increases ciliary muscle contraction (photophobia). When light strikes the unaffected eye, the consensual response exacerbates the pain (consensual photophobia). Protein and white cells are visible by slit lamp in the anterior chamber. The limbus is injected. In severe reactions, there may be hypopyon. The IOP may be increased or decreased. Treatment includes a cycloplegic (2% homatropine or 2% cyclopentolate), a nonsteroidal antiinflammatory medication (for 3 days), and a narcotic analgesic (as needed). The patient is referred to an ophthalmologist (usually within 36 hours), who, in some cases, will prescribe steroids.

SECONDARY CONDITIONS

Endophthalmitis

Eye trauma (25% of cases) and eye surgery (62% cases) predispose to endophthalmitis. It develops in 8% to 13% of eye trauma when there is a retained FB. The percentage rises to 26% if the FB is organic material from a rural setting. The onset is sudden and begins from hours to 2 months after the injury. *Bacillus cereus* infection has been reported to develop within 24 hours, streptococci within 2 days, and *Staphylococcus epidermidis* within 4 days.¹³

Delay in treatment of a few hours, particularly with *Bacillus* species, can lead to the loss of an eye. The symptoms are blurred vision, fever, a red eye, and severe pain. The signs are anterior chamber reaction, acuity decreased (marked), cells and opacities in the vitreous, conjunctival hyperemia, corneal ring abscess, decreased red reflex, hypopyon, increased IOP, and proptosis. There is a noted association between *B. cereus* infections, metallic intraocular FBs, and injuries related to soil. Early diagnosis is imperative for the best outcome; therefore, the EP must maintain a high index of suspicion for endophthalmitis.

Sympathetic Ophthalmia

The incidence is 0.2% after penetrating eye trauma and 0.01% after routine eye surgery. Sixty-five percent of cases begin between 2 and 8 weeks after the insult, and 90% within 1 year (range of 5 days to decades). The signs and symptoms in the sympathetic eye begin as a mild anterior uveitis, which progresses over time to anterior and posterior uveitis. In about 5% of the cases, only the posterior uveitis manifests (blurred vision, floaters, pain, photophobia, and possible redness). The condition of the injured eye (exciting eye) may worsen at the same time.

The emergency management of the patient with a neck injury is one of the greatest challenges in trauma care. Neck wounds occur in 5% to 10% of all trauma victims, with associated mortality exceeding 10%. Either blunt or penetrating trauma can cause damage to multiple systems due to the close proximity of numerous vital structures in the neck. The occult nature of many of these injuries requires a thorough understanding of the anatomy of the neck and a systematic approach to evaluation and management. Whereas early surgical intervention was once the rule, growing experience with other diagnostic modalities and nonoperative management has led to reevaluation of traditional treatment approaches.¹⁵

This chapter focuses on the emergency department (ED) evaluation and management of blunt and penetrating neck trauma. The management of cervical spine injuries and hanging and strangulation injuries is reviewed elsewhere in the text.

ANATOMIC COMPLEXITY OF THE NECK

The neck contains components of the respiratory, gastrointestinal, vascular, musculoskeletal, endocrine, and central and peripheral nervous systems in closer proximity than in any other body region. These structures are partially protected by the mandible anteriorly and the cervical spine and thick paraspinal musculature posteriorly, but the lack of a surrounding skeletal or fibrous covering and the flexibility of the neck place them at risk of injury.

Discussions of surgical anatomy often divide the neck into either zones or triangles.³ Zone I is the region between the clavicles and the inferior aspect of the cricoid cartilage (Fig. 100.1). This area includes the thoracic outlet; proximal portions of the common carotid, subclavian, and vertebral arteries; apices of the lungs; trachea; esophagus; thoracic duct; and thyroid gland. Mortality is highest for zone I injuries because of the risk to intrathoracic structures and the difficulty in attaining surgical exposure and proximal control of vascular injuries.

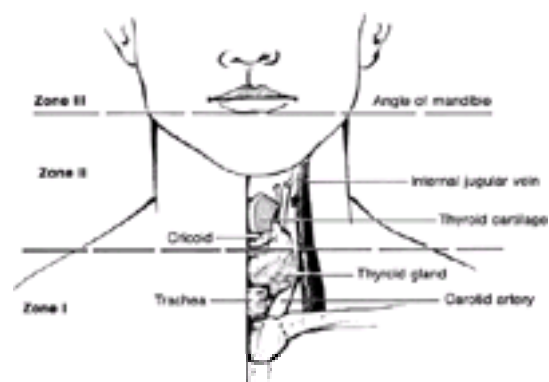

Figure 100.1. Anterior view of the neck. Significant structures and the zones of the neck are illustrated.

Zone II includes the territory between the cricoid and the angle of the mandible. This zone contains the carotid and vertebral arteries; jugular veins; larynx; trachea; esophagus; cervical spinal cord; and vagus and recurrent laryngeal nerves. The mortality rate for zone II injuries is the lowest of the three zones due to easier surgical access and the ability to control hemorrhage from bleeding vessels using direct pressure.

Zone III extends cephalad from the angle of the mandible. As in zone I, the difficult surgical approach and inability to control distal bleeding make management of injuries in this area more challenging than in zone II. The upper aerodigestive tract; salivary glands; distal carotid and vertebral arteries; and cranial nerves IX, X, XI, and XII are at risk in zone III injuries.

The boundaries of the anterior triangle are the anterior border of the sternocleidomastoid muscle, the underside of the mandible, and the midline anteriorly (Fig. 100.2). Wounds to this area are more likely to damage multiple structures but generally pose fewer problems in terms of surgical access.

Figure 100.2. Lateral view of the neck demonstrating the anterior and posterior triangles.

Injuries to the posterior triangle of the neck, bounded by the posterior border of the sternocleidomastoid, the anterior border of the trapezius, and the middle third of the clavicle inferiorly, are particularly difficult to evaluate and are more likely to damage intrathoracic structures. ²⁶

The platysma is a thin superficial muscle that originates over the upper thorax, then extends superiorly across the clavicles and neck before blending into the superficial facial muscles. It is an important surgical landmark because wounds that penetrate this muscle mandate hospital admission and further diagnostic investigation. The deep cervical fascia underlies the platysma and is subdivided into investing, pretracheal, and prevertebral layers. The tight fascial compartments of the neck reduce the chance of exsanguination from vascular injuries but may lead to airway compromise from external compression of the larynx or trachea by a hematoma. ¹⁵

The cartilaginous structures of the larynx, including the hyoid bone, thyroid cartilage, and cricoid cartilage, are held together by connective tissue attachments. The weakest of these is the cricotracheal ligament; direct injury here may cause complete cricotracheal separation. ²⁰ Just superior to the cricoid cartilage, the cricothyroid ligament is penetrated by the recurrent laryngeal nerve as it enters the larynx. Fractures in this location may result in unilateral or bilateral vocal cord paralysis. ¹⁸

CLINICAL PRESENTATION

Penetrating Neck Injuries

Penetrating neck injuries are typically categorized as gunshot or stab wounds, but this division offers little in predicting the severity or extent of the injury. It is more useful to classify wounds based on the amount of energy imparted to tissues. Projectile injuries from handguns, rifles, shotguns, BB guns and explosions differ significantly according to the size and speed of the projectiles and their distance from the victim. For example, birdshot pellets are small (less than 3.5-mm diameter) and have a very short effective range; few serious injuries occur beyond 12 ft. Buckshot pellets are larger and behave more like individual bullets, with an effective range up to 150 ft.

[Table 100.1](#) lists missile injuries in increasing order of severity and morbidity. It also presents a formula for estimating the range from the attacker, which may be more accurate than the estimate provided by the victim. ²¹

1. Stab wounds
2. Long-range (>12 m) birdshot shotgun injuries
3. Handgun injuries (low-velocity single bullets)
4. Buckshot shotgun injuries
5. Rifle injuries (high-velocity single bullets)
6. Close-range (<5 m) shotgun injuries (birdshot or buckshot)
7. Bomb or mortar fragment injuries (multiple high-velocity projectiles)

For shotgun weapons with a choke: estimated range (m) = 2 X radius of wound (in.).
For shotguns with cylinder bore: estimated range (m) = 4 X radius of wound (in.).
Source: Adapted from Ordog GI. Penetrating neck trauma. *J Trauma* 1987;27:543.

TABLE 100.1. Missile Injuries (In Increasing Order of Severity)

Low-energy stab wounds may be inflicted by an imaginative array of objects, including knives, razors, broken glass, screwdrivers, ice picks, meat thermometers, scissors, and axes. Construction and sports equipment, including nails from a nail gun, chain saws, javelins, and golf clubs, have also been reported to cause penetrating neck injuries.

In adults, penetrating injuries to the neck occur most frequently in young males as a result of physical violence. There is a strong association with substance abuse, particularly alcohol intoxication. Knife and gun wounds also predominate among children in the United States, but dog bites and falls onto sharp objects cause a significant number of penetrating neck injuries in younger age groups. ^{12,19}

Blunt Neck Injuries

Blunt neck injuries may result from motor vehicle accidents, assaults, suicide attempts, or recreational and athletic activities such as boxing, karate, and team sports. Multiple system trauma involving the central nervous system, thorax, abdomen, or extremities occurs in 30% to 50% of cases. A common mechanism is the “padded dash” syndrome, a particular pattern of injury sustained by front-seat passengers in automobiles. The victim, often unrestrained or wearing only a lap restraint, is thrown forward at the moment of impact with the neck hyperextended, resulting in a direct blow to the anterior neck against the dashboard or rim of the steering wheel ([Fig. 100.3](#)). Another common scenario is the “clothesline” injury, which occurs when a victim riding a bicycle, motorbike, or snowmobile is struck in the anterior neck by a clothesline or other cable strung across the path of travel. These injuries carry an especially high risk of laryngeal trauma, including complete separation of the trachea at the cricoid cartilage. ²⁰ In children, blunt neck trauma is usually a result of bicycle accidents (usually by striking the handlebars), motor vehicle accidents, and sports injuries. ¹²

Figure 100.3. Mechanisms of laryngeal injury. **(A)** Unprotected larynx hits steering wheel. **(B)** The padded dash syndrome. Hyperextension of the head and neck places the larynx in an unprotected position.

DIFFERENTIAL DIAGNOSIS

The signs and symptoms associated with wounds to various organ systems are listed in [Table 100.2](#).

Vascular Injuries

Vascular structures are damaged in approximately 25% of penetrating neck injury victims. Careful physical assessment of cervical vascular injuries must include inspection for brisk bleeding from the wound site; palpation of radial, ulnar, temporal, and facial pulses; decreased breath sounds due to hemothorax; and signs of air embolism accompanying venous injury.¹⁵ Obvious signs of injury to major vessels include hemorrhage or shock, an enlarging or pulsatile hematoma, absent distal pulses, and neurologic deficits.^{3,16} A hematoma in the supraclavicular space that does not extend below the clavicle is usually due to a subclavian artery injury confined by the coracoclavicular fascia. Hematomas in the axilla are associated with both subclavian and axillary artery injury. Even benign-appearing lacerations may penetrate the carotid artery and lead to subsequent false aneurysm formation and delayed rupture.

Blunt carotid injury may be caused by a motor vehicle accident or by more trivial injury, such as a direct blow to the lateral neck. The usual mechanism of blunt injury to the carotid artery is rapid deceleration with hyperextension or lateral hyperflexion of the neck, which stretches the internal carotid artery over the upper cervical vertebrae, producing an intimal tear. This may result in dissection or pseudoaneurysm formation, with the risk of subsequent thrombosis or cerebral embolism. Blunt carotid injury is rarely diagnosed at the time of initial presentation because symptoms classically do not appear until 12 to 24 hours after injury; neurologic deficits may not appear for weeks or months after injury.⁴ Only half of patients have external signs of neck trauma. The diagnosis should be suspected whenever a neurologic deficit cannot be explained by cranial computed tomography (CT) scan or by spinal cord or peripheral nerve injury. The presence of a lateral neck hematoma, Horner syndrome, transient ischemic attack, or hemiparesis, monoparesis, or aphasia in a patient with no evidence of head trauma should also stimulate a search for carotid injury.^{4,11}

Isolated dissection of the subclavian artery has been attributed to shoulder harness injury following a high-speed motor vehicle accident. Vertebral artery injury has been documented after upper cervical spine fractures (where the artery courses through the transverse foramina), hyperflexion injuries, chiropractic manipulation, and yoga exercises.

Neurologic Injuries

The neck contains a variety of neural structures, including the spinal cord, cervical nerve roots and brachial plexus, cervical sympathetic ganglia, phrenic nerve, and cranial nerves IX through XII. Either blunt or penetrating trauma can injure one or more of these structures, producing the signs listed in [Table 100.2](#).

Spinal cord injury resulting from stab wounds is unusual, but may be caused by an assailant wielding a knife from behind the victim. Most of these injuries do not cross the midline because of the protection afforded by the lateral and spinous vertebral processes. Hemisection of the spinal cord, or Brown-Séquard syndrome, presents as ipsilateral motor paralysis and contralateral sensory loss below the level of the injury. Complete cord transection above the level of C5 results in respiratory arrest due to diaphragmatic paralysis. Complete transection below C5 will result in paraplegia and possibly respiratory distress from paralysis of accessory respiratory muscles. Spinal cord injury may also lead to neurogenic shock.¹⁵

Injuries to Other Structures

Thyroid gland injuries often result in extensive hemorrhage, distorting anterior neck landmarks and complicating attempts to establish a surgical airway. Laceration of the thoracic duct by a knife or missile wound may cause chylothorax or chylous wound drainage, or may be discovered during surgical exploration.²⁵ Soft-tissue injuries, including lacerations, ecchymoses, and abrasions, are managed in standard fashion. Cervical spine injuries are considered elsewhere in the text.

EMERGENCY DEPARTMENT EVALUATION

The initial evaluation of a victim of neck trauma must be rapid, systematic, and thorough. Information gathered from prehospital care providers and law enforcement personnel, combined with meticulous physical examination, allow the emergency physician to plan further diagnostic and therapeutic maneuvers and develop an appropriate disposition from the ED. As with any trauma, initial evaluation of the patient with a neck injury should be conducted according to the ABCs of resuscitation, as outlined in [Table 100.4](#).

TABLE 100.4. Prehospital/Initial Emergency Department Management of Neck Injuries

Prehospital Care

Prehospital personnel should assess and document the mechanism of injury, type of weapons used, estimated blood loss, vital signs and other significant physical findings at the scene, scene time, and transport time. Transport should not be delayed to perform detailed examination or extensive stabilizing measures. In an urban setting, patients should be transported to the nearest level I trauma center without delay.

After basic airway-opening maneuvers have been applied, further immediate management may be required. Persistent stridor may indicate upper airway obstruction from mucosal edema, extrinsic compression by hematoma or other mass, or direct injury to the larynx or trachea.²⁶ Bag-valve-mask ventilation may be used as a temporizing measure but, in the face of penetrating neck injury, can cause dissection of air into surrounding tissues, with resultant airway or vascular complications.

Airway management in the prehospital setting can be extremely difficult if the airway is distorted by presence of blood or secretions, hematoma, edema, or laryngotracheal injury. For this reason, intubation should be attempted only in patients with stridor, severe respiratory distress, or cardiac or respiratory arrest, or if transport time is likely to be long. When prehospital intubation is indicated, the orotracheal route is preferred because it permits direct airway visualization and is associated with fewer complications. Use of neuromuscular paralytic agents should be avoided.

Prehospital cricothyroidotomy may be necessary when orotracheal intubation is unsuccessful or impossible due to massive facial trauma, suspected cervical spine injury, or patient position during entrapment. Cricothyroidotomy should be *avoided* if laryngeal trauma is suspected based on the mechanism of injury (e.g., clothesline injury) or the presence of an anterior neck hematoma or ecchymosis. Routine cervical spine precautions are indicated in blunt trauma victims but are rarely necessary in those with penetrating injury, unless neurologic signs or symptoms are present.

The primary survey continues with evaluation of breathing and circulatory status. Careful examination of the chest for evidence of intrathoracic trauma is critically important, particularly with zone I neck injuries. Emergency medical service personnel should assess the patient for signs of tension pneumothorax and perform needle thoracostomy as indicated. Intractable hemorrhagic shock is a greater risk with zone I injuries as well, because bleeding from innominate or subclavian vessels cannot be tamponaded using direct external pressure.

All patients with penetrating neck trauma should have at least one large-bore intravenous line established en route to the ED. When feasible, it should be placed in

the upper extremity opposite the side of the neck wound in case there is venous injury. Prehospital care providers should cover wounds with air sucking or bubbling through the site with Vaseline gauze and place the patient in the Trendelenburg position to reduce the risk of venous air embolism. ¹⁵

Initial Emergency Department Evaluation

Airway, breathing, and circulatory status must be rapidly reassessed once the patient arrives in the ED (see [Table 100.4](#)). A secure airway must be established early in the management of any victim of neck trauma. Urgent intubation is mandated in the presence of an expanding neck hematoma, tracheal deviation, suspected recurrent laryngeal nerve injury, severe subcutaneous emphysema, or other external evidence of direct laryngotracheal trauma, in addition to the usual indications of airway compromise due to the presence of blood or secretions, respiratory distress, or altered mental status. ¹⁰ Failure to recognize these indications for early placement of an endotracheal tube may lead to both rapid deterioration and increasing difficulty in obtaining an airway. If a cervical collar is in place, remove the anterior half (while an assistant ensures manual immobilization of the head) to examine the front of the neck for signs of injury to the upper airway. ³

Controversy persists regarding the optimal method of controlling the airway in cases of neck injury. Most authors recommend early endotracheal intubation when any sign of airway compromise is present, although others recommend early tracheostomy under local anesthesia as the initial intervention. ^{12,15} The method of choice for airway management depends on the physician's level of comfort and skill with each technique.

In the presence of significant respiratory distress, the initial attempt should usually be orotracheal intubation under direct view. ⁷ This route is associated with fewer complications and allows the physician to visualize the airway during intubation. Orotracheal intubation with manual in-line cervical immobilization is widely accepted for the apneic patient who is neurologically intact, even when the status of the cervical spine is unknown. Rapid-sequence intubation using neuromuscular paralytic agents may be used in carefully selected patients, but bag-valve-mask ventilation may cause air to dissect into the neck, as previously discussed, while the decrease in muscle tone induced by these agents may lead to total airway obstruction.

In stable patients, fiberoptic nasotracheal intubation should be attempted first. Blind nasotracheal intubation is not recommended because it is associated with a higher rate of complications and a greater likelihood of causing further damage to the airway. Intubation over a fiberoptic bronchoscope not only permits careful, atraumatic intubation of the trachea with minimal neck movement, but also is extremely useful in the presence of excessive secretions, foreign bodies, or anatomic distortion. ⁷ Furthermore, endoscopic evaluation is the standard of care for assessing the degree of laryngotracheal injury. ^{12,20} Less frequently used intubation methods include placement of the tube through an open wound that communicates directly with the trachea or into the visible distal segment of the transected larynx or trachea. ¹⁵

In all of these instances, the treating physicians should be ready to provide a surgical airway if intubation attempts are unsuccessful. Cricothyroidotomy may be necessary as the initial airway maneuver in the presence of known cervical spine instability, neurologic deficit, or severe maxillofacial injuries. It is contraindicated in the presence of bruising or hematoma over the cricothyroid membrane or suspected laryngotracheal injury; in these cases, emergency tracheostomy is mandated due to the risk of converting a partial to a complete cricotracheal disruption. The appearance of subcutaneous emphysema and a large air leak after positive-pressure ventilation is initiated indicates tracheal injury distal to the cuff of the endotracheal tube. This situation mandates immediate tracheostomy, and in some cases median sternotomy, to regain control of the distal tracheal segment. ⁵

Identify open or actively bleeding wounds and observe for evidence that the platysma has been penetrated. Blind probing of wounds is *strictly contraindicated* because of the potential for damaging deep structures. Similarly, blind attempts to clamp bleeding vessels risk injury to nerves and other organs and should never be performed. External bleeding is controlled by direct pressure. If this is unsuccessful, tamponade of bleeding, using a Foley catheter balloon, may be attempted. Insert the catheter into the wound toward the estimated source of bleeding. Inflate the balloon with saline until the bleeding stops or moderate resistance is felt. ⁷ Patients with exsanguinating hemorrhage, shock unresponsive to resuscitative measures, or an expanding neck hematoma should be rapidly transferred to the operating room for immediate surgical exploration.

Careful physical examination is the basis of the ED evaluation of neck trauma victims and guides decision making regarding further diagnostic or therapeutic maneuvers. Once the patient has become hemodynamically stable, conduct a thorough secondary survey, giving special attention to the respiratory, digestive, vascular, and nervous systems. Signs and symptoms of injuries to these systems are listed in [Table 100.2](#).

In the hemodynamically stable patient, radiographs of the cervical spine, the soft tissues of the neck, and the upright chest are obtained. Radiographic evidence of air in the soft tissues, due to injury to the airway or gastrointestinal tract, may precede the development of clinically evident subcutaneous emphysema by several hours. ⁵ Other possible findings on soft-tissue neck films include pretracheal or retropharyngeal soft-tissue swelling, distortion or interruption of the tracheal air column, and elevation or fracture of the hyoid bone. If the body of the hyoid bone is elevated above the level of the third cervical vertebral body, or if the greater cornu is located less than 2 cm from the angle of the mandible, complete tracheal transection should be suspected. ²³ Obtain both anteroposterior and lateral chest films when possible, as mediastinal air may not be seen on an anteroposterior view alone in half of cases.

EMERGENCY DEPARTMENT MANAGEMENT

Blunt Neck Injuries

Any patient presenting with hoarseness, subcutaneous emphysema, hemoptysis, or neck tenderness following anterior neck trauma must be evaluated for laryngeal injury. Severe respiratory distress may not necessarily be present, especially in the young, healthy patient. Fiberoptic laryngoscopy has replaced direct laryngoscopy as the standard method of evaluating upper airway injuries. It is useful in assessing airway patency, vocal cord mobility, and the presence of endolaryngeal lacerations or hematoma without causing movement of the cervical spine. Fiberoptic bronchoscopy permits additional visualization of the subglottic airway and may be used to facilitate endotracheal intubation. Direct laryngoscopy may be performed when fiberoptic laryngoscopy is not available, but it requires general anesthesia, may exacerbate mucosal injury, and risks cervical spine movement. CT is the best study for evaluating the laryngeal skeleton and assists in planning the surgical repair. ²⁰

Minor airway injuries amenable to nonoperative management are minimal endolaryngeal edema, hematoma, or laceration seen on laryngoscopy with normal phonation or minimal hoarseness and no or minimal airway compromise. Provide humidified oxygen and elevate the patient's head, and reexamine frequently for signs of impending airway compromise. A tracheostomy tray should be immediately available in case of rapid deterioration. Otolaryngologic consultation and hospital admission are required. ²⁶

Contrast esophagography is indicated when pharyngoesophageal trauma is suspected based on odynophagia, hematemesis, or subcutaneous emphysema. The initial study should be performed using a water-soluble medium (Gastrografin), due to the irritating effect of barium on tissues. If negative, esophagography is then repeated with barium or followed by direct esophagoscopy, due to the high rate of false-negative results when water-soluble contrast is used. ¹⁷ Direct visualization using fiberoptic or rigid endoscopy identifies hypopharyngeal tears but may miss small injuries. CT with contrast is useful to determine the site and extent of the injury and help plan the surgical approach. ¹⁴

Four-vessel cerebral arteriography is indicated when there are abnormal or evolving neurologic findings in the presence of a normal CT scan of the brain. Conventional angiography remains the standard method for diagnosing blunt carotid or vertebral arterial injury. ⁴ Duplex ultrasound (color flow Doppler) imaging is a noninvasive and less expensive alternative to angiography that is sensitive for detecting lesions at the carotid bifurcation (i.e., in suspected zone II carotid injuries) but not for detecting dissection or pseudoaneurysm high in the neck. In selected blunt neck trauma victims undergoing head or abdominal CT scanning for another indication, additional views of the cervical region with intravenous contrast can screen for suspected carotid injury. CT angiography in this setting adds minimal time to the diagnostic workup, can indicate the need for conventional angiography, and may increase the detection of blunt carotid trauma. ²⁴ Magnetic resonance angiography could serve the same purpose, but there is little experience with its use in the acute trauma setting.

If signs of vascular trauma are obvious (e.g., enlarging hematoma, massive hematemesis or hemoptysis), the need for surgical intervention can usually be identified clinically. Although surgical management was previously advocated for the treatment of blunt carotid injuries, more recent studies have suggested that heparin anticoagulation is independently associated with improved survival and neurologic improvement with an acceptable rate of complications. ^{6,11,22}

Penetrating Neck Injuries

The optimal management of penetrating neck injuries remains controversial. There is no debate regarding the need for emergency surgery when obvious signs or symptoms of vascular or aerodigestive tract trauma are present. However, disagreement persists about the role of surgical exploration in those with no clinical sign of significant injuries.⁷

During World War II, combat victims whose injuries penetrated the platysma routinely underwent neck exploration, with a substantial reduction in mortality compared with the pre-World War II period. The success of this strategy led to the dictum of “mandatory exploration” for all penetrating neck injuries.¹⁹ Proponents of routine exploration argue that physical examination is unreliable and that potentially dangerous injuries may be missed. However, high rates of negative exploration (30% to 89%) have led others to propose a more selective approach that uses physical examination findings to guide the use of subsequent diagnostic tests such as angiography, contrast esophagography, and endoscopy.¹⁵ Advocates of a more selective approach cite a lower rate of unnecessary operation, shorter hospitalization, and decreased costs.^{3,16}

Immediate surgery is indicated for any patient presenting with hemorrhagic shock, massive or expanding hematoma, airway compromise, evolving stroke, or deterioration during a diagnostic study.³ Surgical exploration is also mandatory in the setting of wounds caused by high-velocity (i.e., rifle) bullets, explosives and shrapnel fragments, and shotguns at a range of less than 5 m.²¹ Initially stable patients with other signs of injury, such as ongoing hemorrhage, stable hematoma, hemoptysis, dysphonia, subcutaneous emphysema, hematemesis, dysphagia, or peripheral neurologic deficit, may undergo diagnostic evaluation prior to definitive operative management (see [Table 100.5](#)).^{3,9}

INDICATIONS FOR IMMEDIATE SURGERY
<ul style="list-style-type: none"> 1. Hemorrhagic shock 2. Massive or expanding hematoma 3. Airway compromise 4. Evolving stroke 5. Deterioration during a diagnostic study

TABLE 100.5. Indications for Immediate Surgery or Further Studies Following Penetrating Neck Trauma

Four-vessel arteriography is routinely recommended in penetrating zone I injuries, where it may help guide the surgical approach, and in zone III injuries, where it may determine not only the optimal approach, but also the need for surgery. Angiographic embolization of bleeding vessels may also be possible, particularly for vertebral artery lesions.⁷ High-velocity missile wounds, regardless of anatomic zone, are generally best evaluated using angiography because of the unpredictable course of the projectile and the potential for damage to deep vascular structures.⁹ Less agreement exists regarding the role of angiography in zone II injuries due to other causes. Significant vascular injuries in this zone are usually detectable on physical examination, and those that are clinically occult tend to be small carotid intimal tears amenable to nonoperative treatment.^{1,2,8,9} However, the incidence of asymptomatic vascular injuries requiring surgical repair diagnosed by angiography has been reported to be as high as 9%.¹⁶

Duplex ultrasonography has not been studied extensively in the setting of penetrating neck trauma. Early studies have reported the sensitivity and specificity of duplex ultrasound to exceed 95%.⁷ It may be useful as a screening test in individuals with penetrating neck injuries in proximity to major vessels but no physical signs suggestive of vascular injury. Patients with negative duplex scans can probably be safely observed, while those with positive or equivocal results should undergo angiography.^{9,13}

In general, the approach to penetrating neck trauma must be tailored to the capabilities of the individual institution. If selective surgical management is considered, it should be undertaken only at a level I or II trauma center that possesses the necessary facilities and surgical and support staff to provide diagnostic studies and emergency surgery on a 24-hour basis.⁹ In such institutions, hemodynamically stable asymptomatic or minimally symptomatic patients with stab wounds, injuries caused by low-velocity (i.e., handgun) bullets, or shotguns beyond a 5-m range may be selectively managed using a diagnostic approach such as the one outlined in [Fig. 100.6](#).

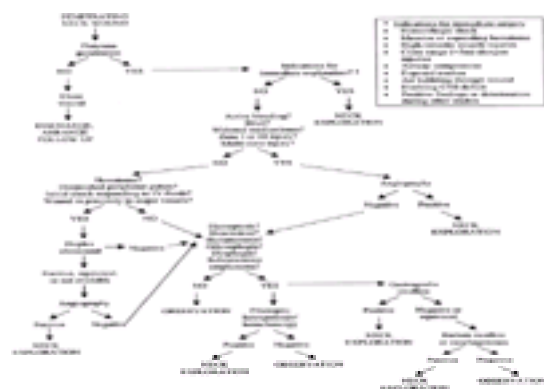

Figure 100.6. Algorithm for management of penetrating neck injuries.

DISPOSITION

Any trauma victim with a wound penetrating the platysma or suspected blunt injury to deeper structures requires admission and observation for at least 24 hours, in addition to further studies that may be indicated. Obtain early consultation in such cases with a trauma or head and neck surgeon. When one of these consultants is not immediately available, transfer the patient to a facility capable of providing comprehensive trauma care. Additional consultation with an anesthesiologist or vascular surgeon should be sought during the resuscitation phase when difficulty with airway management is anticipated or signs of vascular trauma are present.

Minor laryngeal injuries are best managed with voice rest, humidification of inspired air, elevation of the head, and close observation. Prophylactic broad-spectrum antibiotics and a short course of steroids are often recommended. Laryngeal fractures or vocal cord injury must be repaired surgically. Delayed diagnosis of laryngeal trauma may lead to late morbidity, including permanent hoarseness, dysphonia, or aphonia; subglottic or tracheal stenosis; granulations on or paralysis of the vocal cords; and the need for permanent tracheostomy.²⁷

Patients with demonstrated pharyngeal or esophageal perforation require admission and close monitoring. Initial treatment consists of intravenous fluid resuscitation, parenteral antibiotics, and restricted oral intake. Aqueous penicillin G is effective against the usual flora of the oropharynx and esophagus and is thus the drug of choice. An aminoglycoside should be added to the antibiotic regimen in elderly patients, in whom gram-negative colonization of the oropharynx is common. Pharyngeal perforations of less than 2 cm may be managed nonoperatively. Larger perforations or those involving the esophagus require surgical repair and

drainage.¹⁴

The sequelae of vascular trauma include shock, persistent hemorrhage, neurologic deficits, and extremity ischemia. The role of surgical repair of the extracranial carotid artery is controversial when a preoperative neurologic deficit exists, because of fear of converting an ischemic to a hemorrhagic cerebral infarction once circulation is reestablished. Surgery is generally not advocated when the deficit is moderate or dense, but it may be indicated if the deficit is mild or absent.²⁶ Penetrating injuries to the spinal cord are initially managed with wound debridement and prophylactic antibiotics to prevent meningitis.

COMMON PITFALLS

- Avoid blind clamping to control bleeding from open neck wounds.
- Do not blindly probe penetrating neck wounds to determine their depth.
- Seek and recognize the indications for urgent intubation.
- Beware of inept blind intubation attempts or inadvisable attempts at cricothyroidotomy that may convert a partial tear to complete laryngotracheal separation.

[Chapter References](#)

The clinical spectrum of the patient with spinal cord injury varies from the awake patient complaining of pain, paresthesias, numbness, weakness, or paralysis to that of the unconscious patient, usually due to associated head injury, unable to give any clues about the severity of his or her injuries. In the United States, most spinal cord injuries are due to motor vehicle accidents, followed by falls, assaults, and, far less frequently, athletic injuries. Young men in their 20s are the largest single group suffering this tragic injury. Elderly patients frequently suffer compression fractures of the thoracolumbar spine, but these are rarely associated with any cord injury. A large northern California study found 53 spinal cord injuries per million population.⁹ This extrapolates to over 14,000 new cases per year in the United States.

PATHOPHYSIOLOGY

Normally, the spinal column ensures stability and protects the cord, the spinal roots, and the cauda equina from injury. Panjabi and White¹⁴ defined *spinal stability* as “the ability of the spine, under physiologic loads, to maintain the relationships between vertebrae such as there is neither damage nor irritation to the spinal cord or roots, nor incapacitating deformity nor pain due to structural changes.” Injury can render the usually protective spinal column a threat to the cord and its roots. The cord can suffer injury through crush, laceration, penetration, stretch, or ischemia. In unusual circumstances, the spinal column can be rendered unstable due to infectious or inflammatory causes, such as the subluxation of C1 on C2 seen in rheumatoid arthritis or due to the inflammation associated with pharyngeal infections.¹

The most mobile segments of the spinal column (C4, C5, C6, L1, L2) place the adjacent segments of the spinal cord at higher risk for injury. The ribs buttress the thoracic spinal column, providing a relatively safe environment for the cord. There are fewer fractures here, but when there is a fracture with bony displacement, the cord injury is usually devastating. The spinal medullary canal is relatively narrow here, and the thoracic cord is an area of watershed circulation.¹⁶ In animal and human studies, there is roughly an 8-hour window of opportunity for mechanical or pharmacologic intervention to prevent ongoing secondary injury to the cord.

CLINICAL PRESENTATION

The patient may describe pain or tenderness at the level of injury and paresthesias distal to the injury level, either at the time of injury or at a later time. History and physical examination establish motor, reflex, or sensory deficits; fecal incontinence; or urinary retention¹⁵ (Table 101.1). Careful mapping of the level of sensory loss, including attention to areas around the anus for lower segmental lesions and for sacral sparing, identifies the level of cord injury and the level at which radiologic studies need to focus (Fig. 101.1).

Nerve Root Level	Motor	Sensory	Reflex
C3		Lower neck	
C4	Diaphragm	Clavicular area	
C5	Deltoïd, biceps	Lateral upper arm	Biceps
C6	Extensor carpi radialis	Thumb and lateral forearm	Brachioradialis
C7	Triceps, wrist flexors, finger extensors	Middle finger	Triceps
C8	Upper forearm	Little finger	
T1	Hand intrinsic	Medial forearm	
T4	Intercostals	Nipples	
T9	Abdominals	Umbilicus	
T12	Legs	Inguinal area/inguinal ligament	
L1		Upper thigh	
L2		Lower anterior thigh	Quadriceps
L4	Quadriceps	Medial foot	
L5	Extensor hallucis longus	Dorsal foot	Achilles tendon
S1	Gastrocnemius, flexor hallucis longus	Little toe	
S2	Anal sphincter	Perineum	Suboccipital
S4	Anal wink	Anal wink

TABLE 101.1. Motor, Sensory, and Reflex Tests by Nerve Root Levels

Figure 101.1. Sensory dermatomal segments. (Left) Anterior view. (Right) Posterior view.

When the patient has no function of any segment of the cord below the level of injury, the injury is physiologically complete. Such a circumstance carries with it a grim but not hopeless prognosis for meaningful recovery. It is nearly impossible to diagnose accurately a physiologically complete cord injury in the emergency department, because spinal shock may be an intercurrent factor. Spinal shock is the temporary cessation of ascending and descending communication past the injured segment of cord (spinal neurogenic shock will be discussed further). Spinal shock lasts a variable amount of time, typically about 24 hours. Immediately after a severe cord injury, the patient usually exhibits flaccid paralysis. In the long term, a spastic paralysis typically develops. Termination of spinal shock is identified by the return of segmental reflexes. The earliest segmental reflexes to return are often those around the genitals and anus; for example, the bulbocavernosus reflex elicited when squeezing or tugging on the glans penis causes reflex contraction of the anal sphincter.

There are several important partial cord syndromes (Fig. 101.2). The anterior spinal cord syndrome (see Fig. 101.2B) is the result of either direct blunt injury to the cord itself or compression of the anterior spinal artery, causing ischemic damage to the anterior cord. The patient presents with a loss of motor and pain sensation bilaterally below the level of the lesion, but posterior cord function is preserved. Posterior cord function may be tested with a tuning fork for vibratory sensation or by plantar-flexing and dorsiflexing the great toe for gross proprioception. After an appropriate attempt at reduction and reestablishment of the normal diameter of the spinal medullary canal, computed tomographic (CT) myelography should follow to assess for possible soft-tissue masses, such as an extruded disc or hematoma that may continue to exert extrinsic pressure on the spinal cord or anterior spinal artery. If found, these would be relieved by laminectomy. Unfortunately, the prognosis for

recovery with this injury is poor.

Figure 101.2. Transverse section of the spinal cord at the cervical level. **(A)** The ascending and descending tracts. **(B)** Tracts that may be damaged in the anterior spinal artery syndrome. **(C)** Tracts that may be damaged in the central cord syndrome. **(D)** Involved tracts and the superimposed areas of deficit from an injury at T4, resulting in the Brown-Séquard syndrome.

The acute central cord syndrome (see [Fig. 101.2C](#)) usually afflicts patients with a narrowed spinal canal. This may be due to degenerative spine disease or to a congenital stenotic canal. The mechanism of injury is usually hyperextension. The hallmark of this lesion is greater damage to the central portion of the cord than to the periphery. This leads to a variable sensory loss but a predictable motor loss, with motor function of the upper extremities below the level of the lesion more impaired than those of the lower extremities. This is because the motor fibers in the lateral corticospinal tract lie in a laminar fashion, with cervical segments most medial and thoracic, lumbar, and sacral motor fibers progressively more lateral. Management of this injury is usually nonoperative. There is a relatively good prognosis for recovery of at least partial neurologic function, with three-fourths of these patients walking at 1 year.

The Brown-Séquard syndrome (see [Fig. 101.2D](#)) is a hemicord injury that presents with a crossed sensory and motor deficit. Motor function is lost ipsilateral to the cord lesion, but sensory function is preserved on this side. Sensory function is lost on the contralateral side, where motor function is preserved. The crossed lesion is explained by the decussation of motor fibers in the medulla and the decussation of sensory fibers about two segments above the segment at which their sensory root enters the spinal cord. Causes include penetrating injuries, tumor, and disc disease. The prognosis is poor with penetrating injuries.

The patient with a cervical or high thoracic cord injury may present with relative hypotension due to the sudden loss of sympathetic tone below the level of the lesion. The patient has warm, dry skin and normal capillary refill, but with a paradoxical bradycardia. Labeling this condition “spinal neurogenic shock” helps to differentiate it from the aforementioned spinal shock. Spinal neurogenic shock in the patient with signs or mechanisms of multiple injuries may be difficult to differentiate from other causes of shock. Hemorrhagic shock classically presents as hypotension; tachycardia; cool, moist skin; and delayed capillary refill. The hypotensive patient should be assumed to have hemorrhagic shock until all gross external bleeding is controlled and the search for occult hemorrhage in the chest, abdomen, and pelvis is complete. This search should include, at a minimum, chest x-ray, pericardial ultrasonography, pelvic x-ray, abdominal ultrasonography, peritoneal lavage, or abdominal CT. After this survey is complete and no other explanation for shock is found, the hypotension may be attributed to spinal neurogenic shock. At that point, fluid administration is reduced to maintenance levels and the hypotension is treated with dopamine as necessary to maintain perfusion of the brain and spinal cord. Unfortunately, the optimal blood pressure to maintain the patient is unknown.

DIFFERENTIAL DIAGNOSIS

Determination of a cord injury is straightforward in the patient with quadri- or paraplegia. It becomes more difficult in patients with partial cord syndromes, particularly in those with acute central cord syndrome. This is due to both the patchy nature of the sensory loss and preservation of at least some motor function in the lower extremities. Evaluation for cord injury is also difficult in the unconscious patient. Most patients who present to the emergency department with complaints of neck or back pain or tenderness are found to have muscular strains or ligamentous sprains and no associated cord injury. The clinician should not be fooled by the absence of a fracture: A third-degree ligamentous sprain can render the spinal column unstable, allowing motion between vertebral bodies and subsequent cord or spinal root injury.

EMERGENCY DEPARTMENT EVALUATION

The principles of evaluation are the same for all significantly injured patients. Initial attention should be paid to airway, breathing, circulation, disability, exposure, and environment (ABCDEs), with simultaneous resuscitation involving high-flow oxygen, two large-bore intravenous lines, a nasal or orogastric tube, a Foley catheter, and serial vital sign determinations. This primary survey should be followed by critical x-rays, including lateral cervical spine, chest, and pelvis films; ultrasound of the pericardium and abdomen; a secondary survey; definitive care; and, finally, appropriate disposition. During the secondary survey, a careful neurologic examination must be performed. This examination is carefully recorded so that an ascending lesion or deterioration in function can be identified by serial examinations. Motor function for all muscle groups is tested and recorded on a 0 to 5 scale (0 equals no function; 2, muscle activity apparent but cannot overcome gravity; 3, can overcome gravity; 4, diminished but can overcome more than gravity; 5, full normal). The level of sensory loss is plotted to identify the level on which to concentrate with radiographic imaging. This level should be drawn on the body in ink to identify any changes. Gross proprioception or vibratory function is measured to examine posterior column function. Deep tendon reflexes, anogenital reflexes (bulbocavernosus, anal wink), and perianal sensation are elicited to identify spinal shock or sacral sparing. Serial vital sign determinations must be made. Serial neurologic examinations are performed to identify any important change in functional status, which would have a profound influence on the management of the patient by the neurosurgeon or orthopedic surgeon. Deterioration of function implies the need for a CT myelogram to check for the presence of an extrinsic mass compressing the cord, which might be surgically correctable. No specific laboratory studies aid in this evaluation.

After the history and physical examination have identified the level of the lesion, plain films help characterize the lesion. A true lateral projection of the cervical spine identifies 90% of significant bony and ligamentous lesions. Specific attention should be paid to full visualization of all seven cervical vertebrae and the top of T1; atlantooccipital alignment (using the X method, a line drawn from the tip of the basion to midway on the spinolaminar line of C2 should intersect tangentially the edge of the odontoid, and a line drawn from the tip of the opisthion to the posteroinferior corner of the body of C2 should intersect tangentially the spinolaminar line of C1) ^{1c}; a predental space 3 mm or less; prevertebral soft tissue that measures less than 5 mm anterior to C3; the spinal canal on 72-in. plain film, anteroposterior diameter 13 mm or greater; any horizontal subluxation of one vertebra on the next; fanning of the space between spinous processes; fracture of any bone; and incidental findings of the skull or mandible. The open-mouth odontoid view identifies most of the remaining 10% of significant lesions. This view should be examined for the alignment and equal spacing between C2 and the lateral masses of C1 and for fracture of these bones. The anteroposterior view rarely identifies injury not already suspected.

These three views compose the baseline cervical plain film series. The lateral and anteroposterior views form the baseline series for thoracolumbar injuries. Some advocate supine anterior oblique views of the cervical spine to better visualize the posterior elements. ⁶ These views show the neural foramina well in patients with radicular symptoms. They also clearly demonstrate the pedicles, as well as the lamina, which should stack like shingles on a roof.

Flexion and extension views are used carefully to demonstrate spinal column stability if the initial three views raise a question but would predict a stable spinal column (e.g., a small chip fracture of the anterior-inferior margin of the vertebral body, or a step-off of 1 to 2 mm with no other noted abnormalities). Flexion-extension views should be used when the initial three views are normal but the pain seems out of proportion, suggesting greater occult ligamentous damage. Instability should be suspected, and immobilization maintained, if there is more than a 3-mm step-off of one vertebra on the next or if there is an 11-degree or greater angulation between vertebral segments. ¹⁴ In questionable cases, the neurosurgeon will use CT scanning. The neurosurgeon may also use flexion-extension views to prove instability before fusion if the initial three views are suspicious but not diagnostic for instability.

In any case, for this study, the patient carefully and slowly flexes and later extends the head and neck; movement is stopped immediately if pain or paresthesias are elicited. Instability is confirmed if there is displacement of one vertebral body on another or if there is abnormal flaring between spinous processes. The physician

should be present during this maneuver to ensure that no force is applied.

CT scanning is best for bony detail. CT is indicated when a fracture is identified on plain films, when neurologic injury is present, when pain seems out of proportion to the injury and findings on plain film, when instability is suspected based on plain films, and when there are questionable findings on plain film that cannot otherwise be determined. It frequently shows additional fractures, clarifies the extent of the fracture, and adds some information on soft-tissue injury. Neurosurgeons use CT myelography to identify an extrinsic mass pressing on the cord, as evidenced by inability of the dye to pass the level of the lesion. Magnetic resonance imaging (MRI) is better for soft-tissue injury but lacks bony detail. Early in management, the patient may be too unstable in a cardiovascular sense or too uncomfortable to stay still for the prolonged time needed for an MRI study.

The physician must avoid the common diagnostic error of relying on the lateral view alone before removing the semirigid collar. The semirigid collar is removed in a supine, immobilized patient, as needed, to examine the neck. When this examination is complete, the collar is replaced. It should otherwise be left on until the full series of cervical films shows the spine to be stable. Other common diagnostic errors are due to inadequate neurologic examination. One common problem is failing to examine for posterior column function (gross proprioception, vibratory sensation). A second error is failing to examine the sacral area for sparing, which is needed to differentiate a partial cord lesion from a physiologically complete injury.

It is impractical to leave every patient who presents on a spine board immobilized until a radiologist, neurosurgeon, or orthopedist examines the film and patient. The emergency physician must act on his or her interpretation of the films in the vast majority of cases. The physician must not accept inadequate x-rays. The most common problem is that the lateral view of the neck does not fully show the first seven-and-a-third vertebrae. C7-T1 injuries are not common, but nor are they rare. A swimmer's view may be used to see this junction on patients with large shoulders. The physician should not spend too much time obtaining adequate spine films; the patient may die of other injuries. The spinal cord and column should be protected with a long board and semirigid collar while attending to the ABCDEs of the primary survey and resuscitation. The patient can go to the operating room on the backboard if necessary. The surgeon can return to a careful spinal evaluation after surgery once the cardiorespiratory condition has been stabilized.

EMERGENCY DEPARTMENT MANAGEMENT

The pace of acute intervention for the patient with a spinal cord injury should be urgent. The focus should be on identifying and managing life-threatening injuries, while protecting the spinal column from unnecessary motion. Immobilize these patients; do not apply traction until after films carefully define the lesion. Traction that causes distraction on the cord or roots may cause severe, possibly irreparable neurologic damage. The first priority is to ensure that the patient survives, by attending to the ABCDEs. The second priority is to prevent secondary injury to the damaged spinal cord.

The physician must not allow, or cause, the patient to have unnecessary motion of the unstable spinal column. However, at times, such motion may be necessary to preserve the patient's life, such as in the patient with an obstructed airway who needs immediate management when initial maneuvers have proven unsuccessful. In-line immobilization should be used, allowing only as much motion as is needed to successfully control the airway. The physician should prepare to logroll and suction if the patient regurgitates, while maintaining the patient's spinal column as straight as possible. Although x-ray studies show that logrolling is associated with some motion of the thoracolumbar spinal column,¹³ it must be done to prevent aspiration and obstruction in the patient who regurgitates without a protected airway. The backboard can be used to help logroll the patient, provided the straps are properly applied and have not been removed. Straps on the body may be released to remove clothing, while maintaining the head immobilized on the board. The body straps should be immediately reapplied after removing the clothing. A nasogastric tube is placed in the unconscious or intoxicated patient to decompress the stomach and reduce the risk of regurgitation.

The patient must be protected against unnecessary motion until the history, physical examination, and, if indicated, radiologic studies are complete and show that the spinal column is stable. The physician must not be fooled, by the fact that the patient was walking after the injury, into thinking films are unnecessary in a patient who has posttraumatic spinal pain, tenderness, paresthesias, neurologic findings, a high-energy mechanism, other painful distracting injuries, or a decreased level of consciousness. Timely reduction of the displaced column is vital to achieve decompression of the spinal cord. The physician is expected to preserve residual spinal cord function and not to cause a secondary injury to an already damaged cord while managing the patient. The cord can suffer devastating secondary injury if motion is allowed in the direction of instability. (Most injuries are unstable in flexion, but this is unknown until x-rays are obtained.)

The phrenic nerve, providing motor innervation to the diaphragm, arises from the C3 and C4 segments of the spinal cord. An otherwise healthy patient can maintain adequate long-term ventilation with diaphragmatic breathing alone. However, if a traumatic lesion affects C3 or C4, or if the level of the lesion ascends, as sometimes happens, the patient will become ventilator-dependent.

With blunt cord injury, very high doses of methylprednisolone are given early in treatment.^{3,4 and 5} The patient being treated within 3 hours of blunt injury is loaded with 30 mg/kg as a bolus, followed by a continuous drip of 5.4 mg/kg/h for the subsequent 23 hours. The patient being treated from 3 to 8 hours following injury receives the same loading dose but then is maintained on the continuous drip for 48 hours, although this increases the severity of sepsis and pneumonia in this group. Although it is impossible to measure the direct effect on any one patient, this treatment has been shown to lead to a statistically significant improvement in neurologic outcome while not causing a statistically significant increase in wound complications or gastrointestinal bleeds.^{3,4} Very high doses of methylprednisolone are considered the standard of care within 8 hours of blunt injury: Alternate drugs should be used only as part of an approved study protocol. This drug treatment is used on all patients, including the immunocompromised and elderly. Very high dose methylprednisolone is not indicated after penetrating spinal cord injury.¹¹

DISPOSITION

Role of the Consultant

The emergency physician must decide if a spinal column or cord injury exists: Too many patients present with such potential injuries to rely on consultation. Next, the physician must decide whether the column is stable. Consultation should be requested if the emergency physician cannot decide whether an injury is stable or significant, when an unstable injury is found, or when cord or root injury is found. The timing of consultation is urgent—it should be done while the patient is in the emergency department—but not emergent in the sense of an airway problem. It should be requested after attention is focused on primary survey activities and initial resuscitation.

Indications for Admission

Patients are admitted if there is a cord injury or unstable column injury, for pain control, or for an anticipated complication such as the association of ileus with a thoracolumbar compression fracture. Patients with cord or unstable column injuries are admitted to the intensive care unit, and circle beds, rotating frames, or serial inflating devices are used to protect from pressure sores.

Early in their course, patients often have an atonic bladder. A Foley catheter is used to monitor urine output during the resuscitation and to prevent damaging distention of the bladder. Early in hospitalization, the Foley catheter is removed and replaced by intermittent catheterization to decrease the chance of developing an ascending urinary tract infection.

Patients with a stable spinal column injury may be managed on an outpatient basis. This includes the huge number of patients who carry the diagnosis of acute cervical strain or acute lumbar strain. Patients with isolated, stable thoracolumbar compression fractures of less than 40% of the anterior height of the vertebral body are often managed at home. Follow-up care of cervical sprains and strains should be arranged within 2 to 3 weeks to recheck for subacute instability.⁷ The patient should return immediately for a recheck if there is any sign of worsening, such as the development of a cauda equina syndrome with urinary retention, fecal incontinence, or saddle hypoesthesia. Paresthesias are a sign of potential instability.

Transfer Considerations

The patient should be transferred to a specialized trauma facility if the trauma team cannot meet all the special requirements of the cord- or spinal column-injured patient, or for the extensive rehabilitation and specialized care of the cord-injured patient. Deteriorating or unstable internal injuries are best managed before transfer. The patient may be transferred by air or by ground; air transfer may provide a smoother ride. Transport personnel should be, at a minimum, advanced life support certified to ensure the continuous administration of intravenous methylprednisolone. For the emergent transfer, the patient should remain immobilized on a spinal

board with a semirigid collar.

COMMON PITFALLS

- Evaluation errors include a neurologic examination inadequate to identify changes in the neurologic status. Change is a key parameter leading to CT myelography and possible decompressive surgery. It is vital to record an accurate baseline motor, sensory, posterior column, and rectal tone examination. This should be followed by serial examinations.
- Misreading x-rays or accepting inadequate films
- Missing other injuries in the anesthetic or hypoesthetic patient. The patient cannot feel pain or tenderness below the lesion, so common historical and physical examination findings will be absent. The patient requires a very thorough examination, and it is wise to x-ray all significant bruises.
- The most common early management error is applying cervical spine traction instead of immobilization. ^{2,8,12} The patient is at the highest potential risk for traction injury during prehospital placement on a spinal board or during intubation, when in-line immobilization, not traction, should be used.
- Failing to ensure survival by attending to the ABCDEs and initial resuscitation
- Blaming hypotension on spinal neurogenic shock without completing the search for occult injury
- Failing to follow a high-dose methylprednisolone protocol
- Serious medicolegal risk will arise if there is deterioration due to secondary injury. Such risk would be particularly high if the physician allowed unnecessary motion, or if there was deterioration after failure to identify an unstable segment.

When lung tissues or the pleural linings are injured, devastating effects on pulmonary function can quickly ensue. Thoracic trauma is involved in nearly one-third of acute admissions to trauma centers and accounts for 25% of all trauma-related deaths in the United States.¹² The initial emergency department treatment of injuries to the pleura and lung parenchyma is often lifesaving.

PNEUMOTHORAX

A pneumothorax is the abnormal accumulation of air between the visceral and parietal pleurae. Penetrating thoracic trauma can introduce air into the pleural space by violating the chest wall and parietal pleura, resulting in a transient or continuous communication of the pleural space with ambient air. Penetrating trauma can also violate the pulmonary parenchyma, resulting in the flow of bronchoalveolar air into the pleural space.

Blunt thoracic trauma can result in a pneumothorax due to visceral pleural and pulmonary parenchymal damage from thoracic shearing forces and from the sharp fracture lines of injured ribs. Barotrauma can also indirectly result in pneumothorax. The negative pressure differential of the intrapleural space, with respect to both atmospheric air and bronchoalveolar air, results in its filling. Traumatic pneumothorax occurs in 15% to 50% of patients with blunt chest trauma and is almost invariably present in those with transpleural penetrating wounds.⁹

CLINICAL PRESENTATION

Traumatic pneumothorax typically results in the complaints of chest pain and dyspnea. Patient presentation may range widely, depending on the size of the pneumothorax, the degree of prior pulmonary insufficiency, and the presence of other associated injuries. Diminished breath sounds with auscultation, and hyperresonance with percussion, on the side of injury may be appreciated. One patient may present with cyanosis and tachypnea and may appear acutely ill; another patient may have no symptoms or findings except that of mild chest discomfort. In the multiply injured patient, the signs and symptoms of the other injuries may overshadow those of pneumothorax; therefore, a high index of suspicion is mandatory.

DIFFERENTIAL DIAGNOSIS

A simple pneumothorax does not cause the hypotension and profound respiratory distress seen with tension pneumothorax. Hemothorax often demonstrates ipsilateral dullness to percussion as opposed to the hyperresonance seen with pneumothorax.

EMERGENCY DEPARTMENT EVALUATION

The evaluation of a suspected pneumothorax begins with a focused history and physical examination. Gather information from the patient and emergency medical service personnel to determine the mechanism of injury. Observe the chest for wounds or asymmetry. Palpate for crepitance associated with broken ribs, which are associated with pneumothorax in up to one-third of cases. Percuss for hyperresonance, and, most importantly, auscultate for decreased breath sounds on the injured side.

If patient stability warrants, the chest radiograph is the next primary evaluation technique. A supine chest radiograph is acceptable, but an upright view allows air in the pleural space to rise to the apices and makes the diagnosis easier. In a multiply injured trauma victim whose spinal evaluation and clearance may be delayed, clinical suspicion and a supine film may be the only immediately available information sources. Some emergency department stretchers allow Fowler positioning (head of bed up) without compromising spinal precautions, and thus aid in obtaining a more informative x-ray.

A pneumothorax appears on chest x-ray as an area devoid of lung markings ([Fig. 102.1](#)). The initial film should be at full inspiration. If this film does not show a pneumothorax but clinical suspicion remains high, an expiratory film can be obtained. Despite a thorough examination and a good-quality x-ray, pneumothoraces can be elusive. The noisy emergency department environment is often less than ideal to auscultate for breath sounds, and low oxygen saturations are often not evident because injured patients are immediately placed on 100% O₂.

Figure 102.1. Chest film demonstrating a pneumothorax on the right.

Pneumothoraces also frequently may present anteriorly and not be evident on initial supine x-rays. Computed tomographic (CT) scanning of the chest is highly effective in locating intrapleural air.⁸ Although chest x-ray is less sensitive in detecting injuries than is CT, the majority of injuries identified by CT alone are minor and require no treatment.¹³

Pneumothorax size has traditionally been reported as a percentage of lung collapse. A small pneumothorax corresponds to 15% collapse, a moderate pneumothorax to 15% to 60%, and a large pneumothorax to more than 60%. A less ambiguous and simpler system is to measure and report the distance on the chest radiograph of the visceral pleural reflection from the inside of the chest wall at the apex and laterally.

EMERGENCY DEPARTMENT MANAGEMENT

Tube thoracostomy is the definitive emergency department treatment for traumatic pneumothorax. A small pneumothorax in a patient who will not undergo general anesthesia or receive positive-pressure ventilation may be managed with observation while the pleural air collection spontaneously resorbs. All other patients with traumatic pneumothorax should have a large chest tube (36F to 40F in adults) placed. The tube is placed in the fourth or fifth intercostal space just anterior to the midaxillary line. The plane of dissection through the chest wall courses over the top of the rib in order that the neurovascular bundle is not traumatized. The tip of the chest tube is directed apically and posteriorly. All chest tube side holes must lie within the pleural space. Chest radiographs must be taken after tube thoracostomy placement to demonstrate adequate evacuation of the pneumothorax and proper tube placement.¹⁶ It is imperative that emergency medicine physicians become highly skilled in the proper placement and management of tube thoracostomies, as complication rates as high as 14% have been reported.⁵

The chest tube is attached to a three-bottle system, using a trap bottle to collect fluid drainage from the pleura, a water-seal bottle to prevent air from returning to the pleural space during inspiration, and a manometer bottle to generate the suction. These containers are currently combined into a single molded-plastic apparatus. The initial suction placed on this system is usually 20 cm H₂O in adults.

DISPOSITION

All patients with traumatic pneumothorax require surgical consultation and admission. If no other significant injuries are present, admission to a floor surgical bed is adequate.

Air transport of the patient with a pneumothorax poses special risks. As atmospheric pressure decreases with ascent, the trapped gas of an unevacuated pneumothorax expands, increasing the size and lethality of the pneumothorax. A tube thoracostomy must remain on suction or have a one-way seal in place before air transport. The safest air transport is in an aircraft pressurized to sea level.

COMMON PITFALLS

- If a patient has a mechanism of injury consistent with chest wall trauma, assume there is a potential pneumothorax, even if not visualized on initial x-ray.
- Because pneumothoraces are easy to miss on an initial supine film, maintain a high index of suspicion.
- Observe carefully for clinical signs suggesting *progression* of simple pneumothorax to tension pneumothorax.
- Do not allow a patient with a small pneumothorax to undergo positive-pressure ventilation or ascend in an aircraft before tube thoracostomy evacuation.
- Do not insert a chest tube without first inserting a finger to ensure that the tube will not be placed through the lung, diaphragm, liver, or spleen.

TENSION PNEUMOTHORAX

A tension pneumothorax is a critical condition that exists when the communication between the bronchoalveolar and pleural spaces results in a progressive accumulation of intrapleural air. A pulmonary injury can act as a one-way valve, allowing air to enter the intrapleural space with inspiration but preventing its escape with expiration. Intrapleural pressures can rise dramatically because forced inspiration can generate pressures of up to -80 mm Hg. The contralateral lung and the vena cava become compressed. The cavoatrial junction can become distorted, obstructing right ventricular filling.

CLINICAL PRESENTATION

The patient with a tension pneumothorax is extremely ill, with profound respiratory distress and impending vascular collapse. Classic signs include jugular venous distention, tachycardia, hypotension, and absent breath sounds ipsilateral to the injury. The patient may be cyanotic and restless, and the trachea may be shifted contralateral to the side of injury. The patient may have a hyperexpanded hemithorax (highly resonant to percussion), with one side of chest tangibly bigger than the other and immobile. The patient may even present with pulseless electrical activity.

DIFFERENTIAL DIAGNOSIS

A patient with simple pneumothorax will present with unilateral loss of breath sounds, but will not be in extremis from this injury alone. Pericardial tamponade presents with hypotension and central venous distention, but heart sounds are distant and breath sounds are normal unless a pneumothorax is coincident. The patient in hypovolemic shock may be difficult to distinguish from the patient with intravascular volume depletion who has a coincident tension pneumothorax.

EMERGENCY DEPARTMENT EVALUATION

The rapid lethality of tension pneumothorax does not allow the luxury of radiographic evaluation. If the diagnosis of tension pneumothorax is suspected based on the physical examination, the physician should institute immediate treatment. If a radiograph is obtained prior to correction of a tension pneumothorax, marked mediastinal shift contralateral to the affected side and flattening or even partial inversion of the ipsilateral hemidiaphragm are seen.⁶

EMERGENCY DEPARTMENT MANAGEMENT

Immediate intervention is indicated when this diagnosis is suspected. Rapid decompression of the pleural space can be accomplished by placing a large-bore needle (12-gauge) into the second or third interspace anteriorly, or in the fourth or fifth interspace laterally, on the affected side. The lateral approach (anterior axillary line behind body of pectoralis muscle) provides the easiest access, because there is less muscle there and fewer anatomic structures are at risk for injury.¹⁹ This needle decompression reduces the deadly tension pneumothorax to the merely life-threatening communicating pneumothorax. This rapid technique can be easily

accomplished in the prehospital setting. A standard tube thoracostomy must then be performed to evacuate the pleural space completely.

DISPOSITION

All patients with tension pneumothorax must be admitted to the hospital. The proper level of care is determined by the associated injuries. A patient who presented in shock with no other injuries and then stabilized with tube thoracostomy placement could be admitted to a standard floor surgical bed. Additional inpatient care is identical to that of simple pneumothorax.

COMMON PITFALLS

- In the patient with unilateral diminished breath sounds and shock, do not await radiographic confirmation of tension pneumothorax before placing the tube thoracostomy.
- After temporizing needle decompression, placement of a tube thoracostomy must follow as soon as possible.

HEMOTHORAX

The accumulation of blood in the intrapleural space is a hemo- thorax. This hemorrhage may originate from a pulmonary laceration, or injury to the intercostal vessels, internal mammary vessels, or great vessels of the thorax. Enough blood can accumulate to interfere with ventilatory function of the ipsilateral lung. Hypovolemic shock due to the large volume of blood that can fill the thorax is the predominant concern. Hemothorax is often associated with a pneumothorax.

CLINICAL PRESENTATION

The patient with a large hemothorax may present with the signs and symptoms of hypovolemic shock, including tachycardia, hypotension, pallor, and anxiety. Additionally, the patient may demonstrate respiratory compromise, including tachypnea and cyanosis due to diminished vital capacity. Dullness to percussion may be noted over one or both blood-filled hemithoraces. The symptoms of a small hemothorax may be completely overshadowed by other injuries. The signs and symptoms of a pneumothorax are more likely to predominate in the patient with a hemopneumothorax.

DIFFERENTIAL DIAGNOSIS

Tension pneumothorax presents with shock and unilateral diminished breath sounds. Pericardial tamponade presents with shock. Both of these conditions, however, may be accompanied by central venous distention, which would be absent in a large hemothorax.

EMERGENCY DEPARTMENT EVALUATION

Once primary resuscitation with restoration of intravascular volume has been completed, obtain a chest radiograph ([Fig. 102.2](#)). An upright chest radiograph will show blunting of the costophrenic angles when more than 250 mL of fluid is present. Often, because of hemodynamic instability or concern for cervical spine injury, only a supine film is obtained. The supine film may show only a subtle haziness in the lung fields as the blood layers out posteriorly. Ultrasound and CT scan will also detect hemothoraces but are usually not as readily available as a portable film. Transesophageal echocardiograms can be used to evaluate the possible source of bleeding in patients with protected airways. The highest-yield study for evaluating the source of bleeding is an angiogram, but it requires that the patient be stable enough for transport to the angiography suite.

Figure 102.2. Chest film with massive hemothorax on the left.

EMERGENCY DEPARTMENT MANAGEMENT

Once the diagnosis of hemothorax is made, a large-bore tube thoracostomy (at least 36F) should be placed in the fourth or fifth intercostal space just anterior to the midaxillary line and directed posteriorly to evacuate the blood and to monitor ongoing hemorrhage. This tube should be connected to the same suction apparatus previously described for pneumothoraces. Un- contaminated blood obtained from the intrapleural space with a cell-saver device can be reinfused into the hypovolemic trauma patient.

In most cases of hemothorax, tube thoracostomy is the definitive treatment. However, if more than 1500 mL of blood is initially obtained on placement of the tube thoracostomy, or if there is continued drainage of more than 200 to 300 mL/h, the tube should be clamped and an open thoracotomy may be required.³ If there is clinical or radiographic evidence of aortic dissection or rupture, chest tube drainage can lead to rapid exsanguination.²⁰

DISPOSITION

All patients with traumatic hemothorax must have prompt surgical consultation and admission. Patients with ongoing hemorrhage require emergent surgical consultation and intensive care unit (ICU) admission. If stable, they may be admitted to a floor surgical bed. As with pneumothorax, air transport of the patient with hemothorax is hazardous and should be done only with the tube placed on suction or with a one-way seal in place.

COMMON PITFALLS

- Intravascular volume must be replaced adequately.
- Because hemothoraces are easily missed on initial supine films, keep a high index of suspicion.
- A large chest tube must be used to evacuate the intrapleural space because of clotting in small-bore tubes.
- One must recognize that ongoing evacuation of blood may be an indication for open thoracotomy.

PULMONARY CONTUSION

The most common injury identified in blunt chest trauma is pulmonary contusion. Despite improvements in diagnostic imaging and critical care, the associated mortality has not appreciably changed over the last three decades and remains at 25% for blunt trauma.¹ The term *pulmonary contusion* loosely refers to a set of distinct injuries that may be sustained after high-impact blunt chest trauma: True pulmonary contusion is the most common and most serious injury. Pulmonary

contusion, histologically, is the leakage of blood and protein into the alveoli and interstitial spaces of the lung, which stimulates increased secretions, resulting in atelectasis and consolidation. Pulmonary hematoma, a diagnosis that has been more clearly defined since the advent of the CT scan, represents an abnormal collection of blood. Pulmonary hematomas are initially seen as indistinct nodules on chest radiographs and usually resolve without sequelae. Pulmonary lacerations result from a shear force that disrupts the lung, parenchyma, and vessels. Pulmonary lacerations may cause bleeding or, less commonly, an air leak. Pulmonary contusions lead to hypoxia via the production of ventilation–perfusion mismatches.

Pulmonary contusion is a common sequela of blunt trauma in children. Previous reports suggest that children have more favorable outcomes than adults because of differences in mechanisms, associated injuries, and physiologic response. Recent studies have shown that although children and adults differ in regard to injury mechanism (automobile–pedestrian accidents versus motor vehicle accidents, respectively), their overall injury severity and outcomes are quite similar.² In contrast, elderly patients, who have a less compliant chest wall, are much more susceptible to injury and, as a group, have very poor outcomes after pulmonary contusions.¹¹

CLINICAL PRESENTATION

The patient with a pulmonary contusion may initially demonstrate dyspnea and tachypnea. There may be tenderness or obvious ecchymosis and deformity over the affected chest wall. Large pulmonary contusions may be associated with tachycardia, hypotension, and cyanosis. Patients with multiple rib fractures or flail segments of the chest wall are likely to have associated pulmonary contusion. Within 4 to 6 hours, the chest radiograph will show a localized alveolar pattern, ranging from irregular patchy infiltrates to consolidation.⁷

DIFFERENTIAL DIAGNOSIS

The symptoms of adult respiratory distress syndrome are dyspnea, hypoxia, and diffuse radiographic infiltrates, but they typically appear later than contusion. Fat emboli syndrome can occur in the patient with severe long-bone fractures and causes similar symptoms, but is also evident much later than pulmonary contusion and with less focal x-ray findings. A simple pneumothorax can present with findings consistent with contusion and initially may be difficult to differentiate.

EMERGENCY DEPARTMENT EVALUATION

In the emergency department, pulmonary contusion is often a clinical diagnosis. The suspicion of pulmonary contusion is raised whenever there is significant trauma to the chest wall or bony thoracic cage. The chest radiograph can be critical in establishing the diagnosis. Clinical suspicion must initially be relied on because characteristic x-ray findings do not usually appear for 4 to 6 hours.

In a dog model of pulmonary contusion, the initial x-ray films failed to visualize the lung lesion in two-thirds of subjects, whereas 100% of the lesions were discernible by CT scan. At 6 hours, contusions were still not visible in 21% of chest x-rays.⁷ It has been demonstrated that when more than 28% of the airspace is involved with contusion, all patients required mechanical ventilation.⁷ The degree of pulmonary damage can also be evaluated by arterial blood gas analysis. An initially low PaO₂ and a wide alveolar–arterial oxygen gradient may be the first signs of pulmonary contusion. Deteriorating blood gas values predict a poorer prognosis.

EMERGENCY DEPARTMENT MANAGEMENT

Initial therapy includes aggressive pulmonary toilet. Early researchers suggested that fluid restriction would prevent lung edema associated with direct pulmonary contusion. Since then we have learned that mortality in patients with pulmonary contusion is not related to the use of crystalloid or to the volume of fluid used in resuscitation of these patients. Crystalloid should be used to improve end-organ perfusion and optimize tissue oxygen delivery.¹⁴ Patients with pulmonary contusions must be monitored very closely for any signs or symptoms of respiratory decompensation, and early aggressive airway management to support ventilation is warranted.

Positioning the uninjured lung in the dependent position will increase pulmonary blood flow to the segments of the lung that are better perfused. Numerous studies suggest that between 30% and 60% of patients with pulmonary contusion will require intubation and some form of mechanical ventilatory assistance.¹⁴ Patients with pulmonary contusions who have other injuries, such as flail chest with paradoxical movement, or severe pain are at high risk for CO₂ accumulation because of depressed central drive for breathing associated with splinting, hypoventilation, and narcotic sedation. Although volume-controlled ventilatory modes have been traditionally used, new data suggest that pressure-controlled modes are acceptable and probably should be preferred in patients with poorly compliant lungs and in young trauma victims who require high inspiratory flow rates.¹⁷

DISPOSITION

All patients require admission to a critical care bed, where ventilatory status and oxygen saturation can be frequently assessed. These patients usually have multiple serious injuries, which also require critical care monitoring and often prove a clinical challenge to the trauma team. Atelectasis and pneumonia are common complications. Patients with small pulmonary contusions, despite the lack of other apparent injury, should be admitted to a surgical bed for observation.

COMMON PITFALLS

- Realize that signs and symptoms will evolve over several hours and may be missed on the initial evaluation.
- Intervene early with intubation and mechanical ventilation before respiratory failure develops.
- Expect elderly patients to have very poor outcomes from pulmonary contusion, and admit them to an ICU bed.

TRACHEAL AND BRONCHIAL INJURIES

Disruptions of the trachea and bronchi are infrequent (incidence of 0.03%) but life-threatening injuries follow trauma. Because of their effects on ventilation, these injuries are often fatal; however, improved emergency services and transport have been cited as a reason for increasing numbers of patients reaching tertiary care centers. Several studies addressing both penetrating and blunt injuries show that 70% occur as a result of penetrating trauma, whereas 30% occur from blunt trauma.^{10,15} Penetrating injuries involve the relatively unprotected cervical trachea in the majority of cases. Disruptions of the intrathoracic trachea and bronchi are less common. In contrast, the main bronchi are frequently involved in blunt trauma. The right main stem bronchus is involved twice as frequently as the left bronchus.¹⁰

CLINICAL PRESENTATION

Tracheal and bronchial injuries must be considered in any patient with a history of a significant mechanism, such as severe, sudden deceleration of any kind; penetration of neck or chest; or direct blow to neck or chest. Falls from heights over 18 ft cause high-energy impacts that may produce tracheobronchial injuries.¹⁸ Occasionally, few clinical signs or symptoms are present, even with severe tracheobronchial injury. Dyspnea, hoarseness, and aphonia are common, as is hemoptysis. Subcutaneous emphysema is extremely likely to be present. Cervical emphysema, confined to the deep cervical fascia between the mandible and the clavicle, is highly suggestive. With a straddle injury of the mainstem bronchus, surrounding fascia and mediastinal tissue can maintain airflow with few signs and symptoms.⁴

DIFFERENTIAL DIAGNOSIS

Pneumothorax presents with unilateral decreased breath sounds and is corrected by tube thoracostomy. Pulmonary lacerations, hematomas, and contusions may cause hypoxia, abnormal pulmonary examination, and chest x-ray findings, but will not cause a persistent air leak.

EMERGENCY DEPARTMENT EVALUATION

Only a minority of patients with tracheobronchial injuries reach the hospital alive. Those that do are either in severe distress or in extremis, with obvious ventilatory problems, or exhibit other more obvious injuries that are attended to first during the initial resuscitation. All trauma patients require a chest x-ray once the ABCs have been addressed. Mediastinal emphysema may be massive if the pleura are intact. If a chest tube is already in place, tension pneumothorax with a massive air leak will be apparent if the pleura are ruptured. Any time a well-placed tube thoracostomy continues to demonstrate a significant air leak or is unable to reexpand the lung, tracheobronchial injury must be suspected. Rarely, a lobar bronchus is all that is injured, in which case the patient generally will have persistent atelectasis either with or without persistent air leak. Fiberoptic bronchoscopy is required for definitive diagnosis. Bronchoscopy should be mandatory in any patient with penetrating injuries near the trachea of major bronchi.

EMERGENCY DEPARTMENT MANAGEMENT

In a patient with obvious major airway or ventilatory problems, endotracheal intubation should be attempted; if successful, it may temporarily improve the problem. Bilateral tube thoracostomies should be placed if the patient remains in distress and there is any suspicion of a pneumothorax. Occasionally, emergent or urgent sternotomy or thoracotomy must be performed to obtain and secure an airway.¹⁵ A stable patient who exhibits subcutaneous air without obvious pneumothorax should probably receive a tube thoracostomy if he or she will require ventilatory support. All tracheobronchial lacerations and disruptions require surgical repair.

DISPOSITION

All patients with suspected or confirmed tracheobronchial injury should be admitted to a surgical ICU.

COMMON PITFALLS

- If one does not think about the diagnosis of tracheobronchial injury early, the diagnosis will probably be made by the pathologist.
- Early intubation and aggressive airway management, as well as tube thoracostomy, cannot be delayed; they may be temporarily life-saving.
- As soon as the diagnosis is suspected, call a surgical colleague for immediate consultation or transfer to a trauma center.

BLUNT CARDIAC INJURY

Blunt cardiac injury (BCI) refers to a spectrum of heart injuries, including BCI with septal rupture, BCI with free wall rupture, BCI with coronary artery thrombosis, BCI with cardiac failure, BCI with minor electrocardiogram (ECG) or enzyme abnormalities, and BCI with complex dysrhythmias.^{13,16} The terms *cardiac concussion* (*commotio cordis*) and *myocardial contusion* have been used, but lack a consensus for diagnostic criteria. BCI can occur when a moderate-to-severe force is applied to the chest or upper abdomen. Motor vehicle collisions (particularly those in which the driver hits the steering wheel), blast injuries, direct blows, falls from heights, and chest compression are the most common mechanisms. Seventy percent to 80% of blunt chest trauma victims are male, with a peak incidence in the third decade. Alcohol consumption and hazardous occupations are risks. Multiple trauma is associated in two-thirds of these patients. Mortality and morbidity are greater in patients over age 65.

Injuries to the heart occur in 8% to 71% of blunt chest trauma patients.¹⁶ This wide range probably represents the difficulty in diagnosing and defining the problem, rather than representing the actual incidence. Eighty percent to 90% of lethal BCIs are immediately fatal (prehospital). These are usually from cardiac rupture or dysrhythmias (most commonly ventricular fibrillation). Mortality in patients who survive this initial period after BCI is related closely to their concomitant injuries.⁹

PATHOPHYSIOLOGY

By virtue of its location and suspension in the chest, the heart is susceptible to injury from compression of the chest wall or upper abdomen and from deceleration forces. The right ventricle is most commonly injured, probably due to its relatively vulnerable position immediately behind the sternum.

True cardiac chamber rupture is rare. The chamber ruptured most frequently, however, is the right atrium (50%), followed by the left atrium (25%), the right ventricle, and the left ventricle. Death is usually the result of tamponade (two-thirds of cases) or exsanguination (one-third). Less than 10% of patients with cardiac chamber rupture survive more than 30 minutes after injury.¹⁷

The heart valve most vulnerable to blunt trauma is the aortic. When mitral valve dysfunction is present, it is most commonly due to rupture of the chordae tendineae or papillary muscles.

CLINICAL PRESENTATION

Physical findings in BCI may be nonspecific. Seventy percent to 80% of patients with BCI have external signs of chest trauma, including contusions, abrasions, palpable crepitus, and flail segments.⁹ The presence of a fracture of the sternum, once thought to be a marker for BCI, has been shown not to predict the presence of a BCI.⁷ The most common vital sign abnormality is sinus tachycardia. Hypotension is a serious sign and should raise the possibility of cardiac tamponade, cardiac rupture, other noncardiac trauma with hypovolemia, valve rupture, or decreased cardiac output (pump failure). Chest pain is often present, but it is neither a sensitive nor specific symptom in the multiple trauma victim. Cyanosis of the upper torso, head, and neck may be present in up to 75% of patients with cardiac rupture.

Cardiac tamponade is a rare complication of blunt chest trauma (in contradistinction to penetrating trauma). Beck's triad of acute cardiac tamponade is hypotension, elevated jugular venous pressure (JVP), and muffled heart sounds. It is present in only about a third of patients with acute cardiac tamponade of any etiology. Pulsus paradoxus, although present in up to one-third of patients with tamponade, is not pathognomonic for tamponade. It is also present in chronic obstructive pulmonary disease, asthma, obesity, cardiac failure from many causes, constrictive pericarditis, pulmonary embolism, and cardiogenic shock.

New murmurs, or acute congestive heart failure, after chest trauma should raise the suspicion of a ruptured intraventricular septum, valve leaflet, or chordae tendineae. Traumatic ventricular septal rupture presents with a pansystolic murmur auscultable over the entire precordium, especially at the left lower sternal border. This may not be appreciated, however, until the patient has been resuscitated to euvolemia.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of blunt cardiac trauma includes pulmonary contusion, flail chest, simple pneumothorax, hemothorax, aortic injuries, extrathoracic hemorrhage, myocardial infarction, air embolism, and tracheal injuries. In the differential diagnosis of high central venous pressure (CVP) shock, tension pneumothorax is more common than cardiac tamponade.

EMERGENCY DEPARTMENT EVALUATION

There are no widely accepted criteria for making the diagnosis of BCI. No single test or combination of tests has proved useful in reliably confirming the diagnosis. The diagnosis could be entertained in any patient with a compatible mechanism of injury.

The admission ECG is the most important diagnostic tool in diagnosing BCI.⁸ Almost every ECG abnormality has been described in BCI: Dysrhythmias, conduction blocks, axis shifts, ST and T wave changes, and injury patterns have all been described, but none of these changes are diagnostic. Total electrical alternans (both the P wave and QRS complex) is pathognomonic for pericardial tamponade, but this is a rare finding. The presence of abnormalities on the initial emergency department (ED) ECG, however, has the best correlation of any immediately available test with the risk of subsequent cardiac complications. If the initial ED ECG is abnormal, continuous cardiac monitoring for 24 to 48 hours is prudent. If the initial ED ECG is normal, the risk of having a BCI that requires treatment is very slight. Although

many BCIs affect the right ventricle, right-sided ECG tracings have not been proven to be of value.

If the patient with a suspected BCI is hemodynamically unstable or has an elevated CVP, new heart murmurs, or significant dysrhythmias, echocardiography is indicated.¹⁵ Transthoracic echocardiography has several advantages in the evaluation of these patients. This noninvasive test, which can be performed at the bedside, can quickly give information about wall motion abnormalities, pericardial fluid collections, ruptured valves, and ruptured septa, as well as an estimate of ejection fraction.¹⁸ If the transthoracic echocardiogram is suboptimal, a transesophageal echocardiogram should be considered.¹⁹

Creatinine kinase (CK), CK-MB, and cardiac troponin-T (cTnT) determinations do not help in making the diagnosis. These tests lack sensitivity, specificity, and the ability to predict complications.^{5,10} Cardiac troponin-I (cTnI) may be more accurate than CK-MB, but still lacks the ability to predict complications and appears to add no additional clinical value to the initial ED ECG.¹

Chest radiographs are not helpful in diagnosing blunt cardiac trauma *per se*, but they are useful in identifying other thoracic injuries to narrow the differential diagnosis.

Radionuclide imaging studies, including MUGA scans, technetium scans, thallium-201 myocardial scintigraphy, thallium-201 single photon emission CT (SPECT) scans, and antimyosin scintigraphy have never been demonstrated to be superior to the initial ED ECG and echocardiogram in diagnosing BCI, nor in predicting complications.^{5,8,11,12}

EMERGENCY DEPARTMENT MANAGEMENT

The chance that a patient has a BCI in the face of a normal initial ECG and an injury severity score less than 10 is less than 1%. Even in the presence of BCI, young, hemodynamically stable patients with normal ECGs on admission after chest trauma are very unlikely to suffer complications. Intravenous fluids may help support the blood pressure by supplying preload to an injured right ventricle. External cardiopulmonary resuscitation (CPR) in the victim of arrest from cardiac trauma is likely to be ineffective. Standard antidysrhythmics should be used to treat life-threatening dysrhythmias. There are no data to support the use of prophylactic antidysrhythmics. Monitoring the ECG and CVP helps identify patients with developing tamponade. A CVP line should be placed early in the persistently hypotensive patient with a suspected cardiac injury. The patient in shock may benefit from pulmonary artery pressure monitoring to optimize fluid resuscitation. Patients who remain hemodynamically compromised after volume repletion may benefit from pressor support (dobutamine). The last option for refractory cardiogenic shock is the use of intraaortic balloon counterpulsation.

The prognosis for patients with BCI is most closely correlated with the severity and number of other injuries. In patients with suspected tamponade, pericardiocentesis may be diagnostic and may buy some time by stabilizing the patient before surgery. However, false-negative taps can mislead the clinician. Survivors of cardiac rupture are most commonly patients with atrial involvement who undergo early thoracotomy. Some centers advocate thoracotomy in the ED for patients who have had vital signs (palpable pulse or recorded blood pressure) present in the prehospital environment and then lost their vital signs, realizing that the neurologically intact survival rate in blunt trauma arrest is much lower than in penetrating trauma (2.5% vs. 7%).^{2,3} Only 10% of blunt cardiac rupture patients require extracorporeal bypass. Rarely, blunt cardiac trauma can cause coronary thrombosis. The clinical picture is similar to that of acute myocardial infarction. The treatment would be similar except that the use of thrombolytics is contraindicated.

DISPOSITION

Role of the Consultant

Patients with significant blunt chest trauma benefit from evaluation by a trauma center team. A cardiothoracic surgeon should be consulted for suspected myocardial rupture, pericardial rupture, or valve rupture. An echocardiographer or cardiologist may be necessary to aid in heart imaging.

Indications for Admission

Patients with operable blunt trauma to the heart (cardiac rupture, valve rupture, tamponade) need early and aggressive surgical treatment. Because the prognosis of patients with BCI is related to the magnitude of the initial trauma, the preexisting condition of the heart, the size and location of the cardiac injury, and the patient's other injuries, patients who have coronary artery disease, hemodynamic compromise, significant dysrhythmias, a major mechanism of injury, or multiple trauma and suspected blunt cardiac trauma are best cared for in the intensive care unit. A young, healthy patient with no hemodynamic instability, a normal ECG free of significant dysrhythmias, and no other significant extracardiac trauma could be safely discharged after a 6- to 12-hour period of observation in the ED. Such a patient should be observed at home by a reliable adult, with instructions to return for increasing chest pain, lightheadedness, dizziness, syncope, or shortness of breath.

Transfer Considerations

If the patient with blunt cardiac trauma arrives at a hospital that is not equipped to care for the injury, the patient should be rapidly stabilized while arrangements for transfer are made. Stabilizing maneuvers may include endotracheal intubation and mechanical ventilation, volume resuscitation, initiation of transfusion, pressor support, tube thoracostomy, pericardiocentesis, central venous monitoring, and ECG monitoring. Monitoring should continue en route to the receiving facility, and the patient should be accompanied by paramedics (with or without a physician).

COMMON PITFALLS

- Paramedics should not delay transport while attempting stabilizing procedures; these should be accomplished en route if possible.
- Do not ascribe hypotension to cardiogenic shock from BCI with pump failure without a search for hypovolemia.
- Do not wait for Beck's triad to be evident.
- Do not lose sight of the patient's other serious injuries in the search for a BCI.
- Do not allow attempts at pericardiocentesis to delay or cancel definitive surgery in patients with suspected tamponade.
- Do not overlook tension pneumothorax as a more likely cause of high CVP shock.
- Do not forget the utility of blood transfusion, including uncrossmatched blood in the severely hypovolemic blunt cardiac trauma patient.

PENETRATING CARDIAC INJURIES

Wounds that penetrate the heart include stab wounds, gunshot wounds, impalement injuries, and industrial accidents. Most of these injuries are the result of interpersonal violence. Nearly 90% of the victims are male, 75% are between ages of 16 and 35, and the overall mortality of patients transported to the hospital exceeds 50%.^{6,14} Wounds directly over the precordium and epigastrium (the "cardiac box") are more likely to involve cardiac injury than those from more posterior or lateral locations. Due to its location, the right ventricle is the chamber most often injured, followed in frequency by the left ventricle, the right atrium, and the left atrium.⁶

The pericardial sac normally contains 30 to 40 mL of fluid. The fibrous pericardium is only minimally distensible, so after an accumulation of 80 to 120 mL of fluid, the pressure within the pericardium rises. This raises end diastolic pressure, decreases diastolic filling, decreases coronary artery perfusion, and decreases stroke volume and cardiac output. As the pressure continues to rise, compensatory mechanisms fail (tachycardia, increased peripheral vascular resistance, and enhanced contractility), cardiac output drops, and hypotension results. Eighty percent to 90% of patients with stab wounds to the heart and 20% of patients with gunshot wounds to the heart develop tamponade. Up to 70% of these present with "early tamponade" and appear "clinically stable."⁴ The presence of tamponade is associated with a greater chance of survival, presumably because the pericardium prevents rapid exsanguination from the cardiac wound. The patient with a waxing and waning clinical status may have an intermittently decompressing cardiac tamponade with the concomitant accumulating hemothorax.

CLINICAL PRESENTATION

Beck's triad of tamponade—hypotension, elevated JVP, and muffled heart sounds—is present in only about a third of patients with tamponade. Pulsus paradoxus, although present in up to one-third of patients with tamponade, is not pathognomonic for tamponade. Pulsus paradoxus is also present in chronic obstructive pulmonary disease, asthma, obesity, cardiac failure from many causes, constrictive pericarditis, pulmonary embolism, and cardiogenic shock. In the setting of a gunshot wound to the heart, loss of an extremity pulse or focal neurologic deficits should raise the question of arterial embolization of the bullet, pellet, or fragment. New murmurs or acute congestive heart failure after chest trauma should raise the suspicion of intraventricular septum, valve leaflet, or chordae tendineae injuries. Ventricular septal lacerations present with a pansystolic murmur auscultable over the entire precordium, especially at the left lower sternal border. This may not be appreciated, however, until the patient has been resuscitated to eu-olemia.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of penetrating cardiac trauma includes simple pneumothorax, hemothorax, aortic injuries, extrathoracic hemorrhage, air embolism, and tracheal injuries. In the differential diagnosis of high CVP shock, tension pneumothorax is more common than tamponade.

EMERGENCY DEPARTMENT EVALUATION

The most common vital sign abnormality is sinus tachycardia. Bradycardia or pulseless electrical activity (PEA) is often a preterminal sign. Hypotension is a serious sign and should raise the possibility of cardiac tamponade, massive hemothorax from the cardiac wound, other noncardiac trauma with hypovolemia, or valve injury. Measuring the CVP early in the course of resuscitation will help differentiate tamponade (high CVP) from hypovolemia (low CVP) in the patient with systemic hypotension. However, the CVP may not be elevated in the severely hypo-olemic patient in tamponade until a reasonable circulating volume has been restored.

Chest radiographs are not very helpful in diagnosing penetrating cardiac trauma *per se*, but they are useful in identifying other thoracic injuries associated with penetrating cardiac injuries. The radiograph may demonstrate a hemothorax, pneumothorax, pneumopericardium, or the offending missile(s). The blurry image of a bullet overlying the cardiac silhouette should raise the question of an intracardiac location and “movement artifact” on the film.

Echocardiography has several advantages in the evaluation of these patients. A noninvasive test that can be performed at the bedside, it can quickly give information about pericardial fluid collections, valve injuries, and septal lacerations. This test probably gives the most clinically relevant information and is indicated in the evaluation of the patient at risk for a penetrating cardiac injury who exhibits signs of hemodynamic instability: persistent tachycardia, hypotension, elevated pulsus paradoxus, elevated CVP, new heart murmurs, or significant dysrhythmias.^{18,19}

EMERGENCY DEPARTMENT MANAGEMENT

As in blunt trauma, monitoring the ECG and CVP will help identify patients with developing tamponade. A CVP line should be placed early in the persistently hypotensive patient with a suspected cardiac injury. Intravenous fluids may help support the blood pressure by supplying preload to the injured right ventricle.

In patients with suspected tamponade, pericardiocentesis may be diagnostic and may buy some time by stabilizing the patient before surgery. However, false-negative taps can be misleading.

External CPR in the victim of arrest from cardiac trauma is likely to be ineffective. Thoracotomy in the ED is indicated for patients with penetrating trauma to the chest who have a rapidly deteriorating clinical course, uncontrolled hemorrhage, or cardiac arrest. Only 10% of penetrating cardiac trauma patients require extracorporeal bypass.⁴

The role of prophylactic antibiotics has never been proven, but they may be of some benefit. There is no consensus about an antibiotic regimen. The use of a pneumatic antishock garment is contraindicated.

DISPOSITION

Role of the Consultant

Patients with suspected or potential penetrating cardiac injury should have a trauma surgeon involved early during their care.

Indications for Admission

Patients who develop cardiac tamponade following penetrating injuries require surgical intervention. In addition to tamponade, the risk of rapid exsanguination accompanies these injuries. Patients with any potential for cardiac injury should be observed in a monitored setting where any deterioration can be quickly detected.

Patients in whom penetrating cardiac trauma can be ruled out are candidates for discharge. These include patients with low-energy trauma (stab wounds), with no hemodynamic instability, and with normal CVP, normal ECG, normal vital signs, and stable hematocrit (all monitored serially over 8 to 12 hours). They should have no hemothorax, no pneumothorax, and no evidence of other significant trauma.

Transfer Considerations

If a patient with penetrating cardiac trauma arrives at a hospital that is not equipped to care for this injury, the patient should be rapidly stabilized while arrangements for transfer are made. Stabilizing maneuvers may include endotracheal intubation and mechanical ventilation, volume resuscitation, initiation of transfusion, pressor support, thoracostomy, pericardiocentesis, central venous monitoring, and ECG monitoring. Monitoring should continue en route and the patient should be accompanied by paramedics (with or without a physician).

COMMON PITFALLS

- Expedient prehospital transport is vital. Paramedics should not delay at the scene while attempting to perform stabilizing procedures; these should be performed en route, if possible.
- Completely undress the patient and examine the entire body (including the back, buttocks, and axilla) to search for other injuries.
- Minor-appearing exterior wounds (such as from an ice pick) can cause serious cardiac wounds.
- Do not try to predict a bullet's trajectory within the body based on the external wounds.
- Do not wait for Beck's triad to develop.
- Do not allow attempts at pericardiocentesis to delay or cancel definitive surgery in patients with suspected tamponade.
- Do not overlook tension pneumothorax as a more likely cause of high CVP shock.
- Become familiar with the technique of ED thoracotomy.
- Do not forget the utility of blood transfusion, including the use of uncrossmatched blood, in the severely hypovolemic cardiac trauma patient.
- Remember tetanus prophylaxis.

Vesalius first described great vessel injury in 1557, but today great vessel injuries are most commonly caused by rapid and sudden deceleration in the setting of a motor vehicle crash (MVC).¹⁶ Typically, these injuries involve the aorta, but deceleration injuries to the brachiocephalic artery and inferior vena cava (IVC) have also been reported.^{24,31} Nearly 15% of automobile fatalities, accounting for approximately 7,500 deaths yearly, occur secondary to traumatic disruption of the aorta.¹⁴ Penetrating injury to the thoracic great vessels is less common, with an overall incidence of 4%.⁸

Disruption of a great vessel usually portends a poor outcome. The seminal work of Parmley and coworkers²⁶ in 1958 demonstrated that 80% of these patients exsanguinate quickly and do not survive to hospital admission. Weiman et al. confirmed this bleak statistic, reporting that most patients with major injuries of the thoracic outlet die of massive hemorrhage before they reach the hospital.³¹ In 1961, Ochsner et al.¹⁷ reported that 36% of patients sustaining IVC injuries would not survive to hospitalization. More recently, Rosengart and coworkers²⁴ also recorded a significant mortality from blunt IVC trauma.

Those who suffer from penetrating trauma often fare no better. With the exception of select patients who are fortunate enough to have small, contained penetrations or arteriovenous, fistulous communications, which favor hemodynamic stability, the literature is replete with studies demonstrating a poor outcome after penetrating thoracic aorta or subclavian injuries.⁸ The subclavian vessels are the most commonly injured thoracic great vessels, with an overall incidence of 3.3% in patients with penetrating chest trauma. Venous injuries have a worse prognosis than arterial injuries, most probably due to air embolism or the inability of veins to contract to control exsanguination.⁸

Even with the advent of sophisticated prehospital and trauma systems, the early mortality of great vessel injury remains largely unchanged.^{6,17} Victims of blunt aortic injury (BAI) who arrive hypotensive (systolic blood pressure less than 90 mm Hg), with an age greater than 55, have still been consistently shown to experience a bad outcome in great vessel injury.^{10,17,18} Of the initial survivors of BAI, 30% die within 6 hours of presentation, and a further 20% will not live beyond 24 hours, should there be a significant delay in diagnosis or definitive repair.¹²

Demetriades⁸ suggested that in patients with significant vascular injury, any delays of advanced life support on the scene may actually increase mortality. In penetrating torso injuries, Bickell et al.³ similarly posited that some degree of hypotension may be protective by compensatorily serving to reduce bleeding. These authors implied that prehospital fluid resuscitation might have paradoxically led to a significantly higher mortality and longer hospitalization.

The recent literature is somewhat contradictory regarding mortality differences in BAI patients with delayed transport times, but differences between survivors and nonsurvivors do not appear to be related to the time between diagnosis and subsequent thoracotomy.^{10,18} Similarly, Ochsner et al.¹⁷ reported that time from admission to surgical intervention in the setting of IVC injury did not significantly differ between survivors and fatalities.¹⁷ Burch et al. reported an increase in in-hospital mortality from IVC injuries; it was postulated that as more critically ill patients have survived to admission because of decreased emergency medical service transport times, the occurrence of preoperative shock, resuscitative thoracotomy, and death has subsequently increased.¹⁷

PATHOPHYSIOLOGY

Disruption of a great vessel is usually seen in high-speed motor vehicle or airplane crashes, falls from height, or crushing chest injury. Several mechanisms have been postulated to explain BAI. Foremost, rapid horizontal or vertical deceleration produces shearing forces at the aortic isthmus (the weakest and most susceptible portion of the aorta) just distal to the origin of the left subclavian artery, where the aorta changes from relatively mobility to a relatively fixed structure ([Fig. 104.1](#)).² Although the aorta may withstand intraluminal pressures of up to 350 mm Hg, this pressure may be surpassed in a high-speed MVC; a burst or “water-hammer” effect directly compresses the aorta and propagates a pressure wave, which can lead to aortic injury.^{9,19} A direct shearing force secondary to vertebral fractures; a bending stress caused by chest compression, with subsequent flexion of the arch across the left lung hilum; or entrapment of the thoracic vasculature between the anterior chest wall and the thoracic spine have also been implicated in great vessel injury.^{10,19}

Figure 104.1. Rapid decelerative injury causing a tear in the thoracic aorta. The ascending (anterior) aorta tends to continue moving forward, while the more fixed descending aorta is held stationary. The rupture occurs just distal to the ligamentum arteriosum at the level of the isthmus.

In 70% to 90% of cases, the classic site of rupture is just distal to the left subclavian artery at the site of the ligamentum arteriosum.⁷ Anatomically, this can be explained by the fact that the descending aorta is tethered by the ligamentum arteriosum and the intercostal arteries. The ascending aorta is relatively mobile, and, during deceleration, continues to move forward while the descending aorta is held in place. In seatbelted motor vehicle occupants, descending thoracic aortic tears are more common, while ascending aortic disruption tends to be seen more often in unrestrained drivers.¹⁰

The tear usually involves the anteromedial border of the aorta and is almost exclusively a circumferential transverse laceration that disrupts the physical integrity of one or more structural layers of the aorta.¹⁶ If complete, a tear usually results in transmural extension and death due to immediate exsanguination. In survivors, the adventitia remains intact and blood is contained by a false aneurysm formed by the adventitia and surrounding mediastinal tissues. An overall mortality of 5.4% has been reported for this group.¹⁸ If surgical or medical therapy is not initiated, mortality is 66% at 2 weeks and 98% 4 months after the injury.

Concomitant aortic branch vessel injuries occur in 4% to 10% of cases.^{9,14,19} Brachiocephalic injuries, including complete avulsion from the aortic arch, probably result from the decreased space between the sternum and vertebral bodies.³¹ This decrease in space causes the heart to shift to the left and posteriorly, with an increase in tension on the thoracic outlet vessels.

CLINICAL PRESENTATION

In penetrating trauma, physical findings are not insidious. Usually, there is overt bleeding from a visible wound, a massive hemothorax, or continuous bleeding from a thoracostomy tube. In the proper context, an absent or diminished pulse in the arm represents subclavian artery injury, while the presence of a murmur or bruit suggests an aneurysm or arteriovenous fistula.

In the setting of blunt trauma, diagnosis is more difficult and historic features suggestive of a major decelerative mechanism should be sought. Such characteristics are usually seen in victims of an MVC (with speeds greater than 30 mi/h), but may also be present in patients who have fallen from a height (generally greater than 10 ft) or have been struck by an automobile. Prehospital personnel may be able to provide indirect evidence of deceleration by noting the lack of restraint system use and the presence of steering wheel or dashboard damage.

Unfortunately, symptoms of traumatic great vessel injury are often absent or masked by coexisting injuries.²⁶ The most frequently recorded complaints are chest pain (26%), dyspnea (25% to 30%), and back pain (14%). Other symptoms include dysphagia, hoarseness, and ischemic pain of the extremities. Interestingly, half of the deaths after brachiocephalic and carotid artery injury were attributed to ischemic cerebral infarction. The neurologic and clinical symptomatology attendant with such pathophysiology may also be seen.³¹

Physical examination may reveal ecchymosis, abrasion, or tenderness of the anterior chest consistent with impact of this area on the steering wheel. Thirty-one percent of patients with an aortic disruption present with pseudocoarctation syndrome. In these cases, upper extremity hypertension is present, with decreased or absent femoral pulses. This may be due to compression of the aortic lumen by surrounding periaortic hematoma. Reflex stimulation by stretching of cardiac sympathetic fibers at the aortic isthmus may account for the observation that 72% of patients with an aortic rupture manifest a relative hypertension (average blood pressure, 152/98). A harsh systolic murmur over the precordium or interscapular area (thought to be due to turbulent flow across the area of transection) is present in 26% of cases.¹⁴

Less common signs include a diminished left radial pulse, transient anuria, and paraplegia. Some authors have reported swelling at the base of the neck, resulting from extravasation of blood from the mediastinum; however, this finding has not been confirmed clinically in antemortem studies.

Despite the severe nature of traumatic aortic injury, one-third to one-half of patients have no external evidence of chest injury on presentation to the emergency department. Furthermore, many patients have associated central nervous system, abdominal, or bony injuries that may distract the physician from considering great vessel injury promptly. Most often, the presence of great vessel injury cannot be confirmed or ruled out on the basis of physical examination in patients suffering blunt trauma.^{1,14}

DIFFERENTIAL DIAGNOSIS

Ninety percent of patients who suffer from blunt thoracic aortic injury have coexisting lethal injuries. A high index of suspicion must be maintained to detect any of the host of possible injuries, including soft-tissue damage; clavicle, sternum, or rib fractures; hemothoraces or pneumothoraces; tracheobronchial injuries; diaphragmatic rupture; esophageal perforation; pericardial tamponade; coronary artery injury; or myocardial contusion or rupture.¹⁹ Concomitant abdominal, orthopedic, and neurotraumatic injuries often are found. A higher Injury Severity Score has consistently been reported in nonsurvivors versus survivors.¹⁰

EMERGENCY DEPARTMENT DIAGNOSIS

Chest Radiography

Although a normal initial chest radiograph has been reported in 7% to 28% of cases,¹⁰ an upright chest radiograph remains the investigative method of choice for screening for BAI in patients with an appropriate mechanism of injury.^{5,11,14} In penetrating trauma, the chest radiograph may be helpful in identifying missiles or fragments, hemothorax, lung contusions, fractures, or mediastinal hematomas.⁸ Ideally, this study is obtained as an upright posteroanterior chest radiograph, but the traumatized patient is often immobilized and cannot sit or stand for such a radiograph. Portable supine anteroposterior radiographs can be obtained in the emergency department, but technical differences between these two techniques make the radiographic features of traumatic aortic rupture more difficult to interpret.

Despite the many radiographic signs of traumatic aortic injury ([Table 104.1](#), [Fig. 104.2](#)), no single radiographic criterion is diagnostic or can rule out the injury. A widened mediastinum has received the most attention of these radiographic criteria in the literature, but in 6% of cases it may develop late or not at all. Moreover, vertebral fracture or increased aortic tortuosity associated with age may produce mediastinal widening, making it a sensitive but nonspecific indicator of aortic rupture.^{5,11,22,32}

Widening of the superior mediastinum at the level of the aortic knob in an upright radiograph
Mediastinal width–chest width ratio of more than 0.25
Deviation of the trachea or endotracheal tube to the right
Deviation of the nasogastric tube (representing the esophagus) to the right
Narrowing of the carinal angle
Depression of the left mainstem bronchus
Irregularity of the aortic knob contour
Left apical cap
Opacification of a clear space between the aorta and pulmonary artery ("aortic pulmonary window")
Widening of the left or right paraspinal stripe
Hemothorax, sternum or rib fractures

TABLE 104.1. Radiographic Features of Great Vessel Injury

Figure 104.2. Upright posteroanterior chest radiographs of a 20-year-old man involved as a driver in a head-on motor vehicle accident (**A**) compared with that of a normal person (**B**). The first radiograph has several abnormalities suggestive of a great vessel disruption. (**A**) Loss of detail of aortic knob with blurring of the aortic outline. (**B**) Widened mediastinum (mediastinal width–chest width ratio greater than 0.28). (**C**) Opacification of the clear space between the aorta and pulmonary

artery (aortopulmonary window). (D) Obliteration of the medial aspect of the left upper field. The aortogram revealed rupture of the aortic arch. (Radiographs courtesy of the Department of Radiology, St. Luke's Hospital, Milwaukee, Wisconsin.)

Traditionally, great vessel injury has been thought to be associated with first or second rib fractures, given the close anatomic relation. However, several studies have shown that vascular injury does not correlate with the anatomic location or degree of displacement of rib fractures, although multiple rib fractures were more prevalent in the aortic injury group.^{12,13} It has also been postulated that blood or fluid in a widened mediastinum secondary to acute traumatic aortic injury might track up into the neck and cause cervical prevertebral soft-tissue swelling. However, cervical soft-tissue swelling at the level of C3 and C6 did not correlate well with mediastinal width–chest width ratios and seems to be a poor marker of aortic injury.²¹

Despite these shortcomings, a chest radiograph interpreted in the proper clinical context can still form an effective strategy to screen for great vessel injury. Patients with a significant mechanism of injury or abnormalities on the chest radiograph mandate further study. However, in those patients in whom there is a low pretest probability of BAI, the upright chest radiograph has been shown to have a negative predictive value of 98%, making further investigation unnecessary.¹⁹

Computed Tomography

In the past, when the possibility of great vessel injury mandated additional study, aortography was clearly the procedure of choice. However, 80% to 92% of patients with blunt chest trauma who are triaged to angiography because of the mechanism of injury, clinical suspicion, and an abnormal chest radiograph will not have an aortic or brachiocephalic injury.¹⁹ Consequently, this approach has undergone review since dynamic computed tomography (CT) scanning of the chest has become an option for the diagnosis of aortic rupture (Fig. 104.3).

Figure 104.3. Dynamic chest computed tomography reveals an intimal flap (*solid arrow*) and surrounding periaortic hematoma (*open arrow*). This patient underwent successful operative repair of a traumatic disruption located at the “classic” site (ligamentum arteriosum).

CT scanning is noninvasive, requires less time for completion than aortography, and may actually be more cost effective than chest radiography for screening hemodynamically stable patients with blunt trauma.¹⁹ There is also the added benefit of ruling out associated head and abdominal injuries without moving the patient from the CT table.

On the CT scan, positive criteria for the diagnosis of BAI include periaortic hematoma, an irregular aortic contour, change in caliber of the aorta, and intraluminal irregularity (intimal flap).¹ In some studies, mediastinal hemorrhage has not been shown to be as specific a finding as periaortic hematoma. However, when intravenous contrast was utilized in those patients with an equivocal or indeterminate screening chest radiograph, Patel et al.¹⁵ found that mediastinal hematoma, as an indirect CT sign of BAI, had a sensitivity of 100%, was 87% specific, and had a negative predictive value of 100%.

When chest CT was performed without the use of intravenous contrast material, Harris and coworkers prevented unnecessary aortography in 63 of 100 patients with blunt trauma in whom equivocal or indeterminate screening radiographs were obtained.¹⁹ On the basis of clinical outcome, no cases of acute traumatic aortic injury were missed and only six (17%) of the remaining 36 patients who had aortography performed were found to have significant injury.

Transesophageal Echocardiography

In the unstable, severely traumatized patient with an equivocal or indeterminate chest radiograph, transesophageal echocardiography (TEE) provides mobile, real-time imaging of the heart, thoracic aorta, and mediastinum and may offer an alternative to aortography. In at least one study, color flow Doppler has also been shown to be a reliable investigation in the evaluation of neck vessels, including the subclavian artery and vein.⁸

Technically, TEE is performed in a manner similar to flexible endoscopy of the esophagus. Because of the probe's close proximity to the thoracic vasculature, good visualization of both aortic wall disruptions and intimal irregularities such as intimal flaps is facilitated. While TEE shows the area of the ligamentum arteriosum well, it often does not visualize the proximal aortic branches adequately.

TEE findings of mediastinal hematoma include a distance of more than 3 mm between the probe and the aortic wall, a double contour of the aortic wall, or an “ultrasound signal” between the aortic wall and visceral pleura. LeBret et al. found that a distance of more than 3 mm between the probe and the aortic wall was the most accurate of these ultrasonographic signs.¹⁹

There have been several studies specifically evaluating the accuracy of TEE with respect to traumatic aortic injury.^{12,25,26} The largest involved 69 patients (nine true positive) and showed 100% accuracy.¹² More recently, sensitivity and specificity for detecting mediastinal hematoma via TEE of 100% and 75%, respectively, with no false-negative results, were reported.¹⁹ It is unclear, however, how many of these patients would have required operative intervention.

Most awake patients who undergo TEE require sedation to tolerate the examination.¹² Sedation may be problematic, because many multiple trauma patients are prone to hemodynamic instability and may have an increased risk of aspiration without airway protection. In addition, some intubated patients need to have the endotracheal tube cuff deflated so the echocardiography probe may pass; this again increases the risk of aspiration. In centers where TEE is available, its best application may be for patients in whom there is concern for great vessel injury, who are unstable, and who require immediate operative intervention for other life-threatening injuries (e.g., hemoperitoneum). In a situation like this, TEE can be performed intraoperatively to provide a rapid evaluation of the aorta.

Aortography

Irrespective of these other emerging diagnostic modalities, aortography remains the gold standard for depicting the extent of blunt or penetrating thoracic vascular injury.^{8,11,19} With a complication rate of less than 1% in transfemoral examination, aortography has been consistently shown in the literature to have a sensitivity approaching 100% and a specificity of nearly 98%. This is largely because it is the only imaging modality that allows complete evaluation of the thoracic aorta from the aortic root to the diaphragmatic hiatus and the brachiocephalic arteries and their branches.¹⁹ This need to accurately visualize the thoracic vasculature is critically important, because multiple disruptions occur in 18% to 20% of cases.⁷

Classically, findings of aortic intimal injury consist of an intimal irregularity, a linear defect, or a filling defect caused by an intimal flap. False-positive interpretations of atypical or equivocal aortographic findings for acute traumatic aortic injury have been attributed to congenital abnormalities such as a ductus diverticulum, anatomic variants, atheromatous plaques, syphilitic aortic aneurysms, or motion artifact.^{19,23,27} There have been reports of CT and TEE demonstrating small aortic intimal tears

not seen on angiography, but the need for surgical intervention for these tears is controversial.

Major trauma centers may perform several negative investigations to diagnose all aortic disruptions. Most strategies would use chest radiography and dynamic chest CT scanning as initial screening examinations, followed by aortography or TEE as definitive studies. In transmediastinal penetrating injuries, esophagography should be performed in stable patients prior to aortography because of the greater likelihood of esophageal injury in this setting. ⁸

EMERGENCY DEPARTMENT MANAGEMENT

The role of the emergency department thoracotomy (EDT) has been questioned in recent years, in terms of both its overall efficacy and its potential risk of exposing hospital personnel to blood-borne pathogens. In a recent retrospective study involving 950 patients and spanning 23 years at a level I trauma center, a 2.5% neurologically intact survival rate was reported for blunt traumatic arrest when vital signs were present in the field. ⁴ Conversely, the literature is replete with data showing that patients who have sustained a blunt mechanism of injury, are without vital signs in the field, and demonstrate asystole on arrival should not receive an EDT. ⁴ Thus, blunt trauma should not be considered an absolute contraindication to the performance of EDT if the patient had vital signs at the time of initial paramedic contact.

In the setting of penetrating trauma, the EDT may be warranted for those patients who had vital signs in the field (regardless of cardiac rhythm on emergency department presentation) with a total prehospital time of 30 minutes or less. ^{4,16} Indeed, Branney and coworkers ⁴ reported a 16.4% survival rate for penetrating trauma victims with field vital signs. Most interestingly, they also reported a 3.6% survival rate for patients without field vital signs who accounted for 26.5% of the neurologically intact survivors. Four of these patients presented in asystole and went on to have functional survival. They attributed this remarkable statistic to relatively short transport times and on-scene times. Drawing from these data, it would be reasonable to terminate resuscitative efforts in those patients who present in asystole unless there is clinical evidence of penetrating thoracic trauma.

In the presence of a penetrating supraclavicular wound, balloon tamponade using one or two Foley catheters may be effective in controlling the bleeding until surgical control is achieved in the operating room. By inserting the catheter as far as it can go and then inflating the balloon, the physician may be able to compress the subclavian vessels against the clavicle and the first rib, helping to achieve hemostasis. For persistent bleeding, a second catheter may be inserted and the balloon inflated inside the wound tract superficial to the first balloon. ⁸

The role for medical management of great vessel injury in the emergency department setting is rather limited, but in the recent literature this possibility, coupled with delayed surgical repair, has been raised. The use of beta-blocking and antihypertensive agents is integral to this management option and is frequently used in the subset of patients in whom there exists severe comorbid disease or other significant traumatic injuries. The decision to embark on nonoperative management should be made in consultation with the trauma or vascular surgeon. The use of magnetic resonance imaging is an emerging modality and may have an ideal role in monitoring these patients prior to surgical repair. ¹⁹

As systemic hypertension may increase stress on any pseudoaneurysm that may be present and promote rupture, blood pressure and wall tension must be carefully controlled. This may best be done by initial use of a beta blocker such as propranolol, which reduces stress forces to the aortic wall. ^{18,30} Nitroprusside or other pure vasodilators may then be used to reduce the blood pressure appropriately. Hypotension usually indicates hemorrhage and should be managed with volume replacement and rapid transport to the operating room for definitive repair. ¹⁴

DISPOSITION

Traumatic circumferential disruption of the great vessels is a surgical emergency; as soon as the diagnosis is suspected, a surgeon competent in vascular repair should be consulted while definitive investigations are being obtained. If appropriate personnel or technology, either to confirm the diagnosis or to definitively manage the injury, are unavailable, preparations for transfer must be made immediately. ²⁹

Methods of repair and operative intervention are beyond the scope of this text, but even in the best of circumstances, significant morbidity (including chronic thoracic aneurysm, renal failure, and paraplegia) and mortality (15% to 33%) are reported at major trauma centers. ^{7,15,29} The in-hospital surgical mortality rate is largely contingent on the degree of hemodynamic instability, the severity of associated injuries, and the magnitude of the aortic laceration.

COMMON PITFALLS

- Failing to pursue the diagnosis in a patient with a major mechanism of injury and a normal chest radiograph
- Delaying aggressive radiologic confirmation of the diagnosis
- Allowing more obvious injuries to delay pursuit of or obscure the diagnosis
- Failing to transfer the patient promptly to an appropriate trauma center if facilities and personnel necessary to diagnose or treat the patient are unavailable at the initial facility.

ACKNOWLEDGMENT

The authors gratefully acknowledge the contribution of Jedd Roe, MD, who wrote the previous version of this chapter.

DIAPHRAGM

Traumatic injury of the diaphragm may result from either penetrating or blunt trauma to the chest or abdomen. The absence of distinct symptoms, combined with the high incidence of serious and more obvious associated injuries, may lead the physician to overlook these injuries. However, missed diaphragmatic injuries may lead to devastating sequelae acutely or years later.^{4,19,20}

Traumatic diaphragmatic injuries were first described by Sennertus in 1541, when he reported a delayed visceral herniation through a ruptured diaphragm. In 1853, Bowditch published the first antemortem diagnosis of a diaphragmatic hernia. The first surgical repair was in 1886 by Riolfi.^{11,14}

There are no reliable data to suggest the true incidence of this entity, because many cases go undiagnosed. However, it is estimated that diaphragmatic injuries are present in 3.0% to 5.8% of patients who undergo emergency surgery for thoracoabdominal trauma. The relative frequency of blunt versus penetrating injuries varies greatly with published reports.

Stab and gunshot wounds may affect any portion of the diaphragm, but there is a higher incidence of stab wounds to the left hemidiaphragm, theoretically because of the greater number of right-handed assailants. Blunt trauma also has a predilection for the left hemidiaphragm, because the right hemidiaphragm is partially protected by the liver,^{11,16,21} and because the posterolateral portion of the left leaflet is structurally the weakest portion of the diaphragm. [Figure 105.1](#) shows the relative position of the diaphragm with inspiration and expiration.

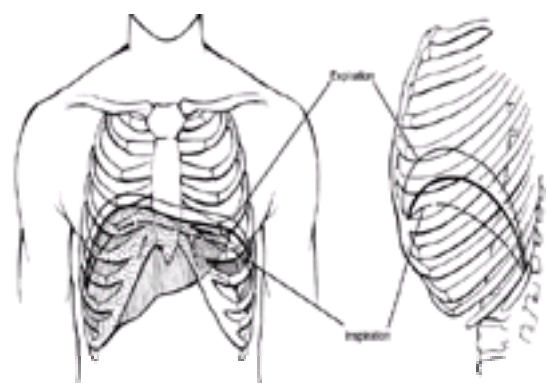

Figure 105.1. Location of the diaphragm with inspiration and expiration.

Blunt trauma typically produces defects greater than 10 cm on the average, and penetrating trauma an average of less than 2 cm. Blunt injuries have a higher mortality rate, directly related to the higher incidence of serious associated injuries.

Ruptures of the diaphragm, regardless of size, are unlikely to heal spontaneously because of the pleuroperitoneal pressure gradient. During quiet respirations, this is normally 7 to 20 cm H₂O, but it may increase to more than 100 cm H₂O during labored respirations. These pressure differentials inhibit or prevent the normal healing process.¹³ In addition, this negative pressure causes herniation of intraabdominal contents into the thoracic cavity and may result in subsequent strangulation of the abdominal viscera as well as respiratory embarrassment. The stomach is the abdominal structure that herniates most often, followed by the spleen, colon, small bowel, and omentum in variable order.^{14,16}

CLINICAL PRESENTATION

Diaphragmatic injuries should be suspected with any penetrating wound between the lower chest and upper abdomen. Significant blunt trauma to the lower chest and upper abdomen is associated with diaphragmatic rupture, usually on the left side.

The signs and symptoms are highly variable, depending on the size of the defect, the mechanism, the viscus that is herniated, and the degree of cardiopulmonary compromise. Common symptoms include cough, dyspnea, nonspecific chest or abdominal pain radiating to the shoulder, and the perception of peristalsis in the chest. Signs include an immobile left hemithorax, decreased breath sounds, and tympany or borborygmi in the left chest. However, in the absence of herniation, a diaphragmatic tear may be completely asymptomatic and without overt signs.

Abdominal viscera may herniate into the thoracic cavity and dilate rapidly, resulting in severe respiratory distress. This condition may be difficult to distinguish from a tension pneumothorax. Therefore, great care should be taken when performing a thoracostomy, always verifying a free pleural space before inserting the chest tube. Intrapericardial rupture of the diaphragm (a rare entity) with herniation may result in a tamponade from compression by the herniating viscus.¹¹

Delayed herniation has been reported in the immediate posttraumatic phase or as long as 40 years after the initial diaphragmatic injury. Delayed presentation is associated with a mortality as high as 20% after visceral incarceration, increasing to 80% after strangulation occurs. This occurs most commonly following unrecognized stab wounds to the diaphragm.

EMERGENCY DEPARTMENT EVALUATION

Serial examinations looking for signs of obstruction, strangulation, or cardiopulmonary compromise are performed. The chest radiograph is the single most important diagnostic tool. Although it is frequently nonspecific, the chest radiograph often arouses the initial suspicion of diaphragmatic disruption. Significant findings include lower rib fractures, pleural effusion, and a unilaterally elevated hemidiaphragm or difficulty in visualizing the hemidiaphragm. If herniation has occurred, one may see an intrathoracic abdominal viscus, a shift of the mediastinum away from the affected side, atelectasis at the base of the lungs, or the nasogastric tube positioned above the diaphragm.⁸

In stable patients, contrast studies are useful if there is herniation of hollow viscera. The position of the stomach, small bowel, and colon can be demonstrated using upper and lower gastrointestinal contrast studies. Findings may include contrast-filled viscera above the diaphragm, obstruction at the level of the diaphragm, and delayed gastric emptying. The entire gastrointestinal tract must be visualized before the study can be interpreted as normal. ⁸

Diagnostic peritoneal lavage has a 25% false-negative rate in the detection of isolated diaphragmatic injury using the criteria of 100,000 red blood cells (RBCs)/ μ L. ^{2,5,8} Some authors advocate lowering the RBC count considered positive to 5000 RBCs/ μ L when evaluating injuries at high risk for diaphragmatic injury (i.e., lower chest or upper abdominal penetrating wounds). ^{1,6,13} Computed tomography (CT) scanning has a low sensitivity because the imaging plane is parallel to the dome of the diaphragm, and the dome is not well visualized. Radionuclide liver or spleen imaging can be of value in the presence of solid viscera herniation. ¹² Laparoscopy and thoracoscopy have been utilized with mixed results. ^{15,17} Ultrasonography may be helpful in some patients. ⁹

Magnetic resonance imaging (MRI) has shown promising results in isolated cases. Boulanger and associates ² used MRI scanning to diagnose diaphragmatic rupture definitively in two patients and to rule it out in three other patients who had equivocal chest radiographs. However, further studies are needed to determine its utility and value in the diagnosis of diaphragmatic injury.

PREHOSPITAL AND EMERGENCY DEPARTMENT MANAGEMENT

In the prehospital setting, basic management consists of volume administration; high-flow oxygen; monitoring; active airway management, if there are signs of compromise; and rapid transport. In the emergency department, basic trauma management should proceed as usual, with early surgical consultation. If the diagnosis of herniation is suspected, a nasogastric tube should be placed for decompression as well as to aid in the diagnosis. The dilated intrathoracic abdominal viscus may masquerade as an atypical pneumothorax, so a chest tube is placed only after careful digital verification of the free pleural space.

Any patient suspected of having a diaphragmatic rupture should be hospitalized. Surgical treatment is mandatory once the diagnosis is established.

BONY THORAX

RIB FRACTURES

Rib fractures account for more than 50% of nonpenetrating chest trauma. Fractures typically occur at the site of impact or the posterior angle, where the rib is structurally the weakest. Fractures are more common in adults because of the relative inelasticity of the mature thorax. Although the fourth through ninth ribs are the most commonly involved, fractures of ribs 9 through 11 deserve special concern, as there is an increased incidence of associated abdominal injuries due to their location. Multiple rib fractures or the presence of a flail chest segment is often associated with intrathoracic injury, usually a pulmonary contusion.

Clinical findings typically include tachypnea, splinting, and point tenderness intensified by deep breathing or coughing, ecchymoses, crepitus, and muscle spasm. Compression over the rib anteriorly or posteriorly produces referred pain to the fracture site. The diagnosis of rib fractures should be made on clinical grounds, because 50% of these injuries are missed on the initial chest radiograph; 10% do not visualize radiographically for 7 to 14 days after the injury, regardless of the views taken. A chest radiograph is valuable, however, when looking for complications of rib fractures, such as hemothorax, pneumothorax, pulmonary contusion, telectasis, and pneumonia. Oxygen saturation should also be measured.

The principal goals in the treatment of simple rib fractures are pain control and maintenance of adequate pulmonary function. The patient should be encouraged to breathe deeply. Binders are not recommended, as they decrease ventilation and promote atelectasis. Mild-to-moderate pain relief may be achieved with oral pain medications, such as nonsteroidal or opioid analgesics. The most effective, but often temporary, relief for moderate-to-severe pain is a long-acting anesthetic such as bupivacaine (Marcaine) in an intercostal block. Hospitalization may be indicated for elderly patients and for those with preexisting pulmonary disease to ensure adequate pulmonary toilet while controlling pain.

Although delayed hemothorax or pneumothorax may develop 6 to 24 hours after the injury, most rib fractures heal uneventfully within 3 to 6 weeks. ¹⁸ Patients should be discouraged from engaging in vigorous contact sports during that time. Rarely, the long-term course is complicated by posttraumatic neuroma.

Costochondral separation presents with signs and symptoms similar to those of rib fractures. The chest radiograph is normal. Healing is delayed due to the poor vascularity of the cartilage, and pain may persist for months. Often there is a snapping sensation with deep breathing. An anterior flail chest may occur from massive costochondral separation, but this is uncommon. ¹⁷

STERNAL FRACTURES

Sternal fractures usually result from high-energy direct trauma to the anterior chest wall, most commonly in motor vehicle accidents, in which the chest strikes the steering wheel, dashboard, or shoulder belt at high velocity. A tremendous amount of force is necessary to fracture the sternum; consequently, these injuries should be viewed as harbingers of severe thoracic trauma. There is a 25% to 45% mortality rate associated with sternal fractures, which is directly proportional to the high incidence of myocardial injury, cardiac tamponade, aortic trauma, pulmonary contusion, and other serious intrathoracic injuries.

The diagnosis is suspected in the patient with a compatible history who complains of point tenderness over the sternum that is intensified with respirations. External signs of trauma, such as crepitus, ecchymoses, swelling, or abrasions, are not always present. The lateral radiograph of the chest is the most useful diagnostic test. ¹⁹ Care should be taken not to misdiagnose as a fracture the nonossified intrasternal cartilage of young patients.

In the field and in the emergency department, these patients should have intravenous access, oxygen, and cardiac monitoring. Isolated sternal fracture is not an indication for active airway management, but this should be undertaken if there are signs of respiratory compromise from associated injuries. ⁷ A widened mediastinum should alert the physician to an associated aortic injury. Mechanical ventilation using positive end-expiratory pressure has been used as internal fixation for grossly unstable fractures. Operative fixation is often unsatisfactory. Occasionally, painful pseudarthroses and overlap deformities develop and require later reconstruction.

Admission should be seriously considered for serial electrocardiograms and cardiac monitoring for myocardial contusions. If transfer is necessary, advanced cardiac life-support personnel should accompany the patient, with continued oxygen, cardiac monitoring, and intravenous access. Particular attention should be paid to the possibility of dysrhythmias, pneumothorax, and pulmonary compromise. These are painful injuries that often require opioid analgesics.

FLAIL CHEST

A flail chest is a free-floating section of chest wall resulting from two or more adjacent ribs fractured in two or more places, or rib fractures in combination with either sternal fractures or costochondral separations. This is a serious injury that carries an 8% to 35% mortality rate, directly related to associated injuries (of which pulmonary contusions are the most common). ¹⁰

These patients often present with pain, crepitus, and ecchymoses over the chest wall. The classically described paradoxical movement of the flail segment refers to its unexpected movement inward during inspiration and outward during expiration, in response to the intrathoracic pressure changes during the respiratory cycle. The paradox may not be seen initially because of muscle splinting, only to become dramatically apparent hours later as the underlying contused lung decreases in compliance and the patient tires. Muscle splinting with subsequent hypoventilation may result in focal atelectasis, decreased tidal volume and vital capacity, pulmonary arteriovenous shunting, hypoxemia, and decreased cardiac output.

The diagnosis is made clinically. The thorax is inspected and palpated in search of areas of tenderness and crepitus. Serial examinations using tangential lighting looking for paradoxical movement may be necessary. In the field, the flail chest may be stabilized by positioning the patient with the injured side down.

In the emergency department, a careful search for other injuries is made, and baseline arterial blood gas measurements, oxygen saturation, and chest radiographs

are obtained. Continuous oxygen saturation monitoring is done. Tube thoracostomy is indicated if intrapleural air or blood is present, or prophylactically if the patient is mechanically ventilated, as such patients are at high risk for developing a tension pneumothorax.

The mere presence of a flail chest is not an indication for endotracheal intubation. There is debate regarding which patients benefit from mechanical ventilation. The following guidelines should be used in conjunction with the patient's overall status. Intubation should be considered if one or more of the following are present: shock, three or more associated injuries, previous pulmonary disease, fracture of eight or more ribs, age above 65 years, or Pa O₂ less than 60 mm Hg (or decreasing O₂ saturation readings) on a nonbreather bag reservoir mask at sea level.

All patients with a flail chest should be admitted to an intensive care unit for aggressive pulmonary toilet, pain control, observation, and monitoring.

COMMON PITFALLS

- All patients with penetrating trauma below the tips of the scapula posteriorly or nipple level anteriorly should be considered at high risk for diaphragmatic perforation.
- Beware of the diaphragmatic hernia masquerading as a "high-riding" or "paralyzed" diaphragm on a chest radiograph.
- Never place a chest tube without first digitally verifying the free pleural space.
- Consider delayed diaphragmatic herniation when there is any history of previous thoracoabdominal trauma, acute signs and symptoms of intestinal obstruction, pulmonary complaints, or radiographic abnormalities.
- Consider the possibility of spleen or liver injury with fractures of ribs 9 through 12.

[Common Pitfalls](#)
[Chapter References](#)

Injuries to the esophagus are a major diagnostic challenge for the emergency physician. With the deep and well-protected location of the esophagus, signs of perforation or other serious esophageal injury are often subtle and frequently masked by injuries to adjacent structures. Because recognition is often delayed, a perforation occurring in the esophagus is more treacherous than in any other part of the gastrointestinal tract. Perforation can produce severe mediastinal and pleural infections due to contamination with bacterial-laden saliva and, occasionally, gastric contents. Left untreated, perforation nearly always results in mortality unless it is very small. There are five basic mechanisms of esophageal injury: penetrating trauma, blunt trauma, barotrauma, ingestions, and iatrogenic injury.

PENETRATING TRAUMA

Penetrating esophageal trauma can be caused by either an impaling or a projectile weapon. Both are generally the result of interpersonal violence, with impalements most frequently the result of domestic violence.⁵ Reported series show a preponderance of cervical esophageal injuries, probably because penetrating trauma to the thoracic esophagus is associated with nonsurvivable injuries to the great vessels or heart. The peritoneal esophagus is relatively short and mobile, and thus is less likely to be injured. In all cases of penetrating esophageal injury, a careful evaluation to delineate the inevitable injuries to adjacent structures is mandatory. Gunshot wounds in particular can be quite complex. A round from a high-velocity military weapon can exert a blast effect well outside the direct path of the bullet, with delayed perforation from the devascularized and mural necrosis.¹⁷

BLUNT TRAUMA

Blunt injuries can occur from several mechanisms. A sharp blow to the upper abdomen can force air and gastric contents into the esophagus. If the proximal esophageal sphincter is closed when this occurs, a rise in esophageal pressure sufficient to cause perforation can result. The usual site of perforation is identical to that seen with a spontaneous rupture associated with vomiting (Boerhaave syndrome). It typically occurs in the left side of the distal esophagus, a physiologically weakened area due to the paucity of circular muscle fibers. Although falls and motor vehicle accidents account for most injuries by this mechanism, there have been several reported cases of perforation caused by the Heimlich maneuver.¹⁴ Finally, cardiopulmonary resuscitation may be associated with a significant rate of esophageal injury.¹³ In one autopsy series, 12% of patients who had undergone cardiopulmonary resuscitation (CPR) had a gastroesophageal perforation.³ This potential complication should be considered in successfully resuscitated patients, particularly those with extended periods of CPR or those who were subjected to abdominal counterpulsation CPR techniques. Compression of the esophagus against the spine can produce longitudinal tears in the upper thoracic esophagus. These lesions are frequently accompanied by a laceration in the membranous (posterior) portion of the trachea, resulting in a traumatic tracheoesophageal fistula. These injuries can go undetected for days in critically injured patients who are intubated if the inflated endotracheal tube cuff seals off the trachea below the level of perforation. Finally, rapid deceleration can produce a traction injury, resulting in a segmental devascularization of the esophagus with delayed perforation.⁶

BAROTRAUMA

As a hollow, potentially air-containing organ, the esophagus is susceptible to barotrauma. While perforation via this mechanism can occur anywhere in the esophagus, the left lateral wall of the distal esophagus is the weakest area and by far the most common site of perforation by this mechanism.

The most well known barotrauma injury is Boerhaave syndrome, or postemetic esophageal rupture, in which a rapid rise in intraluminal pressure due to a forceful vomiting is the culprit. The classically described presentation of chest pain, respiratory difficulty, and subcutaneous emphysema may not be evident, and the diagnosis is often delayed or mistaken for perforated viscus myocardial infarction.⁷

An unusual mechanism for esophageal barotrauma is accidental insufflation of compressed air into the mouth. Air under pressure enters the mouth, overcoming the upper esophageal sphincter and entering the esophagus.¹¹ The cardiac sphincter does not open rapidly enough to dissipate the intraluminal pressure; the result is esophageal perforation. Experimental studies have shown that rupture occurs at 5 pounds per square inch of pressure,¹² a pressure easily achieved by common household items such as aerosol cans, air compressors, inflation devices, and vacuum cleaner exhausts. A remarkable variety of injuries due to this mechanism, including children biting tire inner tubes, eruption of bottled carbonated beverages, discharge of fire extinguishers, and mishaps with compressed air lines, have been reported.^{8,9,15,20}

INGESTION-INDUCED INJURIES

Accidental or intentional ingestion of acids rarely produces significant esophageal injury,¹⁹ while strong alkali (pH greater than 12) ingestions can produce devastating injury to the entire esophagus. The “sticky” nature of bases and the coagulative necrosis they produce allow very prolonged contact times and ongoing injury, while acids have short contact times in the esophagus and tend to produce their most significant injuries in the stomach and duodenum.⁷ Impaction of food or medications can cause injuries ranging from mucosal irritation to frank perforation. Injury occurs as a result of direct chemical effects on the mucosa, pressure-induced necrosis, or both, depending on the composition of the impaction. Patients with strictures or esophageal motility disorders are particularly susceptible to impactions. Finally, any of a vast array of ingested foreign bodies can cause injury, whether from sharp points and edges or pressure-induced necrosis of the esophageal lining from an impacted object.

IATROGENIC INJURIES

The most common cause of esophageal perforation is iatrogenic, with most of these occurring in the thoracic esophagus.¹⁶ The esophagus can be injured during nasogastric¹ or tracheal intubation, esophagoscopy, dilation of strictures, and sclerotherapy for the management of esophageal varices. Injuries due to CPR were discussed earlier in this chapter. Diagnosis of iatrogenic esophageal injuries is frequently delayed, and a high index of suspicion should be maintained in these patients.

CLINICAL PRESENTATION

Pain is the dominant symptom and is present in nearly all cases of thoracic esophageal rupture. Other common signs and symptoms are subcutaneous emphysema (especially in the neck or supraclavicular fossa), unexplained tachycardia, dyspnea, dysphagia, odynophagia, cyanosis, pneumomediastinum, pneumothorax, pleural effusion, and hematemesis.

Because of the nonspecific nature of these findings, it is easy to overlook esophageal perforation. The rarity of the injury, particularly from a blunt mechanism, also contributes to missed and delayed diagnosis. One must, therefore, consider the diagnosis whenever the trajectory of a wounding implement is proximate to the

esophagus. In addition, whenever injury to an adjacent organ is apparent, esophageal injury should be presumed and investigated.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for esophageal injury is limited to trauma to the surrounding structures. Subcutaneous emphysema or pneumomediastinum can be a result of a respiratory tract injury.

Hematemesis or bloody regurgitation implicates gastric or pharyngeal injury. The other signs and symptoms of esophageal injury are so nonspecific that the differential includes all organ systems located in the chest.

EMERGENCY DEPARTMENT EVALUATION

Thoracic esophageal injury can be suspected but not diagnosed on clinical grounds alone. Once the suspicion is entertained, the diagnosis can be confirmed by several means, including esophagography, esophagoscopy, and exploration in the operating room. As a preliminary study, a plain chest film should be performed on all victims of suspected esophageal trauma, looking for subcutaneous and mediastinal air and concomitant chest wall and respiratory tract injuries. Furthermore, in gunshot victims, plain radiographs can be helpful in determining the risk of esophageal trauma. The diagnosis should be suspected and pursued whenever a transmediastinal trajectory is identified.

The choice of initial diagnostic procedure is somewhat controversial, with some authors advocating esophagography¹ and others esophagoscopy.¹⁸ Contrast esophagography has the disadvantage of potentially introducing contrast material into the mediastinum or the tracheobronchial tree. For this reason, the study should first be performed with a water-soluble contrast material that has a much lower risk of mediastinitis or pneumonitis than does barium. If the water-soluble contrast study is negative, the study should be repeated using barium, which provides better detection of small perforations.¹⁵ Both flexible and rigid esophagoscopy have been used in evaluating esophageal injuries, with sensitivities of 90% to 100%^{4,10} and reported instances of esophagoscopy detection of perforations missed by contrast studies. Whatever initial diagnostic procedure selected, it seems prudent in the high-risk patient to use both modalities before declaring the patient free of esophageal injury.

Computed tomography (CT) scanning is not a primary diagnostic study for thoracic esophageal perforation, but it can reveal nonspecific findings suggestive of perforation, such as air in soft tissues or abscess cavities. CT scanning can also be helpful in detecting postoperative leaks and abscess formation.¹¹

EMERGENCY DEPARTMENT MANAGEMENT

Management in the emergency department consists primarily of providing supportive care. Cardiorespiratory instability may result from the associated injuries that are invariably present, and should be addressed by appropriate stabilizing measures, such as airway management, volume replacement, and tube thoracostomy. Nasogastric intubation should also be performed to empty the stomach and lower the risk of gastric contents further contaminating the mediastinum. It may also be of diagnostic help if blood is recovered on aspiration.

Besides providing supportive care and pursuing diagnostic studies, initiation of antibiotic therapy is the only specific management required in the emergency department. Antibiotic coverage should be chosen in conjunction with the consulting surgeon. Infections that arise from esophageal perforations are normally polymicrobial, with gram-negative rods, *Streptococcus*, *Staphylococcus*, and oral flora as the dominant organisms. The antibiotic regimen chosen should be broad in spectrum and should include anaerobic coverage.

DISPOSITION

All patients with confirmed esophageal perforation require admission. Surgical consultation is obtained as soon as possible to coordinate the evaluation and final disposition. Nearly all patients with thoracic esophageal perforation require surgical intervention. Rarely, a patient with a small lesion and a localized infection may be successfully managed with antibiotics alone.² Most, however, require mediastinal drainage with esophageal repair and temporary esophageal exclusion (creation of a cervical esophagostomy and distal esophageal ligature). A few patients require esophagectomy with subsequent reconstruction using the stomach or colon. Surgical management is supplemented by hyperalimentation or tube feedings by way of an operatively placed jejunostomy tube and continuation of antibiotic therapy.

Patients should be transferred to an appropriate facility if resources for care are unavailable locally. Transfer should be effected as promptly as possible.

COMMON PITFALLS

- By far, the most common pitfall is failure to make the diagnosis. If the patient is severely injured, with other indications for surgery, the diagnosis is frequently made when operating. Patients who are managed nonoperatively and/or have isolated esophageal injuries are most likely to be missed, with worsening morbidity and mortality with the delay in the diagnosis. In fact, many authorities quote a twofold increase in mortality when the diagnosis is delayed beyond 24 hours.
- Always consider esophageal injury in patients with pneumomediastinum after blunt trauma. This finding should mandate further evaluation.
- Be sure to follow a negative water-soluble contrast study, with one performed with the more sensitive barium swallow.
- If the index of suspicion is high, consider esophagoscopy if contrast studies are negative.

Blunt abdominal trauma remains an important source of morbidity and mortality, accounting for 10% of all deaths from trauma. It is seen most commonly in the context of motor vehicle crashes. A significant minority of injuries result from sports, assaults, falls, bicycle accidents, and injuries to pedestrians.¹⁴

In the face of frequent concomitant multisystem trauma, the early detection of intraabdominal injury is a challenge to the emergency physician. Unlike other more obvious causes of blood loss, such as hemothorax, external hemorrhage, and pelvic or femur fractures, intraabdominal bleeding may easily go unrecognized. Although injuries to the solid organs are most frequently involved after blunt abdominal trauma, a high clinical suspicion must be maintained for the more subtle injuries to the bowel, mesentery, and pancreas, such as in the “lapbelt syndrome” or from bicycle handlebars.

Many traumatic deaths, such as diffuse axonal injury, transection of the aorta, and cardiac rupture, are inevitable; but death due to abdominal injury may be prevented by early recognition. Therefore, after initial resuscitation, one of the primary objectives of the emergency physician is to decide which patients require early surgical consultation. Although the history and physical examination continue to be essential components of the assessment, the addition of the focused abdominal sonography for trauma (FAST) and helical computed tomography (CT) scanning to the previous armamentarium has significantly enhanced our diagnostic ability and therapeutic approach.

CLINICAL PRESENTATION

It is well recognized that abdominal injuries from blunt trauma can be difficult to diagnose by history and physical alone.¹¹ The presence of an altered sensorium from head injury or substance abuse, distracting injuries, spinal cord injuries, or shock can render the initial assessment unreliable. In addition, because patients with abdominal injuries are often victims of multisystem trauma, dramatic head, chest, and orthopedic injuries may distract the physician's attention.

Although initial vital signs may be helpful in patients with brisk internal bleeding secondary to disruption of the liver or spleen, in those with less profound injury, vital signs may be normal. Injuries that produce minimal bleeding, such as perforation of the bowel or diaphragm, and those that are isolated to the retroperitoneum typically result in a paucity of physical findings. In an effort to identify patients with significant abdominal injuries, one study of 16,000 blunt trauma victims identified seven factors associated with an increased risk of abdominal injuries: (1) gross hematuria, (2) admission hypotension, (3) lower rib fractures, (4) hemothorax or pneumothorax, (5) abdominal wall hematoma or abrasion, (6) HCO₃⁻ less than 21, and (7) pelvic fracture.¹¹

DIFFERENTIAL DIAGNOSIS

Injury to the abdominal musculature may be confused with an intraperitoneal lesion. Contusions of the rectus muscle often produce greater pain when the abdomen is palpated during muscle contraction. To elicit this finding, ask the patient to lift the head or leg off the stretcher during the abdominal examination. Patients with intraperitoneal injury usually have less pain during this maneuver and greater pain on palpation of the relaxed abdomen, as the contracted muscles shield the intraabdominal organs. However, this finding is not absolute, and significant tenderness should always prompt further objective workup. Nausea and vomiting may occur after an injury and may be ascribed to head trauma or stress reaction; however, repeated emesis following abdominal trauma should prompt consideration of a duodenal hematoma, particularly in children.

EMERGENCY DEPARTMENT EVALUATION

As is true of any trauma patient, the assessment of the patient with abdominal trauma must be performed in light of the patient's overall status. Initial attention is directed toward the airway with cervical spine control, breathing, and circulation, with the rapid administration of 2 L of crystalloid to the hypotensive patient. The abdomen is fully examined during the secondary, not the primary, survey. Early categorization of the patient as stable or unstable should be made, and prioritization of resuscitation, evaluation, and diagnosis occurs accordingly. Among victims of motor vehicle crashes arriving in the emergency department without significant external bleeding, abdominal injuries are the most likely cause of hypotension.¹⁴ Therefore, the diagnosis of intraabdominal hemorrhage should be considered in all cases of shock. Although T6 or higher paraplegia may produce neurogenic shock, hypotension in this setting should also be presumed to be secondary to intraabdominal injury until proven otherwise. In general, the more critically injured the patient, the more quickly the emergency physician must determine the need for laparotomy and obtain early surgical consultation.

History

A brief initial history is obtained using the AMPLE format (allergies, medications, past medical history, last meal, and events surrounding the injury). Potential sources of information include the patient, prehospital care providers, and witnesses. The paramedic report should include a description of the mechanism of injury, and, in the case of a vehicular accident, damage to the vehicle, use of seatbelts, air bag deployment, and deformity of the steering column. The paramedic report also must indicate loss of consciousness, initial mental status, vital signs, evaluation of the ABCs, interventions, and significant complaints. Of particular importance is a history of prehospital hypotension.

Physical Examination

The patient is completely undressed, and life threats are addressed before examining the abdomen. Evaluation of the abdomen should begin with inspection for abrasions or ecchymosis. Evidence of ecchymosis over the lower abdomen in a lapbelt distribution is suspicious for hollow viscus injury and warrants consideration for further evaluation, even in the absence of abdominal tenderness. Although Cullen's sign (ecchymosis around the umbilicus) and Turner's sign (ecchymosis of the flanks) are associated with retroperitoneal bleeding and often sought on examination, they are insensitive, often taking hours to manifest. Auscultation for bowel sounds adds little to the assessment, as patients often have multiple reasons for an ileus, as well as the possibility of normal bowel sounds despite significant hemoperitoneum.

Palpation of the abdomen begins with examination of the lower chest. Care should be taken to detect lower rib fractures, because up to 20% of patients with left lower rib fractures have associated splenic injury, and 10% of patients with right-sided injury have hepatic trauma.⁹ The abdomen is carefully palpated, paying particular

attention to the right and left upper quadrants. The finding of Kehr's sign (pain in either shoulder unrelated to shoulder tenderness or range of motion) indicates the presence of blood irritating the diaphragm and is often secondary to splenic or liver injury. Pelvic stability is assessed by applying distraction and compression forces over the iliac crest and over the symphysis pubis. Of patients found to have a major pelvic fracture, up to 50% of patients have an intraabdominal injury.⁹

Rectal examination may demonstrate a high-riding or boggy prostate in patients with urethral disruption. Blood on rectal examination may indicate gastrointestinal disruption and mandates surgical consultation. The patient should be log-rolled with palpation of the lumbar and thoracic area. Lumbar fractures, particularly those in conjunction with the seatbelt sign, are markers of hollow viscus injury.

Despite the necessity of a well-directed physical examination, the emergency physician must be aware of its limitations. One study found physical examination to be 65% accurate in the setting of blunt abdominal trauma,²⁹ and another trauma center reported abdominal examination alone as adequate in only 35% of patients.⁴ The true value of the initial examination is to stratify patients into categories of those who need (1) immediate laparotomy, (2) additional diagnostic adjuncts, or (3) serial clinical examinations.

Plain Radiographic Evaluation

The plain film has limited utility in the evaluation of blunt abdominal trauma and contributes to operative decision making in less than 4% of patients.⁹ Indirect evidence of abdominal injury includes the flank stripe and dog-ear signs secondary to intraabdominal blood. A splenic hematoma may displace the gastric air bubble to the right. However, because these signs are neither reliable nor consistent, and because therapeutic interventions are not made on the basis of the results, routine abdominal films are not warranted. A chest x-ray should be done and rarely may show evidence of free air or a ruptured diaphragm. Pelvic films should be obtained based on the reliability of the examination and on physical findings.

Laboratory Tests

Standard laboratory analysis of the blunt abdominal trauma victim includes a complete blood count, chemistry panel, type and crossmatch, and evaluation of the urine. Additional tests, such as coagulation factors, ethanol level, drug screens, and arterial blood gases (ABGs) should be obtained as appropriate. As is the case for plain films, initial results are often not particularly helpful, and the physician should never rely on a blood test to exclude intraabdominal injury. The most valuable laboratory investigation is a type and crossmatch.

The hematocrit level is influenced by many factors, including the rate of blood loss, dilutional effects of intravenous fluids, fluid shifts from the interstitium to the intravascular space, and preinjury level. Intravenous fluids alone may decrease the hematocrit by up to six points. In light of these confounding variables, most of the utility of hemoglobin and hematocrit levels lies in their use as serial tests over time. However, an initial hemoglobin level less than 8 g/dL in the presence of abdominal injury is a strong indicator of occult hemorrhage.²⁰ The white blood cell (WBC) count is often increased in multiple trauma and lacks diagnostic and prognostic significance. Although a serum amylase level is routinely obtained, several studies have demonstrated that it is neither sensitive nor specific for pancreatic injury.^{8,27} The addition of pancreatic isoenzymes or lipase does not improve the accuracy. Ethanol levels and drug screens may provide additional information about the reliability of the examination.

Coagulation studies are useful in patients on anticoagulants, those with severe liver disease, pregnant patients who may have abruption placentae and possible disseminated intravascular coagulation (DIC), and those receiving massive transfusions. The base deficit provided by ABG analysis accurately measures the severity of shock and the efficacy of fluid resuscitation. Base deficit or serum lactate is a more sensitive indicator of compensated shock than blood pressure or even invasive monitoring. A deficit of -6 or less (i.e., more negative) is a useful indicator of occult hemorrhage and should prompt further evaluation of the abdomen. Serial base deficits or serial lactates indicate trends in patient status.^{12,13}

Diagnostic Peritoneal Lavage

Diagnostic peritoneal lavage (DPL) is an excellent test for determining the presence or absence of intraperitoneal blood, with a sensitivity of 94% to 96%, a specificity of 96% to 99%, a 1.4% false-positive rate, a 1.3% false-negative rate, and a complication rate less than 1%.¹⁵ DPL can be considered in the blunt abdominal trauma patient with (1) an unreliable examination, including those with altered sensorium, spinal cord trauma, or distracting injuries; (2) an abdominal examination suspicious for abdominal injury without frank peritoneal signs; (3) general anesthesia planned in the face of a possible abdominal injury; or (4) as a quick test in the unstable patient with unexplained hypotension. The only absolute contraindication for DPL is the need for emergency laparotomy.

One of the main drawbacks of DPL is its lack of specificity for identifying the underlying intraabdominal injury. DPL was originally popularized prior to the advent of the modern CT and trauma ultrasound, and before the current nonoperative management of many solid-organ injuries. It has been estimated that 30% of patients with a positive DPL have injuries amenable to conservative treatment.³⁴ In addition, although the complication rate is low, it is an invasive procedure that, unless the aspirate is positive, takes a minimum of 10 minutes to complete.¹⁰ As a result, at many centers, CT and ultrasound have replaced DPL in the majority of blunt abdominal trauma victims. Other drawbacks of DPL are its inability to detect retroperitoneal injury and its relatively poor sensitivity for bowel and diaphragmatic injuries.

DPL does still have a significant role in the evaluation of blunt abdominal trauma in many emergency departments, however, particularly in the unstable patient and situations in which CT and ultrasound are unavailable. DPL can be performed open, semi-open, or closed. The closed Seldinger technique is fastest, as well as safe and accurate.^{1,32} In all cases, gastric and bladder decompression must occur first with a nasogastric tube and Foley catheter. Criteria for a positive test after blunt trauma include an initial aspirate of more than 5 mL of blood or greater than 100,000 RBC/ μ L in the lavage fluid. Other lavage criteria based on WBC, amylase, and bile are rarely helpful and should not be relied on.

DPL can be falsely positive in patients with pelvic fractures¹⁸ because of catheter placement through an abdominal wall hematoma or diapedesis of red cells into the peritoneum. In patients with significant pelvic fractures in whom the information from a DPL is needed, the open supraumbilical technique is recommended to decrease the incidence of false-positive results.

Computed Tomography Scanning

CT has become the gold standard for radiographic evaluation of the hemodynamically stable patient with blunt abdominal trauma. Accuracy has been reported as high as 97.6%.²⁷ By its ability to define injuries to the liver, spleen, and kidneys, CT has revolutionized the management of solid-organ injuries.^{24,31} Abdominal CT after blunt trauma is indicated in patients in whom the physical examination has proven unreliable, including those with altered sensorium, spinal cord trauma, or distracting injuries. It is also indicated when an abdominal examination causes the examiner to suspect abdominal injury but there are no frank peritoneal signs, when general anesthesia is planned in the face of a possible abdominal injury, in the case of suspected retroperitoneal injury, or for delineation of a pelvic fracture. In addition, CT may demonstrate an occult pneumo-thorax or hemothorax, injuries to the spine and spinal cord, or vascular injuries. The current use of helical CT has resulted in increased speed, decreased artifact, improved parenchymal and vascular definition, as well as increased sensitivity for diaphragmatic injuries.²⁸

One area of current controversy with respect to the use of CT for abdominal trauma is the need for oral contrast. Three case series suggest that it is unnecessary in this setting.^{7,33,35} However, two of the reports were small, and a prospective study has yet to be performed. When oral contrast is administered, CT should not be subsequently delayed awaiting passage of the contrast material. Although complications of CT can include allergic reactions to the dye and, rarely, aspiration, the most serious potential complications are decompensation in the scanner (hypotension or respiratory arrest) and delay in necessary laparotomy.

Ultrasound

In the United States, which has lagged behind many parts of the world in the use of ultrasound in trauma, the role of ultrasound has increased rapidly over the last decade. The FAST examination is a directed assessment of the abdomen, with the goal of detecting hemoperitoneum. It has become the radiologic screening test of choice in many trauma centers in the United States, and has a sensitivity of 81% to 100% and a specificity of 94% to 98% for identifying intraperitoneal blood.²⁶ Although it has virtually replaced both CT and peritoneal lavage as the primary radiographic tool in at least one hospital,¹⁷ in most centers, its use has been as a substitute for DPL. In this role, ultrasound has several advantages over lavage: It (1) is faster, (2) is noninvasive, (3) can be performed repeatedly, and (4) does not interfere with most other procedures or evaluations. In addition, many of the relative contraindications to DPL do not apply to FAST, such as prior abdominal surgery,

coagulopathy, or pregnancy.

In a prospective study by Healey et al.¹⁷ of patients with blunt abdominal trauma, of a total of 734 negative FAST examinations, only six were found to be false negatives. Of these, one was diagnosed by a repeat ultrasound and required splenorrhaphy; another patient had a positive DPL and an intestinal injury at laparotomy; a third patient had a CT showing omental and ileal injuries requiring surgical repair; three patients required nonoperative management. A study by McKenney et al.²⁵ included patients with suspected blunt abdominal trauma and initial hypotension. Initial FAST examination was normal in 856 patients. Within this group, 15 had a positive CT, but only one required a laparotomy for a colon injury. Ten patients with a negative ultrasound had a subsequent DPL, and, in all cases, the lavage was also normal.

The main advantages of FAST over CT scan are its speed and its location in the resuscitation suite, making it the test of choice in the hemodynamically unstable victim of blunt abdominal trauma. Ultrasound is clearly inferior to CT for identifying specific solid-organ injuries, for evaluating the retroperitoneum, and for identifying small amounts of blood. Therefore, in the stable patient who requires a radiologic evaluation of the abdomen, a CT scan is often performed regardless of the FAST results. FAST also shares some of the inadequacies of CT in that it lacks sensitivity for hollow viscus injuries, and for injuries to the pancreas and mesentery. The only contraindication to ultrasound in trauma is an indication for emergent laparotomy. Reports regarding the amount of hemoperitoneum required for detection by FAST have varied, with earlier studies indicating over 600 mL and more recent reports suggesting less than 200 mL.^{5,19,36}

The FAST examination is performed with the patient supine and is designed to look for hemoperitoneum and for hemopericardium. Four locations are examined: (1) the right upper quadrant (RUQ), (2) the left upper quadrant (LUQ), (3) the suprapubic region, and (4) the pericardium. The RUQ view is generally done first, being the easiest, and the most sensitive for hemoperitoneum. This view is specifically designed to detect blood in Morison's pouch between the kidney and liver. Although this location has the greatest yield, the addition of the other two abdominal views has been found to increase the sensitivity from 51% to 87%.²² The LUQ is examined next, specifically looking for blood in the splenorenal space. Either view of the upper quadrants may also reveal a hemothorax. The suprapubic view looks at the space between the rectum and bladder (the pouch of Douglas or rectovesicular pouch), and the heart and pericardium are examined by a subxiphoid view.

The ability of emergency physicians and surgeons to perform an accurate FAST examination has been demonstrated repeatedly.^{22,30} Clearly, the accuracy of the examiner increases with experience. One study found that sensitivity stabilized after 100 examinations,³⁵ and another reported no false negatives after 200 examinations.²³ The 1994 curriculum guidelines from the Society for Academic Emergency Medicine recommend 40 hours of instruction and 150 examinations.²⁶ In addition to increased accuracy with repeated examinations, the time for completion of the four views has been noted to decrease from 4.7 to 2.5 minutes.³⁰

EMERGENCY DEPARTMENT MANAGEMENT

In level I trauma centers, prehospital criteria such as vital signs, level of consciousness, and mechanism of injury will alert a trauma team before arrival of the patient. In most hospitals, however, the emergency physician is solely responsible for initial trauma management. The seriously injured patient with blunt abdominal trauma must undergo standard ATLS resuscitation.

First, address the airway with maintenance of cervical spine immobilization. Administer 12 L of oxygen by nonrebreather mask initially and continue until oxygenation can be assessed by pulse oximeter or ABG analysis. Obtain vascular access using two large-bore (14-gauge or 16-gauge) intravenous catheters connected to normal saline or lactated Ringer's, and place the patient on a cardiac monitor. Evaluate the neurologic status by pupils and the AVPU method or according to the Glasgow Coma Scale. The patient should be fully undressed, with subsequent prevention of hypothermia. Insert a nasogastric or orogastric tube, and, after ensuring no evidence of urethral injury, place a Foley catheter. By this point, the emergency physician should classify the victim of blunt abdominal trauma as stable or unstable.

Unstable Patients

In the hypotensive or tachycardic patient, administer 2 L of crystalloid wide open; surgical consultation is urgent. If the patient remains hypotensive, give packed RBCs. Because type-specific blood requires only 10 minutes to process, it is preferable to a full crossmatch in the unstable patient. In the massively injured trauma victim, it may be necessary to give O-negative blood.

Emergent laparotomy is indicated for those patients with obvious signs of peritoneal irritation or evisceration. Patients with hemodynamic instability in whom an abdominal injury is clearly the source should also be taken to the operating room. For unstable patients, particularly those with multisystem trauma, in whom intraabdominal injury is a possibility, management options include laparotomy, DPL, and FAST examination. A proposed algorithm is provided in [Fig. 107.1](#).

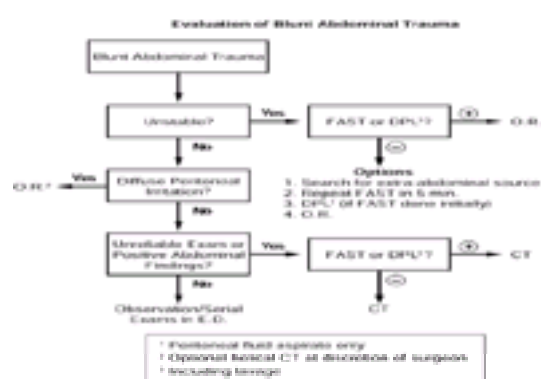

Figure 107.1. Evaluation of blunt abdominal trauma. 1, peritoneal fluid aspirate only; 2, optional helical CT at discretion of surgeon; 3, including lavage.

The speed and sensitivity of the FAST examination for intraabdominal blood, if the immediate availability and expertise exist, make it possibly the best means of evaluation in the unstable blunt abdominal trauma patient. It can be performed in less than 2 minutes. A positive test in this setting mandates laparotomy. Management options of the unstable patient with a negative examination include a further search for nonabdominal sources of hemorrhage, DPL, a repeat FAST examination in 5 minutes, or laparotomy. Obviously, these decisions must be made in concert with the surgeon.

For unstable patients in whom a FAST examination is not available, the peritoneal aspirate component of a DPL remains a useful tool. An initial aspirate of more than 5 mL of blood is an indication for surgery, and can be performed in a time frame similar to the FAST examination. In addition, Fabian and Croce¹⁴ reported that in the presence of a negative aspirate, intraabdominal hemorrhage is an unlikely source of hemodynamic compromise.

In the truly unstable patient, it is impractical to continue with the complete lavage, because after a minimum of 10 minutes just to complete the procedure, definitive results must still await laboratory analysis. The physician's ability to estimate RBC counts based purely on visual inspection of lavage fluid has repeatedly been shown to be grossly inaccurate.^{3,16} Despite the improved speed of the current generation of scanners, CT does not have a role in the persistently unstable victim of blunt abdominal trauma.

Stable Patients

For patients with blunt abdominal trauma and hemodynamic stability, either persistently or after initial resuscitation efforts, the approach to patient management is somewhat different (see [Fig. 107.1](#)). Victims of blunt abdominal trauma who are awake and alert, with a reliable, benign abdominal examination, can be followed clinically with serial examinations in the emergency department. For stable patients with positive abdominal findings, an unreliable examination, significant distracting injuries, possible retroperitoneal injury, or planned general anesthesia, abdominal CT is the diagnostic test of choice.³⁷

Although an initial FAST examination can be done, a subsequent CT is indicated regardless of the results. If intraabdominal blood is visualized on FAST, CT will determine whether the underlying injury can be managed nonoperatively. CT of patients with a negative FAST examination may identify significant injuries that have

not resulted in intraabdominal bleeding, particularly those in the retroperitoneum, pelvis, spine, and lower chest. In a situation in which there is no CT capability and no evidence of other injuries that would necessitate transfer, DPL should be performed. If transfer is inevitable, it should be arranged emergently and DPL performed at the discretion of the accepting surgeon. If DPL is done, it should not delay transfer, and the lavage fluid should accompany the patient.

Concomitant Head Injury

The greatest risk to a patient who has both a head injury and shock is death from uncontrolled intraabdominal bleeding. In patients who cannot be hemodynamically stabilized, diagnosis and management of uncontrolled intraabdominal hemorrhage takes precedence over neurosurgical imaging. Patients who are head injured with hypotension that is unresponsive to fluid administration should undergo a FAST examination (or DPL) in the emergency department. If the CT scanner is adjacent to the emergency department, and it is felt that the patient can tolerate a single cut through the lateral ventricles, this procedure may provide useful information to the neurosurgeon. If the patient's status, or the results of the FAST or DPL, warrant immediate laparotomy, the neurosurgeon should be present in the operating room to consider the placement of burr holes or an intraventricular bolt.

The patient with blunt abdominal trauma who is head injured but not hypotensive may undergo CT scanning of the head and abdomen. If the CT scan is positive for a neurosurgical lesion, surgery should not be delayed for a prolonged abdominal scan. In this case, a current generation spiral scanner may be used to perform an abdominal CT in less than 1 minute. If an older generation scanner is being used, the abdominal scan should be canceled. In this case, a FAST examination or DPL should be performed by the surgeon in the operating room as the patient undergoes craniotomy.

DISPOSITION

If there is no trauma team present and the patient is critically injured, the physician should notify the surgeon after performing the primary and secondary surveys and initiating resuscitative efforts. When in-house capability exists, the ultimate disposition of these patients with hemodynamic instability or significant injuries is straightforward. For stable patients who require evaluation by CT, although CT scanning is not 100% sensitive, two recent studies ^{6,21} indicate that patients with a normal CT scan and a brief period of observation in the emergency department can be safely discharged from the emergency department. However, it is worth noting that outcomes were measured only to 20 hours in one study and to 1 week in the other. Patients who are awake and alert, with a reliable, benign abdominal examination, can be followed clinically with serial abdominal examinations in the emergency department over a 4- to 6-hour period.

Transfer Considerations

Delay to operation is the primary cause of preventable deaths in patients with blunt abdominal trauma. At a very early stage, the emergency physician must determine whether a patient is a candidate for transfer. FAST examination or DPL may be the most expedient way to make this determination in a small rural hospital. However, the receiving institution may elect to have a patient transferred on the basis of the primary and secondary surveys alone, allowing the accepting surgeon to determine whether DPL, CT scanning, or further investigation is warranted.

If, on the basis of the initial assessment, the patient is a candidate for trauma center transfer, multiple investigative studies at the transferring hospital will only delay care. However, resuscitation efforts must be initiated prior to transfer, including attention to the ABCs, two large-bore intravenous lines, a Foley catheter, and a nasogastric or orogastric tube. A chest x-ray should be obtained and chest tubes placed for hemothorax or pneumothorax. The transferring physician must immobilize the neck and place the patient on a backboard. A cross-table lateral cervical spine film is helpful but not imperative, as patients should be immobilized during transport. Extremity x-rays are unnecessary prior to transfer; splint clinically apparent fractures, reduce dislocations if possible, and cover open fractures or dislocations with moist sterile gauze.

COMMON PITFALLS

- Failing to consult the surgeon early
- Attributing hypotension to extraabdominal causes, such as chest trauma, spinal shock, or external blood loss
- Failing to evaluate the abdomen in the patient with an unreliable examination
- Performing an abdominal CT scan in the hemodynamically unstable patient
- Delaying transfer while performing unnecessary studies

The application of mandatory surgical exploration for penetrating abdominal injuries remains a firm surgical dictum, and was so for the greater part of this past century. Although occasionally performed by aggressive surgeons during the nineteenth century, laparotomy for penetrating wounds was infrequently used because of its uniformly poor outcome. Of note, during the U.S. Civil War, expectant management was the treatment of choice, with laparotomy reserved for penetrating wounds with evisceration.¹⁶

By the late 1800s, the folly of the noninterventional approach was better appreciated, yet surgical outcomes remained dismal.³ During World War I, surgical exploration became more commonplace, and by World War II, surgical treatment had gained international acceptance,¹ with a survival rate of 75% for gunshot wounds to the abdomen.

The incidence of penetrating trauma continues to rise as our society becomes increasingly violent. A stab wound (SW) results from impalement by a sharp, narrow instrument, with injury depending on the depth and type of tissue traversed and being confined to the instrument's path.¹⁰ A gunshot wound (GSW) carries significantly greater force, with injury and cavitation extending along, as well as radial to, the missile tract. The likelihood of peritoneal penetration is also dependent on the mode of injury. GSWs to the abdomen require surgical repair in 80% to 95% of patients, whereas SWs require laparotomy in only 25% to 33% of cases. Therefore, both mortality and the need for operative intervention are significantly higher for GSWs, which require a more aggressive management strategy.

The goal of triage and diagnosis in penetrating abdominal injury is expedience. Because of the wide range of scenarios and possible injuries, the emergency physician and trauma surgeon play critical roles in the treatment of these patients. The evaluation, resuscitation, and method of definitive diagnosis are dependent on the type of penetrating injury, the zone of penetration, and, most important, the hemodynamic status of the patient.

CLINICAL PRESENTATION

Although penetrating abdominal trauma is often considered relatively straightforward, its clinical patterns can be confusing. Not only is patient assessment frequently complicated by the presence of alcohol or drugs, but signs and symptoms can be lacking as well, despite the presence of major injury. The critical determinant in the initial assessment is the patient's overall status and hemodynamic stability. In the treatment of any patient with a penetrating traumatic injury and unstable vital signs, immediate surgical consultation must occur as resuscitation efforts are underway.

Evaluation of a penetrating injury to the abdomen requires an understanding of the anatomic zones of the abdomen, which aids in the prediction of underlying intraabdominal injuries.

Anterior abdomen: The zone demarcated by the costal margins to the inguinal ligaments and bordered by the anterior axillary lines is the anterior abdomen. This area of injury involves peritoneal structures in approximately one-third of cases. If the peritoneal cavity has been violated, one must assume internal injury has occurred, and steps should be taken to confirm or refute this assumption. Surgical consultation must be sought if peritoneal penetration has occurred.

Thoracoabdominal area: The zone demarcated by the nipples to the costal margin anteriorly and the scapular tips to the costal margin posteriorly is the thoracoabdominal region. Although the risk for intrathoracic injury in this area is obvious, it is equally important to recognize the possibility of intraabdominal and diaphragmatic injuries. All thoracoabdominal SWs should be evaluated with surgical consultation.

Flank: The zone demarcated by the costal margins to the iliac crests between the anterior and posterior axillary lines is the flank. Flank zone injuries are often difficult to evaluate because the physical examination can prove unreliable. In addition, there is often a delay from the time of injury to presentation. The higher risk of retroperitoneal injury and colonic injury necessitates the evaluation of flank wounds by means of computed tomography (CT) scan and possibly rectal contrast.

Back: The zone demarcated by the costal margins to the iliac crests between posterior axillary lines is the back. This area may be the most difficult to assess for intraperitoneal involvement. It is also more likely that there has been retroperitoneal injury in the event of penetrating back injury. As in flank wounds, the back zone often requires CT scanning for adequate assessment.

DIFFERENTIAL DIAGNOSIS

Unstable vital signs are typically the result of intracavitary hemorrhage, but tension pneumothorax, pericardial tamponade, or, in delayed presentation, sepsis can be causal factors. Rapid assessment as to zone of involvement, chest x-ray, and ultrasound are invaluable in delineating hemoperitoneum, tension pneumothorax, cardiac tamponade, and the likelihood of hypotension due to massive hemothorax. The main differential diagnosis depends on which structures are injured.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The principal tenet in the management of penetrating abdominal trauma is to discern the presence of organ injury that requires operation. Standard practices of resuscitation and stabilization prevail.

Stab Wounds

Peritoneal violation occurs in 50% to 70% of anterior abdominal SWs; laparotomy is required in approximately half of these cases. Therefore, only one-fourth to one-third of patients who sustain SWs to the anterior abdomen ultimately require operative intervention. Thus, diagnostic strategies are intended to separate those patients who require operation from those for whom expectant management will suffice. For this determination, serial clinical examinations, local wound exploration, diagnostic peritoneal lavage (DPL), CT, and laparoscopy are used as fundamental or complementary tools ([Fig. 108.1](#)).

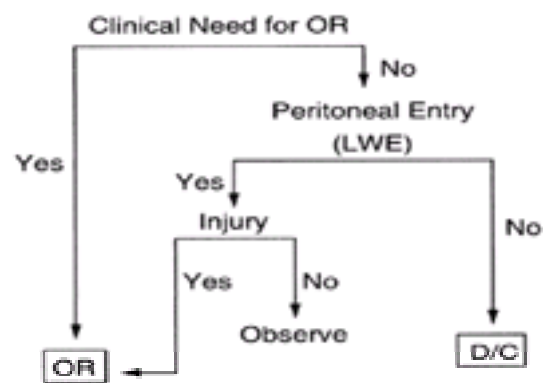

Figure 108.1. Algorithm for emergency department management of abdominal stab wounds. Most centers proceed to laparotomy if intraperitoneal injury is suspected. Further evaluation may be appropriate in selected cases. OR, operation; LWE, local wound exploration; D/C, discharge.

Laparotomy Warranted

Certain clinical features portend a high likelihood of intraperitoneal pathology, but none is an absolute indicator of intraperitoneal injury.

Unstable vital signs: Patients with unstable vital signs are always surgical candidates. Surgical consultation is mandatory while proceeding with chest x-ray and ultrasound. Very few unstable patients with abdominal SWs are managed expectantly.

Gastrointestinal hemorrhage: Treat upper or lower gastrointestinal hemorrhage in the context of an abdominal SW with exploration of the abdomen. This finding usually signals perforation of the stomach or duodenum.

Evisceration: Coincident intraperitoneal injury requiring operation is found in approximately two-thirds of patients with omentum or bowel evisceration. Therefore, most institutions will explore evisceration on a mandatory basis. Some trauma centers with a large number of SW victims have managed these injuries with reduction of the evisceration in the emergency department and expectant observation. This approach should not be considered commonplace, nor attempted without surgical consultation.

Diaphragmatic injury: Thoracoabdominal SWs may cause injury to the diaphragm, which may or may not be seen on chest x-ray. If such injury is present, exploration is mandatory. Often, penetrating trauma inflicts small tears in the diaphragm, producing limited clinical or radiographic signs of injury.⁴

Peritoneal signs: The lack of sensitivity and specificity for peritoneal signs is well documented.

Implement in situ: The prevailing maxim is to remove implements *in situ* of the torso in the operating room.

Determination of Peritoneal Penetration

For those patients who do not satisfy any clinical requisites for laparotomy, the presence of peritoneal violation can be assessed by other means.

Free intraperitoneal air: The presence of free air on an upright chest or left lateral decubitus film establishes that the stabbing implement penetrated the peritoneal cavity and drew air in with it. It does not, however, establish that a hollow viscus injury has necessarily occurred.

Local wound exploration: Local exploration can be performed safely on the anterior abdomen only. A negative local wound exploration establishes that the end of an SW tract is anterior to rectus fascia, present only on the anterior abdominal wall. Such patients can be discharged from the emergency department after appropriate wound care.^{5,19} An indeterminate local wound exploration must be considered positive. Patients who have multiple wounds or who pose technical obstacles, such as being massively obese, may not be candidates for this procedure.

CT scan: CT scans for SWs are particularly helpful in the case of injuries to the flank and back. In addition, after a penetrating abdominal wound, if CT reveals violation of the transversus abdominus muscle or the presence of a hematoma near the colon, surgical consultation and likely exploration are warranted.

Equivocal Findings of Peritoneal Penetration

At present, several diagnostic modalities are available to aid in the triage of patients who have sustained penetrating trauma with equivocal findings and possible intraperitoneal injury. Although the role of ultrasound is expanding rapidly, its primary use has been for visualization of the pericardial space in the rapid evaluation of upper abdominal and low chest penetration. As familiarity with this modality grows, it may become a more useful adjunct in other situations.^M

Diagnostic peritoneal lavage: DPL, although invasive, is rapid, generally considered safe, and carries a 90% to 95% accuracy rate for the discovery of intraperitoneal pathology.⁶ Its main drawback is false-positive peritoneal aspiration results caused by drainage of free blood from the SW site into the peritoneal cavity. Debate remains as to the appropriate red blood cell (RBC) count to depict a positive study, with ranges from 5,000 to 25,000 RBCs.

Serial examination. Careful patient selection is required for serial examination. Although safely employed in trauma centers with large numbers of stabbing victims, it requires meticulous, ongoing observation, which may be impractical on a hectic trauma service.⁸

CT scan: The CT has become an integral diagnostic procedure following blunt trauma. It is excellent for detecting solid visceral injury, but is not as accurate in determining hollow viscus pathology, which predominates after penetrating trauma.⁹ It is also insensitive for small diaphragmatic tears. As previously discussed, CT can be a valuable adjunctive tool where colorectal injury is more likely.⁹

Laparoscopy: Laparoscopy has been used with success as an intermediate step in discerning peritoneal penetration prior to formal exploratory laparotomy. Some trauma centers have espoused its usefulness for direct inspection of the diaphragm and certain solid viscera. Significant experience is required to render this approach reliable for hollow viscus injury, and only a limited number of centers have accepted this approach.²⁰

Laparotomy: When there is any doubt as to the possibility of an internal injury, exploration by a surgical consultant should be sought.

Stab Wound—Special Cases

The chance of retroperitoneal injury is significantly greater after an SW to the flank and back than after one to the anterior wall. In addition, the risk of intraperitoneal organ injury ranges from 15% to 40% after SWs to these sites. Local wound exploration can be very difficult to perform in these areas because of the lack of a definite fascial plane of demarcation with the peritoneal cavity. DPL can discern the presence of intraperitoneal and diaphragmatic injury. The addition of rectal contrast to a standard double-contrast CT scan may be indicated for SWs to the low abdomen, flank, and back, where colorectal injuries are most likely. Because missed injuries to the diaphragm may eventually cause substantial morbidity and mortality, certain centers promote mandatory exploration to inspect the diaphragm when it is considered at risk, based on the wound entry site alone. Although exploratory laparotomy is the most sensitive technique of injury determination, it incurs the highest complication rate. Thus, laparoscopy, thoracoscopy, and DPL are more commonly employed to aid in diagnosing an injury prior to formal open laparotomy.

Gunshot Wounds

In most institutions, the determination of peritoneal violation by missile is enough to prompt laparotomy. A more comprehensive approach employs additional diagnostic tests, such as DPL, serial physical examinations, CT, and laparoscopy.^{11,12} In contrast to SWs, multiple-organ and cavity entry is the rule in GSWs, with a mortality that is ten times greater. GSWs to the anterior abdomen incur peritoneal violation in 80% to 85% of patients, and, in this circumstance, laparotomy is required in 89% to 98%. Together, these data support a more conservative strategy, whereby laparotomy is the ultimate diagnostic procedure in most patients (Fig. 108.2).

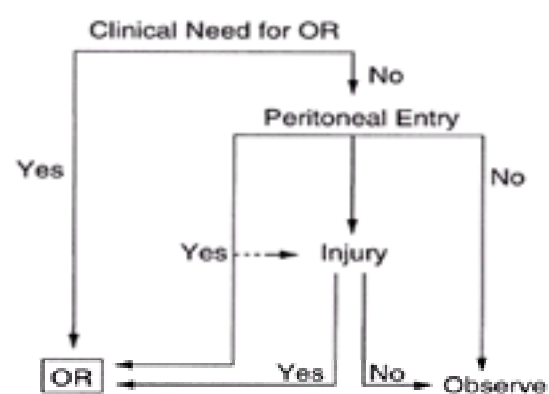

Figure 108.2. Algorithm for emergency department management of abdominal gunshot wounds. Most centers proceed to laparotomy if peritoneal entry is determined. Most centers proceed to laparotomy if intraperitoneal injury is suspected. Further evaluation may be appropriate in selected cases. OR, operation.

Laparotomy Warranted

As with SWs to the abdomen, GSWs to the abdomen have accepted criteria for immediate surgical consultation and operation.

Unstable vital signs: Any victim of a GSW with unstable vital signs requires immediate surgical consultation. If the GSW is to the abdomen, there are relatively few cases that are managed outside the operating theater.

Gastrointestinal hemorrhage: As is true in the case of SWs, gastrointestinal bleeding in association with a GSW to the abdomen, flank, or back mandates surgical exploration.

Evisceration: Because of the greater energy transference and cavitation that occurs with GSWs to the abdomen (compared with SWs), evisceration warrants surgical exploration.

Peritoneal signs: As with SWs, there is a well-documented lack of specificity of peritoneal signs with GSWs.

Determination of Peritoneal Penetration and Trajectory

Multiple studies have been conducted to assist with the determination of trajectory and thereby include or exclude peritoneal penetration following GSWs to the abdomen. Of these, CT and DPL have received the most attention, with a smaller number of studies evaluating laparoscopy.

CT scan: In patients with torso injuries, CT has been studied in an attempt to determine trajectory and avoid nontherapeutic invasive procedures.⁴ There is evidence that, in this scenario, CT scan can be helpful in excluding peritoneal or transpelvic trajectories. This group of patients, however, is highly selective in that it accounts for less than 2% of all GSWs evaluated by the trauma service.² A more common use for CT, whether the standard or triple-contrast technique, is to provide information and assist in the management of select hemodynamically stable patients with penetrating trauma to the abdomen, flank, or pelvis.

Diagnostic peritoneal lavage: The use of DPL to exclude a transabdominal trajectory has been examined by Nagy et al.¹³ at Cook County Hospital in Chicago. They retrospectively reviewed their use of DPL in 529 patients with GSWs in the vicinity of the abdomen and without a definite indication for surgery. Using a threshold of 10,000 RBC/ μ L to define a positive study, 150 patients were found to have a positive examination and underwent laparotomy, of which six had no evidence of peritoneal penetration or injury. Two patients had negative lavages but subsequently developed symptoms requiring surgical exploration. Both were found to have injuries that had been missed. With its limitations, DPL appears to offer adjunctive information in determining peritoneal penetration but is far from an ideal test for this diagnosis.

Laparoscopy: Likely indications for this procedure following penetrating trauma include determining peritoneal penetration and identifying injuries for either operative repair or those without need for further operative intervention. A minimally invasive exploration can proceed in a timely fashion, although it, too, has its liabilities. To date, laparoscopy's main use has been as a diagnostic procedure.^{6,22}

Ultrasound: As familiarity grows with ultrasound in trauma, its use will invariably increase. There are currently at least two studies in progress in the United States that are looking into the role of ultrasound in penetrating abdominal trauma. At this point, there is no consensus as to its role, and it should probably not be employed outside of study protocols for abdominal GSWs.

Gunshot Wound—Special Cases

Nonoperative Management

As specific injury patterns are better understood and newer diagnostic modalities are incorporated into clinical practice, it is clear that not every patient with a penetrating abdominal injury requires surgery. A selective approach to nonoperative management for abdominal SWs was proposed a number of years ago²¹ and has included a limited experience with a similar management protocol for abdominal GSWs.¹⁵ This approach has received renewed interest,^{14,17} partly because of improved understanding of the nontrivial morbidity associated with unnecessary abdominal explorations.¹⁶ Patient physiology, reliability of examination, and availability of the patient and surgeon for reexamination all need to be factored in with immediate accessibility of an operating room. If these issues cannot be addressed satisfactorily, this method of management should not be attempted. GSWs of the low chest, flank, or back create the same issue as for SWs, and similar diagnostic strategies are in order.

DISPOSITION

Role of the Consultant

The earliest notification possible should be made to the on-call trauma surgeon, trauma team, and operating personnel. Information gleaned from prehospital communication alone can be sufficient to alert consultants.

Indications for Admission

After an SW, patients with a negative local wound exploration may be discharged after wound care and attention to toxicologic concerns. Patients who undergo an apparently negative DPL, CT, or laparoscopy should be held for 12 to 24 hours to ensure absence of injury resulting from the original mechanism or the diagnostic

procedure.

It is rarely possible to determine with confidence that a low-velocity GSW is superficial. If there is doubt, a 12- to 24-hour observation period is necessary. High-velocity GSWs impose tremendous energies and can cause serious intraperitoneal damage despite an extraperitoneal course.

Transfer Considerations

Optimally, all patients with an SW or a GSW are triaged from the point of injury directly to a level I or a level II trauma center. When this does not occur, transfer to such a center at the earliest opportunity is advised. Only life-saving maneuvers such as endotracheal intubation, tube thoracostomy, pericardial aspiration, and fluid resuscitation are indicated before initiating transfer.

COMMON PITFALLS

- Failure of recognition. All patients with suspected trauma must be completely undressed and scrupulously examined. In penetrating trauma in particular, the scalp, axilla, and perineum easily hide narrow but deep and dangerous wounds. The examiner should not be swayed by prehospital or patient testimony or by the identification of a single site of penetration.
- Minimizing the injury. "It's probably OK," should never be stated. One must determine the severity of the injury and never assume it.
- Unnecessary delay. The speed with which operation is undertaken depends on the patient's clinical status. It may be appropriate to wait for serial examinations or the results of peritoneal lavage. However, transport to the operating suite must immediately follow resuscitation measures when a patient's status is precarious.
- Blind probing. Plunging digits and instruments into wound tracts is inaccurate and hazardous.
- Failure to observe. No patient should be summarily discharged without a complement of careful, repeated examinations, necessary diagnostic studies, or both. Presumption that a "negative" study, notably DPL or CT, warrants immediate discharge is incorrect. If the test was necessary, then an appropriate period of observation is necessary.
- Delay to consultation. It is wise to give an early warning to consultants. A timely operation should never be delayed because of a failure to notify consultants.
- Radiology. The most precarious place for a trauma patient is the radiology department. Be assured of proper monitoring and, if needed, recruit personnel to assist in observing patients in the radiology department and CT scanner.

ACKNOWLEDGMENT

The authors gratefully acknowledge the contribution of John A. Marx and Stephen Collucciello, who wrote the previous version of this chapter.

The approach to genitourinary (GU) trauma is an essential although frequently misunderstood component of the evaluation of blunt and penetrating trauma. GU injuries occur infrequently; when they do occur, they are usually associated with other multisystem trauma. It is frequently quoted that as many as 10% of acutely injured patients may have associated GU injuries.^{27,32} Large-scale studies, however, have demonstrated an incidence of 1.5%¹⁵ to 3.1%.¹⁸

GU injuries frequently may be overlooked because of their relative rarity and failure of the clinician to consider the diagnosis. The injury may be occult, and clues to suggest the possibility of GU trauma may lie in the mechanism of injury, or a constellation of associated injuries and physical findings identified during the secondary survey. Furthermore, GU injuries may be overshadowed by more dramatic and immediately life-threatening injuries. A systematic approach and thorough understanding of the available diagnostic modalities are necessary to efficiently and effectively evaluate GU injuries and provide complete information to urologic consultants.

This chapter focuses on trauma to both the upper (kidney and ureters) and lower (bladder and urethra) urinary tracts. Evaluation and management of upper and lower tract injuries are discussed separately because the mechanisms of injury and diagnostic modalities employed are unique to each. Considerations for both blunt and penetrating injuries are included.

UPPER URINARY TRACT

CLINICAL PRESENTATION

The kidneys and ureters lie in an anatomically sheltered vantage, secured in the retroperitoneum, beneath the lower ribs and musculature of the back. Therefore, injuries to the upper urinary tracts typically occur in the setting of high-energy multisystem trauma. Blunt force to the back, flank, or abdomen; falls from height; or, less commonly, rapid deceleration may result in injuries to the kidneys or ureters.²⁶ While hematuria may reveal an injury, it is not a reliably sensitive marker in isolation. Penetrating injury may be suggested by transaxial wounds or wounds in anatomic proximity. Penetrating injuries may account for 20% of renal injuries.¹⁷

DIFFERENTIAL DIAGNOSIS

Upper urinary tract injuries must be differentiated from myriad other blunt and penetrating injuries to the abdomen and pelvis. Upper tract injuries may occur alone. Much more commonly, however, the high-energy mechanisms that result in renal injuries concurrently produce associated bony, vascular, and visceral injuries that directly contribute to the observed morbidity and mortality.¹⁵ In addition to aortic, splenic, and liver trauma, renal pedicle injuries must be considered as a cause of refractory hypotension following a fall from height or rapid-deceleration injury.²⁶ Traumatic injury to the ureters and kidneys may be suggested on the basis of the mechanism of injury, hematuria, or location of penetrating wounds.

Classification of upper tract injuries is by anatomic involvement and severity. This classification system reflects differences in clinical management. Eighty-five percent of patients suffering blunt renal trauma have only minor injuries that may be managed expectantly. Renal contusion is the most common of these minor injuries. Hematuria (microscopic or, less commonly, gross hematuria) and a normal renal outline, intact collecting system, in the absence of a perirenal hematoma, identify patients with renal contusions. Other minor injuries include ruptures of the renal fornix and shallow cortical lacerations not extending into the collecting system or deep medulla.^{27,30}

Intermediate injuries comprise segmental vascular infarcts and deep lacerations of renal parenchyma. The depth of the laceration correlates with the risk of hemorrhage or extensive perirenal hematoma. Major injuries constitute only 5% of blunt injuries but as many as 50% of penetrating renal injuries. These include renal rupture, fractured or shattered kidney, renal pedicle injury, and avulsion of the renal pelvis.

Vascular pedicle injuries are more commonly associated with blunt trauma (75%) than with penetrating trauma (25%). Pedicle injuries typically imply an extremely high-energy mechanism, and are associated with multisystem trauma and a higher injury severity score.^{7,26} Injuries include intimal tears and partial or complete tearing of the renal artery, vein, or segmental branches.

EMERGENCY DEPARTMENT EVALUATION

The emergency department evaluation of a multiply injured trauma patient begins with the standard advanced trauma life-support assessment and resuscitation. In this manner, immediately life-threatening injuries are identified and treated. Identifying and staging injuries to the upper urinary tracts within this high-risk population requires adjunctive radiographic studies. The emergency physician must determine the necessity of further evaluation and which diagnostic modalities to employ.

The first task is to identify those patients at risk for significant renal trauma requiring further evaluation. Mee et al.²⁸ published the influential article establishing criteria for the evaluation of blunt renal trauma. Their 10-year prospective study of 1,007 consecutive blunt trauma patients who underwent radiographic evaluation established markers associated with increased risk of major renal lacerations. Those were gross hematuria, microscopic hematuria (greater than 5 red blood cells [RBC]/HPF) with shock either in the prehospital setting or in the emergency department, or, less commonly, a history of significant deceleration without hematuria or shock. The authors concluded that if radiographic evaluation were limited to those patients, no significant renal injuries would have been missed. These guidelines have been supported by subsequent studies and have become the criteria defining the population of patients who require further radiographic evaluation.^{7,12,18,29} It should be noted, however, that this schema is based on the assumption that patients with microscopic hematuria in the absence of any hemodynamic instability or high-energy mechanism are likely to have minor injuries that would be managed by simple observation.

Almost all authors advocate radiographic imaging in the setting of penetrating trauma to evaluate for upper urinary tract injuries, as a substantial percentage of patients may have significant injury in the absence of hematuria^{2,6} (Table 109.1).

Penetrating trauma
 Blunt trauma with gross hematuria
 Blunt trauma with microscopic hematuria and hemodynamic instability (hypotension or tachycardia)
 High-energy mechanism or suspected associated intraabdominal injuries

TABLE 109.1. Indications for Radiographic Evaluation

It has become convention that urine dipstick analysis for blood is used as a screening test for traumatic hematuria to identify those patients requiring further evaluation. This practice is based largely on the work of Daum and associates,¹¹ who demonstrated urine dipstick analysis to be 100% sensitive in identifying patients with greater than 5 RBC/HPF by spun urine microscopy. Although the specificity was only 58%, these characteristics support the use of a urine dipstick as a screening test for hematuria. Other authors and subsequent studies have confirmed these findings.¹⁹

Computed tomography (CT) scan has largely supplanted intravenous pyelography (IVP) as the preferred diagnostic modality for evaluating the hemodynamically stable patient with blunt or penetrating trauma ([Fig. 109.1](#)). Several characteristics make CT the preferred modality. CT clearly defines parenchymal lacerations, hematomas, and the presence of urinary extravasation and may identify renal vascular injuries. Furthermore, the findings of IVP, when abnormal, are frequently nonspecific and require CT scan to better define the extent of the renal injury.^{4,6,15,18,27} Finally, as previously described, patients at risk for blunt or penetrating injuries to the upper GU tract have incurred a high-energy mechanism and have a high incidence of associated bony, visceral, and vascular injury. These associated injuries may have direct bearing on the operative or nonoperative management. CT scan is required to adequately assess and stage these associated injuries.

Figure 109.1. (A, B) Renal laceration with perirenal hematoma.

IVP still has a distinct role in the evaluation of the unstable patient requiring resuscitation or immediate operative intervention who is not a candidate for CT scan. It may be done during the acute resuscitation or in the operating room. A bolus of contrast media is injected intravenously (2 mL/kg to a maximum of 100 mL). An anterior–posterior (AP) abdominal radiograph is then obtained 5 minutes after contrast bolus. In this setting, IVP may confirm the presence of bilateral kidneys, and may suggest the extent of the injury.

The most significant findings are either nonfunctional renal unit or extravasation of urine. Nonfunction suggests extensive trauma to the kidney, pedicle injury, or severely shattered kidney. Extravasation of contrast material implies trauma involving the capsule, parenchyma, and collecting system. Other findings are less reliable and require additional evaluation and staging.²

Arteriography is reserved for stable patients requiring further clarification of pedicle injuries, following equivocal CT findings. Arteriography may demonstrate intimal tears and complete or partial disruption of the renal vasculature. CT findings requiring further evaluation by arteriography include large perirenal hematoma, major renal fractures, or segmental areas of nonenhancement. Penetrating trauma with renal laceration or retroperitoneal hematoma requires arteriography because of the high risk of associated renal vascular injury.¹³ Small hematomas do not require further evaluation. A hypotensive patient requires surgical intervention, and further studies may be delayed until the patient is stabilized. Nonenhancement of the kidney on CT scan is diagnostic of renal artery thrombosis and is sufficient indication for surgery without additional studies.^{7,8}

The role of magnetic resonance imaging (MRI) and ultrasound remains limited. Several studies have suggested that the performance of MRI approximates that of CT scan. The additional time and expense required limit its clinical application.^{20,21} Ultrasound has performed poorly in the evaluation of patients with suspected injuries to the upper GU tract³⁵ ([Table 109.2](#)).

Diagnostic Modalities	Advantages	Disadvantages
CT scan	<ul style="list-style-type: none"> Study of choice in blunt trauma Most sensitive/specific Better staging information Evaluation for other associated injuries 	<ul style="list-style-type: none"> Requires stable patient Commonly misses ureteral injury May incompletely identify vascular pedicle injuries
IVP	<ul style="list-style-type: none"> Rapid and readily available for unstable patients Useful as screening test in patients with isolated renal trauma 	<ul style="list-style-type: none"> Nonspecific findings require additional studies Hypotension may preclude adequate visualization Commonly misses ureteral injury May miss minor injuries
Arteriography	<ul style="list-style-type: none"> Gold standard for vascular pedicle injuries 	<ul style="list-style-type: none"> Requires stable patient Invasive and time consuming
MRI	<ul style="list-style-type: none"> Performance may equal that of CT scan Can be used in iodine-allergic patients 	<ul style="list-style-type: none"> Expensive

TABLE 109.2. Diagnostic Modalities for Evaluating Upper Tract Injuries

Ureteral injury remains a diagnostic dilemma. A third of ureteral injuries are not identified on initial evaluation. Hematuria was present in only 63% of patients with no other GU injuries. This underscores the lack of reliability of hematuria in identifying isolated ureteral trauma. The most successful means of identification were surgical exploration and retrograde pyelography. IVP and CT were diagnostic in only a third of cases.⁵

EMERGENCY DEPARTMENT MANAGEMENT

The principles of care for the patient with multisystem trauma apply equally to the patient with trauma to the upper GU tract. Crystalloid and blood products are

indicated for hemodynamic instability.

The most contentious issue remains which patients require operative intervention and which may be managed nonoperatively ([Table 109.3](#)). It is generally accepted that patients with minor injuries (grades I and II) may be managed nonoperatively. It is generally accepted that patients with renovascular injuries, shattered kidneys, extensive urinary extravasation, or an unconfined, expanding, or pulsatile hematoma require early surgical intervention (grade V).

MINOR INJURIES
Grade I: Contusions and contained subcapsular hematomas
Grade II: Nonexpanding perirenal hematomas and cortical lacerations

MAJOR INJURIES
Grade III: Parenchymal lacerations into the corticomedullary junction and thrombosis of a segmental artery without an associated parenchymal laceration
Grade IV: Renal lacerations involving segmental renal vessels, lacerations violating the collecting system, and contained injuries to the renal vessels
Grade V: Avulsion of the renal hilum, thrombosis of the main renal artery, shattered kidney

*American Association for the Surgery of Trauma Grading System.

TABLE 109.3. Grading System for Renal Injuries^a

There is less universal agreement concerning other major injuries (grades III and IV). There is an increasing trend toward nonoperative management. Several authors have reported series of selective nonoperative management of major renal injuries.^{15,24,26,27} In general, the majority of blunt renal trauma may be managed nonoperatively. Delayed interventions may be necessary in a subset of patients managed nonoperatively. Those most likely to require delayed intervention include those demonstrating extravasation of urine, devitalized renal segments, or both, on initial CT scan. Recent advances in percutaneous and endourologic techniques have decreased the morbidity of these complications.^{24,32}

There is a lower threshold for operative exploration and intervention in penetrating trauma. Most penetrating injuries are explored and repaired. Ureteral injuries are repaired surgically and stented, or repaired in a staged fashion.^{1,2}

DISPOSITION

Patients with microscopic hematuria in the absence of any hemodynamic instability, or an isolated renal contusion demonstrated on CT scan without other injuries, may be discharged with follow-up repeat urinalysis. An isolated renal injury is, however, uncommon. Most patients with blunt renal injuries will have associated injuries requiring admission. All patients with penetrating renal or ureteral trauma require admission or transfer to a facility capable of providing definitive diagnostic and therapeutic care.

COMMON PITFALLS

- In the setting of acute traumatic injury, remember to consider kidney and ureteral trauma as potentially concurrent or occult injuries.
- In the absence of hematuria, upper tract injury must not be ruled out on that basis alone. While most patients with significant blunt injury requiring intervention will demonstrate gross hematuria or microscopic hematuria with hypotension, patients with renal pedicle injury or penetrating trauma resulting in ureteral injury may not demonstrate hematuria.
- In the setting of penetrating trauma, ruling out significant injury based on a suboptimal local flank wound exploration. If the wound is suspicious and in anatomic proximity, the patient requires further diagnostic evaluation.

LOWER URINARY TRACT

CLINICAL PRESENTATION

Blunt trauma to the lower urinary tract (bladder and urethra) is usually associated with pelvic rami fractures and symphyseal diastasis. Anterior urethral injuries (penile and bulbous urethra below the urogenital diaphragm) are associated with self-instrumentation, falls, and straddle injuries. Posterior urethral injuries (membranous and prostatic urethra above the urogenital diaphragm) commonly accompany pelvic fractures. As the urinary continence mechanism and autonomic innervation responsible for erection are contained in the posterior urethra, posterior urethral injuries may result in permanent incontinence and erectile dysfunction. Signs of anterior urethral injury depend on the integrity of Buck's fascia. If this fascial layer is torn, blood and urine may pass into the penis, scrotum, and abdominal wall.

A mechanism of injury suggestive of pelvic ring disruption, pelvic tenderness, or instability, or radiographic findings further define the population at risk for lower tract injury. Clinical signs such as blood at the urethral meatus, high-riding prostate, scrotal hematoma, hematuria, or difficulty voiding may be directly suggestive of lower tract injury. These signs may be absent in as many as 57% of patients with urethral injury.²³

Extraperitoneal bladder injuries are most commonly associated with pelvic fractures and bladder laceration by bony fragments. Extraperitoneal bladder injury less commonly may occur alone. Intraperitoneal bladder injuries result from compressive forces in the presence of a full bladder, and rupture occurs at the dome of the bladder.

As with penetrating trauma to the upper GU tract, penetrating injuries to the lower tract are suggested by location of wounds. Any penetration of the lower abdominal wall in the region of the pelvis raises the possibility of urinary tract injury. Given the variability of projectile tract, any gunshot wound in the region should include consideration of GU tract injury.

DIFFERENTIAL DIAGNOSIS

The primary differential of lower urinary tract injury is that of hematuria due to upper tract injury. The emergency physician, trauma surgeon, or urologist must determine whether the bleeding originates from the urethra, bladder, ureter, kidneys, or some combination of sources.

EMERGENCY DEPARTMENT EVALUATION

The fundamental principle in the approach to traumatic GU injuries dictates that the urinary tract be evaluated from lower to upper sequentially. Therefore, once the potential for injury has been identified based on mechanism of injury, physical findings, and/or radiographic evidence of associated high-risk injuries, the urethra should be evaluated first. It is important that the presence of urethral injury be ruled out prior to catheter placement, because catheter placement may potentially convert a partial urethral tear to a complete urethral disruption. The diagnostic modality for evaluating the urethra is the retrograde urethrogram.

The study is done with the patient supine to avoid moving the patient (oblique views, advocated by some authors, add little and risk disrupting a retroperitoneal hematoma). A preinjection KUB is obtained for comparison. A Foley catheter is then passed approximately 1 to 2 cm to the fossa navicularis, and the balloon is inflated with 1 to 2 mL of saline. Alternatively a 60-cc Toomey syringe with Christmas tree or Cooke adapter may be gently inserted until snug. Lateral traction is applied to the penis to avoid the column effect, and 60 mL of water-soluble contrast material is injected over 30 to 60 seconds. The radiograph is exposed as the last 10 mL of contrast material is injected.³⁸

Extravasation of contrast material or failure of contrast material to reach the bladder is diagnostic of urethral injury, mandates urologic consultation, and precludes the passage of a urethral catheter by the emergency physician ([Fig. 109.2](#)).

Figure 109.2. Retrograde urethrogram with partial tear of membranous urethra.

If a team member places a urinary catheter prior to adequate evaluation for urethral injury, *do not remove it*. It is not necessary to remove the catheter to perform a retrograde urethrogram. Instead, document the presence or absence of urethral injury by passing a small feeding tube beside the catheter and performing a modified retrograde urethrogram.³⁸

Following assessment of the urethra, evaluate the bladder. Extraperitoneal bladder rupture is more common and is typically associated with pelvic fracture. Intraperitoneal bladder rupture may result from compressive forces in the presence of a distended bladder. The retrograde cystogram is the most reliable study for evaluating bladder injuries. After exclusion of urethral injury and placement of catheter, retrograde cystography is obtained as follows: Obtain a precontrast KUB for comparison. Then instill radiocontrast dye under gravity through the catheter until a total of 400 mL of contrast is instilled. Then clamp the Foley catheter and obtain a full-bladder AP radiograph.

If bladder contraction occurs prior to administration of 400 mL, contrast refluxes into the Toomey syringe. Simply wait a few minutes and then reintroduce the contrast material to the volume that stimulated contraction previously. Then gently administer an additional 50 mL, clamp the catheter, and similarly obtain a full-bladder AP radiograph.³⁸

Then allow the bladder to empty, and obtain postvoid radiographs. In the presence of intraperitoneal rupture, contrast material will extravasate, outlining intraperitoneal structures. In the presence of extraperitoneal rupture, contrast material will extravasate at the pubic symphysis or pelvic outlet.

Take care to avoid spillage of contrast externally, which may produce false-positive findings or obscure the findings. Multiple studies have demonstrated false-negative cystography due to insufficient contrast material (less than 400 cc), particularly in penetrating trauma, in which inadequate distension of the bladder may allow a tenuous seal of a penetrating wound, thereby failing to demonstrate extravasation of contrast.^{3,38}

Cystography remains the standard for evaluating the bladder, although a CT scan with retrograde contrast may be useful in patients undergoing CT for other indications ([Fig. 109.3](#)). This is simply done by instilling contrast in a similar retrograde fashion prior to imaging. Intraperitoneal rupture results in contrast dye within the peritoneum. Extraperitoneal rupture may be more difficult to visualize but may be evident on pelvic cuts.^{3,14}

Figure 109.3. Cystogram with extraperitoneal bladder rupture.

Penetrating trauma to the pelvis presents numerous therapeutic challenges, but the diagnostic approach is relatively straightforward. Any and all structures at risk because of their anatomic proximity to the injury need to be evaluated, including the bladder, the urethra, the vasculature, and the gastrointestinal tract.

EMERGENCY DEPARTMENT MANAGEMENT

Once a urethral or bladder injury is identified, the emergency physician must take steps to manage the injury while continuing to address immediate life-threatening injuries. Patients subject to high-energy mechanisms responsible for urinary tract injury are also at risk for serious intraabdominal injuries.

If a urethral disruption is identified, a suprapubic cystostomy should be performed to allow drainage of the bladder. This may be done in the resuscitation bay if the patient is stable. If the patient is unstable and requires operative intervention for associated injuries, it may be done in the operating room. If a catheter was placed prior to identifying the injury, it should be left in place. Occasionally, a catheter may be placed through a partial urethral tear. Once the partial disruption is identified, however, any gentle and limited attempts at urethral catheterization should be done by a urologist.

The acute management of bladder rupture is bladder drainage via Foley catheter. Patients with intraperitoneal bladder rupture undergo primary surgical repair. Those patients with extraperitoneal bladder rupture are typically managed nonoperatively, with simple urinary drainage by Foley catheter or cystostomy. If, however, the patient is undergoing exploratory laparotomy for another indication, some authors advocate primary repair at that time.^{3,10,36}

DISPOSITION

All patients with injuries to the lower GU tract require hospital admission or transfer to a facility capable of managing these injuries and their potential complications. Early involvement of urologic consultants and good communication between the emergency physician, urologic consultant, and trauma surgeons are essential to the global management of the patient. It is also worth remembering that extremely painful injuries, such as pelvic fractures, may mask other serious injuries, including cervical spine and thoracoabdominal injuries.

COMMON PITFALLS

- Placing a Foley catheter before adequately ruling out urethral injury risks converting a partial tear to a complete disruption. However, if the catheter was placed before radiographic evaluation, to rule out urethral injury, do not remove the catheter to perform a urethrogram.
- Insufficient contrast dye administered during retrograde cystogram may fail to adequately distend the bladder to demonstrate extravasation.
- Allowing spillage of contrast dye externally may obscure radiographic findings on retrograde cystogram.

INJURIES TO THE MALE GENITALIA

Intentional amputation of the penis has been reported and has received a great deal of media attention. There have been several reported cases of successful microvascular reimplantation. Successful repair depends on the condition of the severed part and ischemic time. In the prehospital and emergency setting, the amputated penis should be preserved in a manner similar to that for other amputated parts. Prompt urologic and microvascular consultation is imperative for successful reimplantation.⁴⁰

The incidence of penetrating trauma to the external genitalia resulting from gunshot wounds and stabbing has been increasing (Fig. 109.4). Penetrating trauma to the external genitalia mandates early surgical exploration and conservative debridement, followed by, in most cases, primary repair. Most patients require a retrograde urethrogram to rule out urethral injury. Some patients with minimal injury may be candidates for nonoperative management, but delayed complications are not uncommon. The majority of patients with penile trauma will retain erectile and urinary function.^{9,16}

Figure 109.4. Gunshot wound—retrograde urethrogram with extravasation at penile urethra.

Penile fracture most commonly occurs during overzealous vaginal intercourse, although several other mechanisms have been reported. The fracture involves rupture of the tunica albuginea of the corporal body. Authors have advocated operative repair, proposing that it may decrease the incidence of erectile deformity and may speed recovery. There is, however, no accepted standard of treatment.³⁷ Entrapment of the penis in a zipper occurs most often in uncircumcised young boys. Nolan and associates³³ described the successful atraumatic removal by cutting the median bar of the zipper with bone cutters. The upper and lower shields of the zipper device separate, releasing the skin with minimal injury. Penile incarceration may be managed by the string technique, similar to that described for removal of rings from fingers.³⁹

The evaluation of blunt scrotal trauma can be clinically challenging. Suspicion of testicular rupture should prompt timely urologic consultation, as surgical repair within 72 hours dramatically improves the salvage rate. Several studies have suggested that ultrasound may be useful in the evaluation of acute scrotal trauma, by identifying patients for surgical exploration.^{22,25,34} A small series has questioned its diagnostic accuracy, although a normal scrotal ultrasound had a high negative predictive value in a high-risk population.³¹ The role of ultrasound in the evaluation of blunt scrotal trauma requires further study.

CHAPTER 110

Peripheral Vascular Injuries

Peter T. Pons

[Clinical Presentation](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Prompt recognition and management of peripheral vascular injuries are crucial to limb salvage and preservation of function. Penetrating trauma accounts for approximately 85% of vascular injuries; blunt trauma and iatrogenic causes are responsible for the rest. Until the advent and widespread use of antibiotics, these wounds were treated by ligation or amputation. Once infection could be controlled, the already developed methods of primary vessel repair were used and are now the mainstay of management.

Vascular injury may result from direct or indirect trauma. Direct injury may produce partial or complete transection, contusion, laceration, or arteriovenous fistula. Indirect injury may cause spasm, external compression, mural contusion, thrombosis, or aneurysm formation. The vessels most often involved are the brachial and axillary arteries in the upper extremity and the femoral and popliteal arteries in the lower extremity.

Vascular damage should be suspected in penetrating trauma when the penetrating object has traversed the path of a vessel or is in proximity to one. Blunt vascular injury may be subtler in presentation. Stretching, tearing, or shearing forces may damage a vessel, yet leave little external evidence. The classic example is dislocation of the knee, with associated popliteal artery injury. Failing to recognize this complication frequently leads to amputation of the leg, which can be prevented by appropriate evaluation. The emergency physician must obtain a careful, complete history and be aware of the mechanics that may produce vascular injury, even if there are no or few physical findings that suggest vessel damage.

CLINICAL PRESENTATION

The most obvious sign of arterial injury is profuse, spurting red blood. Venous laceration may be manifested by a continuous flow of dark blood, which also may be profuse. Significant blood loss may produce shock. However, many vascular injuries, either blunt or penetrating in origin, appear relatively innocuous at first glance. Penetrating wounds of an extremity can present with a small entrance site that harbors significant underlying vascular damage. Blunt injury may be quite misleading because of few obvious external signs. The vessel wound, either arterial or venous, may produce a significant hematoma. Occasionally, a pulsatile mass is felt.

The absence of a palpable pulse distal to the site of injury in a normotensive patient is pathognomonic of vessel injury. However, the presence of a pulse does not exclude a significant wound. Collateral circulation or transmitted pressure waves through a small clot or intimal flap can produce a distal pulse, misleading the unwary physician. A patient in shock must have repeated examinations to assess vascular status, as the physical findings may change as the patient is resuscitated. The presence of a palpable thrill or bruit suggests an arteriovenous fistula. Comparison of blood pressure using a Doppler in the injured and uninjured extremities, or in the injured extremity compared with an arm, can be helpful.⁹ If the ratio of the blood pressures is less than 0.9 to 1.0, vascular injury is suggested.^{9,12} In addition, an arm/ankle (ABI) blood pressure comparison is also useful: the ankle blood pressure should be equal to or greater than the arm (brachial) pressure. If these blood pressure comparisons are abnormal, arteriography is indicated.

Classic signs of arterial compromise of an extremity have been described as “the five P’s”: pallor, pulselessness, pain, paresthesias, and paralysis. Additional findings may include tenseness of the extremity, coolness to touch, and delayed capillary refill (greater than 3 seconds). Unfortunately, some of these signs require a patient who can relate these complaints, and many multiply injured patients cannot. In addition, concomitant neurologic injury of the extremity may present with similar findings. Careful examination is necessary to differentiate the paresthesias of vascular insufficiency from those of neurologic injury. As many as 70% of upper and 30% of lower extremity vascular injuries have associated nerve damage, of which 40% to 45% result in permanent deficit.

Doppler examination of distal blood flow can assist in the evaluation of patients with swelling, hematoma, displaced fractures, or obesity. Pulse deficits and limb comparisons can be performed with greater sensitivity using the Doppler device.

Finally, the structural integrity of the skeletal system must be evaluated. About 18% of patients with peripheral vascular injuries have an associated fracture.

A growing body of literature documents the importance and value of the physical examination in determining the presence or absence of a peripheral vascular injury.^{4,5,8}

EMERGENCY DEPARTMENT EVALUATION

The mainstay of evaluation and diagnosis has been contrast arteriography. However, if the peripheral pulse is absent, obvious signs of major vessel injury are present (i.e., pulsatile hemorrhage), or the location of the injury is apparent from physical examination, immediate surgery is indicated and should not be delayed for radiographic imaging unless the location of the vessel injury cannot be determined clinically. Angiography has been used in patients with so-called soft signs of vascular injury and in those with wound trajectories in proximity to a major vessel but without obvious signs of damage. Arteriography is 97% to 99% sensitive in detecting arterial injury.

Digital subtraction angiography has been used with significant success to evaluate vascular injuries. This study may be performed by either intravenous or intraarterial injection. This technique appears to be more sensitive in detecting extravasation of contrast material, whereas conventional arteriography is better for subtle findings, such as intimal disruption. Digital subtraction studies require a cooperative patient who can remain still, as it is very sensitive to motion artifact.

Studies have focused on the need for angiography in patients without obvious physical signs of vessel injury and in those with “proximity” wounds.^{1,2,3,4,5} and ^{6,8,9,11,13,14} Several studies have shown that surgically important lesions in these patients are rare and that most of these patients do not need surgery. Instead of angiography, serial physical examination with measurement of blood pressures in the injured extremity compared with an uninjured extremity^{3,4,5,6,8,9} and ¹⁰ and evaluation with color-flow duplex Doppler ultrasonography^{1,2,7,11,13} have been advocated as the primary methods of evaluation in this select group of patients.

Shotgun wounds to an extremity have a much higher incidence of vascular injury due to the nature of the weapon (i.e., multiple missiles and multiple trajectories).^{3,13} Therefore, more of these patients are likely to undergo an angiographic study.

Each institution should determine in advance how it plans to evaluate patients with potential peripheral vascular trauma by having in place protocols agreed on by the emergency medicine and surgery physician staffs.

EMERGENCY DEPARTMENT MANAGEMENT

Prehospital and emergency department management priorities include control of hemorrhage, fluid resuscitation, and assessment and management of other life threats.¹⁰

Hemorrhage should be controlled by direct pressure over the bleeding site. Blind clamping of vessels deep in a wound is to be condemned, as adjacent structures such as nerves and tendons may be crushed in the attempt to stop bleeding.¹⁰ If a bleeding vessel can be identified and isolated, it may be clamped using a noncrushing vascular clamp. Fluid restoration is accomplished by initiating one or more intravenous lines (as the trauma mechanism and vital signs dictate) and

infusing crystalloid. After bleeding is controlled and resuscitation started, a careful examination for other life-threatening injuries is performed. As with all trauma patients, a patent airway and adequate ventilation must be ensured while circulation is being addressed. Vascular injuries are treated after other potential life threats have been assessed and managed.

Angulated fractures associated with pulse deficits should be anatomically repositioned and splinted. This may restore perfusion to an ischemic extremity.

Blood for type and crossmatch should be sent to the laboratory, and appropriate preparations made for transfusion if blood loss or anticipated surgical needs indicate. Unless indications for immediate surgery are present, rapid diagnosis by means of arteriography should follow.

Tetanus immunization status should be ascertained and the patient immunized, if necessary. Prophylactic antibiotics are indicated when operative repair or vascular grafts are to be undertaken. Anticoagulants should generally not be given until surgical consultation has been obtained, the absence of other major injuries has been determined, and the patient is ready to undergo arterial repair.

DISPOSITION

Surgical consultation must be obtained as early as possible, as the amount of time elapsed from injury until operative repair is a crucial determinant of successful repair and decreased morbidity. Endovascular embolization may be an option for treatment of nonessential vessels in select situations. Observation for a period of 12 to 24 hours is appropriate for patients without obvious signs of vessel injury and normal ABIs. If surgical intervention or arteriography is unavailable in the primary receiving institution, the patient should be transferred, as soon as possible after appropriate stabilizing procedures have been performed, to a facility capable of providing the necessary therapy.

COMMON PITFALLS

Vascular injuries may be subtle in origin and misleading on physical examination. Failure to appreciate injury mechanics or vessel proximity to a penetrating wound may lead to misdiagnosis. Up to 25% of patients may have normal pulses distal to the site of injury, and 16% may have normal physical examinations. Delay in diagnosis of vascular compromise may lead to permanent deficit or loss of the limb.

Approach to Musculoskeletal Injuries

David F. Gaijeski and Joseph Bernstein

[Types of Injury](#)

[Sprain](#)

[Strains](#)

[Contusions](#)

[Fractures](#)

[Subluxations and Dislocations](#)

[Tendinitis](#)

[Chronic Musculoskeletal Pain Syndromes](#)

[Muscle Spasms](#)

[Emergency Department Management](#)

[Disposition](#)

[Common Pitfalls](#)

[Bibliography](#)

Musculoskeletal injuries represent a significant percentage of all emergency care rendered. In a recently completed study by the authors in the emergency department (ED) of a large, urban, teaching hospital, musculoskeletal problems accounted for at least 11% of total patient visits. Clearly, a coherent and systematic approach to patients with orthopaedic injuries and other musculoskeletal complaints is essential. These injuries range from tendinitis, trivial sprains, and contusions to life- and limb-threatening trauma. Often, but not always, acute trauma is responsible for the presenting complaints; and often, but not always, the primary impairment is an inability to move a part of the body without pain or discomfort. The mechanisms of trauma are protean, ranging from sports injuries to assaults to motor vehicle accidents to falls in the home to industrial catastrophes. When acute trauma is absent, overuse syndromes or repetitive movements are often the culprit.

The immediate tasks of the emergency physician evaluating a patient with a musculoskeletal complaint include:

- Correctly determining injuries that need only symptomatic care and those that require more complex, timely intervention
- Differentiating injuries that can be handled solely by an emergency physician (the vast majority of musculoskeletal injuries) from those that require emergent consultation with, or timely referral to, an orthopedic surgeon (e.g., open fractures, compartment syndrome, acute meniscal tears in the young to middle-aged patient, and flexor tendon injuries)
- Formulating a logical, cost-effective algorithm for the diagnosis and management of each patient
- Managing pain early and effectively, recognizing, for example, that “a mere contusion” can be the source of exquisite pain
- Recognizing that care is not complete when emergency care has been delivered; rather, successful management of the patient is only complete when appropriate follow-up has been arranged, as a large percentage of acute musculoskeletal injuries require reevaluation and ongoing care (e.g., physical therapy and rehabilitation) for optimal recovery.

TYPES OF INJURY

Sprain

A sprain is a ligamentous injury. Ligaments link bone to bone. Damage to the fibers of the ligament range from microscopic damage to complete disruption. A sprain can result from an abnormal (nonbiomechanical) force vector applied to a joint, an excessive force applied along a normal vector, or a combination of the two mechanisms. The phrase “just a sprain” is probably best relegated to the past; it is possible to sustain a sprain that is significantly more severe than an analogous fracture. For example, a complete lateral ankle ligament rupture and a transverse avulsion fracture of the distal fibula cause the same pattern of instability, but, because bone regenerates without scarring, the outcome for the latter injury is usually much better. The grading of sprains is based on the severity of the damage:

- *Grade I sprain:* A grade I sprain (in older terminology, “first-degree”) represents microscopic tears of the ligament, which lead to localized hemorrhage and inflammation as the healing process evolves. Active range of motion is usually preserved but painful. Abnormal movement of the joint stabilized by the sprained ligament is not elicited by stress maneuvers, but these maneuvers may produce focal pain and the area overlying the sprained ligament is tender to palpation.
- *Grade II sprain:* In a grade II sprain “second-degree”, or partial tear, the overall architecture of the ligament is preserved, with the majority of fibers still in continuity, but some of them have been completely ruptured. Hemorrhage is more extensive and swelling is pronounced. Loss of function secondary to decreased and painful range of motion is the hallmark. When the joint that the ligament stabilizes is stressed, there may be some gapping of the joint, or abnormal motion. However, frank instability does not occur and a clearly defined end point is reached.
- *Grade III sprain:* A grade III sprain “third-degree” denotes a complete tear of the ligament and is synonymous with a complete rupture. Hemorrhage is more extensive and healing involves the formation of scar tissue in the area between the fragments of the ligament. Stressing the joint reveals greater gapping than in the case of a grade II sprain, and frank instability without a well-defined end point may be elicited. This frank instability can be summed up by the examiner’s thought, “I should stop stressing this joint, as it isn’t going to resist my efforts.”

Common ligament sprains seen in the ED include lateral ankle sprains, injuries to the anterior cruciate and collateral ligaments of the knee, and ligamentous injuries of the shoulder, associated with either glenohumeral dislocations or acro- mioclavicular separations.

The clinical signs of a sprain typically include point tenderness to palpation, swelling, painful and/or decreased range of motion, and ecchymosis. A complete sprain, with no fibers in continuity, may be completely pain-free when stressed. Often, athletes will continue play after a grade III sprain of the medial collateral ligament of the knee, but it is rare that they continue activities after a grade II sprain. In fact, pain may be inversely proportional to the severity of the injury: A grade I sprain is extremely painful when stressed, as there are many intact but damaged and inflamed fibers that will be stretched, triggering the discharge of pain fibers as the ligament is loaded with force; with a grade III sprain, the same maneuver does not cause any stretching of the ligament, as it cannot be loaded by force and the only pain fibers triggered by the stress maneuver will lie in surrounding soft tissue. Bone can be injured at the same time as a ligament is damaged; for example, grade III sprains of the medial, deltoid ligament of the ankle are often accompanied by fibula fractures. Bony evidence of sprains on x-ray includes small avulsion fractures at the point of insertion of the ligament into the bone, impaction injuries, and simple joint-space widening. Thus, in many instances, radiographs are appropriate when a ligamentous injury is suspected.

Strains

Tendons connect muscles to bone. A strain is an injury to the musculotendinous unit, which can range from mild “pulled muscles” to complete tendon ruptures. The mechanisms of injury are twofold: (1) stretching a muscle beyond its normal range of motion by forced extension (an “overstretching injury”) and (2) tearing of muscle or tendon fibers by a violent, uncontrolled contraction or repetitive, prolonged contractions, often in attempted compensation for an unexpected change in direction of movement, unanticipated variations in terrain, or a sudden force applied to the antagonist muscle group (an “overexertion injury”).

Strains are graded from first-degree to third-degree, reflecting the severity of damage:

- In a first-degree strain, microscopic damage occurs to the muscle or tendon, with associated localized hemorrhage, inflammation, and tenderness to palpation. Active range of motion is often unrestricted, but pain can be elicited by resisted contraction or forced extension of the muscle group.
- A second-degree strain involves more severe damage, with rupture of some fibers of the muscle or tendon. Hemorrhage is usually visible, swelling more severe, and range of motion limited by pain.
- In a third-degree strain, the muscle or tendon is completely ruptured. The rupture can occur in the muscle belly, at the musculotendinous junction, within the tendon itself, or at the point of insertion of the tendon into bone.

Common strains seen in the ED include those to the quadriceps, hamstring, and rotator cuff muscles; “groin pulls”; and Achilles tendon ruptures.

The clinical signs of a strain include pain, ecchymosis, edema, and decreased or painful range of motion. With complete disruption of the muscle or tendon, a palpable defect is often present. Physical examination should include inspection of the injured area, observation of active and passive range of motion, palpation of the affected area, and provocative maneuvers—either resisted contraction or passive stretching—to elicit the location and extent of injury. In addition, with certain suspected injuries, specific tests should be performed. For example, if an Achilles' tendon rupture is suspected, then Thompson's test is performed. While the patient lies prone with his or her foot and ankle hanging off the end of the examination bed, the examiner squeezes the calf on the affected side and observes whether the foot plantar-flexes in response to the calf being squeezed), the presence of plantar flexion indicates an Achilles' tendon that is at least partially intact.

Contusions

A contusion is a bruise caused by a direct blow to a body part. Contusions can occur to bone, with significant pain from periosteal bruising, or, more commonly, to soft tissue, especially fat and muscle. In these crush injuries, the degree of injury is proportional to the force of the blow and the surface area of impact; tissue damage occurs as the energy transmitted by the impact dissipates into or is absorbed by surrounding structures.

Fundamentally, *the diagnosis of contusion is one of exclusion*, with fracture, sprain, and strain being the most important diagnoses that must be eliminated. Common contusions seen in the ED include bruised quadriceps muscles, rib cage contusions, contusions of the ulnar aspect of the forearm in “defensive maneuvers” during an assault, and direct blows to the anterior tibia.

Either the blow itself or the body's reaction to it causes signs and symptoms that prompt the patient to seek emergency care. Typically, they include pain, swelling, ecchymosis, and decreased range of motion of the affected part.

Usually, the entities that are ruled out (e.g., fracture, sprain, and strain) are potentially more serious than the diagnosis of contusion itself, but the clinician must remember that contusions can lead to serious complications, including severe pain, rhabdomyolysis, compartment syndrome, and *myositis ossificans*.

- **Severe pain:** One of the most common reasons that patients seek reevaluation in an emergency room is inadequate analgesia following a soft-tissue injury. Initial attention to adequate analgesia ensures patient comfort and decreases the incidence of reevaluation.
- **Rhabdomyolysis:** Severe muscle breakdown can occur after strenuous exercise without an acute, isolated injury or after a significant contusion to an extremity. Rhabdomyolysis consists of the destruction of the integrity of the cell membranes of myocytes. The subsequent release of intracellular contents, including potassium, myoglobin, uric acid, phosphate, and the enzyme creatine kinase, into the bloodstream results in a number of systemic complications, including metabolic abnormalities and acute renal failure. The emergency physician must assess the extent of tissue involvement, the degree of tissue destruction, and the potential for systemic complications. If rhabdomyolysis is suspected, urinalysis for evidence of myoglobinuria (dipstick positive for blood without microscopic evidence of erythrocytes) should be performed and the level of serum creatine kinase checked. (Please see [Chapter 179](#) for details.)
- **Compartment syndrome:** Compartment syndrome occurs when pressure within soft tissues in a fixed body compartment increases to the point at which it compromises venous blood flow and limits capillary perfusion, leading to muscle ischemia and necrosis. Most commonly associated with long-bone fractures, it can occur in the setting of severe contusion or excessive exertion and must be considered in any patient with pain out of proportion to physical findings or with swelling causing obvious tautness in a nonexpandable compartment, such as the anterior tibial compartment. When this diagnosis is considered, it must be objectively ruled out by manometry. (Please see [Chapter 122](#) for details.)
- **Myositis ossificans:** Severe hemorrhage into a muscle can initiate a cascade of “healing,” which can lead to the formation of ectopic bone within the muscle. A large number of these cases have occurred in athletes treated with early, aggressive nonsteroidal antiinflammatory drugs (NSAIDs), heat, massage, and physical therapy in the hope of facilitating early return to athletic competition. This is of concern to the emergency physician for a number of reasons. If severe quadriceps tear and resultant hemorrhage and ecchymosis are suspected, the initial management should include ice, a brief period (24 hours) of immobilization in a stretched position (knee flexed to 120 degrees for severe quadriceps contusion), and acetaminophen, instead of NSAIDs, for pain control. This regimen limits the ongoing bleeding and inflammation in the area. These patients must be referred for appropriate long-term follow-up care. In addition, a patient's complaint of decreased range of motion, ongoing pain, and a mass or firmness in soft tissue weeks to months after sustaining a contusion should suggest the possibility of *myositis ossificans*. A soft-tissue x-ray is the best way to evaluate for heterotopic bony formation. If heterotopic bone is present, the patient should be referred to an orthopaedic surgeon for close follow-up care and potential resection of the bone when it has matured (usually at 9 to 12 months).

Fractures

Most fractures require urgent medical attention, and without appropriate emergency care, many will not heal properly or healing will be accompanied by unnecessary complications. A *fracture* is defined as a partial or complete break in a bone. Bone is unique in that it is the only tissue in the human body, other than the liver, that heals by regeneration, not by scarring. For regeneration to occur, however, the bone must be immobilized to allow uninterrupted formation of new bone. Ensuring appropriate immobilization is one of the fundamental tasks of the emergency physician when dealing with musculoskeletal problems.

The process of new bone formation begins with hematoma bridging the realigned fracture fragments. Hematopoietic cells in the hematoma secrete growth factors, which stimulate the formation of granulation tissue at the fracture ends, resulting in slow resorption of the hematoma. Over the next several weeks, a primary callus is formed, beginning as a soft callus and progressing to a hard callus. The final phase of healing is remodeling, during which the bone reassumes its original architecture as it is exposed to the normal stresses of weight bearing and movement.

Fractures also require immediate attention for several other reasons: Virtually all fractures are painful; the vast majority of them result from high-energy trauma (relative to sprains, strains, and contusions) and, because of force vectors, are accompanied by well-known associated injuries (e.g., 15% of calcaneal fractures sustained in a fall from height have associated lumbar vertebral fractures); and many fractures place the patient at risk for specific complications (e.g., compartment syndrome in long-bone fractures, blood loss in pelvic fractures, avascular necrosis in scaphoid fractures of the hand).

A working knowledge of the nomenclature of fractures is essential to the successful management of fractures in the ED, and to clear communication with radiologists and consulting orthopaedic surgeons. Adequate description of a fracture includes whether it is open or closed, the bone(s) involved, the location within the bone, the direction of the main fracture line, the number of fragments, the alignment of the fracture fragments, the displacement of the fragments, various additional descriptive modifiers, and notation of associated complications.

Closed Versus Open Fractures

The old terminology of simple (closed) and compound (open) is best abandoned. In a closed fracture, the skin and soft tissue overlying the fracture have not been violated; therefore, no communication exists between the outside environment and the fracture fragments. Any break in the skin overlying a fracture must be considered an open fracture until proven otherwise. It may be difficult to tell whether there has been actual communication between the bone and the environment or whether the patient has simply sustained an abrasion (from the trauma that caused the fracture) to the skin overlying the fracture.

Open fractures are traditionally classified into three types based on the size of the wound and the amount of soft-tissue injury. Type I wounds are less than 1 cm long, the energy dissipated by the mechanism of injury is low, and there is minimal soft-tissue trauma. Type II wounds are less than 10 cm long, the mechanism of injury has dissipated a low or moderate amount of energy, and there is moderate soft-tissue trauma but no gross contamination of the wound, major crush injury, or soft-tissue defects or flaps. Type III wounds are greater than 10 cm long. These include high-velocity gunshot wounds, close-range shotgun wounds, open fractures with major vascular injuries, fractures more than 8 hours old, or open fractures sustained in environments where exposure to fecal contents is a concern (e.g., barnyard accidents), or extensive soft-tissue or periosteal stripping of bone, or evidence of gross contamination or significant crush injury.

Open fractures are orthopedic emergencies and require immediate control of hemorrhage; splinting, with reduction if neurovascular compromise exists; copious irrigation; early administration of sufficient analgesia and appropriate antibiotics; tetanus prophylaxis; and emergent consultation with orthopedic surgery for definitive irrigation, debridement, reduction, and fracture repair. Early intervention is the best way to prevent complications; the incidence of infection following open fracture is directly proportional to the time from injury to definitive irrigation and debridement.

Bone Involvement and Location within Bone

The description of the injury should include the side of the body, the specific bone, and the location within the bone. By convention, long bones are divided into proximal, middle, and distal thirds, and these divisions are used to describe the fracture location. If the fracture lies at the junction of any two thirds of the bone, it should be described as such.

Direction and Description of Nature of Fracture

The *direction* of a fracture refers to the configuration of the fracture—the way the fracture disrupts the bone. Convention stipulates that this descriptive modifier communicates the direction of the fracture in relation to the long axis of the involved bone ([Fig. 111.1](#)). A *transverse* fracture disrupts the bone perpendicular to its long axis; an *oblique* fracture lies at an angle to the long axis of the bone; a *spiral* fracture results from a rotational force and spirals around the center of the long axis of the bone.

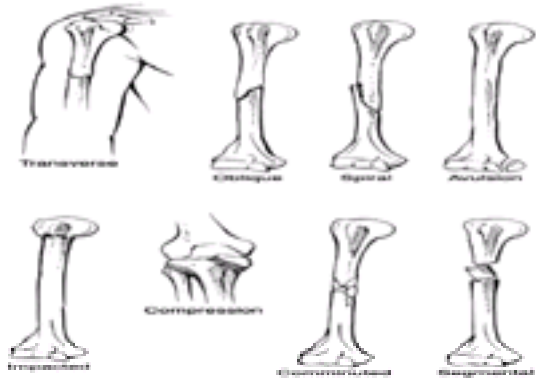

Figure 111.1. Fracture configuration.

Additional terms used to describe the configuration of a fracture include *comminuted*, referring to a fracture in which there are three or more fragments; *segmental*, referring to the presence of two or more fractures in a bone, creating at least one segment of bone that is not connected to either end of the bone; *avulsion*, referring to a piece of bone that is pulled off at the site of insertion of a tendon or ligament; *impacted*, referring to the fractured surfaces of the bone being forced into each other, foreshortening the bone; *compression*, referring to a fracture in which the trabeculae of the bone are compressed, decreasing the overall volume of the affected part of the bone. Avulsion fractures are usually the result of traction injuries. Their presence indicates potential instability at the joint, which is caused by the loss of stabilization normally provided by the avulsed ligament or tendon. On computed tomography (CT) scan, impacted fractures are often comminuted with numerous small fragments wedging across the main fracture line.

Alignment of Fracture

A fracture is also described in terms of its alignment—the relationship of the fracture fragments to each other. The fracture may be *displaced*, *angulated*, or *rotated*.

A fracture is *displaced* if the fragments are offset in a transverse or longitudinal plane. The position of the distal fragment in relation to the proximal fragment is described, and the distal fragment may be displaced anteriorly, posteriorly, medially, laterally, radially, ulnarly, proximally, or, less frequently, distally, among other possibilities. The amount of displacement is commonly measured in terms of the width of the fractured shaft, using fractions of the width in the description.

A fracture is *angulated* if there is a deviation from the normal relationship of the bony fragments along the longitudinal axis of the bone ([Fig. 111.2](#)). The direction of angulation may be described in two ways. It may be described in terms of the direction of the apex of the angle formed at the fracture site by the two main fracture fragments: The apex may point anteriorly, posteriorly, laterally, or medially. The direction of the apex may also be described by other adjectives, including ulnarly, radially, dorsally, or volarly, depending on the involved bones. A second way to describe the angulation of the fracture is in terms of the relation of the distal fragment to the proximal fragment. If the distal fragment is angled away from the midline of the body, there is *valgus* angulation (the fracture is in valgus); if the distal fragment angles toward the midline, the fracture is in *varus* (there is varus angulation to the distal fragment).

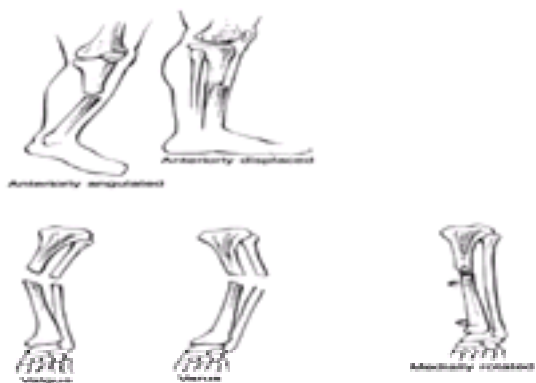

Figure 111.2. Fracture alignment.

Rotation refers to twisting of the distal fragment in relation to the proximal fragment around the center of the long axis of the fractured bone. When viewed along the long axis of the bone from the most distal point on the bone, if the distal fracture fragment has rotated toward the midline in relation to the proximal fragment, it is *medially rotated*; if it has rotated away from the midline, it is *laterally rotated*.

Other Descriptive Modifiers

An *incomplete* fracture involves only one cortex of the bone; a *complete* fracture disrupts both cortices. A *pathologic* fracture occurs in an area of abnormal bone, weakened by disease or prior trauma, and is often the result of apparently trivial trauma or a biomechanically routine force applied along a natural vector. Pathologic fractures occur at sites of old fractures, through primary osteosarcomas, at sites of tumor metastases, near cysts, and in bone weakened by Paget disease, rickets, osteomalacia, tuberculosis, osteomyelitis, chronic steroid therapy, anorexia, and many other disease processes. A *stress* fracture is the result of the bony cortex becoming fatigued by repeated low-level loading rather than disrupted by one acute episode of trauma. The repeated stress to the cortex causes bone resorption, is manifest clinically as pain with activity and tenderness to palpation over the affected bone, and may result in overt fracture if adequate healing is not allowed. Eating disorders and amenorrhea predispose to stress fractures in female athletes. Stress fractures are most common in the proximal tibia but have also been described in the spine, pelvis, femur, tarsal navicular, metatarsals, and sesamoid bones, among other sites.

Complications of Various Fractures

No assessment and description of a fracture is complete without a thorough assessment for, and identification of, possible associated complications ([Table 111.1](#)).

Well-recognized complications of fractures are suggested by the site of the fracture and the mechanism of injury.

Vascular injuries	Ischemic necrosis
Nerve injuries	Delayed union
Compartment syndrome	Nonunion
Infection	Malunion
Shock	Joint stiffness
Cast-induced injuries	Posttraumatic arthritis
DVT	Reflex sympathetic dystrophy
Fat embolism	

TABLE 111.1. Complication of Fractures and Dislocations

Blood Loss and Shock. Bone has a generous blood supply, and fractures can disrupt the blood vessels, causing localized bleeding. If this bleeding results in the loss of a significant percentage of the patient's blood volume, hypovolemic shock can result. Rarely, exsanguination occurs. An isolated long-bone fracture is rarely the cause of shock, with a unilateral tibia and fibula fracture typically resulting in loss of around 500 mL of blood; certain femoral fractures can have 3 or 4 U of blood loss into the thigh, producing class III shock. Hemorrhagic shock can occur with pelvic fractures, in which typical blood loss is between 1,500 and 3,000 mL. If a bleeding disorder such as hemophilia A, thrombocytopenia, or marked anemia is present, a fracture that typically results in modest blood loss may be the source of life-threatening hemorrhage. This is also true in patients on anticoagulation therapy, and the occasional, isolated long-bone fracture will require the administration of vitamin K, fresh-frozen plasma, and transfusion of packed red blood cells.

Vascular Injuries. Vascular injuries occur most commonly in open fractures, widely displaced fractures, or fracture-dislocations, and at sites where the vessels lie close to the bone or are held in a relatively fixed position. Vulnerable sites include the popliteal artery at the knee, which may be injured in supracondylar fractures of the distal femur or in fracture-dislocations of the knee; the axillary artery at the shoulder, injured in fractures of the proximal humerus and humeral head; and the brachial artery at the elbow, which is at risk in supracondylar fractures of the distal humerus ([Fig. 111.3](#)). Even at the most vulnerable sites, these injuries are rare, but if they are not diagnosed in a timely fashion, the consequences can be devastating.

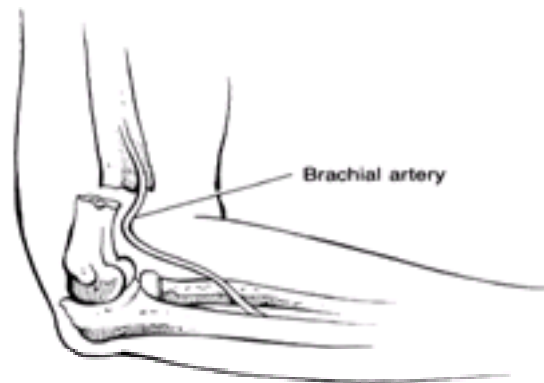

Figure 111.3. Fracture-associated vascular injury.

The classic signs of vascular injury are the “Five P’s”: pain, pallor, pulselessness (or diminished pulse), paresthesia, and paralysis. The Five P’s are present only in a complete injury to the vessel. A partial injury can have subtle clinical signs and symptoms or be completely asymptomatic. In addition, collateral circulation may maintain distal flow around a vascular injury. Vascular compromise may also be delayed, as in the case of an initial vascular intimal injury leading to progressive thrombosis. Therefore, the location of the fracture and the mechanism of injury determine the need to assess for a potential vascular injury in the asymptomatic patient. Initial evaluation should involve assessment of pulses, evaluation with a Doppler stethoscope if palpable pulses are diminished or absent, observation of the color of the distal extremity, and assessment of capillary refill. If vascular injury is suspected, further evaluation with angiogram, magnetic resonance angiography (MRA), or surgical exploration is usually warranted. Complications of fracture-associated vascular injuries include *in situ* thrombosis, false aneurysms, true aneurysms, compartment syndrome, arteriovenous fistulas, and distal limb ischemia with mechanical dysfunction.

Nerve Injuries. Nerves are more frequently injured than vessels in association with fractures and can be damaged by blunt trauma, along the trajectory of penetrating trauma causing an associated fracture, or by the fracture fragments themselves. Nerves are at increased risk of injury when they are superficial to the skin, lie close to the bone, or span the joint, making them susceptible to stretch injury.

The most frequently injured nerves in association with specific fractures include the axillary and musculocutaneous nerves in shoulder fracture-dislocations; the radial nerve in fractures of the distal third of the humerus; the radial, median, and/or ulnar nerves in supracondylar elbow fractures; the median nerve in fracture-dislocations about the wrist; the peroneal and tibial nerves in knee fracture-dislocations; and the peroneal nerve in fractures of the fibular head or proximal fibula (see [Fig. 111.4](#)).

Figure 111.4. Peroneal injury in a knee fracture.

Nerve injuries are classified based on the amount of damage to the nerve according to Seddon's staging system:

- **Neuropraxia:** The most minor injury, neuropraxia involves a contusion to the nerve, with minor injury to the myelin sheath. Sensory loss and transient paralysis may occur, but spontaneous and complete recovery occurs over a period of several days to weeks to, at most, a few months.
- **Axonotmesis:** In axonotmesis, more severe crush injury to the nerve occurs with axonal breakdown followed by distal wallerian degeneration. The epineurium and the continuity of Schwann tubes are maintained. Prolonged paresthesias and muscle weakness are the clinical hallmarks. Recovery can be complete but takes months to years, as the axon has to regenerate proximally to distally, and for functional conduction to occur, the myelin sheath must be fully repaired.

Often, recovery is incomplete or spotty.

- *Neurotmesis*: The most severe form of nerve damage is neurotmesis, with disruption of the axon, epineurium, and Schwann cell sheath or complete severance of the nerve. When complete disruption occurs, all functions controlled by the injured nerve are interrupted.

The emergency evaluation of a nerve injury should involve assessment of motor strength, deep tendon reflexes, light touch, and two-point discrimination. Formal testing can be done by electromyogram (EMG); however, this is rarely necessary in the ED.

Compartment Syndrome. Compartment syndrome (fully discussed in [Chapter 122](#)) should be suspected in long-bone fractures and fractures associated with significant vascular injuries or pronounced swelling, especially when the patient has pain out of proportion to physical examination findings or when paresthesias occur. Manometry must be performed if compartment syndrome is suspected, as the clinical signs are variable and may be delayed.

Infection. Infections occur primarily in open fractures, especially in those in which there is a delay in treatment. Infection can also occur with extensive hematoma, after open reduction, and after internal fixation repair, and may be seen independent of fracture in cases of osteomyelitis, septic arthritis, and abscesses eroding to bone. Septic arthritis should be suspected in the patient with monoarticular arthritis and ruled out in those patients with rheumatoid arthritis or gout who present with a swollen, erythematous, hot joint. Aspiration for crystal analysis, Gram stain, cell count, and culture is the standard of care. Many orthopedic surgeons recommend aggressive arthroscopic lavage to prevent destruction of the joint space by bacteria and inflammatory-mediated damage. Lavage can be performed in the emergency room if other options are not available, utilizing an influx catheter for the delivery of sterile saline and an outflow catheter for the removal of the irrigation fluid along with the pathologic contents of the joint space.

Casts and Splints. Immobilization devices may cause postinjury problems. They may become too tight as swelling increases during the first 24 to 48 hours postinjury and cause pain and impair circulation. Pressure sores may occur on the skin in areas where a cast or external fixation device exerts localized excessive pressure (e.g., over the heel in a patient with a bimalleolar fracture). Immediate steps should be taken to correct the problem. A cast that is too tight can be split lengthwise; the underlying padding can then be cut and the cast spread open. A cast that is pressing on a particular site can have a window cut out. The window may be replaced more loosely with plaster or covered with soft dressing. An ill-fitting splint can be trimmed.

Deep Venous Thrombosis. A deep venous thrombosis (DVT) is a clot that forms in one of the deep veins of an extremity, usually a leg. When a lower extremity DVT propagates above the popliteal fossa, the patient is at risk for having a piece of clot break free and flow up the inferior vena cava to the pulmonary circulation, with the potential to cause respiratory distress, hypoxia, pleuritic chest pain, circulatory compromise, syncope, and death. (Upper extremity DVTs are responsible for a much lower incidence of pulmonary emboli [PEs], and the clot burden associated with these PEs is much lower. Nevertheless, upper extremity DVTs should be diagnosed and treated aggressively, usually with anticoagulation therapy.) When a patient develops signs and symptoms suggestive of a DVT or PE, including calf or arm swelling, erythema, induration, pain on ambulation, a palpable cord in the calf, shortness of breath, tachycardia, hypoxia, or pleuritic chest pain, duplex Doppler of the affected extremities, impedance plethysmography (IPG), and ventilation–perfusion scanning (V/Q scan) should be performed as indicated.

Fat Emboli Syndrome. Single or multiple long-bone fractures in the young and hip fractures in the elderly predispose to fat emboli. Twenty percent of patients with pelvic or long-bone fractures have detectable fat droplets in their blood. The vast majority of these patients remain asymptomatic. Fat emboli syndrome is the most common form of nonthrombotic embolism and has a characteristic clinical course. Its etiology is unclear, but three main hypotheses have been postulated: (1) After fat droplets enter the bloodstream, the liberation of free fatty acids from marrow fat by circulating lipase causes a toxic vasculitis and capillary leak syndrome; (2) it is the end result of extensive platelet–fibrin thrombosis; and (3) it results from direct obstruction of distal vascular lumen by fat emboli. Clinically, a fracture is sustained, and the patient often remains asymptomatic, other than the fracture and associated pain, for 12 to 36 hours before suddenly and unexpectedly developing a life-threatening syndrome characterized by rapid cardiopulmonary and neurologic deterioration, including agitation, hallucinations, delirium, coma, hypoxia, dyspnea, tachypnea, and tachycardia. If this deterioration is not quickly reversed, refractory hypotension, anemia, thrombocytopenia, disseminated intravascular coagulopathy (DIC), and adult respiratory distress syndrome (ARDS) often ensue, with an associated high morbidity and mortality.

Ischemic or Avascular Necrosis. Ischemic or avascular necrosis is characterized by bone death that occurs following the interruption of blood supply to bone. Avascular necrosis is most frequently associated with carpal scaphoid fractures, lunate dislocations, hip dislocations, femoral neck fractures, and complex fractures of the talus.

Delayed Complications. Other complications of fractures may occur some time after the initial injury is seen by the emergency physician. Many fractures require reduction of the displaced fracture fragments in the ED or the operating room. The goal in reduction is always to reestablish anatomic position; eliminate displacement, angulation, and other forms of malalignment; and immobilize the broken bone in the reestablished anatomic position to promote healing. Sometimes, this ideal condition is not achieved and the systematic progression from hematoma to callus formation to bony union is delayed or interrupted. *Delayed unions* are fractures that take longer than usual to heal; *malunions* are fractures that heal in a faulty position; *nonunions* occur when the process of fracture healing stops before the fracture is united.

Joint stiffness, posttraumatic arthritis, and reflex sympathetic dystrophy (RSD) may also occur as delayed complications of extremity trauma. For example, any intraarticular fracture of a weight-bearing joint predisposes the patient to early degenerative changes, and the patient may present to the ED years after a fracture, complaining of *perceived* sudden onset of joint pain and decreased range of motion. Radiographs typically demonstrate extensive *osteoarthritis*.

RSD, formerly known as *causalgia*, is a three-stage, posttraumatic syndrome of unclear etiology, the development of which has no correlation to the severity of the initial injury. The first, or early, stage, characterized by continuous burning and aching in the posttraumatic extremity, is exacerbated by weight bearing and by movement. After a variable period of time, the middle, or dystrophic, stage ensues, characterized by the development of shiny, cool skin over the affected extremity and a progressively decreased range of motion. In the final, or atrophic, stage, the skin atrophies, the muscles waste, and flexion contractures develop.

In 1992, Gibbons and Wilson, in the *Clinical Journal of Pain*, developed an RSD score, which was proposed as a strict system for the clinical diagnosis of RSD. The scoring system consists of nine criteria and has more than academic interest, as early diagnosis improves outcome, interrupting the progression from burning to dystrophy to atrophy. The nine criteria are (1) allodynia—the phenomenon whereby pain is increased by stimuli that activate the involved nerve, such as a breeze blowing on the area, temperature changes, or emotional outbursts—or hyperpathia; (2) burning pain; (3) edema; (4) change in color or hair growth in the affected area; (5) change in sweating; (6) change in temperature; (7) demineralization of bone in the involved limb, as documented in radiographs; (8) quantitative measurements of vasomotor disturbances; and (9) a triple-phase bone scan consistent with RSD. A score of five points qualifies as a clinical diagnosis of RSD, with one point being given for each positive criterion, zero points for each negative criterion, and one-half point for each equivocal criterion. Application of heat or cold, exercises, early sympathetic blockade, or sympathectomy to the affected limb can halt the progression to atrophy. A minority of patients have been helped by a short course of high-dose prednisone (a 3-week taper) in conjunction with heat, cold, and exercise therapy.

Subluxations and Dislocations

Acute or chronic ligamentous laxity or tearing can result in subluxation or dislocation of a joint. Chronic ligamentous laxity is usually the result of an overuse syndrome, in which repetitive microtrauma leads to an attenuation of the static restraints of the joint; acute ligamentous tears are the result of excessive or abnormal forces applied to the joint. The classic example is subluxation or dislocation of the glenohumeral joint. Subluxation occurs when one bone becomes partially disarticulated from the other bone that forms the joint. The articular surfaces forming the joint remain partially intact. Dislocation occurs when the bones are completely disarticulated and no parts of their articular surfaces are in contact. Dislocations can occur in isolation or with an associated fracture ([Fig. 111.5](#)). Often, the fracture is anatomic evidence of the direction of the pathologic force vector resulting in the dislocation. For example, 90% to 95% of shoulder dislocations occur anteriorly, disrupting the continuity of the anterior capsule and the labrum. Sometimes, these structures resist the forces producing dislocation to the point that a fracture occurs, avulsing a piece of bone from the anterior glenoid rim, known as a bony Bankart lesion.

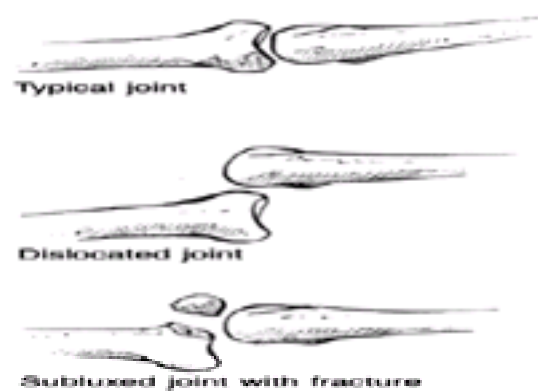

Figure 111.5. Joint subluxation and dislocation.

The nomenclature of subluxations and dislocations is straightforward. Most subluxations and dislocations occur at a joint formed by two bones, and the subluxation or dislocation is named after the affected joint (e.g., posterior dislocation of the distal interphalangeal (DIP) joint of the fourth finger of the right hand). If a joint is formed by three bones, and the two major bones are disarticulated, the subluxation or dislocation is named after the joint involved (e.g., posterior dislocation of the knee). If the joint is formed by three bones, and the minor bone is subluxed or dislocated, the abnormality is named after the minor bone (e.g., lateral dislocation of the patella). As for fractures, direction is assigned referential to the distal segment.

Specific subluxations and dislocations are frequently seen in the ED and need to be skillfully and efficiently reduced, with restoration of anatomic position, by the emergency physician. These include anterior and posterior dislocations of the shoulder joint; anterior and posterior dislocations of the sternoclavicular joint; posterior dislocations of the elbow joint; posterior dislocations of the proximal interphalangeal (PIP) and DIP joints, often with accompanying avulsion fractures; posterior dislocations of the hip joint; posterior dislocations of the knee joint; lateral dislocations of the patella; and fracture–dislocations of the ankle.

The hallmarks of subluxations and dislocations are pain, deformity, and decreased range of motion. Certain dislocations are associated with specific complications, and these must be ruled out in the evaluation and treatment of the injury. For example, the aorta and trachea are at risk in posterior dislocations of the sternoclavicular joint, and injury to them can lead to rapid respiratory compromise or intrathoracic hemorrhage; the axillary nerve and, less commonly, the musculocutaneous nerve are at risk in anterior shoulder dislocations, and their function must be clearly assessed prior to any attempted reduction and then reassessed after the reduction is complete; the popliteal artery can be stretched, torn, or completely disrupted in a posterior dislocation of the knee, and many experts recommend angiogram followed by close observation in any knee dislocation. Radiographs should be obtained prior to attempts at reduction, and after the reduction has been achieved, to document the position of the bones, restoration of anatomic position, and the presence of associated fractures.

Techniques for the reduction of specific joints are discussed in the chapters dedicated to those joints, but certain principles hold true for all subluxations and dislocations: Increasing length of time between injury and relocation corresponds proportionally to the severity of spasm and swelling that will occur and the difficulty involved in reducing the joint; adequate pain control and sedation facilitate smooth reduction; excess force applied during the reduction can result in fractures, nerve damage, and vascular injury; the technique used to reduce the dislocation should initially replicate the mechanism of injury to release the dislocated bone from the anatomic structure that is keeping it dislocated; in certain dislocations, the incidence of delayed complications is directly proportional to the time from injury to relocation. For example, avascular necrosis of the femoral head occurs in 10% to 20% of hip dislocations, and the rate is directly proportional to the total time from injury to successful reduction; similarly, myositis ossificans is a well-recognized complication of posterior dislocation of the elbow, and its incidence is directly related to three variables: the number of attempts at reduction, the length of time from injury to successful reduction, and whether the joint is adequately immobilized after reduction.

TENDINITIS

Tendinitis can be viewed as a subset of strain because it is an injury to the musculotendinous unit, but it is better viewed as a separate entity. Tendinitis differs from strain in that the inflammation is *isolated* to the tendon and *involves the insertion of the tendon into the bone*, which occurs via a transitional, calcified fibrocartilage known as Sharpey's fibers. Tendinitis can result from chronic use or from one acute episode of overuse. In acute inflammation, the tendon is irritated and an acute inflammatory response occurs, initiated by fibroblasts within the tendon and perpetuated by the migration of macrophages into the tendon tissue and their fundamental role in the prostaglandin-mediated healing process; with repeated irritation, signs of chronic inflammation develop, including the continued migration of macrophages to the site of injury, influx of plasma cells into the tendon matrix, phagocytosis of debris, and a cellular pre-dominance of lymphocytes within the tendinous fibers occurs. If this cycle is not interrupted, permanent changes in the architecture of Sharpey's fibers and atrophy of the tendon fibers occur.

Common tendons involved in acute or chronic tendinitis presenting to the ED include patellar tendinitis, quadriceps tendinitis, rotator cuff tendinitis, Achilles' tendinitis, lateral epicondylitis of the elbow, and de Quervain's stenosing tenosynovitis of the first dorsal compartment of the wrist (the abductor pollicis longus and extensor pollicis brevis tendons).

Clinically, tendinitis presents with pain during active range of motion, loss of function, point tenderness over the affected tendon near its insertion in bone, and, often, localized edema and erythema. Forced contraction of the affected muscle against resistance elicits pain, which is exacerbated by pressure over the point of insertion. Pain can also be elicited by forced extension of the tendon, stretching the inflamed fibers. Calcific tendinitis is a different entity. It is usually associated with chronic inflammation and consists of calcium deposition within the body of the tendon. It is often an indication of tendinous degeneration altering the macrostructure of the tendon. Calcific tendinitis has a characteristic radiographic appearance, revealing the calcium depositions within the tendon; for example, a band of calcification can be seen passing over the bicipital groove in calcific biceps tendinitis at the shoulder.

Chronic Musculoskeletal Pain Syndromes

In a recent study conducted in the emergency room of a tertiary care hospital in an urban setting, 10% of all patients presenting for evaluation and treatment of a musculoskeletal complaint sought treatment for a chronic musculoskeletal pain syndrome. These patients accounted for 1% of total ED visits; the primary reason for their presentation to the ED was dissatisfaction with their current level of pain control. In some instances, patients such as those in the study are obviously undermedicated and can be easily helped; in other cases, they are already on one or more powerful analgesics, and addressing their complaints can be a difficult, potentially frustrating therapeutic encounter for the emergency physician; and another group of patients will raise concerns about physical and psychologic dependence on narcotics—they often have multiple drug allergies and often present to the ED late at night or on weekends when their regular doctors are “unavailable.”

When patients with chronic musculoskeletal pain syndromes are followed at your institution and their x-rays, reports of other imaging studies, laboratory values, and management plans can be reviewed, their ED management is often straightforward. If they are followed at outside institutions, it can be a daunting challenge to adequately assess their pathology; decide when repeat imaging studies are necessary; ensure that they have not been misdiagnosed, that a complication has not been overlooked, or that a significant progression in their pathology has not occurred; and successfully treat their pain while continuing to orchestrate patient flow in a busy ED. Often, allowing them a *reasonable but finite period of uninterrupted time to “tell their story”* is the most efficient way to approach a new patient presenting with chronic pain. Knowing when to redirect their thoughts and concerns is a learned art that requires sensitivity and confidence.

Muscle Spasms

Muscle spasms are a poorly understood phenomenon in which a voluntary muscle undergoes sustained involuntary contraction, leading to depletion of stored glycogen, localized build-up of lactic acid, and severe pain. The causes of muscle spasm are not known, but hypotheses include localized alterations in blood flow, regional or systemic electrolyte imbalances (especially sodium and calcium; less often, potassium), and postural abnormalities that place a bone in a nonanatomically neutral position, causing attached musculature to fire continuously. For example, overdevelopment of the muscles on one side of the body in a racquet-sports athlete can cause latissimus dorsi spasm, as the proprioceptors present in the latissimus sense that the arm is out of the neutral position and cause repetitive muscle

contraction in attempted compensation.

Muscle spasms typically seen in the ED include spasms of the gastrocnemius, levator scapulae, trapezii, rhomboids, and latissimus dorsi. Rectus abdominus muscle spasm can mimic an acute abdomen and will respond best to intravenous benzodiazepine therapy.

Treatment includes freezing the muscle belly with fluoroethane spray, followed by passive, gentle, forced range of motion to “break the spasm”; massage; treatment with muscle relaxants, including diazepam and other benzodiazepines; pain control with acetaminophen, NSAIDs, or opioid analgesics; and laboratory evaluation of serum electrolytes, including calcium, sodium, and potassium (which are low yield in most situations). Muscle spasm must be distinguished from myoclonus, as the implications of the two conditions are very different.

EMERGENCY DEPARTMENT MANAGEMENT

The ED management of any injured patient begins with the basic ABCs: airway, breathing, and circulation. In the conscious, cooperative patient who, for example, sprained his ankle playing basketball, evaluation of the ABCs is routinely done in triage by asking the patient, “Why did you come to the emergency room today?”; listening to his response; noting that his voice is normal and his speech is unlabored; watching him breathe in and out in a symmetric, unlabored fashion; and taking his vital signs—pulse, blood pressure, and respiratory rate. *In other words, in most instances, a simple, human interaction encompasses an adequate primary trauma survey.* When the patient is reliable, not intoxicated, and has an isolated injury, and the mechanism of injury does not suggest other possible injuries that are being ignored by the patient because he or she is distracted by the pain of the obvious injury, evaluation and treatment can be limited to the injured joint along with the joints immediately proximal and distal to the injury (and the contralateral partner of the injured joint or limb for comparison of range of motion, anatomy, and laxity).

In patients with multiple injuries, head trauma, amnesia, intoxication, or medical illnesses resulting in their musculoskeletal injury (e.g., a distal radial fracture after syncope), a complete physical evaluation is mandatory and should follow basic trauma guidelines, beginning with a primary survey, assessing the ABCs; evaluating neurologic disability, including a formal grading of their Glasgow Coma Scale; then continuing with complete exposure of the patient, searching for any accompanying injuries, before systematically evaluating the underlying medical problem that could have produced the trauma (unless it is of significant severity, e.g., a myocardial infarction or arrhythmia, that it is addressed earlier in the primary survey). If a problem is identified, it should be addressed before moving on to the next step in the systematic evaluation. For example, the motorcyclist thrown from the cycle, who presents with an open fracture of the tibia and fibula and flail chest, needs breathing stabilized before the leg is further evaluated. In extremity wounds, hemorrhage can often be rapidly but temporarily controlled with a direct-pressure dressing, ensuring continued circulatory stability until the source of bleeding can be systematically evaluated. After the primary survey, each joint should be palpated and ranged systematically, and the integrity of long bones assessed by inspection, palpation, and range of motion.

As alluded to previously, certain extremity injuries are true orthopedic emergencies, meriting expeditious evaluation and management. These include vascular injuries, compartment syndromes, open fractures and dislocations, and certain dislocated joints ([Table 111.2](#)). They should be addressed immediately after the ABCs have been evaluated, stabilized, and recorded on a trauma flow sheet. To reiterate, if vascular compromise is suspected, immediate consultation with the orthopedic or vascular surgeon is advised. When vascular insufficiency is caused by stretching of the vessel across the site of a dislocation or displaced fracture, reduction of the fracture or dislocation may correct the problem. Pulses must be documented after the reduction. If an injury to the vessel itself is suspected, arteriography, MRA, or surgical exploration may be indicated. In certain instances, Doppler evaluation, followed by close observation with serial neurovascular examinations, is a standard of care. These decisions should be left to the consulting surgeon. Blood flow to an ischemic extremity should, ideally, be reestablished within 6 to 8 hours to prevent permanent injuries, including ischemia and necrosis.

Vascular injuries
Compartment syndrome
Open fractures
Open joints
Dislocated hip

TABLE 111.2. Orthopedic Emergencies

Similarly, if compartment syndrome is suspected, it must be ruled out by manometry. This is usually done through emergent consultation with an orthopedic surgeon. If compartment pressures are elevated, emergent fasciotomy is mandatory.

The initial management of open fractures and joints should be directed toward reducing the chances of infection. Gross particulate debris in the wound should be removed. Exposed bone *should not be replaced in the wound*, because this may further introduce contamination. A sterile dressing should be applied. The extremity is splinted to prevent further tissue and neurovascular injury. Intravenous antibiotic therapy, usually with a first- or second-generation cephalosporin, is instituted (if not contraindicated by drug allergies), and tetanus prophylaxis (sometimes including tetanus immune globulin) given when indicated. (A macrolide antibiotic or trimethoprim–sulfamethoxazole is a good choice for the penicillin-allergic patient.) After these initial management steps have been taken, orthopedic consultation should be obtained. Most open fractures and dislocations require formal debridement in the operating room, which should be performed within 8 hours of the injury. The incidence of infection is directly proportional to the length of time from injury until copious irrigation and formal debridement.

Dislocated hips may later develop ischemic necrosis, and dislocated elbows may later develop Volkmann's ischemic contracture (compartment syndrome, decreased blood flow, necrosis, and contracture following a dislocation). Avascular necrosis of the hip is thought to be caused by damage to the vessels supplying the femoral head. In general, these vessels are not completely torn in the dislocation; rather, they are stretched and blood flow through them is compromised. Therefore, the incidence of avascular necrosis is directly related to the length of time from injury to adequate relocation of the hip. Similar principles apply to the development of Volkmann's ischemic contracture following elbow dislocation. Therefore, reduction should be accomplished as soon as is feasible.

After all life- and limb-threatening injuries have been addressed, attention can be directed toward the management of individual injuries—fractures, dislocations, sprains, strains, tendinitis, and spasm. In the majority of cases presenting to the ED, a brief confirmation of stable ABCs will be followed immediately by an evaluation of the injured joint or extremity. This evaluation begins with a *thorough history*, ascertaining the mechanism of injury, previous injury to the limb, handedness where applicable, and medical problems potentially contributory to current disability. It is not a sufficient history to note that a patient sustained a puncture wound “on the job.” Was it from a nail gun? A high-pressure grease gun? Or a sewing machine? Different mechanisms of injury imply different potential problems. What was the timing of the injury? Has the patient experienced associated symptoms of pain, paresthesia, or weakness, or signs of pallor, deformity, and so forth? *Inspection follows.* Does the injured area appear normal? Is it deformed, swollen, erythematous, ecchymotic? Is exposed bone visible? Is a spot of grease visible at a minute puncture wound? Is purulent fluid draining from a wound? Is there an obvious abrasion, laceration, or puncture wound over the injured area? *Palpation follows.* Is there a palpable deformity? Is tenderness focal or diffuse? Is there edema? Calor? Induration? Palpation must include a careful assessment of neurovascular integrity. Is the injured area dusky or mottled? Are distal pulses intact? Symmetric with the unaffected side? Is capillary refill normal? Is sensation to light touch unaffected? Hypesthesia often occurs over an area of acute injury. Active range of motion should be tested. In the majority of acute injuries, the patient is not enthusiastic about actively ranging the joint, and passive range of motion and provocative maneuvers are of limited utility secondary to pain.

Radiographs are the cornerstone of further evaluation and management of most musculoskeletal complaints. Many fractures can be diagnosed clinically, but, in the vast majority of cases, the diagnosis should be supported radiographically. Radiographs frequently determine the need for operative reduction, the length of time the fracture needs to be immobilized, and potential complications during the rehabilitation process. Criteria for obtaining radiographs of specific injuries are formalized but constantly evolving, and are beyond the scope of this chapter. They are addressed in the chapters on injuries to specific joints. The goals of objective criteria for obtaining radiographs include reduction in unnecessary imaging, increased efficiency of patient flow in the ED, decreased exposure to radiation, and containment of

health-care costs. For example, the “Ottawa Ankle Rules” are objective criteria for obtaining an ankle series after an ankle injury, and state that ankle films are required in patients over 18 years old if pain in the malleolar area is accompanied by inability to bear weight (defined as walking four steps) immediately after the injury and in the ED, or by bony tenderness over the posterior aspect of the distal 6 cm of the medial or lateral malleolus. In a study in the *Journal of the American Medical Association* in 1993, by Stiell et al., strict implementation of the Ottawa Ankle Rules was shown to reduce the number of ankle series ordered by 28%, increase ED efficiency, and decrease ED costs without increasing the percentage of missed fractures.

When the decision is made to obtain roentgenograms, the correct views must be obtained, they need to be of sufficient quality to competently evaluate for fracture, and they need to be read thoroughly, in an unhurried fashion. Poor-quality films should never be accepted. Many fractures have been missed because of technically inadequate films. In addition, thorough examination of the soft tissue and every bone in the x-ray is essential to avoid missing subtle findings that may indicate fracture or dislocation. For example, the fat pad sign on an elbow x-ray may be the sole indication of a radial head fracture.

Other pitfalls in interpretation include the following:

- Misinterpretation of a nutrient foramen, housing a nutrient artery, as a fracture. A nutrient foramen will appear less radiolucent than a fracture (very smooth-edged) and will angle obliquely from the edge of the bone through the cortex, and then terminate without involving the cortex on the other side of the marrow.
- Confusing sesamoid bones or accessory ossicles with fractures. These anatomic variants usually have smooth edges and are well corticated, and no defect in the adjacent bone will be noted. In some instances, a comparison view can help clarify the structure in question. For example, the patient with pain over the patella following a dashboard injury, who is found to have a two-part patella on x-ray in the area corresponding to his clinical pain, may have bipartite patella, which is confirmed by its presence on an x-ray of the unaffected knee.
- Misinterpretation of fat folds, clothing folds, casts, or splints as fractures; misinterpretation of jewelry or body piercings as foreign bodies.

Every x-ray series should include a minimum of two views that are *shot at right angles to each other*. If the plane of the fracture is at 90 degrees (perpendicular) to the plane of the x-ray beam, the fracture may not be evident on that view but would be readily visible on an x-ray taken in a plane parallel to the plane of the fracture line.

Fractures in the shaft of long bones are often accompanied by additional fractures in that bone proximal or distal to the main fracture site or by dislocations at the joints at either end of the bone. Therefore, all long-bone shaft fractures require imaging of the entire length of the bone, including adequate views of its joints. For example, a midshaft femur fracture requires x-rays of the entire shaft, a two-plane knee series, and a two-plane hip series.

Fractures to paired long bones, such as the radius and ulna or the tibia and fibula, present with different associated fractures: A fracture to one bone is sometimes accompanied by a distant fracture to the other bone in the pair. For example, medial malleolar ankle fractures resulting from a lateral twisting mechanism sometimes have an associated proximal fibular or fibular head fracture or dislocation. The mechanism of injury explains this association: The twisting force that breaks the medial malleolus is transmitted up the shafts of the tibia and fibula and is dissipated at the weakest point, the proximal fibula, resulting in either fracture or dislocation. Thus, more complex ankle fractures require imaging of the entire shafts of the fibula and tibia and a two-way series of the knee. For an additional example, certain forearm fractures are commonly associated with a fracture–dislocation of the other bone of the forearm, such as a radial shaft fracture and distal radioulnar joint dislocation, known as a Galeazzi fracture ([Fig. 111.6](#)).

Figure 111.6. Galeazzi fracture dislocation.

Additional views are sometimes helpful. A dedicated scaphoid view can aid in the detection of a subtle scaphoid fracture. An axial view of the calcaneus can reveal a fracture missed on standard ankle and foot series. Many posterior dislocations of the shoulder are not evident, except on an axillary view of the glenohumeral joint, clearly depicting the relationship between the humeral head and the glenoid fossa. In certain instances, comparison views to the patient's other side are helpful. For example, in distal clavicle osteolysis, characterized by pain and osteolysis of the distal clavicle—seen in power lifters and in contact athletes suffering significant blunt trauma to the point (acromion) of the shoulder—bilateral clavicle views help confirm the diagnosis when a larger separation is seen at the affected acromioclavicular joint compared with the unaffected one.

Adequate films, correctly interpreted, are not 100% sensitive for fractures. Nondisplaced, or hairline, fractures often become visible, or radiolucent, only on roentgenograms 7 to 10 days after injury, as bone resorption widens the fracture line, hematoma develops, and new bone formation proceeds. If there is potential morbidity associated with a missed fracture on plain x-rays, a clinically fractured joint should be treated as a fracture, or more sophisticated imaging studies should be obtained, if possible. A patient with a story and an examination consistent with a femoral neck fracture, who has normal plain radiographs and remains non–weight bearing in the ED, needs to be treated as having a nondisplaced hip fracture, kept non–weight bearing, and seen in orthopedics follow up in 7 to 10 days. On the other hand, MRI scan may reveal the fracture, and bone scan can be diagnostic. Similarly, snuff box tenderness (the space on the radial side of the wrist between the extensor pollicis longus tendon and the paired extensor pollicis brevis and adductor pollicis longus tendons) following a *fall on an outstretched hand* (FOOSH) needs to be treated as a scaphoid fracture, *even if the radiographs are normal*. If the radiographs show no fracture, immobilization in a thumb spica with follow-up examination and repeat radiographs in 10 days is mandatory.

DISPOSITION

ED care is not complete when the diagnosis is made. Appropriate immobilization needs to be instituted, and instructions for immediate care and follow-up given. These need to be tailored to the specific injury but, in general, involve rest, ice, and elevation. These simple, cost-effective steps are often overlooked in the rush to discharge patients from the ED and can, in some cases, affect more than the patient's comfort. For example, the simple application of ice to a lateral ankle sprain during the first 24 hours after injury has been shown to decrease time to return of full function by 50%.

Depending on the injury, the patient may be instructed to remain non–weight bearing or keep the injured joint immobilized; in other cases, activity as tolerated is appropriate and may speed recovery (e.g., low-back strain). Pain control must be achieved in the ED, and the pain medications given for the outpatient setting need to be commensurate with the injury. For example, the patient who requires morphine in the ED for a rib cage contusion is mismanaged if he or she is discharged with instructions to take acetaminophen as needed for pain. Adequate postinjury pain control improves outcome and decreases repeat visits to the ED.

Patients should be instructed to return to the ED if they experience any signs or symptoms of neurovascular compromise, excessive pain, coldness, erythema, fevers, chills, cough, pleuritic chest pain, or a cast or splint that feels too tight or causes pain. Appropriate follow-up depends on the nature and extent of the injury and can range from a visit to the patient's primary care doctor in 2 weeks, to orthopedic referral in 10 days' time, to being seen by a hand surgeon in the next few days for operative repair of a flexor tendon laceration.

COMMON PITFALLS

- Ordering the wrong x-ray because of an inadequate physical examination. For example, an x-ray of the ankle might be ordered when the tenderness is actually

over the base of the fifth metatarsal.

- Not recognizing all injuries because the physician's (and often the patient's) attention is focused on one specific injury. For example, the patient who falls off a ladder and presents with a grade II lateral ankle sprain may have a calcaneal fracture from the initial impact, which goes unnoticed because of the obviousness of the ecchymosis and edema accompanying the lateral sprain.
- Acceptance of poor-quality x-rays or relying on a single view without an accompanying view shot at 90 degrees to the initial view. There are well-defined criteria for the radiographic evaluation of different injuries, and these must be strictly adhered to if the physician wants to avoid missed diagnoses.
- In the case of long-bone fractures, failure to include the length of the bone, the joint above, and the joint below in adequately exposed radiographs.
- Failure to rule out infection in a patient presenting with a swollen joint or similar condition, such as olecranon bursitis. It is a mistake to assume that the swollen joint in the patient with a history of gouty arthritis is another flare of gout. With rare exceptions, in a patient presenting with monoarthritis, fluid should be obtained, analyzed for crystals, and sent for cell count, Gram stain, and culture, to confirm the diagnosis and to rule out concomitant infection. In most cases, antibiotics should be initiated until infection is excluded, unless this can be done over the course of a few hours in the emergency room.
- Failure to realize that drops of blood or small abrasions on the skin in the area of a fracture connote an open fracture until clearly proven otherwise.
- Not checking, or documenting, a complete neurovascular examination on initial presentation and after any procedures to reduce a fracture or a dislocation.
- Not obtaining radiographs prior to and/or after the reduction of a fracture or a dislocation to rule out accompanying avulsion fracture from the dislocation or from the reduction procedure. X-rays should not be obtained only when the delay created by x-raying the dislocation or fracture–dislocation could contribute to morbidity. If x-rays are only obtained post-reduction, there is no way to know whether the bony Bankart lesion accompanying the reduced anterior shoulder dislocation was caused by the dislocation or the reduction procedure.
- Attributing pain in an extremity to an unrelated injury. Frequently, when patients develop extremity pain, they try to think of any injury that they have recently sustained and attribute the pain to that injury. The examiner may then be misled into believing that the pain, actually due to an independent condition, such as tumor or septic arthritis, was caused by some unrelated injury. If a patient describes being struck by a vacuum cleaner nozzle over the carpal bones on the dorsum of the hand, but physical examination reveals a boggy, erythematous, warm carpal joint and tenosynovitis, disseminated gonococcal infection must be explicitly ruled out, despite the conflicting history.
- Attributing pain noted after a fracture to the fracture itself, rather than thoroughly investigating other potential sources of pain, such as a cast problem, neurovascular compromise, or compartment syndrome.
- Considering compartment syndrome in the differential of a patient's pain but not formally evaluating for it. Once the physician considers the diagnosis of compartment syndrome, it must be excluded, explicitly, by manometry.
- Suspecting a fracture clinically but not pursuing additional studies when the plain radiographs are normal or not treating the clinical fracture as a fracture on discharge. Assessment of a patient's ability to ambulate is essential prior to discharge, and the inability to ambulate can further confirm the presence of an occult lower extremity fracture.
- Not providing patients with printed or clearly written, simply worded discharge instructions for the immediate management of their injuries and for post-ED follow-up care. Instructions should include specifics about the application of ice, elevation of the injured extremity, analgesia, and weight bearing. Some orthopedic injuries heal well with benign neglect; many have suboptimal outcomes when treated apathetically.

delineate fractures adequately.

Four views of the shoulder are optimal to evaluate the proximal humerus and glenoid joint for fractures and dislocations. The trauma series recommended by Neer ¹² includes an AP view of the shoulder in addition to a transscapular projection commonly known as the Y view. The transscapular view is obtained by placing the radiographic film along the lateral side of the humerus, with the beam projected along the length of the scapula. This view is helpful in identifying shoulder dislocations. In addition to the two-view trauma series, an AP internal rotation view of the humerus and an axillary view permit full evaluation of the shoulder and proximal humerus, including the articular surface.

FRACTURES

Clavicular Fracture

Clavicular fractures are the most common childhood fracture. They are often encountered in newborns secondary to birth trauma. Clavicular fractures account for 5% of all fractures seen for all age groups. Two mechanisms are commonly responsible: (1) force applied directly to the clavicle and (2) force applied to the outer end of the clavicle, which can push the shoulder inward toward the chest, causing a shearing force and fracture of the clavicle. ¹⁴

Evaluation

Most patients have swelling and tenderness over the fracture site. Middle-third clavicular fractures usually result in a downward and inward slump of the involved shoulder due to loss of support.

Management

Eighty percent of all clavicular fractures occur in the middle third. Nondisplaced middle-third fractures in adults have an intact periosteum. These require a sling for support and ice to reduce swelling. Figure-of-eight splints can be used for reduction and maintenance of position for displaced middle-third clavicular fractures in adults and children; however, they show no benefit over a simple sling for fractures in children. Complications of middle-third clavicular fractures include malunion; excess callus formation, resulting in cosmetic defect; and neurovascular compromise. Rarely, nonunion occurs in fractures treated with open reduction and internal fixation.

Fifteen percent of clavicular fractures occur in the distal third. Nondisplaced fractures of the distal clavicle are splinted by the surrounding intact ligaments and muscles. They are usually treated symptomatically with ice, analgesics, a sling, and early motion. Complications include delayed union of displaced fractures treated conservatively, and degenerative arthritis with intraarticular involvement.

Medial-third fractures represent only 5% of all clavicular fractures. Considerable force is required to fracture the medial clavicle, so associated injuries, such as vascular injuries, should be sought. Management includes ice, analgesics, and a sling for support. Displaced fractures require orthopedic referral for reduction. Degenerative arthritis frequently accompanies these fractures.

Proximal Humerus Fracture

Proximal humeral fractures account for 5% of all fractures. They are most common in the elderly. ¹⁹ Anatomically, proximal humeral fractures include all humeral fractures proximal to the surgical neck.

Evaluation

Two mechanisms of injury commonly produce proximal humeral fractures: (1) a direct blow on the lateral aspect of the arm and (2) a fall on an outstretched arm. Patients present with tenderness and swelling over the upper arm and shoulder. Most commonly, the arm is held adducted. Patients who present with the arm abducted have a much higher incidence of neurovascular injury.

Using the Neer classification system for proximal humerus fractures, the proximal humerus is divided into four segments: greater tuberosity, lesser tuberosity, anatomic neck, and surgical neck. ^{12,13} This classification system has both prognostic and therapeutic implications, and depends on the relation of the bone segments involved and their displacement. The Neer system divides the fractures into one-part, two-part, three-part, and four-part fractures, depending on the displacement and angulation of the fracture (Fig. 112.3).

Figure 112.3. Examples of one-, two-, three-, and four-part fractures as described by Neer.

Management

If all the proximal humeral fragments are nondisplaced and without angulation (less than 45 degrees), the injury is classified as a one-part fracture. The humeral fragments are held in place by the periosteum, rotator cuff, and joint capsule. Examples of one-part fractures are a surgical neck fracture with less than 45 degrees of angulation, a nondisplaced anatomic neck fracture, and a nondisplaced greater tuberosity fracture. Therapy for one-part fractures requires immobilization in a sling and swathe and orthopedic referral. Circumduction exercises should begin as soon as tolerated, and should be followed by passive exercise of the elbow and shoulder at 2 to 3 weeks. Shoulder motion exercises can usually be started within 3 to 4 weeks.

Two-part fractures have either a fragment with more than 1 cm of displacement or one with over 45 degrees of angulation to the intact proximal humerus. Surgical neck fractures with over 45 degrees of angulation, and displaced anatomic neck fractures, require immobilization with a sling and swathe and emergent orthopedic referral for reduction. Anatomic neck fractures have a high incidence of avascular necrosis.

The insertions of the supraspinatus, infraspinatus, and teres minor on the greater tuberosity complicate fractures in this region. Displaced greater tuberosity fractures (two-part fractures) are always associated with a tear of the rotator cuff. Greater tuberosity fractures are also seen in about 15% of all anterior shoulder dislocations. ^{5,17} Therapy for displaced greater tuberosity fractures depends on the patient's age. Young patients require internal fixation or excision of the fragment, with repair of the torn rotator cuff. Older patients are usually not candidates for surgical repair and require ice, immobilization with a sling and swathe, and early orthopedic referral. Complications of greater tuberosity fractures include impingement on the long head of the biceps, resulting in chronic tenosynovitis and eventually tendon rupture; nonunion; and myositis ossificans.

Lesser tuberosity fractures commonly occur in conjunction with posterior shoulder dislocations, due to intense contraction of the subscapularis muscle, which inserts on the lesser tuberosity. Management of these fractures includes sling and swathe immobilization. Most orthopedic surgeons recommend 3 to 5 days of immobilization, followed by gradually increasing range-of-motion exercises. Some orthopedists prefer surgical fixation, so early consultation is advised.

Combination fractures—Neer three- and four-part fractures—result from severe forces. Three-part fractures involve two fragments that are individually displaced from the proximal humerus. Four-part fractures involve three fragments individually displaced from the remaining proximal humerus. Combined proximal humeral fractures are associated with shoulder dislocations, rotator cuff injuries, and neurovascular compromise. Therapy includes sling immobilization and emergent orthopedic referral. These complex injuries usually require admission. Virtually all combined fractures require surgical repair. Many four-part fractures require the insertion of a prosthesis, as a high incidence of avascular necrosis of the humeral head occurs secondary to compromised blood supply.

Articular surface fractures, also referred to as impression fractures, often result from direct trauma to the lateral arm. Fractures that involve less than 20% of the joint surface can be treated with sling and swathe immobilization in external rotation and early referral. Fractures involving more than 20% of the joint surface require surgical repair, and possibly prosthesis insertion. Complications of these fractures include joint stiffness, arthritis, and avascular necrosis with severely comminuted fractures.

Scapular Fractures

Scapular fractures represent only 1% of all fractures, and 5% of fractures involving the shoulder.⁷ Many fracture patterns are associated with scapular fractures.

Management

Because a great deal of force is usually required to fracture the body or spine of the scapula, these fractures are often associated with much more serious injuries. Typically, there is little displacement, due to the support of the investing muscles and periosteum. Treatment includes sling and swathe immobilization, early limited exercise, and orthopedic referral.

Acromion fractures result from a direct downward blow to the shoulder. Due to the large amount of force required to produce these fractures, they are often accompanied by associated injuries, including brachial plexus injuries, rotator cuff tears, and superior shoulder dislocations. Nondisplaced fractures may be treated with sling immobilization in conjunction with an elastic circular dressing that pushes the elbow up and the lateral clavicle down. Displaced fractures require internal fixation.

Glenoid rim fractures are associated with two mechanisms of injury. A direct blow may result in a stellate fracture. An upward force, secondary to a fall on the flexed elbow, may cause a displaced glenoid rim fracture. Therapy for fractures with small fragments consists of sling immobilization, ice, and analgesia. Large or widely displaced fragments and stellate fractures require surgical fixation.

Coracoid process fractures may occur from a direct blow to the superior part of the shoulder, or from violent contraction of one of the inserting muscles, causing an avulsion fracture. The patient presents with tenderness to palpation over the coracoid process. Radiographs should include an axillary lateral view for delineation of any displacement of the fragment. Coracoid fractures are usually treated symptomatically with a sling, ice, and analgesics.

SHOULDER DISLOCATIONS

Anterior Shoulder Dislocation

Anterior shoulder dislocation is one of the most common dislocations, accounting for half of all dislocations presenting to the emergency department. This injury occurs when a blow to an abducted, externally rotated arm disrupts the anterior capsule and the glenohumeral ligaments.⁵ There are three types of anterior dislocations: subclavicular, subcoracoid, and subglenoid.

Evaluation

The patient presents with the arm held to the side. The acromion is prominent, and there is loss of the normal rounded contour of the shoulder. Axillary nerve injury is the most common associated neurologic injury in anterior shoulder dislocations, occurring in about 12% of cases. Nerve injury is assessed by testing pinprick sensation over the lateral aspect of the deltoid. A defect in the posterior lateral portion of the humeral head is often seen on radiographs: This impaction fracture of the humeral head is known as the Hill-Sachs deformity.

Management

Adequate analgesia and muscle relaxation improves patient comfort and the success rate of reduction. There are numerous reduction techniques.

Scapular Manipulation Technique. The patient lies prone on the table, with the affected arm hanging off the table and suspended with about 5 to 10 lb of weight, similar to the Stimson technique (discussion follows). The physician pushes the tip of the scapula medially and the superior aspect of the scapula laterally.¹¹ This technique may be performed on an upright patient, with an assistant grasping the patient's arm and applying mild traction while the physician rotates the scapula in a similar fashion. For patients immobilized in the supine position due to multiple trauma, the scapular manipulation technique involves placing the affected extremity in adduction and 90-degree flexion at both the shoulder and elbow joints. Steady, gentle, upward traction is applied on the arm while the inferior tip of the scapula is gently manipulated with a force directed medially.⁴

Hennepin Technique. The external rotation requires little manipulation and permits the shoulder muscles to reduce the dislocation with minimal analgesia. The patient is seated upright or at 45 degrees. One of the physician's hands supports the elbow, and the other hand slowly externally rotates the patient's arm (Fig. 112.4). The arm is externally rotated to 90 degrees. The rotation must be performed gradually, and the patient must remain relaxed. After reaching 90 degrees, the shoulder may have reduced spontaneously. If not, the arm is slowly elevated, and the humeral head is lifted into the socket if it does not spontaneously reduce on elevation. Each of the aforementioned techniques requires little or no sedation or anesthesia and can be successfully performed within a few minutes.⁶

Figure 112.4. Hennepin technique for anterior shoulder dislocation reduction. (Adapted from Simon RR, Koenigsnecht SJ. *Emergency orthopedics*. Norwalk, CT: Appleton & Lange, 1994.)

Stimson Technique. The patient is placed in the prone position, with the arms dependent over a pillow or folded sheet and hanging over the side of the stretcher. A

strap is added to the wrist and weights are applied (10 to 15 lb) over 20 to 30 minutes.^{13,19,20} If unsuccessful, the examiner may rotate the humerus gently, externally and then internally with mild force, which usually reduce the dislocations.

Traction and Countertraction. With the patient lying in the supine position, an assistant applies countertraction with a folded sheet around the upper chest while the examiner applies traction to the arm (Fig. 112.5). Additional lateral traction may be added with a second sheet applied to the proximal portion of the humerus, with lateral force applied to this area. To prevent avulsion injuries⁸ when using this maneuver, the patient must have good muscle relaxation. Alternatively, traction can be applied with the patient seated in an upright position of a chair. The patient sits as straight as possible. Traction is provided by a 3-ft loop of 4-in.-wide cast stockinette placed around the proximal forearm of the involved extremity, with the elbow flexed at 90 degrees. Countertraction is provided by the chair. An assistant maintains the patient upright by standing adjacent to the unaffected shoulder and clasping his or her hands around the chest in the axilla of the affected side. The physician places a foot in the stockinette loop to provide firm downward traction.³

Figure 112.5. Traction–countertraction technique for reducing anterior shoulder dislocations. (Adapted from Simon RR, Koenigsnecht SJ. *Emergency orthopedics*. Norwalk, CT: Appleton & Lange, 1994.)

If the dislocation cannot be reduced by these methods, general anesthesia should be considered and reduction attempted in the operating room. Irreducible dislocations are usually due to soft-tissue interposition.

For patients less than 30 years old, after reduction the shoulder is immobilized for 3 weeks, followed by gentle active range-of-motion exercises. The patient should avoid abduction and external rotation for an additional 3 weeks. For patients over age 30, the shoulder is immobilized for 1 week, followed by active range-of-motion exercises, avoiding abduction and external rotation.¹⁸ The shoulder may be kept immobilized for circumduction exercises. The older the patient, the earlier the mobilization should be instituted to avoid stiffness. Exercises forcing internal rotation of the arm strengthen the subscapularis muscle, helping to prevent recurrent anterior shoulder dislocations.

Complications of anterior shoulder dislocations include tears of the rotator cuff, avulsion of the greater tuberosity, axillary nerve injury, and fracture of the humeral head. Operative repair is indicated in patients who have sustained more than three dislocations.

Postreduction radiographs are not necessary if the reduction was performed smoothly and postreduction physical examination shows no suspicion of unsuccessful reduction.⁸

Posterior Shoulder Dislocations

Posterior dislocations are less common than anterior dislocations and are the most frequently missed major dislocation. There are three types of posterior dislocations: subacromial, subglenoid, and subspinous. Almost all dislocations are the subacromial type. The mechanisms involved in this injury include violent internal rotational force occurring during a fall on the forward-flexed, internally rotated arm; and internal rotational force following a generalized tonic–clonic seizure.

Evaluation

On physical examination, the arm is held in adduction and internal rotation, with abduction severely limited. External rotation of the shoulder is blocked. There is a prominence in the posterior aspect of the shoulder, accompanied by a flattening of the normal anterior shoulder contour.

Radiographically, there is loss of the normal elliptic pattern produced by overlap of the humeral head and the posterior glenoid rim. The greater tuberosity is internally rotated. Isolated fractures of the lesser tuberosity are associated with posterior shoulder dislocations.

Management

Posterior shoulder dislocations may be reduced using the Stimson method, or other techniques that push the posteriorly displaced humeral head forward. If there is severe pain or muscle spasm, general anesthesia may be necessary to reduce the dislocation. Surgical intervention is needed for major displacement of the lesser tuberosity that cannot be reduced on reduction of the dislocation. Neurovascular compromise is uncommon.

Inferior Dislocations (Luxatio Erecta)

Inferior dislocations of the shoulder are uncommon, and occur due to hyperabduction. These injuries are always associated with detachment of the rotator cuff.

Evaluation

On physical examination, the patient is in severe pain and holds the arm at 180 degrees of elevation. The humeral head can be palpated along the lateral chest wall. Compression of the axillary artery and brachial plexus may occur as the humeral head tears through the inferior capsule. Vascular injury is more common with inferior dislocations than with any other form of shoulder dislocation.¹¹ Associated fractures of the acromion, inferior glenoid rim, and greater tuberosity may occur.¹⁰

Management

To reduce the dislocation, the physician applies traction in the longitudinal axis of the humerus while an assistant applies countertraction with a folded sheet wrapped around the supraclavicular region. With traction maintained, the arm is rotated inferiorly in an arc toward a position of complete adduction. After reduction, the shoulder is immobilized for 2 to 4 weeks. Occasionally, general anesthesia may be required to reduce the dislocation and repair the torn rotator cuff.

ACROMIOCLAVICULAR JOINT INJURY

The AC joint functions to elevate and abduct the arm. Stability is provided by two ligaments: the AC and the coracoclavicular. Most injuries of the AC joint are caused by a direct force applied to the point of the shoulder.

Evaluation

The diagnosis of an AC joint injury is made by examining the patient in the upright position and looking for a deformity at the tip of the shoulder. This deformity represents a prominence of the distal clavicle, created by a tear of the AC ligament, and possibly the coracoclavicular ligament. Coracoclavicular ligament injury may

involve the conoid ligament, the trapezoid ligament, or both.

For suspected AC joint injury, stress views taken in the AP position with 5 to 10 lb of weight should be obtained only when one cannot clinically demonstrate the classical features of third-degree injury. Hand-held weights temper the actual degree of separation, so weights should be suspended from the arm or wrist for full effect.

Management

The therapy for AC joint injuries depends on the degree of AC and coracoclavicular ligament injury. The traditional three-part *Aliman classification* of AC joint injuries has been expanded to a six-part classification system.

Type I injuries are a simple sprain of the AC ligament and involve an incomplete tear of that structure. The patient complains of tenderness over the joint. Swelling is minimal and no subluxation is present. Radiographs are negative, even with stress views. Therapy includes rest, ice, and a sling, with early range of motion.

Type II injuries involve disruption of the AC ligament, with sprain of the coracoclavicular ligament ([Fig. 112.6](#)). There is a partial subluxation of the distal end of the clavicle from the acromion. The patient experiences tenderness to mild palpation, and moderate swelling is present. Routine radiographs are usually normal, although subluxation with stress views is noted. The pathognomonic radiographic finding is a separation of the distal clavicle by no more than half its diameter from the acromion on stress films. Separation of the clavicle by more than half its diameter indicates a type III injury. Type II injuries are treated conservatively with ice, rest, and immobilization in a sling. Additional measures for reducing the clavicle and holding it in place with a brace-strap (Kenny-Howard sling) may be used, but clavicular support has not been shown to produce superior improvement in long-term function over that produced by a sling.

Figure 112.6. Acromioclavicular subluxation and dislocation. **(A)** A grade II sprain with tear of the acromioclavicular ligament. **(B)** A grade III sprain with tear of both the acromioclavicular and coracoclavicular ligaments.

Type III injuries result in complete dislocation at the AC joint, with upward displacement of the clavicle and disruption of both the AC and coracoclavicular ligaments (see [Fig. 112.6](#)). Controversy exists regarding therapy. In the past, type III injuries were treated surgically in young patients. However, conservative treatment similar to type II therapy has been shown to produce results as good as those after surgical intervention. ^{12,15} Immobilization in the Kenny-Howard sling should be used for 3 weeks. Type III injuries require orthopedic referral. In *type IV* injuries, the clavicle is displaced posteriorly into or through the trapezius muscle.

Type V injuries are severe injuries that involve disruption of all ligaments above the joint. The clavicle is displaced far cephalad toward the base of the neck.

In *type VI* injuries, the clavicle is dislocated inferiorly, with the lateral end displaced under the acromion or the coracoid process. Type VI injuries are associated with clavicle fractures, rib fractures, or brachial plexus injuries.

Types IV, V, and VI injuries require surgical intervention.

STERNOCLAVICULAR JOINT INJURIES

The SC joint is stabilized by the SC ligament and the costoclavicular ligament. The most common mechanism of injury to this joint is a force that thrusts the shoulder forward.

Evaluation and Management

First-degree SC joint injury is a sprain of the SC joint and involves incomplete tears of the SC and costoclavicular ligaments. The patient experiences minimal swelling and complains of tenderness over the joint. Therapy includes ice, analgesics, and a sling for 3 to 4 days.

Second-degree SC joint injury involves subluxation of the clavicle from its manubrial attachment: Complete rupture of the SC ligament and partial rupture of the costoclavicular ligament occur. There is pain on abduction of the arm, and swelling is noted over the joint. Treatment includes 6 weeks of immobilization with a figure-of-eight clavicle strap and a sling to hold the clavicle in its normal position. This immobilization permits ligamentous healing.

Third-degree SC joint injury involves complete rupture of the SC and costoclavicular ligaments, permitting the clavicle to dislocate from its manubrial attachment. Anterior dislocations are much more common, but posterior dislocations result in much more serious injuries. Patients experience severe pain, increased by any motion of the shoulder. Posterior dislocations may constitute a true orthopedic emergency, for respiratory embarrassment may occur secondary to tracheal compression or a pneumothorax, or venous congestion may occur secondary to compression of vessels in the neck. These associated injuries necessitate emergency reduction of the SC joint dislocation by the physician in the emergency department.

Reduction is accomplished by placing a folded sheet between the shoulders, with the patient supine, which serves to separate the clavicle from the manubrium. The arm is abducted and traction is applied. For anterior dislocation, while traction is maintained, the clavicle is pushed in place ([Fig. 112.7](#)). For posterior dislocations, using the same maneuver, the clavicle should be grasped near its medial border with a towel clip (following the instillation of local anesthesia) and pulled out of its posterior position. General anesthesia may be required to relocate a posterior dislocation of the SC joint.

Figure 112.7. Reduction of a displaced sternoclavicular joint injury. The arm is abducted and traction is applied. With traction maintained, an assistant pushes the clavicle back into its normal position for anterior dislocations (*not shown*). With posterior dislocations, the clavicle is pulled back into its normal position. In difficult

cases, the clavicle can be grasped with a towel clip. (Adapted from Simon RR, Koenigskecht SJ. *Emergency orthopedics*. Norwalk, CT: Appleton & Lange, 1994.)

Complications of an anterior SC dislocation are cosmetic, with chronic swelling around the joint. About 25% of posterior dislocations are associated with complications, including pneumothorax, laceration of the superior vena cava, occlusion of the subclavian artery or vein, and rupture or compression of the trachea.

ROTATOR CUFF INJURY

Tears of the rotator cuff are more common in the elderly because of degenerative changes that occur with advancing age. In young patients, a tear requires much more trauma. The mechanism of injury is a sudden forceful elevation of the arm against resistance in an attempt to cushion a fall, heavy lifting, or a direct impact to the shoulder. The most common area of disruption of the cuff is at its anterior superior portion, at the attachment of the supraspinatus muscle. At this point, the tendon is worn down by the compressive forces between the humeral head and the coracoacromial arch.

Evaluation

Patients complain of pain, aggravated by activity, that radiates to the anterior aspect of the arm. Abduction of the arm is painful and weak. Tenderness is present over the insertion at the greater tuberosity.

The *drop arm test* is positive in patients with significant tears. This is performed by horizontally elevating the arm to the 90-degree position and asking the patient to continue to hold the arm in this position. Slight pressure on the distal forearm will cause the patient to drop the arm suddenly. In addition, the patient cannot bring the arm from the abducted position to the side in a slow fashion, but drops it precipitously.

Thirty percent or more of the tendon must be ruptured to produce a significant reduction of strength. The extent of the tear is directly related to the limitation of shoulder abduction.² Arthrography may be used to detect the location and extent of the tear.

Management

Emergency treatment includes ice, immobilization, and orthopedic referral. Conservative therapy results in a good outcome in only 50% of patients. Arthroscopic treatment can be performed in a number of rotator cuff tears, particularly in the young. Anterior tears have been shown to have the best outcome with arthroscopic repair.⁹ Patients with large posterior rotator cuff tears are poor candidates for arthroscopy. In the young, early surgical repair is indicated for complete tears of the rotator cuff.¹ In the elderly patient who has a more sedentary life, repair may not be indicated.

COMMON PITFALLS

- Not obtaining a transscapular radiographic view (Y view) when assessing the shoulder for dislocation
- Forgetting that lesser tuberosity fractures are often associated with posterior shoulder dislocations
- Not searching for other injuries in patients with scapular fractures
- Forgetting that posterior sternoclavicular joint dislocations may constitute a true orthopedic emergency due to impingement on the trachea, transection of subclavian vessels, or a pneumothorax.

[Additional Readings](#)

The elbow is a synovial hinge joint consisting of three articulations between the distal humerus, radius, and ulna. The humerus widens distally to form the lateral and medial condyles. The capitellum is a spheroidal cartilaginous structure of the lateral condyle that articulates with the radial head, permitting pronation and supination. The trochlea is a spoon-shaped cartilaginous projection of the medial condyle that articulates with the deep trochlear notch of the ulna, permitting flexion and extension at the elbow. The articulating surfaces of the head of the radius and ulna are held together by the annular ligament. The anterior capsule combined with the radial and ulnar collateral ligaments provide stability at the elbow joint.

The wrist flexor and pronator muscles originate from the medial epicondyle. The wrist extensor and supinator muscles attach to the lateral epicondyle. The brachial artery is palpable medial to the biceps tendon in the antecubital space. The median nerve transverses deep in the antecubital fossa medial to the brachial artery. The ulnar nerve courses posteriorly in the cubital tunnel between the medial epicondyle and olecranon process. The radial nerve passes between the heads of the triceps in the posterior humerus and may be injured in humeral shaft fractures.

There are several bursal structures in the elbow. The superficial olecranon bursa lies beneath the skin over the olecranon process and is particularly vulnerable to traumatic and infectious processes.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The assessment of elbow injuries should include a detailed history of the mechanism of injury. The most common complaints are pain, restriction of movement, and swelling. A description of the location and duration of pain, aggravating factors, and presence of paresthesias or loss of movement is important. Elbow pain may also be referred from injuries to the shoulder, forearm, or wrist. An occupational history may provide a clue to the diagnosis in patients presenting with chronic pain.

Inspection of the involved extremity for swelling, open wounds, deformities, effusions, and discoloration is the first step in the physical examination of the patient with elbow pain. The involved joint should not be extensively manipulated until radiographs have been obtained to exclude fracture and dislocation. The shoulder, forearm, wrist, and hand should be examined. Laceration over the medial epicondyle should raise suspicion of an ulnar nerve injury. Any abnormality noted in the involved extremity should be compared with the contralateral extremity.

An effusion is best palpated over the soft-tissue area lateral to the radial head. The bony prominences of the medial and lateral condyles, olecranon, and radial head should be palpated for tenderness. The radial head is best palpated with the thumb of one hand while pronating and supinating the forearm with the examiner's other hand. With the elbow flexed to 90 degrees, the medial and lateral condyles and the olecranon should form a triangle. In an elbow dislocation, this triangle is disrupted with displacement of the olecranon. A posterior dislocation or extension-type fracture is suggested by a prominent olecranon. Loss of the olecranon prominence suggests an anterior dislocation or supracondylar fracture. The triangular relationship is maintained in supracondylar fracture. Each of the muscle groups should be tested against resistance and the muscle belly palpated during contraction.

Careful neurovascular examination is of critical importance. Brachial, radial, and ulnar pulses should be palpated and capillary refill assessed. The brachioradialis, biceps, and triceps reflexes should be elicited. The radial nerve is tested by evaluating wrist and finger extension. Wristdrop results from radial nerve injury. Flexion of the wrist and digits and pronation of the forearm are the functions of the median nerve. Inability to flex and abduct the thumb is diagnostic of median nerve injury. Loss of strength of the interossei muscles and adduction of the thumb suggests ulnar nerve paralysis. The sensory component of the radial nerve innervates the dorsum of the hand and is best tested in the web space between the thumb and index finger. Median nerve sensation is tested over the palmar aspect of the thumb and the digits to the radial one-half of the ring finger. The ulnar nerve is tested over the fifth digit. The neurovascular examination of the extremity should be repeated after manipulation and at regular intervals for increased edema and potential neurovascular compromise.

Radiography of the Elbow

The radiographic examination of the elbow should consist of a minimum of two views: the anteroposterior and lateral. Oblique views may provide additional information. Specialized views, such as the radial head–capitellum view, are indicated when a high index of suspicion for particular injury exists.

On the lateral radiograph, a line parallel to the anterior border of the humerus should intersect the anterior portion of the middle third of the capitellum ([Fig. 113.1](#)).¹⁰ If this intersection is displaced, usually anteriorly, a supracondylar fracture should be suspected.

Figure 113.1. Anterior humeral line. The anterior humeral line is a line drawn on the lateral radiograph along the anterior surface of the humerus through the elbow. Normally this line transects the middle of the capitellum (**left**). With an extension fracture of the supracondylar region, this line will either transect the anterior third of the capitellum or pass entirely anterior to it (**right**). (Adapted, with permission, from Simon RR, Koenigsnecht SJ. *Emergency orthopedics: the extremities*, 2nd ed. Norwalk, CT: Appleton & Lange, 1987.)

The radiocapitellar line extends from the center of the radius and should intersect the middle third of the capitellum on the lateral view. ¹⁰ Disruption of this line

suggests radial head dislocation or fracture and is most useful in evaluating subtle fractures in children.

Fat pad signs are helpful in diagnosing occult fractures within the joint capsule. The anterior fat pad is a combination of fat in the coronoid and radial fossa. This radiolucent fat overlaps and appears as a triangular area over the distal humerus on a lateral radiograph of the elbow. The posterior fat pad is located in the olecranon fossa and is normally hidden by the overlying humeral condyles on a lateral radiograph.

When an effusion is present, it distends the joint capsule and displaces the fat pads ([Fig. 113.2](#)). The anterior fat pad displaces anteriorly and superiorly and appears as a “ship’s sail.” The posterior fat pad becomes visible on radiography and is highly indicative of intraarticular disease. In the setting of elbow trauma, a positive fat pad sign in the absence of visible fracture should mandate a search for occult fracture, most commonly of the radial head.

Figure 113.2. Anterior and posterior fat pad signs are indicated by the *large arrows*. *Small arrows* indicate the radial head fracture that produced the effusion displacing the fat pads.

Positive fat pad signs can also be present with any intraarticular disease process and are not pathognomonic for fracture. Fat pad signs may be seen with arthritis, gout, pseudogout, infection, neoplasia, or other disease process causing an intraarticular fluid collection. ⁸ A fat pad sign may not be present with severe injury causing disruption of the joint capsule.

Computed tomography (CT) scanning may be useful in delineating complex fractures in adults. Magnetic resonance imaging has become the procedure of choice for evaluating soft tissues, cartilaginous surfaces, joint space, and trabecular bone. ⁶

Fractures of the Elbow

Supracondylar Fractures

Supracondylar fractures occur in the distal humerus proximal to the epicondyles and are most commonly seen in children. In adults, because of their stronger bones, elbow dislocations from ligamentous disruption are more common. These fractures most commonly result from a fall on the outstretched hand with the elbow in extension.

Twenty-five percent of supracondylar fractures are nondisplaced. Treatment of nondisplaced fracture is a posterior splint from axilla to palm, with the elbow flexed to 90 degrees. These patients should be referred to an orthopedic surgeon. A child with elbow tenderness and swelling should be splinted, even without a demonstrable radiographic fracture, because of the possibility of occult fracture.

In displaced fractures, the distal fragment is usually displaced posteriorly (extension injury), and an abnormal anterior humeral line will be visualized on the lateral radiograph. Anterior displacement of the distal fragment (flexion injury) occurs less frequently and is caused by a direct blow to the posterior aspect of the flexed elbow.

Assessment of neurovascular function is essential, especially with extension injuries, because occult injury to the brachial artery may occur. A strong pulse does not rule out arterial injury, and an arteriogram should be performed if injury is suspected. Closed reduction of displaced fractures should be attempted if neurovascular compromise is present.

Displaced fractures require internal fixation or percutaneous pinning if good alignment is not maintained with closed reduction. Patients with displaced fractures should be admitted because of the risk of delayed swelling and neurovascular compromise, including Volkmann ischemia and, eventually, contracture. Flexion fractures may also require internal fixation and should be splinted in extension. Range-of-motion exercises after internal fixation are encouraged and should be started within 1 to 2 weeks.

A common complication of supracondylar fracture is an abnormal carrying angle. The normal carrying angle is 10 degrees to 15 degrees of valgus. Measurement of the Baumann angle, formed by a line perpendicular to the humeral shaft and a line through the lateral humeral condyle, is predictive of an acceptable carrying angle. ¹⁴ This angle normally measures about 75 degrees. A discrepancy of greater than 5 degrees to 10 degrees, compared with the uninjured extremity, is an unacceptable reduction.

Intercondylar Fractures

Intercondylar fractures usually occur in older patients as a result of direct trauma to the flexed elbow. They usually occur in “T and Y” configurations, and treatment is based on the displacement of the humeral condyles from each other and the proximal humerus. Neurovascular complications are so uncommon that these fractures rarely require manipulation by the emergency physician.

Nondisplaced fractures are treated in a posterior splint for 3 weeks, and then active range of motion is begun. Displaced fractures are treated with internal fixation and early range of motion beginning after 1 week. Severely comminuted fractures may be treated with olecranon traction for 3 to 4 weeks if operative repair is not possible.

Humeral Condyle Fractures

Isolated humeral condyle fractures are caused by a fall on the outstretched hand, by direct trauma, or by avulsion of bone from the pull of the flexor or extensor muscles from the medial and lateral condyles, respectively. Lateral condyle fractures are more common than medial fractures and frequently involve the joint surface.

Nondisplaced lateral condyle fractures are immobilized in a posterior splint, with the elbow flexed to 90 degrees and the forearm in supination with the wrist extended. The forearm should be in pronation and the wrist flexed for medial condyle fractures. Active range of motion is begun as early as 2 to 3 weeks after injury. Operative fixation is required for displaced fractures, owing to instability caused by the pull of the forearm muscles. All of these patients should be treated in consultation with an orthopedic surgeon.

Epicondyle Fractures

Epicondyle fractures in adults are usually caused by a direct blow. The medial epicondyle is involved more commonly than is the lateral, and ulnar nerve function should be evaluated.

Nondisplaced fractures may be treated with immobilization and early range of motion. If displacement of more than 10 mm is present, then surgical fixation is required. Intraarticular fragments may impede joint mobility and are difficult to visualize radiographically. Entrapment of the ulnar nerve is a possible complication.

Articular Surface Fractures

Fractures of the capitellum and trochlea usually occur as a result of a posterior elbow dislocation. Isolated fractures are rare, and joint stability is maintained because the condyles remain intact, but motion may be impeded.

Nondisplaced fractures with normal anatomic alignment can be treated with immobilization for 2 to 3 weeks. Displaced small fragments may be excised, whereas larger fragments require internal fixation with early range of motion. Common complications of capitellar fractures include restriction of motion and, rarely, nonunion and avascular necrosis.

Olecranon Fractures

Olecranon fractures are usually intraarticular and may result from a direct blow or an avulsion injury from the pull of the triceps muscle. On examination, the patient is unable to extend the elbow against resistance. Because of its proximity, the ulnar nerve may be injured, and its function should be assessed.

Treatment of these injuries varies with the amount of displacement and requires orthopedic consultation. Nondisplaced fractures may be splinted with the elbow in a semiflexed position and with early range of motion begun in 2 to 3 weeks. Complete healing generally occurs in 6 to 8 weeks. If greater than 2 mm of displacement is present, then operative intervention is indicated. Treatment options include tension band wiring, olecranon screws, or plates. ⁵ Range-of-motion exercises may be started in 1 week. Management of severely comminuted fractures is controversial and may require removal of the loose fragments.

Radial Head Fractures

Radial head fractures are the most common elbow injuries in adults. They usually occur as a result of a fall on the outstretched hand, which drives the radial head into the capitellum. On examination, patients have tenderness to palpation over the radial head and pain with pronation and supination of the forearm.

Fractures are classified as nondisplaced, displaced, or comminuted. Nondisplaced fractures may be difficult to visualize on standard radiographs. Any disruption of the normally smooth, concave cortical contour of the radial head suggests fracture. A positive fat pad sign on a lateral radiograph without evidence of fracture should raise suspicion for an occult radial head fracture. This fracture may be better visualized radiographically with a radial head–capitellar view.

Nondisplaced fractures are treated with a posterior splint or sling, with early range of motion in a few days. Aspiration of the hemarthrosis in the emergency department may provide pain relief and expedite mobilization. Minimally displaced fractures may be treated in a similar manner. Fractures displaced more than 3 mm or involving more than one-third of the joint surface should be treated with operative fixation using small screws. These patients should begin early range of motion postoperatively.

Comminuted fractures may be treated with a sling and early range of motion in 1 to 2 weeks. Joint aspiration and injection of a local anesthetic will aid in assessing joint mobility. The treatment of severely comminuted and displaced fractures is controversial and may include excision of fragments or complete radial head excision, with or without prosthetic implants.

Any patient with a radial head fracture should also be examined for wrist tenderness. The Essex-Lopresti lesion, a radial head fracture with disruption of the distal radioulnar joint ligaments and forearm interosseous membrane, must be recognized early for internal fixation to produce the best results. ¹

Nursemaid's Elbow

Subluxation of the radial head is most commonly seen in children 1 to 3 years of age. The mechanism of injury is a sudden longitudinal pull of the forearm, causing fibers of the annular ligament to become stuck between the capitellum and the radial head. The child is unwilling to move the arm, and the elbow is held in slight flexion with pronation of the forearm.

When a child presents with the characteristic history for radial head subluxation, radiographs are not necessary. However, the presence of swelling or deformity, or the child's refusal to resume normal use of the arm after reduction, is an indication for a radiograph.

Treatment is supination and flexion of the forearm in one continuous motion. The examiner's thumb can be used to apply pressure over the radial head. With successful reduction of a nursemaid's elbow, the child will resume using the arm normally within several minutes, and no further treatment is necessary.

Monteggia Fracture

Fracture of the proximal one-third of the ulna with dislocation of the radial head is a Monteggia fracture ([Fig. 113.3](#)). Based on the position of the radial head, there are four types of Monteggia fractures. The radial head dislocates anteriorly in 60% of cases, with posterolateral, lateral, and posterior dislocations being less common. The mechanism of injury involves direct trauma, forced hyperpronation, or hyperextension. The most commonly associated injury is paralysis of the radial nerve. The usual treatment is open reduction with internal fixation.

Figure 113.3. Monteggia fracture. The first component is fracture of the proximal one-third of the ulna; the second component is dislocation of the radial head.

Aspiration of the Radiohumeral Joint

Aspiration of the radiohumeral joint is indicated to relieve pain, promote early range of motion, and assess joint mobility with radial head fractures. It is also indicated to diagnose a septic joint. The aspiration should be performed over the lateral elbow in the center of the triangle that connects the radial head, lateral epicondyle, and olecranon process ([Fig. 113.4](#)).¹² No neurovascular structures are located in this area, and the joint capsule is present beneath the skin and the thin anconeus muscle.

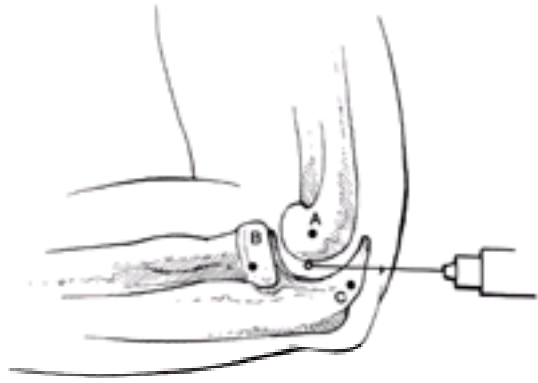

Figure 113.4. Elbow aspiration. The safest place to aspirate the elbow is in the center of a triangle produced by connecting (A) the lateral epicondyle of the humerus, (B) the radial head, and (C) the olecranon. (Adapted, with permission, from Simon RR, Koenigsnecht SJ. *Emergency orthopedics: the extremities*, 2nd ed. Norwalk, CT: Appleton & Lange, 1987.)

Under sterile technique, the skin over this area is anesthetized with a local anesthetic. An 18-gauge needle on a 10- to 20-mL syringe is directed into the center of the triangle and perpendicular to the skin. Aspiration of up to 5 mL of blood from the joint and injection of 1 to 2 mL of a long-acting anesthetic provide relief of pain and allow assessment of joint mobility.

Elbow Dislocation

Dislocation of the elbow accounts for 20% of all dislocations and is described by the direction in which the forearm is displaced in relationship to the distal humerus. Posterior and posterolateral dislocations account for 90% of all elbow dislocations. Dislocation may also occur between the radius and ulna. Posterior dislocations are caused by a fall on an extended and abducted arm. Patients present with significant swelling, tenderness, and deformity, with the elbow held in flexion and prominence of the olecranon. Anterior dislocation is the result of a blow to the olecranon while the elbow is held in extension with the forearm supinated and is associated with loss of the olecranon prominence.

Radiographs should be obtained before reduction to exclude associated fractures, which occur in up to 60% of patients with elbow dislocation. Supracondylar fractures in the younger patient and avulsion fractures of the medial epicondyle are the most common. A complete neurovascular examination must be done on presentation. Neuropraxia is present in 20% of patients, most commonly involving the ulnar and median nerves. As with most nerve injuries associated with dislocations and fractures, these deficits are usually transient.⁹ Brachial artery injury is most commonly associated with open dislocations and those with concomitant fractures. The incidence of vascular injury is greater with anterior dislocations.

Analgesia and muscle relaxation are required for closed reduction. Posterior, medial, and lateral dislocations are reduced using the same technique. With the patient lying supine, the area of the wrist and forearm is grasped and traction is applied along the long axis of the forearm. An assistant provides countertraction to the upper arm. Any medial or lateral displacement is corrected. While forearm traction is continued, the elbow is flexed and a palpable clunk should be felt as the elbow is reduced. Downward pressure over the proximal forearm may aid in disengaging the coronoid from the olecranon fossa (Fig. 113.5). After reduction, the neurovascular examination should be repeated and postreduction films obtained. The elbow should be flexed to 90 degrees as long as good pulses are maintained and then immobilized in a posterior splint. All patients should follow up with an orthopedic surgeon within 1 week to begin early range-of-motion exercises and help prevent contractures.

Figure 113.5. Technique for reduction of posterior dislocation of the elbow.

Indications for open reduction include an associated fracture, open dislocation, neurovascular injury, or inability to accomplish a closed reduction. Long-term complications include stiffness, contractures, neurovascular injury, heterotopic bone formation, and ankylosis. Recurrent elbow dislocations are rare.

Epicondylitis

Tennis elbow, or lateral epicondylitis, is an “overuse syndrome” characterized by inflammation at the radiohumeral joint or the lateral epicondyle. It is believed to represent a failure of the extensor carpi radialis brevis attachment to bone in this region.¹¹ It is most commonly seen in athletes or adults with occupations requiring repeated rotary motion, as in twisting or grasping (e.g., tennis players, pipefitters, and carpenters).³ The gradual onset of a dull ache appears over the lateral epicondyle and radiates into the forearm. Dorsiflexion of the wrist and supination of the forearm against resistance with the elbow extended will reproduce the pain. Radiographs should be obtained to exclude an associated fracture. In chronic conditions, calcification may be seen over the lateral epicondyle.

The mainstay of treatment is avoidance of the offending activity and immobilization. A posterior splint is applied with the elbow flexed 90 degrees, the forearm supinated, and the wrist slightly dorsiflexed. Moist heat, nonsteroidal antiinflammatory agents, and physical therapy may be helpful. Local infiltration of the affected area with 1 to 2 mL of a corticosteroid and anesthetic mixture will give dramatic relief. All patients should have an orthopedic referral.

Medial epicondylitis is similar to tennis elbow and involves the common flexor origin at the medial epicondyle of the humerus. It is seen in golfers but occurs more frequently in people who routinely perform household chores, manual labor, and other tasks involving repetitive movements. Maximal tenderness is localized over the medial aspect of the elbow and medial epicondyle. Treatment is similar to that of lateral epicondylitis, and orthopedic follow-up is essential.

Olecranon Bursitis

Olecranon bursitis is most commonly caused by a direct blow to the olecranon process. Patients present with erythematous, warm, and painful swelling over the posterior aspect of the elbow. Flexion of the elbow may be slightly restricted, owing to tightening of the skin over the inflamed bursa. Repetitive trauma can result in a chronic inflammatory process and a thickened, rubbery, and usually painless bursa.

Aspiration of the bursa is essential for both diagnostic and therapeutic purposes if infection is suspected. The aspirated fluid should be analyzed for crystals, cell count (greater than 1000 white blood cells/ μ L in septic bursitis), Gram stain, and cultures. *Staphylococcus aureus* is the most commonly identified organism in septic olecranon bursitis, and high resistance to penicillin has been reported.⁴ Intravenous antibiotics, drainage of bursal fluid, moist heat, and splinting are the

recommended treatment measures.

In traumatic olecranon bursitis, the mainstays of treatment are a compression dressing after drainage, nonsteroidal antiinflammatory agents, and protective measures to prevent recurrence.

Distal Rupture of the Biceps or Triceps Tendon

Distal rupture of the biceps tendon may be the result of degenerative changes or sudden, forceful flexion of the elbow against resistance. Patients present with a history of a painful snap at the elbow. Flexion of the elbow and supination of the forearm are weakened. On flexion, the belly of the biceps retracts, producing a bulbous swelling in the upper arm. The treatment is surgical if significant motor weakness is present, and should occur within 2 weeks postinjury. ¹³

Avulsion of the triceps tendon should be considered in patients with pain, swelling, and weakness with arm extension. A defect is often palpable just proximal to the olecranon. Associated injuries include radial head and neck fractures and wrist fractures. The diagnosis is confirmed radiographically when a bony avulsion is seen on the lateral view of the elbow. Orthopedic consultation should be obtained, and surgical treatment is recommended.

Osteochondritis Dissecans

Osteochondritis dissecans is a process of avascular necrosis of the subchondral bone and the overlying articular cartilage, and is most common in males and adolescents. There is usually a history of trauma or sports-related activities. Patients may complain of the gradual onset of dull, aching pain; limited extension; intermittent swelling; and catching, locking, or clicking of the affected elbow. ⁷ The capitellum is the most common site of involvement, and joint effusion may be present. Treatment consists of immobilization with a sling or cast, avoidance of all throwing activities, and nonsteroidal antiinflammatory agents. Loose bodies within the joint may restrict movement of the elbow and should be surgically removed. Prognosis is usually good.

COMMON PITFALLS

- Radiographs are most commonly misread because a true lateral view of the elbow is not obtained. In one university emergency department setting, the incidence of missed elbow fractures was 12%.²
- Injuries to the elbow may refer pain to the wrist. Identification of one injury should not preclude the search for other injuries.
- The most common injury that is overlooked is an occult radial head fracture. A high index of suspicion is needed when a positive fat pad sign is present on radiography without demonstrable fracture. Several oblique views of the radial head may need to be taken to visualize the fracture.
- Any fracture of the proximal ulna should prompt the examiner to assess the radial head for dislocation. Monteggia fractures require internal fixation, whereas isolated ulna fractures are treated with immobilization.
- Patients with radial head fractures should have their wrist examined for the Essex-Lopresti lesion. These patients require internal fixation, whereas radial head fractures are usually treated conservatively.
- One should never assume that a negative radiograph rules out elbow injury. Injuries to cartilaginous and ligamentous structures, as well as the soft tissues, may be present. Splinting of the elbow and orthopedic referral should be considered when a significant mechanism of injury is present.
- Radiographs should always be obtained before the reduction of dislocations to exclude associated fractures. Postreduction films should always be obtained.
- A potential medicolegal pitfall is missing the diagnosis of neurovascular injury. A careful neurovascular examination should be documented, in addition to interval reexamination.
- A commonly missed injury is avulsion of the biceps muscle from the bicipital tuberosity of the radius. The patient will still be able to flex the elbow with the brachialis muscle.
- Another commonly overlooked injury is the supracondylar fracture in children. Measure the anterior humeral line to aid in diagnosing these fractures. Splint the arm if a significant mechanism of injury or swelling exists, and refer for orthopedic consultation.

Hand Injuries

The hand is the primary organ with which we manipulate objects and interact with our environment. Damage to the complex and intricate structure of the hand from injury, infection, or disease may cause a loss of function, resulting in severe disability. Hand injuries are a common problem in the emergency department, accounting for 10% to 20% (1.4 million) of emergency department visits, most commonly for lacerations (42%) and least commonly for infections (5%).^{6,10,19} Hand infections are

through the anatomic snuffbox and terminates as the deep palmar arch. The ulnar artery passes into the hand through the Guyon canal superficial to the flexor retinaculum to form the superficial palmar arch. A deep branch of the ulnar artery anastomoses with the deep palmar arch, and a superficial branch of the radial artery anastomoses with the superficial palmar arch. The four common digital arteries arise from the superficial palmar arch and then divide to form the proper digital arteries.

The thick palmar skin is adherent to the underlying palmar aponeurosis by numerous fibrous bands, which may produce a gritty sensation when lacerated. The palmar aponeurosis is the triangular, thick, deep fascia of the palm. It is attached to the distal flexor retinaculum, where it receives the insertion of the palmaris longus tendon and spreads distally to the base of the four fingers. In contrast to that of the palm, the dorsal skin of the hand is thin and supple, with little underlying adipose or fibrous tissue. For this reason, edema from hand injuries is often more pronounced on the dorsal surface.

CLINICAL PRESENTATION

Most patients with acute hand injuries present with varying degrees of pain, swelling, loss of function, and laceration or puncture after either blunt or penetrating injury. Obvious deformity may or may not be present or may be obscured by associated swelling. In contrast, injuries resulting from repetitive motions or systemic or bone diseases usually present more insidiously, with chronic waxing and waning symptoms.

EMERGENCY DEPARTMENT EVALUATION

In the appropriate clinical setting, initial emergency department evaluation should focus on the need for resuscitation, followed by a general assessment of the patient to detect other significant injuries and control hemorrhage. Rarely will more than direct pressure and hand elevation be required to control bleeding from a hand wound; in such situations, the careful and intermittent use of a tourniquet (i.e., proximal blood pressure cuff) will usually gain control of the bleeding and allow adequate visualization of the wound. Blind clamping of bleeding vessels should be avoided, because adjacent nerves and tendons may be injured.

A focused, but thorough history is essential in the evaluation and treatment of the injured hand. Important historic information includes the patient's age, dominant hand, occupation and avocations (e.g., musician, typist, mechanic), other patient activities that require special use of the hands, smoking status (particularly for replantation candidates), prior hand injuries, preinjury hand function, medical history (e.g., diabetes mellitus, immunosuppression), time of the injury, mechanism and circumstances of injury (e.g., power tools, contaminated environment, associated burn or chemical exposures, potential for foreign bodies), position of the hand at the time of injury, treatment administered before arrival, and previous tetanus immunization.

A systematic and careful examination of the hand is also of paramount importance to the accurate diagnosis of hand injuries. Initially, the hand should be observed at rest, completely exposed. All rings should be removed because swelling may become diffuse and create a tourniquet effect, even on apparently uninjured fingers. The location and type of wounds, skin loss, ecchymosis, pallor, swelling, and resting attitude of the digits should be noted. The normal resting cascade of the fingers reveals progressive flexion of the digits from the index to the little finger, which is generally symmetric.

Alterations in this stance may indicate an underlying tendon injury. For example, a flexor tendon injury may appear as an extended digit on account of unopposed extensor tone, while an extensor tendon injury may reveal a flexion deformity. In addition, the hand can be observed during passive flexion and extension of the wrist. With wrist extension, the fingers naturally assume a flexed posture, and with wrist flexion, the fingers will passively extend.¹⁷ Knowledge of this may be particularly helpful in evaluating children or patients who are uncooperative because of intoxication or pain.

The hand should be carefully palpated to identify areas of tenderness, bony step-off, and crepitus. Finally, in patients with phalangeal or metacarpal fractures the presence of rotational malalignment must be sought. Clinically, rotational deformity may be diagnosed by having the patient make a fist. Normally, all of the fingers point to the same spot on the scaphoid (Fig. 114.3). Scissoring of the digits and loss of the usual parallel relationship of the fingernails are additional signs of rotational deformity. Radiographically, there is asymmetry of the diameters of the shafts on each side of the fracture (Fig. 114.4).

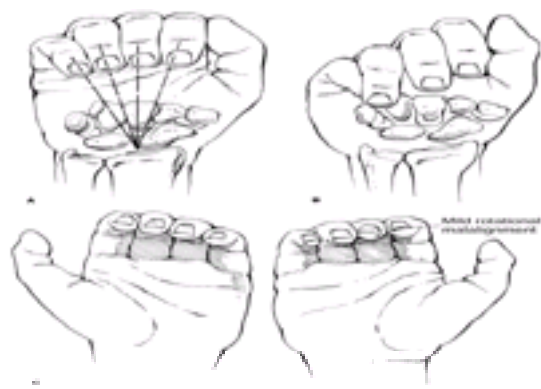

Figure 114.3. Clinical signs of rotational malalignment. **(A)** Normally, all fingers point to the same spot on the scaphoid when making a fist. **(B)** With rotational malalignment, the affected finger does not point to the scaphoid. **(C)** Loss of the usual parallel relationship of the finger nails with rotational malalignment. (Redrawn from Simon RR, Koenigskecht SJ. *Emergency orthopedics: the extremities*, 3rd ed. Norwalk, CT: Appleton & Lange, 1995:64.)

Figure 114.4. Radiographic sign of rotational malalignment. Note the asymmetry of the diameters of the shafts on each side of the fracture.

Nerve integrity is assessed by testing both sensory and motor function. Sensation should always be evaluated before the administration of any anesthetic agent. Digital nerve sensory function is best assessed by two-point tactile discrimination. This test is easily performed with any number of devices, such as a paper clip bent into a U shape, electrocardiographic calipers, or a device specifically designed for this purpose. It is helpful to first explain and demonstrate the technique on the noninjured hand. The volar lateral aspects of the digits are lightly stroked in a longitudinal direction with the two points. Normal discrimination is 2 to 5 mm at the fingertips but may vary between individuals and appears to worsen with age.²¹ Comparison with the opposite hand may be helpful.

In young children or uncooperative patients, it can be difficult to convincingly perform two-point tactile discrimination. In these circumstances, nerve integrity can be assessed through the presence of sympathetically mediated skin wrinkling and skin sweating. Soaking the hand in warm water for 30 minutes should cause wrinkling of the normally innervated skin. Skin sweating can be assessed by stroking the digit with a smooth object (e.g., the barrel of a pen). Less resistance (due to loss of sweating) should be noted over the denervated area. Alternatively, the hand can be painted with povidone–iodine solution, allowed to dry completely, then placed in

a sterile glove. Normal digital sweating will moisten the povidone–iodine and cause the talc in the glove to turn black.

Vascular integrity of the hand is evaluated by noting cyanosis or pallor, noting skin temperature, assessing capillary refill (normal is less than 2 seconds), and assessing palpation of the ulnar and radial artery at the wrist.¹⁷ The Allen test is used to test the patency of the radial and ulnar arteries and the palmar arches. The test is performed by having the patient clench the fist to exsanguinate the hand while the examiner occludes the radial and ulnar arteries. When the hand is blanched, pressure over one of the arteries is released. Normal hand color should return in 3 to 5 seconds.¹⁷ The test is then repeated releasing the other artery. A digital Allen test performed in a similar fashion has also been described.¹⁷

Testing for musculotendinous integrity of both the extrinsic and intrinsic hand muscles is another important aspect of the hand examination (see [Table 114.1](#)). It should be noted that a significant portion of the population does not have independent function of the flexor digitorum superficialis to the small finger, and the ring finger PIP joint may also need to flex for an accurate examination.²²

When evaluating finger lacerations, the digit should be moved through a full range of motion against light resistance, because a tendon laceration may be proximal or distal to the skin wound, depending on the position of the hand when the injury occurred. A high index of suspicion must be maintained, because partial tendon lacerations are easily missed (see [Tendon Lacerations](#)). In addition, the action of the lumbricals and interossei to independently extend the IP joints and flex the MCP joints may mask a tendon laceration. Furthermore, a bloodless field may be necessary to adequately assess the wound for foreign body or subtle tendon laceration. The tourniquet should not be left in place for more than 20 minutes. The digit is milked proximally and then a local tourniquet or Penrose drain is applied at the base of the finger and held in place by a hemostat.

Radiographs of the hand or wrist should be obtained whenever the mechanism could cause bony disruption, joint instability, or a retained foreign body. Standard views of the hand and fingers include posteroanterior (PA), lateral, and external oblique views. When evaluating an injured finger, a true lateral view is needed to adequately evaluate the DIP and PIP joints for volar lip injuries, and a frontal view of the hand is recommended to avoid overlooking an adjacent fracture. An internal oblique view may be helpful in visualizing phalangeal or metacarpal fractures after an initially nondiagnostic standard radiographic series.^{9,24} Hand radiographs differ in technique from wrist radiographs, so both series must be obtained for the adequate evaluation of both hand and wrist symptoms. If there is suspicion of a foreign body despite negative plain radiographs, xeroradiography, ultrasonography, or computed tomography (CT) scanning may be required to localize the object.¹³

EMERGENCY DEPARTMENT MANAGEMENT

Emergency department management of hand injuries includes ice application and elevation of the extremity to reduce swelling. The liberal use of oral or parenteral analgesics is also recommended. Intravenous antibiotics are indicated for open fractures and dislocations and for severely contaminated or infected wounds. Tetanus immunization status should be assessed and updated appropriately. Open wounds should be covered with a sterile, moist gauze dressing pending radiographs, surgical consultation, or wound closure. In addition, fractures (or suspected fractures) should be temporarily immobilized with a bulky hand dressing or an appropriate splint while awaiting radiographs, reduction, or surgical consultation.

The disposition of patients with a hand injury depends on the nature and severity of the injury. A hand surgeon should be consulted in the case of suspected or actual nerve and tendon injuries, one who may examine such injuries in the emergency department directly. Alternatively, the injury can be vigorously irrigated and cleaned, the skin closed, and the hand splinted, with follow-up in 1 to 3 days for definitive management.

Important discharge instructions for all patients include elevation of the extremity and the use of ice for the initial 24 to 48 hours. Instructions regarding signs of infection, the timing of return visits for complications, wound checks, and suture removal are mandatory. Patients with injuries that are splinted should also receive instructions regarding splint care and signs or problems that should prompt an immediate return to the emergency department. Appropriate and timely follow-up arrangements should be provided for all patients treated in the emergency department. There will be institutional and regional variations in the specialty background of hand surgery consultants. In this chapter, we refer to hand surgeons or surgical consultants, recognizing that this category may include orthopedic surgeons, plastic surgeons, and surgeons who limit their practice to hand surgery.

Anesthetic Techniques

Anesthesia for the evaluation and repair of hand injuries can be provided by local infiltration (dorsum of the hand and superficial wounds of the palm), digital nerve block, or regional nerve block at the wrist. In addition, a hematoma block is useful for the reduction of metacarpal fractures.¹⁵ Lidocaine without epinephrine should be used in 2% concentration for nerve blocks and in 1% or 2% concentration for infiltration. Use of a 25- to 30-gauge needle, slow injection, and buffering with bicarbonate (1:10 dilution) will help reduce injection pain. A longer acting agent (i.e., bupivacaine) can also be used if prolonged anesthesia is required.

A digital block can be performed by injecting 2 to 3 mL of local anesthetic either at the medial and lateral aspect of the base of the proximal phalanx or at the level of the metacarpal head. Some authors prefer to perform a digital block at the metacarpal head because there is more space for tissue distention.¹⁶ With either technique, infiltration of the proximal dorsal surface of the digit is also required to anesthetize the dorsal digital nerves and complete the block. Complete anesthesia usually requires 5 to 10 minutes. Circumferential infiltration of the digit is not recommended because it may result in distal necrosis.

Regional nerve blocks at the wrist can anesthetize the median, ulnar, and radial nerves. A median nerve block is performed by injecting 5 to 7 mL of local anesthetic 1 cm proximal to the distal wrist flexion crease radial and deep to the palmaris longus tendon, or deep to the ulnar aspect of the flexor carpi radialis tendon in those individuals lacking a palmaris longus tendon. An ulnar nerve block is accomplished by injecting 5 to 7 mL of local anesthetic 1 cm proximal to the distal wrist flexion crease just radial and deep to the flexor carpi ulnaris tendon. The ulnar artery at this level lies in close proximity to the ulnar nerve, and aspiration before injection is important to avoid intravascular injection of the anesthetic. The dorsal sensory branch of the ulnar nerve is blocked by subcutaneous infiltration of anesthetic just distal to the ulnar styloid. A radial nerve block is performed by subcutaneous infiltration of 5 mL of anesthetic agent just distal to the radial styloid. If paresthesias are elicited during insertion of the needle, it should be withdrawn before injection, because direct injection into the nerve may cause neuritis. Ten to 15 minutes is often required before complete anesthesia occurs. A hematoma block is performed by injecting a local anesthetic into the hematoma surrounding a fracture. A 27- to 30-gauge needle is inserted over the fracture site. When blood is aspirated into the syringe, indicating correct needle placement, 5 to 10 mL of anesthetic is injected. Up to 15 minutes may be needed for full anesthetic effect.

SPECIFIC INJURIES

Carpal Injuries

Most carpal injuries are caused by a fall on an outstretched hand (i.e., FOOSH injury), resulting in forced dorsiflexion of the wrist, or by a direct blow or crush injury to the wrist. Carpal fractures account for 7% to 10% of all hand and wrist injuries and are among the most frequently missed fractures in the emergency department.⁵ The scaphoid is fractured most commonly (60% to 70% of carpal fractures), followed by the triquetrum, lunate, trapezium, pisiform, hamate, capitate, and trapezoid. Carpal dislocations are less common but are associated with severe sequelae if not diagnosed and treated appropriately.

CLINICAL PRESENTATION

Patients will complain of pain, swelling, and a limited range of motion in the wrist. However, the presentation will vary, depending on the nature and severity of the injury.

DIFFERENTIAL DIAGNOSIS

Carpal injuries may include fractures, dislocations, or a combination of the two. Fractures of the distal radius or ulna may be confused with, or accompanied by, a carpal injury. De Quervain tenosynovitis often presents with wrist pain, though there is commonly a more protracted history of pain with repetitive motions.

EMERGENCY DEPARTMENT EVALUATION

As discussed previously, emergency department evaluation begins with a careful history and physical examination. Radiographs are indicated in all but trivial injuries. In addition to standard x-ray review, the frontal radiograph should be examined for abnormalities of the carpal joint spaces (normally 1 to 2 mm), the shape of the scaphoid (normally elongated), the radiolunate articulation (at least one-half of the articular surface of the lunate should be in contact with the radius), and the radial slope (normally 15 to 30 degrees). The navicular fat stripe, normally seen on the frontal radiograph as a radiolucent line on the radial side of the scaphoid near the distal radius may be obliterated with a scaphoid fracture.¹² On the lateral projection, the normal linear alignment of the radius, lunate, and capitate should be carefully evaluated. The lunate appears as a “cup in a saucer” articulating with the distal radius. The capitate articulates with the distal concavity of the lunate and creates an angle of 10 to 20 degrees. The scaphoid and lunate should form an angle of 30 to 60 degrees. Additional radiographs that may be helpful include frontal views with maximum radial and ulnar deviation, lateral views with maximum flexion and extension, and carpal tunnel views for suspected hamate fractures. The presence of unfused epiphyses in children and adolescents can make interpretation of radiographs difficult. In this situation, comparison views may be helpful. Radiographs of the joint above or below the injury are indicated for pain, tenderness, or limitation of motion in those joints or in the presence of a fracture of the distal radius or ulna.

Scaphoid Fractures

The blood supply to the scaphoid is through ligamentous attachments, primarily to its distal pole. Blood supply to the proximal pole is, therefore, dependent on continuity with the upper pole. As a result, scaphoid fractures have a high incidence of delayed union, nonunion, avascular necrosis, and pseudoarthrosis.² On examination, anatomic snuffbox tenderness and swelling, pain with axial compression of the thumb, and pain with supination of the wrist against resistance are sensitive signs of a scaphoid fracture.^{14,25} Unfortunately, 10% to 20% of scaphoid fractures will not be apparent on initial four-view radiographs. For this reason, patients with suspicion of a scaphoid fracture have historically had their injuries immobilized and reevaluated in 10 to 14 days. However, one study has demonstrated a 100% sensitivity for initial detection of scaphoid fractures using six-view radiographs (PA, lateral, extreme ulnar deviation, radial deviation, 25-degree pronation and supination views).¹⁴ The authors of this study suggest that an initially negative six-view radiographic series may obviate the need for immobilization and follow-up. However, the number of patients in this study was small and a larger corroborating study is needed before this can be recommended as a standard of care. Until then, patients with clinical signs of a scaphoid fracture, despite negative radiographs, should be placed in a thumb spica splint, with the forearm in midposition and the wrist in approximately 25 degrees of extension, and referred for follow-up in 10 to 14 days.

Patients with nondisplaced fractures may be treated initially with immobilization in a thumb spica splint (with the forearm and wrist positioned as just described) and timely follow-up. Immobilization of the elbow, using a long-arm versus a short-arm thumb spica splint, is controversial; therefore, discussion with the on-call hand surgeon is advised. Interestingly, evidence exists to support both practices.²⁵ As many as 95% of nondisplaced fractures will heal with simple immobilization. Unstable fractures or those displaced 1 mm or more require consultation with a hand surgeon. These fractures should be immobilized in a thumb spica splint pending definitive care, which usually involves open reduction and internal fixation. Prognosis is dependent on the location of the fracture and the presence of any displacement; oblique and proximal pole fractures are associated with a worse prognosis.

Triquetrum Fractures

The majority of triquetrum fractures are dorsal chip (avulsion) fractures due to a FOOSH injury. Less often, a direct blow to the wrist may cause a fracture of the body of the triquetrum. Body fractures are frequently associated with other carpal injuries (e.g., perilunate dislocation), but an isolated fracture of the body is rare. Triquetrum fractures are best seen on lateral or oblique radiographs of the wrist. Emergency department management involves immobilizing the wrist in a short-arm volar splint and close surgical follow-up.

Triquetrum fractures generally heal well with proper immobilization but may be complicated by damage to the deep branch of the ulnar nerve, with subsequent motor impairment.

Lunate Fractures

Isolated lunate fractures are relatively rare, accounting for only about 3% of traumatic wrist injuries.¹⁶ More commonly, lunate fractures occur in association with other wrist injuries. Similar to the scaphoid, the blood supply to the lunate is through ligamentous attachments primarily to the distal pole; hence these injuries have a high incidence of avascular necrosis, leading to Kienbock disease, nonunion, and subsequent carpal instability. The lunate is located distal to the Lister tubercle, and a fracture of the lunate results in marked tenderness and swelling in this area. In addition, axial compression of the third metacarpal usually causes marked discomfort. Unfortunately, initial plain radiographs of the wrist often fail to demonstrate the fracture. Therefore, if there is clinical suspicion of a fracture (or diagnostic radiographs), the wrist should be immobilized in a long-arm thumb spica splint and the patient referred for prompt surgical follow-up.

Kienbock Disease

Kienbock disease, or osteonecrosis of the lunate, is a disabling affliction resulting from avascular necrosis of the lunate. The pathogenesis is thought to be a combination of vascular predisposition, mechanical risk, and loading forces on the lunate that result in vascular compromise, bony degeneration, and eventual collapse. A shortened ulna (a normal variant known as ulna minus variant) may also be a predisposing factor to the development of Kienbock disease. Patients present with pain localized in the area of the lunate, stiffness, occasional swelling, and marked loss of grip strength. A history of significant wrist trauma is often lacking, but carpal tunnel syndrome may be the presenting symptom in some cases.¹ Diagnosis is usually confirmed by plain radiographs that demonstrate sclerosis, collapse, and, ultimately, fragmentation of the lunate. However, radiographs may be normal early in the course of the disease. Patients suspected of having Kienbock disease should be immobilized in a short-arm volar splint and referred to a hand specialist.

Scapholunate Dissociation

Scapholunate dissociation is a subtle injury often misdiagnosed as a simple wrist sprain. The mechanism of injury is forced dorsiflexion resulting in a torn scapholunate ligament. Patients usually present with pain, swelling, and a clicking sensation in the wrist.⁴ The diagnosis should be suspected when there is tenderness over the area of the scapholunate ligament, located just distal and radial to the Lister tubercle, and painful motion of the scaphoid. A gap of greater than 3 mm between the scaphoid and the lunate on the frontal view of the wrist is diagnostic. Other helpful radiographic signs include volar angulation of the scaphoid (e.g., a radioscapoid angle greater than 60 degrees), lack of parallelism of the articular surfaces of the scaphoid and lunate, and V-shaped notching of the normally smooth C-shaped line formed by the volar surfaces of the scaphoid and radius.⁹ Emergency department management includes immobilization in a thumb spica splint and prompt referral. Although some controversy exists regarding optimal treatment, most hand surgeons favor open reduction and repair of the scapholunate ligament.

Lunate and Perilunate Dislocations

Lunate and perilunate dislocations can be viewed as similar injuries.⁸ With extreme dorsiflexion, forces transmitted through the wrist dorsally displace the capitate and disrupt the capitollunate joint. Disruption of this joint allows volar or, rarely, dorsal displacement of the lunate, resulting in lunate dislocation. Perilunate dislocation results from the same mechanism, although the lunate remains aligned with the distal radius, and the capitate and metacarpals are dislocated, usually dorsally. Perilunate dislocations can be associated with carpal bone fractures and are described as transradial, transscaphoid, transcapitate, or transtriquetrum perilunate dislocations, depending on which carpal bones are fractured. In both perilunate and lunate dislocations, the frontal radiograph may reveal increased carpal bone overlap, shortening of the scaphoid, or other carpal bone fractures. In addition, with lunate dislocations, the normally rectangular lunate appears triangular on the frontal view.

In evaluating the lateral view, an imaginary straight line should be drawn through the distal radius, lunate, and capitate. If this line does not pass through the centers of the lunate or capitate, a lunate or perilunate dislocation should be suspected, respectively. In addition, on the lateral radiograph, a perilunate dislocation demonstrates disarticulation of the capitollunate joint, with the capitate dorsally displaced and the lunate remaining in normal alignment with the distal radius. With a lunate dislocation, the capitate has a near linear alignment with the radius, but the lunate is volarly rotated and displaced (i.e., “spilled teacup” sign). Emergency department management of a lunate or perilunate dislocation includes immobilizing the wrist in the neutral position in a volar splint and immediate consultation with a hand surgeon for reduction. Some surgeons believe that if reduction is not accomplished and maintained easily, open reduction and internal fixation with repair of the

damaged ligaments is required.⁸

DISPOSITION

Patients with closed, nondisplaced carpal bone fractures can be discharged from the emergency department with prompt (24 to 72 hours) referral to a hand surgeon. In most cases, discussion with the follow-up physician is recommended before discharge. Patients with displaced fractures and lunate or perilunate dislocations should be evaluated by a hand surgeon in the emergency department. All patients with open fractures or dislocations will require intravenous administration of an antibiotic (e.g., cefazolin) and operative lavage and debridement.

COMMON PITFALLS

- Failure to diagnose an associated injury when confronted with a clinically or radiographically obvious carpal injury
- Misdiagnosing a scaphoid fracture or scapholunate dissociation as a wrist sprain and not providing adequate immobilization and follow-up
- Failure to appreciate radiographic evidence of a lunate or perilunate dislocation and obtain hand surgery consultation
- Failure to provide adequate analgesia and sedation for patients requiring fracture or joint reduction
- Failure to provide adequate discharge instructions regarding splint and/or cast care, extremity elevation, and specific precautions regarding splint and/or cast complications

METACARPAL INJURIES

CLINICAL PRESENTATION

Patients with metacarpal injuries generally present with pain, swelling, deformity, and limitation of movement after a direct blow to the hand, a crush injury (e.g., industrial press), a missile injury, or striking an object with a closed fist. The location of maximal tenderness and the presence of crepitus and deformity will help localize the area of injury. Furthermore, in patients with a metacarpal head fracture, axial compression of the extended digit causes severe discomfort; in patients with a metacarpal base fracture, flexion or extension of the wrist or longitudinal compression exacerbates the pain. Metacarpal fractures are classified according to which bone is injured, as well as the fracture site. Fractures of metacarpals 2 through 5 are classified together and divided into head, neck, shaft, and base fractures. First metacarpal fractures are classified as extraarticular base and shaft fractures and intraarticular base fractures.

DIFFERENTIAL DIAGNOSIS

Metacarpal injuries include fractures, dislocations, or combinations of the two. Carpal–metacarpal dislocations may accompany or be confused with proximal metacarpal injuries, while proximal phalangeal injuries and MCP joint dislocations must be included in the differential diagnosis of distal metacarpal injuries.

EMERGENCY DEPARTMENT EVALUATION

Evaluation should include a detailed history and physical examination and standard radiographs, as outlined earlier. Diagnosis and correction of rotational malalignment (see [Fig. 114.3](#) and [Fig. 114.4](#)) is particularly important with metacarpal injuries.

EMERGENCY DEPARTMENT MANAGEMENT

Nondisplaced metacarpal fractures are managed by immobilization in an ulnar gutter splint (metacarpals 4 and 5), radial gutter splint (metacarpals 2 and 3), or thumb spica splint (metacarpal 1) and by prompt referral. It is imperative that malalignment, especially rotational malalignment, is excluded by radiographs and careful physical examination (see [Fig. 114.3](#) and [Fig. 114.4](#)). The wrist should be splinted in 20 degrees of extension, the MCP joints near 90 degrees' flexion, and IP joints in extension. All open fractures, unstable fractures, multiple metacarpal fractures, and fractures that cannot be reduced by closed technique require surgical consultation for open reduction and internal fixation.

Metacarpal Neck Fractures

Most commonly seen in the fifth metacarpal (i.e., boxer fracture), neck fractures are usually the result of striking an object with a closed fist. Metacarpal neck fractures are easily reduced, but reduction is often difficult to maintain due to comminution of the volar cortex. Furthermore, because metacarpals 2 and 3 are relatively fixed and immobile, reduction of these fractures must be near anatomic. Any volar angulation will project the metacarpal head into the palm and impair grip strength. Greater angulation is acceptable in metacarpals 4 and 5 because they have greater mobility and can move dorsally without impairment of grip strength. Most hand surgeons will allow up to 40 degrees of angulation in fractures of the fifth metacarpal neck and 20 degrees of angulation in fractures of the fourth metacarpal neck. In contrast, as little as 10 degrees of angulation is unacceptable for metacarpals 2 and 3. Reduction of a metacarpal neck fracture is accomplished by taking advantage of the fact that the MCP joint collateral ligaments are taut in flexion and the proximal phalanx can be used as a lever to manipulate the distal fracture fragment. Reduction techniques are the same regardless of which metacarpal is fractured; however, surgical consultation is recommended before reduction of metacarpals 2 and 3, because some surgeons prefer operative fixation. After adequate anesthesia has been obtained, the MCP and PIP joints are flexed to 90 degrees and pressure is applied to the PIP joint in a dorsal direction to force the metacarpal head into its normal position. Stabilizing volar pressure should be applied with the physician's other thumb just proximal to the fracture site ([Fig. 114.5](#)). If reduction is difficult, longitudinal distraction may be needed to disimpact the fracture before attempting reduction. A gutter splint incorporating the adjacent finger should be placed while carefully keeping the MCP joint flexed to maintain reduction. The wrist should be splinted in 20 degrees' extension, the MCP near 90 degrees' flexion, and the IP joints in extension. It is very important to immobilize the MCP joint as close to 90 degrees as possible, because the metacarpal head is cam shaped, causing the collateral ligaments to be taut in flexion and relaxed in extension. Shortening of the collateral ligaments from immobilization in extension can permanently limit flexion of the MCP joint. Furthermore, the “90–90” splint that maintains both the MCP and PIP joints at 90 degrees should never be used, because it may cause skin sloughing over the PIP joint and PIP joint stiffness.⁷ Follow-up should be arranged within 5 to 7 days; if loss of reduction occurs, operative fixation may be needed.

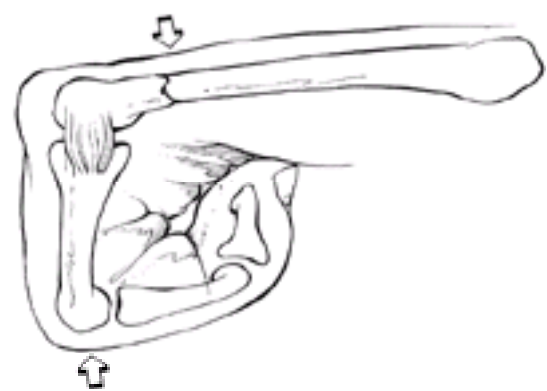

Figure 114.5. The 90–90 method of reduction for metacarpal neck fractures.

Metacarpal Head Fractures

Usually the result of a direct blow or crush injury, metacarpal head fractures are often comminuted and may be complicated by rotational malalignment. Management consists of temporary immobilization in a bulky hand dressing or well-padded volar splint. Emergency department evaluation by a hand surgeon is indicated for most metacarpal head fractures because anatomic reduction, which is essential to prevent loss of function, frequently requires operative intervention. Even with optimal

management, severe metacarpal head fractures may have a poor functional outcome. Extensor tendon damage and fibrosis and interossei muscle fibrosis are complications of metacarpal head fractures.³

Metacarpal Shaft Fractures

Metacarpal shaft fractures usually result from a direct blow to the hand, resulting in a transverse or comminuted fracture, or from a rotational force to a digit, causing an oblique or spiral fracture. The action of the interossei muscles usually causes transverse fractures to angulate dorsally, while oblique or spiral fractures tend to shorten and rotate.³ Nondisplaced transverse fractures are treated by immobilization in a gutter splint, with the wrist in 20 degrees of extension, the MCP joint in 60 to 90 degrees of flexion, the PIP joint in 20 to 30 degrees of flexion, and the DIP joint in 10 to 15 degrees of flexion.²³ Whenever possible, displaced transverse metacarpal shaft fractures should be reduced by a hand surgeon. However, if consultation is not available, reduction may be attempted by the emergency physician by applying volar force over the dorsal apex of the fracture and dorsal pressure on the flexed MCP joint. It is essential that any rotational deformity be corrected. If reduction is successful, the hand is splinted as described earlier and the patient is referred for follow-up in 3 to 5 days. If a transverse fracture cannot be reduced, or if an oblique, spiral, or comminuted fracture is present, consultation with a hand surgeon for operative repair is indicated.

Metacarpal Base Fractures

Base fractures of the metacarpals are generally stable, but even slight rotational deformity will be greatly amplified at the fingertip.⁷ Nondisplaced fractures without rotational deformity may be treated by immobilization in a gutter or volar splint and by surgical referral. Displaced or intraarticular base fractures require hand surgery consultation for open reduction and internal fixation.

First Metacarpal Fractures

First metacarpal fractures are usually the result of a direct injury to the thumb. These fractures usually occur at or near the base and may be either extraarticular or intraarticular. Extraarticular fractures are more common and are usually transverse or, less often, oblique. Because of the mobility of the first metacarpal, as much as 20 to 30 degrees of angulation may be present without loss of mobility or function. Transverse fractures with less than 30 degrees of angulation are treated with immobilization in a short-arm thumb spica splint and prompt follow-up. A transverse fracture with greater than 30 degrees of angulation requires reduction, which involves manipulation of the fracture, using the thumb for distraction. After reduction, the thumb is splinted as described earlier, and the patient is referred for follow-up. Oblique fractures are often unstable and frequently require percutaneous pinning for adequate immobilization; therefore, consultation is advised before manipulation or discharge.

There are two types of intraarticular fractures: Bennett fracture and Rolando fracture. In a Bennett fracture, the fracture line extends through the articular surface and creates a fragment off the volar lip of the metacarpal base. Because of the pull of the abductor pollicis longus, the metacarpal base is subluxed or dislocated proximally and radially. A Rolando fracture is a T- or Y-shaped intraarticular fracture of the base of the first metacarpal—in essence, a comminuted Bennett fracture. Both fractures result from an axial blow to the metacarpal, commonly sustained by striking an object with a closed fist. Emergency department management includes immobilization in a bulky hand dressing and hand surgery consultation. If surgical consultation is not readily available, the thumb may be immobilized in a short thumb spica splint and follow-up arranged within 24 hours. Definitive therapy for a Bennett fracture frequently requires pinning for a stable anatomic reduction. A Rolando fracture often requires open reduction and has a poor prognosis, even with optimal management.⁷

Metacarpal Dislocations

Dislocations involving the metacarpals are either carpometacarpal (CMC) or metacarpophalangeal (MCP). CMC dislocations require a significant force and are usually caused by a crush injury; a direct blow, causing a longitudinal force along the metacarpals; or a levering, dorsiflexion force. These dislocations are generally dorsal and often associated with metacarpal or carpal fractures and significant soft-tissue trauma. The presence of a displaced proximal metacarpal fracture should prompt a careful search for an associated CMC dislocation. The lateral view is usually the most helpful for diagnosing CMC dislocations. However, overlapping densities on standard wrist radiographs (PA, oblique, and lateral) may make the detection of CMC dislocations difficult. Special views (e.g., anteroposterior [AP] in supination, 30-degree radial, and ulnar obliques) may also be useful in detecting CMC dislocations. Emergency department care is supportive pending hand surgery consultation. CMC dislocations are easily reduced with the patient under general anesthesia or brachial plexus block, but operative fixation (i.e., Kirschner pinning) is usually required to maintain reduction, particularly if multiple fractures or dislocations are present. Complications of CMC dislocations are ulnar and median nerve injuries, extensor tendon injuries, and circulatory compromise.

MCP dislocations are usually dorsal, occasionally lateral, and rarely volar. They are generally well visualized on standard radiographs of the hand. Dorsal MCP dislocations are classified as simple (reducible) or complex (irreducible). Simple dorsal dislocations are the most common and are usually readily reduced in the emergency department. Complex dorsal dislocations are irreducible by closed techniques because the volar plate is forced between the metacarpal head and the proximal phalanx, trapping the metacarpal head between the flexor tendons and the lumbricals (Fig. 114.6). On examination, complex dislocations often appear less deformed than simple dislocations (because of overlap of the proximal phalanx on the metacarpal head) and are associated with puckering of the palmar skin overlying the metacarpal head. Radiographically, the presence of a sesamoid bone within the MCP joint space is pathognomonic of a complex dislocation.⁷ Simple dorsal dislocations are reduced by slight flexion of the wrist to relax the extrinsic flexors, followed by gentle hyperextension of the MCP joint (not beyond 90 degrees) and firm pressure on the dorsal aspect of the proximal phalanx. Longitudinal traction and extreme hyperextension are to be avoided, because this may interpose the volar plate, converting a simple dislocation to a complex one. After reduction, the hand is immobilized, with the wrist in 20 degrees of extension, the MCP joint in 50 to 70 degrees of flexion, the PIP joint in 20 to 30 degrees of flexion, and the DIP joint in 10 to 15 degrees of flexion. One attempt at reduction of a possible complex dislocation may be warranted, but multiple attempts should be avoided. These patients require open reduction and repair of the volar plate injury.

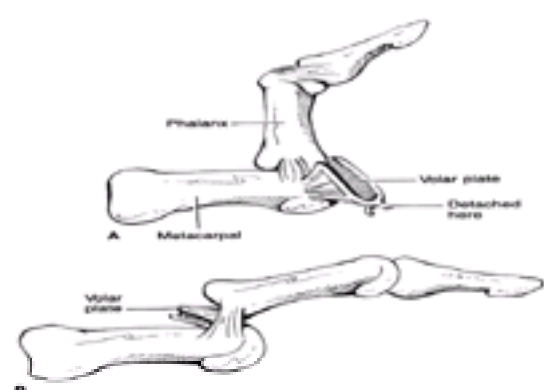

Figure 114.6. Dorsal dislocation of the MCP joint. (A) Simple dorsal dislocation. (B) Complex dorsal dislocation; note entrapment of the volar plate.

Collateral MCP ligament injuries occur infrequently and are often missed acutely. The presence of an avulsion fracture from the metacarpal head or corner fracture of the base of the proximal phalanx suggests an MCP collateral ligament injury. Consultation with a hand surgeon is recommended for patients with a collateral ligament injury, because some surgeons prefer operative reduction and repair of these injuries, especially if the fracture involves greater than 20% of the articular surface or is displaced more than 2 to 3 mm.⁷ Emergency department care involves immobilization in a gutter splint, with the MCP in at least 50 degrees of flexion, and appropriate referral.

Gamekeeper Thumb (Skier Thumb)

Initially described as a chronic laxity of the thumb MCP joint ulnar collateral ligament in British gamekeepers (a result of the technique by which they killed wounded rabbits), the term *gamekeeper thumb* has come to include all injuries to the thumb ulnar collateral ligament. Today, acute rupture of the ulnar collateral ligament

caused by sudden abduction of the thumb is much more common and is most often due to falls while skiing, earning the eponym *skier thumb*.

Plain radiographs may be normal or may reveal an avulsion fracture from the base of the proximal phalanx. If plain radiographs do not reveal a fracture, stressing the ligament may help determine the degree of injury (e.g., partial vs. complete tear). The joint should be stressed in slight flexion to reduce the stabilizing effect of the volar plate. A difference of greater than 10 degrees between the injured and uninjured thumb is considered positive. Unless the joint is grossly unstable, local anesthesia may be needed for a reliable examination. In equivocal cases, stress radiographs of both sides may be diagnostic. ⁷

Emergency department management includes immobilization in a thumb spica splint and early (i.e., 24 to 48 hours) referral. A frequent complication of ulnar collateral ligament rupture is chronic laxity of the MCP joint due to interposition of the adductor aponeurosis between the ends of the torn ligament that prevents healing. ^{7,11} As a result, many surgeons prefer operative repair of the torn ligament. The presence of a fracture involving greater than 25% of the articular surface or of a displaced avulsion fracture is also an indication for open repair. ⁷

DISPOSITION

Most patients with metacarpal injuries can be discharged from the emergency department with appropriate immobilization and instructions. Those patients with open fractures, irreducible fractures or dislocations, or circulatory compromise should be evaluated by a hand surgeon in the emergency department. Patients with stable fractures, anatomically reduced dislocations, and ligamentous injuries can be discharged with early follow-up, because operative repair or fixation can be performed 3 to 5 days after the injury.

COMMON PITFALLS

- Failure to appreciate volar angulation of fractures of metacarpals 2 and 3
- Failure to diagnose associated or multiple hand injuries
- Failure to appreciate and correct rotational deformity in metacarpal fractures
- Failure to appreciate CMC dislocation due to overlapping densities
- Improper splinting of the hand. In most circumstances, the hand should be splinted, with the wrist in 20 degrees of extension, the MCP joint in 60 to 90 degrees of flexion, and the IP joints in 10 to 15 degrees of flexion.

Phalangeal Injuries

Phalangeal injuries are commonly thought of as trivial, but they can result in significant functional disability if not recognized and treated appropriately. Injuries to the fingers are usually a result of direct trauma to the digit.

CLINICAL PRESENTATION

Patients present with varying degrees of pain, swelling, and tenderness; limited or complete loss of function; and deformity of the involved digit.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of acute phalangeal injuries includes fractures, fractures–dislocations, and ligamentous injuries. Associated metacarpal injuries must always be excluded, especially in the presence of a proximal phalanx injury.

EMERGENCY DEPARTMENT EVALUATION

As with all hand injuries, a detailed history and physical examination are essential. The presence of rotational deformity must be carefully sought (see [Fig. 114.3](#) and [Fig. 114.4](#)) and corrected, particularly with proximal phalangeal fractures. Radiographs are indicated in most injuries. It is important to accept only high-quality radiographs, because subtle injuries may be missed on lesser-quality films.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment of closed phalangeal injuries depends on the nature of the injury (discussion follows). Open phalangeal fractures, with the exceptions of distal amputations and distal phalanx fractures, are managed in a fashion similar to that for other open fractures.

Proximal and Middle Phalangeal Fractures

Stable, nondisplaced middle and proximal phalangeal fractures without angulation or rotational deformity can be managed with dynamic splinting (i.e., “buddy taping”) to an adjacent normal digit. An absorbent material (e.g., felt, gauze, lamb’s wool) should be placed between the digits for padding and to prevent maceration of the skin. The patient should bend the fingers normally and use the hand as comfort allows. Radiographs are obtained in 7 and 14 days to assess angulation and healing. Unstable fractures of the proximal and middle phalanges (e.g., oblique, condylar, displaced, or angulated transverse fractures) and displaced intraarticular fractures generally require operative reduction or fixation. Emergency department management of these fractures includes immobilization in a gutter splint and surgical consultation.

Of special note are avulsion fractures off the dorsal aspect of the base of the middle phalanx. If not recognized and treated appropriately, these fractures can result in a boutonniere deformity (i.e., fixed flexion of the PIP joint and fixed hyperextension of the DIP joint). This deformity is caused by avulsion of the central slip of the extensor tendon, with loss of extensor function at the PIP joint, and unopposed force from the flexor digitorum superficialis. With time, the lateral bands of the extensor expansion sublux laterally and volarly, becoming PIP joint flexors and DIP joint extensors; contractures make this a fixed deformity. These fractures should be immobilized in a volar splint, with the PIP joint in extension, followed by prompt referral. Avulsion fractures from the volar aspect of the base of the middle phalanx can be indicative of a volar plate injury. These injuries should be immobilized in a volar splint in 15 degrees of flexion, followed by appropriate referral. Unrecognized or improperly managed volar plate injuries at the PIP joint may result in a swan-neck deformity, characterized by hyperextension of the PIP joint and flexion of the DIP joint.¹⁸

Distal Phalanx Fractures

Distal phalanx fractures are divided into intra- and extraarticular fractures. Extraarticular fractures usually result from a direct blow to the distal phalanx. These injuries are frequently associated with a subungual hematoma and nail bed laceration. Nondisplaced extraarticular fractures are managed with a protective splint for 3 to 4 weeks, elevation, and appropriate analgesia. A U-shaped splint can be constructed using commercially available aluminum and foam splints and positioned in either a sagittal or a coronal plane. Displaced extraarticular fractures are reduced by applying dorsal traction to the distal fragment. If reduction is successful, the digit is immobilized in a volar splint and the patient is referred to a hand surgeon; otherwise, hand surgery consultation is indicated.

Intraarticular fractures most commonly involve the dorsal surface of the joint and are often referred to as a mallet finger. This injury is frequently caused by a ball striking the tip of an extended finger. The mechanism of injury is forced flexion of the distal phalanx with the finger in taut extension, resulting in injury to the extensor tendon (e.g., stretching, rupture) or an intraarticular avulsion fracture of the dorsal aspect of the distal phalanx with loss of extensor function. Patients typically present with tenderness and swelling over the dorsal aspect of the DIP joint and loss of extension at the DIP joint. Emergency department management includes immobilization using a Stack splint or a padded dorsal aluminum splint with the DIP joint in extension. If the fracture involves less than 25% of the articular surface, immobilization is maintained for 6 to 8 weeks to coapt the tendon or fracture segments. If the fracture involves more than 25% of the articular surface, the patient should be referred for surgical fixation. Open distal phalanx fractures are treated by copious irrigation and wound closure, ensuring complete soft-tissue coverage of exposed bone. Prophylactic antibiotics generally are administered but are likely of benefit only in high-risk cases (e.g., gross contamination, delayed presentation,

immunosuppression).

Proximal Interphalangeal Joint Dislocations

Dislocation of the PIP joint is the most common dislocation of the hand. Dorsal dislocations result from hyperextension forces, such as occurs when the outstretched finger is struck by a ball, and are accompanied by partial or complete rupture of the volar plate or collateral ligaments. Volar dislocations occur less often but are associated with complete rupture of the volar plate and collateral ligaments, as well as the central slip of the extensor mechanism. Patients usually present with pain, swelling, and deformity of the PIP joint. Rarely, severe swelling will mask an otherwise obvious deformity. The presence of pain and a locking sensation with flexion suggests a volar plate injury. Radiographs are diagnostic for acute dislocations, but small avulsions of the volar plate may not be visible or are seen only on the lateral postreduction view. Most dorsal dislocations are easily reduced, but the volar plate may become interposed in the joint space, preventing reduction by closed techniques. If this occurs, open reduction is required. For closed reduction, a digital nerve block will provide adequate anesthesia. The distal portion of the digit is firmly grasped and slightly hyperextended; then, with gentle traction parallel to the middle phalanx, the base of the middle phalanx is pressed back into position and the PIP joint is flexed. The PIP joint should be immobilized using a volar splint, in 15 to 20 degrees of flexion for 2 to 5 weeks.

Some authors recommend dynamic splinting (buddy taping) for 3 to 6 weeks if the collateral ligaments are stable and there is no evidence of a fracture. ^{7,24} Volar dislocations can be reduced by traction with both the MCP and PIP joints flexed. Consultation with a hand surgeon before reduction is recommended, because some surgeons prefer to treat these dislocations operatively to prevent a boutonniere deformity. Joint stiffness is a common complication after both volar and dorsal dislocations.

Distal Interphalangeal Joint Dislocations

Dislocations of the DIP joint are relatively uncommon injuries. They are almost exclusively dorsal and often associated with an open wound. DIP joint dislocations can usually be reduced with digital block anesthesia and simple traction. After reduction, the DIP joint should be immobilized in extension using a dorsal splint and the patient referred to a hand surgeon in 3 to 7 days.

DISPOSITION

Patients with stable, anatomically reduced phalangeal injuries can be discharged from the emergency department with appropriate follow-up. Patients with open fractures or nonreducible or unstable fractures or dislocations require consultation with a hand surgeon.

COMMON PITFALLS

- Failure to diagnose subtle fractures due to inadequate radiographic studies, including lack of true lateral views of injured digits, and both pre- and postreduction views
- Failure to recognize a volar plate disruption that may lead to a swan-neck deformity
- Failure to appreciate and correct rotational deformity in a phalangeal fracture
- Inadequate splinting or lack of appropriate surgical referral
- Inadequate instructions regarding cast or splint care or indications that should prompt an immediate return to the emergency department

HAND LACERATIONS

The objectives of emergency department care of hand lacerations are to preserve function, prevent infection, minimize scar formation, and provide the optimal wound environment for rapid healing. Simple lacerations (clean, less than 6 hours old, and not involving tendons, joints, or neurovascular structures) are managed in the same manner as lacerations elsewhere (see [Chapter 95](#)). However, in many areas of the hand, vital structures are extremely superficial, and injuries to these structures are not always readily apparent. Therefore, great care must be taken in the evaluation of hand lacerations to identify associated injuries, particularly injuries to tendons, nerves, or arteries.

CLINICAL PRESENTATION

Hand lacerations may range from clean, superficial wounds to severely contaminated crush injuries or amputations. Associated tendon injuries may cause a partial or complete loss of motor function, and injury to surrounding nerves may result in loss of both motor and sensory function. Due to their close proximity, digital nerve and flexor tendon injuries frequently occur together.

DIFFERENTIAL DIAGNOSIS

The diagnostic challenge of hand lacerations lies in the detection of underlying injuries that may threaten function of the hand. Tendon lacerations and injury to bones, joints, nerves, and arteries must be excluded by examination, radiography, and/or direct exploration of the wound.

EMERGENCY DEPARTMENT EVALUATION

Evaluation of a hand laceration begins with a pertinent history and meticulous examination. Adequate exploration of the wound requires a clean, bloodless, well-illuminated field and adequate anesthesia. Hemostasis can generally be obtained by direct pressure over the wound. A proximal blood pressure cuff (for hand and wrist wounds) or finger tourniquet (for digit wounds) may be needed to control hemorrhage. Blind clamping of bleeding vessels may injure adjacent nerves or tendons and should be avoided. Anesthesia may be obtained by direct infiltration of a local anesthetic or regional nerve block but should never be attempted until a complete sensory examination has been performed. When a complex injury requiring hand surgery consultation is apparent from the initial evaluation, the instillation of local anesthetic should await examination by the consultant. Pain control can be provided with systemic analgesics. Radiographs are indicated in any case in which the mechanism of injury could produce a fracture, dislocation, joint capsule injury, or retained foreign body.

EMERGENCY DEPARTMENT MANAGEMENT

All hand lacerations, regardless of the depth, must be carefully explored, because injury to significant underlying structures can occur with even very small surface wounds. In addition, exploration should be carried out through a full range of motion, otherwise injury to underlying structures, particularly tendon lacerations, may be missed. Simple lacerations are cleaned, irrigated, and repaired in the same fashion as in other areas of the body. Deep sutures should be avoided. After repair, lacerations over areas of motion should be splinted until the skin edges are well adherent. In addition, lacerations that cross the flexor surface of joints may create a flexion contraction as they heal. This can be prevented by performing a Z-plasty, which creates a transverse scar. Antibiotics are generally not required for simple hand lacerations in otherwise healthy patients.

Clenched-Fist Injuries

Lacerations over the MCP joints are often a result of striking an object (e.g., an opponent's teeth during an altercation) with a clenched fist and may be associated with extensor tendon injury, joint capsule violation, or metacarpal neck fracture. Because of the devastating consequences of inadequate treatment (wound infection, septic arthritis), any laceration over the MCP joints must be approached with suspicion and assumed to be a human bite wound until proven otherwise. Treatment includes copious irrigation, immobilization and elevation, intravenous antibiotics (penicillin G 2 million units, and cefazolin 1 g), and hand surgery consultation for admission and possible debridement in the operating room. These wounds are not closed, owing to the high incidence of infection.

Tendon Lacerations

Tendon injuries are frequently associated with hand lacerations. A high index of suspicion combined with a detailed examination and careful wound exploration are essential in detecting these injuries. There are a number of reasons that tendon injuries are missed on initial presentation. Discomfort and anxiety may reduce patient

cooperation, making a reliable examination difficult. This problem can be overcome by the judicious use of local anesthesia. Frequently, the tendon is only partially cut, allowing limited or even complete function. In this case, only a high index of suspicion and meticulous wound exploration will prevent the complications associated with a missed partial tendon laceration (i.e., adhesions, delayed rupture, triggering, bow-stringing). Once identified, management of a tendon laceration depends on the type of tendon injured, the cross-sectional area of tendon involved, and the location of the laceration.

Because of their complex structure (tendon sheaths, pulley system), deep location, and high complication rate after injury (10% to 30%), all suspected flexor tendon lacerations (partial and complete) require consultation and repair by a hand surgeon. In circumstances in which a hand surgeon is not immediately available, the wound can be copiously irrigated and the skin closed primarily without tendon repair. The hand is then immobilized in a volar splint, with the wrist in 20 to 30 degrees of flexion, the MCP joint in 60 to 70 degrees of flexion, and the IP joints in 10 to 15 degrees of flexion; and the patient is referred to a hand surgeon for delayed repair within 7 to 10 days. Broad-spectrum antibiotic coverage (i.e., first-generation cephalosporin) is generally recommended for tendon lacerations.

In contrast to flexor tendons, extensor tendons are anatomically less complex, have a more superficial location, and are associated with fewer complications after repair. As a result, emergency department repair of many simple extensor tendon lacerations has become an accepted practice. Tendon lacerations at or distal to the DIP joint (open mallet finger) and lacerations over the metacarpals, middle phalanges, and proximal phalanges (not involving the PIP joint) are amenable to emergency department repair. Lacerations over the PIP joint may involve the lateral bands or the central slip of the extensor mechanism, which, if not repaired correctly and followed closely, can result in a boutonniere deformity. Therefore, these patients are best referred to a hand surgeon for repair. Partial extensor tendon lacerations involving greater than 10% of the cross-sectional area of the tendon should also be repaired.

Tendon lacerations at the level of the wrist and distal forearm require repair in the operating suite, because proximal extension of the wound is often needed to search for retracted tendons. Multiple tendon lacerations or injuries with underlying fractures will also require operative repair. Moreover, because increased attention is now being given to recovery and rehabilitation after extensor tendon repairs, particularly dynamic splinting and early mobilization, timely hand surgery referral should be arranged for all patients undergoing tendon repair in the emergency department.

Technique of Repair

Wound preparation of a hand injury is similar to that for injuries of other areas of the body (see [Chapter 95](#)). However, the entire hand should be sterilely prepped and draped so that the laceration and digits distal to it can be manipulated during exploration. An alternative is to place a sterile surgical glove over the patient's hand and cut away a portion of the glove to expose the wound. This is especially useful in repairing digital lacerations, in which a tourniquet can be created by removing the fingertip of the glove and rolling the remainder of the glove finger proximally. As always, copious irrigation with normal saline is essential. Extension of the wound may be necessary to visualize the tendon laceration or locate the proximal tendon slip. Extending incisions should start from one corner of the wound and generally follow the course of the involved tendon, avoiding obvious veins. Scar contractures are less problematic on the dorsum of the hand than on the palm. Once the involved tendon is identified, a holding stitch can be placed through the proximal tendon for traction during repair. The tendon can then be repaired with 4-0 or 5-0 simple, interrupted sutures or a horizontal mattress suture with the knot "buried" between the ends of the tendon. Nylon or polyglycolic acid, either braided or monofilament, is an acceptable material for tendon repair. More reactive or less long-lasting material (e.g., silk, plain gut, chromic gut) should be avoided. Sutures should be placed 5 to 10 mm from the cut edge of the tendon to avoid the suture tearing through the end of the tendon.

The hand or digit should be splinted in a position with the extensor mechanism relaxed. Tendon repairs at or distal to the DIP joint can be treated with a Stack or mallet finger splint, leaving the PIP joint mobile. Injuries at or proximal to the PIP joint should be splinted with the wrist in 30 degrees of extension, the MCP joint in 10 to 20 degrees of flexion, and the IP joints in slight flexion. Splinting may be required for up to 6 weeks, although some surgeons prefer to allow early protected motion. It is advisable to reevaluate patients for signs of wound infection 36 to 48 hours after tendon repair.

Nerve Injuries

The emergency physician should be proficient in the diagnosis of hand injuries complicated by nerve injury, because outcome is improved with early diagnosis. It is imperative that a careful examination of the hand is performed before the instillation of any local anesthetics; and if suspicion of a peripheral nerve injury exists, anesthetics should be withheld until consultation with the hand surgeon. Nerve repair requires microsurgical techniques and can be performed down to the level of the digital nerve proximal to the DIP flexor crease.²¹ Reapproximated peripheral nerves will regenerate at a rate of 1 to 4 mm/d. When nerve injuries occur in fresh, clean, well-perfused tissue, most surgeons prefer immediate repair. However, when necessary, repair can be delayed for 2 weeks to 3 months.²¹

Arterial Injuries

Arterial injuries may complicate either blunt or penetrating trauma and are frequently associated with nerve injuries due to their close proximity to peripheral nerves. However, because the hand has a dual blood supply, ischemia is uncommon with a single artery injury. Wound exploration is important, because even complete arterial lacerations may spasm and stop bleeding by the time the patient is evaluated. Arterial injuries with distal ischemia or associated nerve injury usually require surgical repair. However, isolated injury to the radial or ulnar artery without distal ischemia or sensory impairment is often managed by simple ligation. If a severed digital artery is not repaired, both the proximal and distal ends should be ligated to avoid rebleeding.

DISPOSITION

Patients with simple hand, or extensor tendon, lacerations repaired in the emergency department can be discharged. Reevaluation in 36 to 48 hours for signs of wound infection is advisable for all but minor lacerations. Surgical referral should be made for any complex injury. Discharge instructions should include strict hand elevation, application of ice for the first 24 hours, and splint precautions. Patients should receive written instructions on specific signs or symptoms for which to return to the emergency department.

COMMON PITFALLS

- Failure to suspect a tendon injury because of a small skin wound
- Failure to recognize a partial tendon laceration due to inadequate wound exploration
- Failure to identify a foreign body in a wound as a result of inadequate exploration or omission of a radiograph
- Inadequate splinting or lack of hand surgery referral when indicated
- Inadequate discharge instructions, particularly not explaining the signs of infection or need for immediate return should these signs develop

FINGERTIP LACERATIONS, AVULSIONS, AND AMPUTATIONS

Fingertip injuries are classified according to the extent and level of injury. Simple lacerations and small avulsion injuries are easily managed by the emergency physician. However, injuries that involve significant tissue loss or bony exposure should be referred to a hand surgeon for repair.

CLINICAL PRESENTATION

Patients may present with a minor laceration or a severe injury with significant tissue loss or destruction. There may be considerable discomfort, particularly with crush injuries and amputations. Bleeding is usually not severe unless there is associated injury to a digital artery.

EMERGENCY DEPARTMENT EVALUATION

Evaluation should include a focused history and careful hand examination. Standard radiographs of the injured hand should also be performed.

EMERGENCY DEPARTMENT MANAGEMENT

Crush injuries, amputations, and avulsion injuries in which there is significant soft-tissue or bone loss or bone exposure require evaluation and repair by a hand

surgeon. These injuries frequently necessitate split- or full-thickness skin grafts or the use of skin flaps for adequate coverage. Pending consultation, emergency department care includes administration of a parenteral antibiotic (e.g., cefazolin), appropriate analgesia, wound cleansing, and elevation. Avulsion injuries with minimal soft-tissue loss (wound area less than 10 mm²) and no bone loss or exposure may be allowed to heal by secondary intention, with excellent cosmetic and functional results. This is particularly true in children, who have excellent regenerative capacity. The technique consists of debriding all dead and devitalized tissue, followed by copious irrigation. The digit is then bandaged with a nonadherent dressing (e.g., Xeroform) and gauze and splinted for comfort and protection. The patient or family member is then instructed on how to perform daily dressing changes. Healing will occur in 14 to 21 days, and the patient is often able to return to work within 1 month. Complications include cold intolerance, hypersensitivity in the area of the scar, and a volar curving of the nail at the amputation site.

DISPOSITION

Patients with simple lacerations and minor avulsion injuries may be discharged from the emergency department. A follow-up visit at 48 hours to check for infection is advised. Patients with more significant injuries require surgical consultation.

Nail Bed Injuries

Subungual Hematoma

A subungual hematoma is a collection of blood under the nail plate. It commonly occurs after a direct blow to the fingertip and may be associated with a nail bed laceration or distal phalanx fracture.

CLINICAL PRESENTATION

Patients frequently complain of severe throbbing pain. A variable amount of blood will be visible beneath the nail plate and appears as a blue or black discoloration. There may also be associated injury to the nail bed and surrounding nail folds.

EMERGENCY DEPARTMENT EVALUATION

Evaluation should include a focused history and careful hand examination. Standard radiographs of the injured digit should also be performed.

EMERGENCY DEPARTMENT MANAGEMENT

One study has shown that all subungual hematomas, regardless of size or the presence of a distal phalanx fracture, may be treated by simple nail trephination as long as the nail plate and surrounding nail folds are intact.²⁰ The use of a hand-held, portable, high-temperature cautery device is recommended as a safe, effective, and painless method to drain a subungual hematoma. Heated paper clips may introduce carbon particles known as “lampblack” into the nail bed. These particles act as foreign bodies and can delay wound healing. Use of a needle, drill, or scalpel can be very painful and often requires the use of a digital block. Furthermore, the opening produced by these instruments is small and will frequently be occluded by clotted blood. After trephination, the digit should be dressed with absorbent gauze and splinted if a distal phalanx fracture is present. If there is disruption of the nail plate or surrounding nail folds, the nail plate should be removed and proper alignment of the nail bed assured through careful wound repair (see [Nail Bed Lacerations](#)).

NAIL BED LACERATIONS

Nail bed lacerations include simple lacerations, stellate lacerations, crush injuries, and avulsions. Failure to properly repair lacerations can result in a split nail deformity, irregular nail surface, or failure of the nail to adhere to the nail bed; these deformities are significant from both a cosmetic and a functional standpoint.

CLINICAL PRESENTATION

Presentation varies from innocuous-appearing injuries to those with severe deformity and tissue loss. There is usually throbbing pain, swelling, and tenderness. The nail plate may be intact, broken, partially avulsed, or completely torn away. Bleeding is usually not significant, but if a digital artery is injured, it can be profuse.

EMERGENCY DEPARTMENT EVALUATION

Evaluation should include a focused history and careful hand examination. Standard radiographs of the injured digit are also indicated.

EMERGENCY DEPARTMENT MANAGEMENT

Management depends on the type and severity of the injury. Crush and avulsion injuries often require a grafting procedure and are best repaired by a hand surgeon. However, management of simple and stellate lacerations may be performed in the emergency department under digital block anesthesia and tourniquet hemostasis using a 1-in. sterile Penrose drain placed securely around the proximal portion of the finger. If present, a broken nail can be removed using a small hemostat or iris scissors by gently opening and closing the instrument beneath the distal free edge of the nail until the nail plate is loose. The distal end of the nail is then grasped with a Kelly clamp and gently removed. The lacerations should be explored carefully for foreign bodies and then irrigated copiously. Debridement of the wound margins should be conservative, because removal of even small amounts of tissue can increase tension on the wound edges, leading to enhanced scar formation. Simple lacerations should be closed with interrupted 6-0 chromic sutures (or other adsorbable suture material) on an atraumatic needle. The use of loop magnification aids in accurate approximation of the wound edges. The sutures should be tied with only three to four knots so that they do not interfere with nail replacement. Stellate lacerations are repaired in a similar manner, keeping in mind that accurate approximation of each arm of a stellate laceration is essential for normal nail growth.

After repair, the involved nail (if available) should be used as a protective covering for the injured nail bed. Replacing the nail has many advantages, including reduced postoperative pain, less adherence of the gauze dressing, the ability to mold the healing nail bed, minimization of formation of granulation tissue or adhesions between the eponychium and the nail bed, and the ability to splint fractures of the distal phalanx. The nail should be inspected for debris or foreign matter and rinsed in normal saline before replacement. No squamous tissue should be removed from the undersurface of the nail, because replacing the nail in its normal position often replaces avulsed tissue as well. This tissue acts as a free graft that reduces nail bed scarring. A hole should be placed in the center of the nail to permit blood drainage. The proximal end of the nail is inserted under the eponychium until the nail is in its normal position on the nail bed. A 5-0 monofilament nylon suture placed through the fingertip and the distal free border of the nail secures the nail plate. The suture is cut in 2 to 3 weeks, allowing growth of the new nail to push out the old one. If the nail is missing or damaged, various materials can be used to cover the injured nail bed and keep the nail fold open. These include an INRO surgical nail splint, metal foil, polyurethane foam sponge, silicone sheeting adaptic, Xeroform, or sterile urine cup trimmed to fit under the nail fold and over the nail bed. An absorbent gauze dressing and application of a splint for comfort and protection are important adjunctive measures.

DISPOSITION

Patients with a subungual hematoma may be discharged from the emergency department. If a fracture was detected on the radiograph, the digit should be immobilized as described previously under distal phalanx fractures. In addition, all patients should be informed about the possibility of nail loss or deformity. Follow-up in 2 to 3 days is recommended for patients with a distal phalanx fracture, to check for infection. Similarly, those with a simple or stellate laceration may be discharged with a wound check arranged in 48 hours. Antibiotics are unnecessary in immunocompetent patients with clean, fresh wounds. For high-risk patients (e.g., immunosuppressed, delayed care, contaminated wound), many practitioners still recommend prophylactic use of an antibiotic, such as cephalexin or dicloxacillin, for 3 days.

Injuries to the Wrist

ANATOMY AND TERMINOLOGY

The ulna is essentially a straight bone, while the radius has outward bowing; these configurations allow the relatively mobile radius to rotate around the relatively fixed ulna during supination and pronation. A fibrous interosseous membrane joins these bones along their entire length. They become proximate only at the ends to form the complex distal and proximal radioulnar joints. Because of this close relationship, injury to one bone usually disrupts the other or causes a dislocation of either the distal or proximal joint (Galeazzi or Monteggia fracture–dislocations) ([Fig. 114.7](#) and [Fig. 114.8](#)). These bones are under the influence of multiple muscle groups, including the supinators and pronators such as the biceps brachii. Neurologic innervation of the wrist extensors is provided by the radial nerve, which traverses the lateral epicondyle. The radial nerve then gives off the posterior interosseous nerve, which traverses the proximal radius and innervates the muscles that extend the thumb and fingers. The distal portion of the radial nerve is sensory, innervating the posterior radial aspect of the hand. Therefore, injury level in the forearm dictates which functions of the radial nerve will be disturbed. The proximal median nerve controls basic wrist flexion and the wrist flexor nerve. In addition, the previously described hand flexion and palmar hand sensation from the radial aspect of the ring finger to the thumb are provided by the distal median nerve. The ulnar nerve provides innervation to a few forearm muscles.

Figure 114.7. Severely displaced Galeazzi fracture–dislocation in frontal (A) and lateral (B) projections. The distal radioulnar dislocation (*open arrow*) is secondary to the marked shortening of the radius caused by the severe ulnar displacement and dorsal angulation of the distal radial fragment. (From Harris JH Jr, Harris WH. *The radiology of emergency medicine*, 3rd ed. Philadelphia: Lippincott–Raven, 2000:390, with permission.)

Figure 114.8. In this variation of the Bado I Monteggia injury, the fracture site is comminuted and the volar angulation less than usual. The volar dislocation of the radial head and the ulnar fracture make this a Bado I fracture–dislocation. (From Harris JH Jr, Harris WH. *The radiology of emergency medicine*, 3rd ed. Philadelphia: Lippincott–Raven, 2000:365, with permission.)

The wrist is commonly injured, but specific diagnosis may be subtle. It is mandatory to understand the mechanics of the injury, the functional anatomy of the wrist unit, and utilize proper clinical assessment so as to appropriately recognize and manage important injuries. The wrist includes the area from the carpometacarpal joints to the distal radius and ulna. This is a complex structure, with multiple articulations among the distal radius and ulna and the eight carpal bones.

The distal radius is the only forearm bone that directly articulates with the carpal bones, specifically the lunate and scaphoid. This distal radius has three articular surfaces: the distal radioulnar; the radiocarpal, which is tilted in two planes; and the triangular fibrocartilage, which is the main stabilizing unit of the distal radioulnar joint. The distal radioulnar joint is also stabilized by volar and dorsal radioulnar ligaments, which merge with the triangular fibrocartilage. The distal radius has a concave notch on its ulnar aspect, which articulates with the curved surface of the ulnar head, allowing wrist rotation. The triangular fibrocartilage complex separates the ulna from the carpal bones and supports the triquetrum and lunate on the distal ulna. The proximal carpal row functions as an intercalated segment, or mobile link, between the distal row and the radius, making it potentially unstable.

The scaphoid serves as the stabilizing link between the distal and proximal carpal rows, placing it at greater risk for injury. The carpal bones are stabilized to the bones of the forearm by the two volar arcades and one dorsal arcade of extrinsic ligaments. The apex of one volar arch inserts on the lunate and supports the proximal carpal row, while the other arch attaches to the capitate of the distal carpal row. The space of Poirier, an inherently weak spot, lies at the junction of the capitate and lunate between these two palmar arches and widens with wrist dorsiflexion. Because of the mobile nature of the proximal carpal row, the intrinsic

ligaments of this row—the triquetrolunate and scapholunate—are particularly prone to injury. Forearm muscles that insert on the base of the metacarpals produce wrist movement. Except for the pisiform, a sesamoid of the flexor carpi ulnaris, there are no direct tendon insertions on the carpal bones. These bones move passively as a function of hand position. Wrist motion is equivalently produced by midcarpal and radiocarpal joint movement.

CLINICAL PRESENTATION

Injuries most often occur to the wrist because of falls on the outstretched hand (FOOSH). If the thenar eminence is impacted, the scaphoid and its supporting ligaments are more commonly injured, while hypothenar impact most commonly injures the pisiform or triquetrum and supporting ligaments. The age of the individual affects the maturity of the bones in the wrist and therefore directly influences the type of injury seen. Carpal injuries are rare in children. Injuries in the pediatric patient often involve the immature, relatively weak metaphysis of the radius or epiphyseal plate. The carpus in children is primarily cartilage. Young adults are more likely to injure the wrist with significantly greater force, and fracture either the distal radial metaphysis or the carpi. In the elderly, the distal radial metaphysis is injured most commonly because of its increased osteoporosis.

Injuries may be localized by careful inspection and palpation of the anatomic landmarks of the wrist for tenderness. The most clearly visible landmark on the volar wrist is the crease that marks the proximal carpal row. At the base of the thenar eminence lies the scaphotrapezium joint. The most important landmark on the dorsal surface is the anatomic snuffbox, with the radius styloid at the proximal base and the scaphoid at the apex of the triangle.

A palpable indentation in the middle of the wrist, immediately ulnar to the scapholunate joint, overlies the capitate and the lunate. With flexion of the wrist, the lunate is palpable at this location. Just distal to it lies the triangular fibrocartilage and the triquetrum.

Standard radiologic evaluation of the wrist includes a posteroanterior (PA) view, a lateral view, and oblique views. Additional special views may be required to identify more specific carpal injuries. Key positioning of the hand is integral to these examinations. On the PA view, three smooth arcs should outline the articular surfaces at the midcarpal and radiocarpal joints. Any disruption of these lines suggests a possible subluxation, dislocation, or fracture. The ulna and adjacent radius should appear of equal length, and the distal radius should articulate with at least one-half of the lunate at the distal radioulnar joint. With injury to the triangular fibrocartilage, the ulna may translocate and will not appear to contact the radius to the usual degree. On this same view, the radial styloid should project 8 to 18 mm beyond the distal radioulnar joint and create a 15- to 25-degree ulnar inclination of the distal radius. Distal radius fractures will alter these. The lateral view provides important information regarding the alignment of the carpi and the degree of fracture angulation present. The “three C’s”—the capitate, lunate, and radius—should be colinear on this view. Actual measurement of the scapholunate and capitulate angles will provide a more accurate view of carpal alignment. The scaphoid axis should form an angle that is between 30 degrees and 60 degrees with the lunate on this view, because of its normal palmar flexion on lateral view. Oblique views are performed in either supination or partial pronation. They project the pisiform or scaphotrapezium joint away from the adjacent overlapping carpal bones.

FRACTURES

Fractures of the carpal bones are discussed in the Hand Injuries section of this chapter.

ULNAR FRACTURES

Isolated ulnar fractures result most often from direct blows to the forearm, most commonly to ward off an assailant's blow (nightstick fracture). Undisplaced fractures are immobilized in a long-arm cast or splint, depending on the amount of initial swelling, and closely monitored for displacement or further significant swelling. Displaced fractures, those with greater than 10 degrees' angulation or with greater than 50% displacement of the width of the bone, usually require open reduction and internal fixation with a compression plate and screw to prevent length loss, angulation, or rotation. Again, these injuries should be examined carefully for evidence of associated radial dislocation or fracture.

Ulnar styloid fractures may be produced by forced radial dorsiflexion, radial deviation, and rotary stress. These styloid fractures may occur solely or accompany other fractures, such as the Colles fracture. Displaced ulnar styloid fractures may be accompanied by important injury to the triangular fibrocartilage. Often, individuals with this accompanying injury will complain of a painful locking sensation or clicking sensations in the wrist. Delineation of accompanying triangular cartilage injury may require wrist arthrography or magnetic resonance imaging. Ulnar styloid fractures are treated with casting or splinting in the neutral position of the wrist and slight ulnar deviation.

Fracture of the ulnar shaft with associated radial head dislocation is referred to as the Monteggia fracture–dislocation (see [Fig. 114.8](#)). This is usually a diaphyseal fracture in the proximal one-third of the ulna, with an associated anterior dislocation of the radial head. Occasionally, posterolateral or anterolateral radial head dislocation or a metaphyseal ulnar fracture may be seen. Clinically, the forearm may appear angulated and shortened. The ulnar fracture is clearly noted. Although less obvious than the ulnar findings, there is usually pain and swelling at the elbow, and the radial head may be palpated in the posterior or anterior location. On plain radiography, the apex of the ulnar fracture points toward the radial head dislocation, and the radial head may not point toward the capitellum on all views. In adults, these are treated with open reduction internal fixation (ORIF) of the ulna and closed reduction of the radial head dislocation. In children, adequate reduction may be achieved by closed reduction of both bones and long-arm casting. Complications of this fracture–dislocation include redislocation, infection, paralysis of the posterior interosseous nerve, and nonunion.

DISTAL RADIUS FRACTURES

Fractures of the distal one-third of the radial shaft are produced by either a direct blow or FOOSH in forced pronation. A force directed along the radial side of the hand can produce an oblique or transverse fracture of the radial styloid. This is most easily seen on an anteroposterior (AP) radiograph as a thin, lucent line proximal to the radial styloid. Displacement of this fracture can produce carpal instability because of the major carpal ligaments of the radial side of the wrist on this styloid. A displaced fracture may often require ORIF. Accompanying scapholunate dislocation should be sought. Posttraumatic arthritis may be worsened if the examiner fails to recognize associated intercarpal ligament tears.

FOOSH most often produces a dorsally angulated and displaced distal radial metaphyseal fracture called a Colles fracture ([Fig. 114.9](#)). Due to compression forces on the dorsal surface, dorsal bone comminution is often seen. The fracture line may also extend into the radiocarpal or radioulnar joint and comminute. A fracture of the radial styloid is often seen, which may suggest associated injury to the triangular fibrocartilage. On clinical examination, the wrist will appear in the classic “silver fork” or dorsiflexion deformity. Associated pressure on the median nerve may produce palmar paresthesias. On an AP radiograph, the dorsum may appear shortened, due to the angulation or comminution of the bone.

Figure 114.9. Extraarticular (Colles) distal radial fracture (arrow) in frontal (A) and lateral (B) projections associated with a fracture of the base of the ulnar styloid (curved arrow, A). (From Harris JH Jr, Harris WH. *The radiology of emergency medicine*, 3rd ed. Philadelphia: Lippincott–Raven, 2000:386, with permission.)

Stable fractures may be either reduced by the orthopedic surgeon, utilizing traction via finger traps and pushing the distal and palmar fracture fragment against the firmly held forearm, or treated with a splint and compression dressing until they can be evaluated by the consulting orthopedic surgeon. Particularly in younger patients, the goal is to restore normal radial inclination, volar tilt, and proper length to the radius. Unstable fractures, recognized radiologically by angulation greater than 20 degrees, intraarticular involvement, more than a centimeter of shortening, or marked comminution, often require ORIF or casting with external fixation, pinning, and possible bone grafting. In addition, any neurovascular compromise or an open fracture requires immediate hand surgery, plastic surgery, or orthopedic consultation. Complications of Colles fractures include median nerve injuries, radioulnar and radiocarpal instability, triangular cartilage injury, arthritis, and malunion.

A reverse Colles fracture or Smith fracture ([Fig. 114.10](#)) is a volarly angulated fracture of the distal radius. This injury is produced by a blow to or fall onto the dorsum of the hand and wrist or a FOOSH in supination. The hand is palmarly displaced in the so-called garden spade deformity. AP radiographs appear similar to those seen with a Colles fracture, with a distal metaphyseal fracture that may be either comminuted or shortened. On a lateral radiograph, the fracture is volarly angulated and displaced. The complications and treatment are similar to those for a Colles fracture, but the angulation is in the opposite direction.

Figure 114.10. Smith fracture characterized by a transverse fracture (arrows) of the distal radius, with volar and proximal displacement of the distal radial fragment (asterisk). (From Harris JH Jr, Harris WH. *The radiology of emergency medicine*, 3rd ed. Philadelphia: Lippincott–Raven, 2000:386, with permission.)

A Barton fracture ([Fig. 114.11](#)) is a volar or dorsal rim fracture of the distal radius. The more common dorsal rim fracture results from forced pronation and dorsiflexion of the wrist, while the less common volar rim fracture results from a fall on the supinated outstretched hand. Often, initially subtle subluxations or fracture–dislocations are seen, because the hand is frequently displaced in the direction of the fracture and associated ligamentous injuries produce radiocarpal instability. On AP radiography, a comminuted fracture of the distal radial metaphysis is often seen. On a lateral view, an intraarticular fracture of the dorsal or volar rim of the radius is seen, often with accompanying carpal subluxation in the same direction. Fractures with minimal displacement can be treated with closed reduction and a splint or cast until they are reevaluated with the consulting orthopedist. Unstable fractures, which involve more than 50% of the radioarticular surface or have associated carpal subluxation, require reduction and immobilization by the consulting hand specialist, orthopedist, or plastic surgeon, as they frequently require open reduction and fixation.

Figure 114.11. Classic volar Barton fracture. The oblique intraarticular fracture (arrows) involves the volar aspect of the distal radius. The separate fragment (asterisk) and the bones of the wrist and hand are volarly and proximally displaced. (From Harris JH Jr, Harris WH. *The radiology of emergency medicine*, 3rd ed. Philadelphia: Lippincott–Raven, 2000:388, with permission.)

A distal radial shaft fracture is often complicated by a distal radioulnar joint dislocation (Galeazzi or reverse Monteggia fracture). The radius fracture is usually short oblique or transverse with dorsolateral angulation. Localized tenderness is seen over the wrist and distal radius. AP-view plain films may exhibit only a slight increase in the distal radioulnar joint space. The lateral view will exhibit dorsal displacement of the ulna. This injury is managed by the consultant with ORIF, with compression plating and screws of the radius fracture. Reduction of the distal radioulnar joint is maintained with either immobilization of the forearm in supination or K-wire fixation for 6 weeks.

LIGAMENTOUS INJURY

Radioulnar disruption is usually seen with fractures of both bones of the forearm, or intraarticular or distal radial shaft fractures. Isolated injury is uncommon and may go unrecognized in 50% of cases. Unfortunately, these often more obvious injuries may cause the examiner to miss associated radioulnar joint disruption, with the injury discovered later because of pain and decreased wrist movement. Volar dislocation, which is rare, is produced by forced hypersupination of the wrist. The more commonly seen dorsal dislocation is usually produced by falls on the wrist in hyperpronation. The presentation is one of wrist pain and restricted range of motion, with an occasional palpable prominence of the head of the ulna. Appropriately positioned lateral radiography shows either dorsal or volar displacement of the ulna. AP radiography demonstrates overlap and narrowing of the distal radioulnar joint. Computed tomography scanning may be required to establish the diagnosis. The wrist should be immobilized in supination to reduce dorsal dislocation, while pronation will reduce volar dislocation. These injuries require consultation with a hand or orthopedic surgeon or a plastic surgeon because they have a high recurrence rate and may require reconstructive surgery.

COMMON PITFALLS

- Failure to appropriately position the wrist and hand for radiography
- Failure to recognize associated ligamentous or triangular cartilage injury with fracture
- Failure to recognize the complex of Galeazzi or Monteggia fractures
- Failure to appropriately and expeditiously consult the hand surgeon, orthopedist, or plastic surgeon.

The reader is referred to any of the commonly used orthopedic texts for a more specific discussion of the anatomy, evaluation, and management of each of the aforementioned injuries.

[Chapter References](#)

Low back pain (LBP) is one of the most common and expensive medical disorders. Almost 80% of adults experience at least one incapacitating episode of LBP during their lifetime. LBP is the most common cause of restricted activity in people younger than 45 years of age and the third most common cause of disability in people older than 45 years, following heart disease and arthritis. The cost of diagnosis, treatment, disability, worker's compensation, and litigation approaches \$50 billion annually, making LBP the third most expensive medical problem in the United States after heart disease and cancer.⁹

Many patients with LBP present to the emergency department for evaluation. An emergency physician should identify those patients with LBP who harbor underlying organic disease, determine the presence of intervertebral disc herniation, suspect when patients may be malingering, know when to obtain appropriate diagnostic tests, recognize the indications for emergent orthopedic or neurosurgical consultation, initiate appropriate treatment for nonemergent patients, and maximize patient satisfaction.

CLINICAL PRESENTATION

Low back strain, the most common cause of LBP, results from injury to the ligaments and muscles of the lower back. Pain and stiffness secondary to inflammation and subsequent muscle spasm begin minutes to hours after the initiating event but may not reach peak intensity until several hours or several days later. Occasionally, patients with nonmusculoskeletal disease, structural skeletal disorders, and skeletal malignancies; infections; or inflammatory disorders may present in a similar fashion.

Approximately 75% of patients with low back strain recover without residual symptoms within 1 to 4 weeks. Patients with symptoms persisting for more than 4 to 6 weeks should be evaluated for underlying organic disease and for psychosocial problems that might be inhibiting recovery.¹ Approximately 7% of patients have symptoms that persist longer than 6 months. At this point, the term *chronic LBP* is employed; patients with this designation rarely become asymptomatic, often experience recurrences, and rarely return to a normal lifestyle. The pathophysiology or psychopathology underlying chronic LBP is not well understood.

DIFFERENTIAL DIAGNOSIS

Nonmusculoskeletal Disorders

Disorders that can present as LBP include pleural effusions, pancreatic disease, perforated peptic ulcer, retrocecal appendicitis, large-bowel obstruction, renal disease, pelvic disease, prostatic disorders, retroperitoneal bleeding, and abdominal aortic aneurysm.⁹ History and physical examination exclude these disorders in most instances.

Malignancy

Malignancy that is either primary or metastatic to the vertebral column should be suspected in patients with known malignancy (particularly breast, lung, and prostate cancers) and in patients older than 50 years of age who have LBP associated with unexplained weight loss, pain lasting longer than 1 month, or failure of symptoms to improve with conservative therapy. High-risk patients should be evaluated with spinal radiographs and an erythrocyte sedimentation rate (ESR).⁷

Spinal Infections

Spinal infections, including osteomyelitis, disc space infection, and epidural abscess, are usually blood-borne from other sites, particularly the skin and urinary tract. Patients at highest risk include children, immunosuppressed patients, and intravenous drug users. Only 50% to 80% of patients with spinal infections have a fever at the time of presentation but almost all have significant pain and local spinal tenderness at the infection site. High-risk patients should be evaluated with spinal radiographs and an ESR.³

Ankylosing Spondylitis

Ankylosing spondylitis should be suspected in patients younger than 40 years of age who complain of the slow onset of LBP persisting longer than 3 months, with a daily pattern of morning stiffness followed by improvement with exercise. Patients at risk should be evaluated with an ESR and a pelvic radiograph to evaluate the sacroiliac joint.²

Fractures

Fractures of the thoracolumbar region of the vertebral column can be broadly classified as either minor or major injuries. Minor injuries (isolated fractures of the spinous process, transverse processes, or articular processes) are uncommon, usually result from direct blows, and have little clinical significance except for patient discomfort. Major injuries (fractures of the vertebral body or posterior elements) usually result from motor vehicle accidents or falls from heights, are easily overlooked due to their occurrence in the setting of major multisystem trauma, and may result in permanent neurologic dysfunction, particularly when the bony injury is unstable. Pathologic fractures, even in the absence of a history of trauma, may be seen in cancer patients with bony spinal metastases, patients receiving chronic corticosteroid treatment, and patients who are chronically bedridden or are older than 70 years of age.

Spinal Stenosis

Spinal stenosis is the progressive narrowing of the distal spinal canal or vertebral foramina, sometimes associated with nerve compression, that can occur in elderly patients. Patients present with slowly progressive symptoms, usually over several years, characterized by pain in the lower back and legs after walking (termed *neurogenic claudication*). There may be neurologic deficits in the lower extremities, particularly after the onset of symptoms following a period of walking. Neurologic and vascular examination of the lower extremities usually differentiates neurogenic claudication from arterial ischemic claudication.⁵

Intervertebral Disc Herniation

Disc herniation occurs in 20% to 30% of adults, but most disc herniations cause minimal or no symptoms. Clinically significant disc herniation should be suspected in patients with LBP that radiates to a lower extremity (termed *sciatica*). Patients with sciatica may have pain that is referred down a leg as the result of inflammation of the sciatic nerve or that radiates down a leg as the result of nerve root impingement (usually from a herniated lumbar disc or narrowing of a vertebral foramina from spinal stenosis). Referred pain is usually dull and poorly localized, does not radiate distal to the knee, and is not associated with a positive straight-leg-raising (SLR) test or neurologic impairment of the lower extremities. Alternatively, nerve root impingement results in sharp, well-localized radicular pain that frequently (but not always) radiates distal to the knee, is invariably associated with a positive SLR test, and may be associated with neurologic impairment. ^{12,13}

Cauda Equina Syndrome

The cauda equina syndrome is usually caused by a massive midline disc herniation impinging on multiple nerve roots within the distal spinal cord. It is characterized by severe LBP that develops acutely or over days to weeks in association with unilateral or bilateral sciatica, evidence of bowel or bladder dysfunction, a positive SLR test, and neurologic deficits. The most common sensory deficit involves the buttocks and perineal region (termed *saddle anesthesia*); the most common motor deficits are diminished rectal sphincter tone and urinary retention.

Malingering

Malingering is occasionally seen in patients presenting with LBP who are seeking drugs, worker's compensation, litigation, increased attention from loved ones, or other sources of secondary gain. Malignancy should be suspected in the presence of nonorganic signs and symptoms, as discussed in the following section. However, nonorganic signs are also seen in patients with psychiatric disorders, chronic pain syndromes, and occasionally in individuals with underlying organic disease.¹³ As a result, the diagnosis of malingering should rarely, if ever, be made in the emergency department.

EMERGENCY DEPARTMENT EVALUATION

Patient history should be directed at raising or lowering suspicion for disorders other than simple low back strain. In addition, the medical record should note whether an injury was work-related, the nature and duration of symptoms (particularly muscle weakness and bowel or bladder dysfunction), and the patient's impression of the severity of symptoms.

Physical examination should include a general description of the patient's degree of distress and limitation of movement. Chest and abdominal examinations should be performed routinely. Depending on the history, rectal and pelvic examinations may be indicated. Musculoskeletal examination should note areas of maximal tenderness and the presence or absence of muscle spasm. In the setting of major multisystem trauma, the signs and symptoms of spinal injury may be subtle or nonexistent due to alterations in mental status or the presence of other painful, distracting injuries.

Neurologic examination should document neurologic deficits (Table 115.1) and the results of SLR tests. The SLR test is performed by placing the patient supine and slowly elevating the involved leg until the patient experiences pain. A positive test occurs when the patient complains of a sharp pain that radiates down the involved leg, indicating nerve root impingement. However, only 60% to 80% of patients with a positive SLR test are ultimately found to have a disc herniation. The crossed-SLR test is performed by slowly elevating the opposite (asymptomatic) leg, until the patient experiences pain. A positive test occurs when the patient complains of a sharp pain that radiates down the contralateral (symptomatic) leg. The crossed-SLR test is less sensitive than the SLR test, but it is highly specific for nerve root impingement.⁹

Disk	L4	L5	S1
Pain	Front of leg	Side of leg	Back of leg
Weakness	Extension of leg at knee	Dorsiflexion of foot	Plantar flexion of foot
Sensory loss	Knee	Lateral lower leg and web space of great toe	Back of calf and lateral foot
Reflex loss	Knee jerk	None	Ankle jerk

TABLE 115.1. Pain Distribution and Neurologic Abnormalities Seen with Common Lumbar Disc Herniations

Nonorganic signs, which may connote malingering or a psychogenic component to a patient's symptoms, include the following: pain that does not follow an organic pattern, endorsement of false symptom suggestions, cogwheel weakness, sensory deficits with a stocking-glove distribution, weakness to manual tests not seen in other activities, disablement disproportionate to objective findings, and overreaction during the examination. However, as previously noted, the presence of nonorganic signs does not necessarily exclude the existence of true underlying disease and discomfort.

Ancillary tests used to assess patients with LBP include lumbar spinal radiographs, ESR, and computerized tomography (CT) or magnetic resonance imaging (MRI). Spinal radiographs are indicated in cases of significant trauma, when neurologic deficits are present, or when a spinal malignancy or infection is clinically suspected.^{1,8} An ESR should be obtained when a malignancy, infection, or inflammatory disorder is suspected. CT or MRI is indicated in the acute setting for the following indications: suspected cauda equina syndrome; suspected disc herniation, causing significant and progressive motor weakness; and suspicion for the presence of either a spinal epidural abscess or metastasis causing any neurologic deficit.³ A CT scan is also indicated in victims of major trauma when routine spinal radiographs identify a major injury, to both fully evaluate the extent of injury (particularly the posterior elements) and assess the integrity of the neural canal.

EMERGENCY DEPARTMENT MANAGEMENT

Most patients with symptoms severe enough to bring them to the emergency department benefit from parenteral treatment with either an opioid analgesic or a nonsteroidal antiinflammatory drug (NSAID). Pain relief appropriate for a patient's degree of discomfort should be provided as soon as possible. Early symptom management facilitates accurate patient assessment and improves patient satisfaction with care. Patient satisfaction is further optimized when physicians perform more than a superficial examination (the "laying on of hands" effect) and when they spend time with patients, explaining the cause of symptoms and their treatment recommendations. When this is done, unnecessary spinal radiographs do little to improve overall patient satisfaction.

DISPOSITION

Emergent surgical intervention may be indicated for patients with severe cauda equina syndrome, disc herniation associated with severe and progressive motor weakness, and spinal epidural abscess in the presence of any neurologic impairment. Patients with suspicion for these disorders should receive an emergent CT or MRI scan in addition to immediate orthopedic or neurosurgical consultation. Emergent treatment with parenteral steroids and radiation therapy is indicated for patients with spinal epidural metastasis causing acute neurologic impairment. The decision to hospitalize patients other than those just described depends on multiple factors, including a patient's degree of distress and disability, the presence and extent of neurologic deficits, the patient's home environment, and the local practice of orthopedic and neurosurgical consultants.

Outpatient treatment of low back strain should include analgesics, bed rest, and follow-up evaluation. All patients with symptoms severe enough to bring them to the

emergency department should receive a prescription for an analgesic appropriate for their degree of distress. NSAIDs should be prescribed for patients with mild-to-moderate distress, whereas opioid analgesics may be a necessary adjunct for patients with moderate-to-severe symptoms.¹⁰ Opioid analgesics should not be required after the first 2 to 3 days. Muscle relaxants, when used in combination with analgesics, cause increased analgesia, increased drowsiness, and increased cost. Their major benefit may come from improved patient compliance with instructions for bed rest due to sedation. Bed rest, in the supine position on a flat and firm surface, may be of benefit to some patients, but should not be prescribed for more than 2 to 3 days.¹⁷ Follow-up with the patient's physician of choice, particularly for work-related low back strain, is important to identify patients with persistent or worsening symptoms. Early, aggressive rehabilitation may prevent such patients from developing chronic LBP.

The outpatient management of patients with suspected lumbar disc herniation, particularly if associated with a neurologic deficit, should consist of NSAIDs and opioid analgesics, 7 to 10 days of bed rest, and follow-up with an orthopedic surgeon or neurosurgeon. Fortunately, conservative management is effective in most instances, and only 2% to 5% of patients eventually require surgical treatment.¹¹

Patients with thoracolumbar fractures are almost invariably hospitalized for further evaluation and treatment. Patients with minor fractures resulting from direct blows may be treated as outpatients when there are no other associated injuries, when there is no suspicion of involvement of the posterior elements (this frequently requires CT scan), and when patient distress does not require treatment with parenteral narcotics.

Numerous studies have touted the benefits of heat or cold application, steroids or other medications, traction, corsets or braces, flexion or extension exercises, acupuncture, and the use of transcutaneous nerve stimulation for the treatment of LBP. None are of proven benefit.¹¹ Both spinal manipulation and back schools appear to benefit patients with symptoms that persist for 1 to 6 weeks, but their effectiveness appears to diminish thereafter.⁴

COMMON PITFALLS

- Failure to perform an abdominal examination. Numerous abdominal disorders, including abdominal aortic aneurysm, can present with LBP.
- Failure to recognize the potential for underlying pathology in high-risk patients (children, elderly patients, immunosuppressed patients, and intravenous drug users) who present with apparent low back strain.⁶ Normal spinal radiographs and ESR exclude underlying disease in most instances.
- Failure to diagnose thoracolumbar fractures in the setting of major multisystem trauma. Examination of the back may be deferred while more immediately life-threatening injuries are addressed. In addition, the signs and symptoms of spinal injury may be subtle or nonexistent due to an alteration in mental status or other painful injuries that distract the patient. A complete examination of the spine should be performed in trauma patients once they are hemodynamically stable. Spinal radiographs should be obtained in patients who cannot be assessed clinically when the mechanism of injury suggests the possibility of a spinal injury.
- Failure to practice cost-effective medicine. Studies have repeatedly shown that 40% to 80% of spinal radiographs performed to evaluate LBP are unnecessary.⁸
- Failure to practice the "art" of medicine. Patient satisfaction is determined by a physician's attitude and willingness to examine and talk to patients, not by the number of radiographs and other tests that are performed.

CHAPTER 116 Pelvic Fractures

Paula S. Wadbrook and Charles V. Pollack, Jr.

[Clinical Presentation](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Pelvic fractures are among the most common significant injuries of motor vehicle accident victims. Because of the pelvis's bony and ligamentous stability, a force that results in a fracture should alert the emergency physician to the possibility of adjacent as well as anatomically distant injuries. Although the mortality of blunt multiple trauma with pelvic fracture reaches 20%, in some reports, up to 80% of pelvic fractures are relatively minor injuries from which patients typically recover without sequelae.⁶ The widely varying figures for morbidity and mortality associated with pelvic trauma reflect the use of multiple classification schemes. (Some classifications include these minor injuries, while others do not.) Regardless of variability, the emergency physician should remain cognizant of the fact that for any patient who presents with a pelvic fracture and who is hypotensive, the mortality is 40% to 50%.¹

Vehicular and automobile-versus-pedestrian accidents account for 60% of pelvic fractures; falls from a height are responsible for another 30%.⁹ The last 10% is largely composed of two disparate groups: elderly osteoporotic women who fall from a sitting or standing position, and young, otherwise healthy athletes who sustain avulsion fractures of the ischium and iliac wings. Although the mechanism of injury may help predict optimal overall emergency management of each patient, the bony pelvis and its contents may be evaluated in a systematic fashion. After reviewing the anatomic and radiographic considerations of pelvic trauma, we will outline such a management scheme. Related injuries will be considered, but a detailed discussion of trauma to the pelvic contents is found in other chapters.

CLINICAL PRESENTATION

The bony pelvis supports the trunk and lower extremities and protects the lower abdominal viscera. As such, it absorbs much of the impact transmitted to the long or transverse axis of the body; injuring forces directed toward the pelvic bones are, in turn, often transmitted to the contents of the pelvis. The pelvis is a ring of two identical innominate bones (each consists of the fused ilium, ischium, and pubis) joined to the sacrum posteriorly by the sacroiliac complex ligaments and to each other anteriorly at the symphysis pubis ([Fig. 116.1](#)).

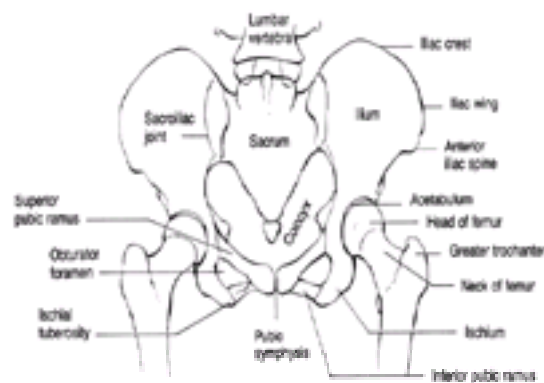

Figure 116.1. The pelvis.

Because the bony pelvis derives its strength from its ringlike structure, pelvic fractures are best differentiated according to the extent of ring disruption: stable or unstable fractures—one or two or more disruptions, respectively. Because this distinction is generally apparent clinically and radiographically, it provides a useful reference point for the emergency physician. Also, because specific mechanisms of injury are predictably associated with stable or unstable fractures, it provides the most practical scheme for evaluating, categorizing, and managing pelvic trauma. This system is presented in [Table 116.1](#) and will be followed for discussion purposes.

Mechanism	Typical Pelvic Fracture	Typical Associated Injuries	Typical Presentation
Motor vehicle without restraint	Stable anterior fractures of anterior superior iliac spine, ischial tuberosity	None	Pain, restricted motion of hip/ankle/shoulder on accident; hip/groin pain; groin pain
Fall from standing height or direct blow	Stable, bony, compression fractures (iliac spine, ischial tuberosity, superior pubic rami, ischium)	None	Pain, tenderness, localized tenderness with subtle groin pain
Lateral compression force	Stable isolated fracture of greater sciatic foramen fracture (transverse acetabular fracture)	Usually isolated mild bowel contusion; occasional small bowel wall contusion; ureter hematuria	Pain, localized tenderness with subtle groin pain
AP compression force	Stable pubic rami fracture or simple iliac fracture	Lower urinary tract posterior iliac fracture; ureter contusion	Pain, tenderness; occasional rectal/urinary signs
Shear force	Unstable complex ligamentous disruption of symphysis and SI joints ("ring avulsion" or open-book pelvis)	Lower GI and GU injury; hemorrhage	Pain, tenderness, groin crepitus; hematuria or rectal/urinary signs
Vertical shear force	Unstable, high-energy fracture, with anterior-posterior and/or lateral SI joint disruption	SIJ, ureteral, focal bowel or renal injury; hemorrhage	Pain, tenderness, groin crepitus; hematuria or rectal/urinary signs
Crash, fall from great height	Unstable, any combination of above injuries with or without avulsion fracture	High morbidity and mortality; hemorrhage; ureteral injury; open fracture	Pain, tenderness; hematuria; rectal/urinary signs; open fracture
Avulsion	Isolated fracture of iliac spine, ischial tuberosity, or superior pubic ramus (SIJ intact in the ring) but may be associated with avulsion pelvic fracture	Forward head, stable, some injury; hip dislocation	Pain, tenderness or crepitus; some deficit

TABLE 116.1. Pelvic Fractures Categorized by Mechanism

Avulsion fractures are among the most trivial of pelvic fractures and are often sustained by athletes who stress muscular or ligamentous insertions onto the bony pelvis ([Fig. 116.2](#)). Avulsions of the anterior superior iliac spine generally occur in adolescent hurdlers and long jumpers and reflect forceful contraction of the sartorius muscle or abdominal musculature transmitted to the iliac epiphysis.¹¹ Less commonly, the anterior inferior iliac spine may be avulsed by intense contraction of the straight head of the rectus femoris muscle; this injury may occur in athletes playing sports that involve kicking (e.g., soccer and rugby).⁶

Figure 116.2. Fractures due to stress on muscular or ligamentous insertions onto the bony pelvis.

Rarer still is an avulsion fracture of the ischial tuberosity. This injury usually results from strenuous stretching of the pelvic ring, as in hurdling or pole vaulting.⁶ Patients with avulsion fractures generally present with a characteristic history and local tenderness. In isolated trauma, there are usually no associated complaints or injuries. These are stable fractures because the integrity of the pelvic ring remains intact.

A fall from a standing height frequently presents as pelvic pain localized to the bony prominences. Areas such as the iliac spine, ischial tuberosities, superior pubic rami, and coccyx are particularly susceptible to direct trauma. These fractures are stable injuries and are particularly common in elderly osteopenic patients. Presentation involves localized pain, swelling, and ecchymosis. There are usually no associated injuries.

Lateral compressive force to the bony pelvis may result in any of several fracture patterns: pelvic wing fractures, pubic rami fractures, “bucket handle” fractures, or transverse sacral fractures. Although these are generally stable injuries, the forces required to cause them (e.g., broadside impact in a motor vehicle crash) are significantly greater than those previously considered. Therefore, the potential for associated injuries with lateral compressive force is higher.

The “stove-in,” or *pelvic wing fracture* (Fig. 116.3), was first described by Duverney in 1751. It may produce an unstable fragment off the iliac crest, but the load-bearing stability of the pelvic ring is not jeopardized. The patient with ipsilateral fracture of both pubic rami from lateral compressive force presents with pelvic or hip pain; there may be trauma to the bladder or proximal urethra. This injury may be stable or may be associated with disruption of the sacroiliac complex, rendering the pelvic ring unstable. Rami fractures due to lateral force injuries are typically horizontally oriented.

Figure 116.3. Duverney fracture. Pelvic wing or “stove-in” fracture.

A *bucket handle fracture* (Fig. 116.4) occurs when lateral force is sustained in combination with upward rotatory force.^{6,9} Generally, there is a fracture or disruption of the sacroiliac complex ipsilateral to the impact and a double pubic ramus fracture contralaterally. The hemipelvis that absorbed the blow is medially and superiorly rotated, presenting a recognizable clinical and radiographic picture. Because there are fractures on both sides of the pelvic ring, these are unstable injuries. Lateral compression of the pelvis can also transfer force to the sacrum. This force may fracture the bone and can separate the ilium from its ligamentous connections unilaterally or bilaterally.

Figure 116.4. “Bucket handle” fracture.

Sacral fractures occur in transverse upper, transverse lower, and vertical planes and are associated with different presentations. Upper sacral fractures are frequently difficult to recognize both radiographically and clinically, often presenting only as buttock and perianal pain. These fractures may injure sacral nerve roots, resulting in decreased anal sphincter tone and loss of perineal sensation. Lower sacral fractures are equally painful but are rarely complicated by neurologic injury. Vertical sacral fractures occur as a result of vertical shear injury and are discussed later.

Anteroposterior compressive force is most commonly applied from the front; typical examples are the pedestrian struck head-on by a car and the front-seat passenger who hits the dashboard. Patients injured by the former mechanism manifest injury of the anterior (symphysis pubis) or posterior (sacroiliac complex) pelvic stabilizers. Those injured by the latter mechanism manifest injuries from transmission of the force through the femurs into the acetabula. (Acetabulum fractures are considered later.) Anteroposterior-force pelvic injuries include pubic ramus fractures, simple symphysis diastasis, and the more severe and potentially unstable “open-book” or “sprung pelvis” injuries. As discussed, *isolated ipsilateral double pubic ramus fractures* are stable injuries, but they require careful clinical and radiographic examination to exclude further injury to the posterior pelvic elements.

Diastasis of the symphysis pubis can occur as an isolated, stable injury; however, the posterior urethra and pudendal vessels are at risk. Symphyseal separation of more than 2.5 cm on the anteroposterior pelvic radiograph indicates injury to the posterior sacroiliac ligaments.² When both the symphysis and sacroiliac complex are disrupted by anteroposterior force, the result is an open-book or sprung pelvis (Fig. 116.5). The stability of these injuries depends on the remaining integrity of the posterior sacroiliac ligaments⁹ and may not be discernible on plain radiography alone. Bladder rupture is relatively common in connection with this injury.

Figure 116.5. “Open-book” or “sprung” pelvis.

Straddle injuries (Fig. 116.6) are characterized by bilateral double pubic ramus fractures and are, by definition, unstable. The lower genitourinary tract is particularly susceptible to injury by this mechanism. Classically, as the name implies, this fracture is caused by falling while straddling a solid object between the legs. However, both lateral and anteroposterior compressive forces can cause straddle injuries as well. These are usually closed fractures; patients present with perineal tenderness, ecchymosis, and frank hematuria (or sometimes, in males, inability to void). The incidence of hemorrhage and bowel injury is greater than 33%.⁹

Figure 116.6. Straddle injury.

Vertical shear mechanisms create pelvic fractures that are also unstable. First described by Malgaigne in 1859, these injuries still bear his name. They are the least common of the major fractures and generally result from a fall from a height onto the lower extremities. The resulting fractures are longitudinally oriented through the anterior and posterior pelvis (Fig. 116.7); they are usually unilateral but may be bilateral. The acetabulum is frequently involved, but even when it is not, the patient has diminished motion of the ipsilateral lower extremity. If the sacrum fractures vertically, it may be occult radiographically. This is considered the posterior component of a Malgaigne fracture. Vertical shear injuries are associated with significant intraabdominal and concomitant thoracic injuries and hemorrhage; morbidity and mortality rates are high.

Figure 116.7. Vertical shear (Malgaigne) fracture.

Crush injuries of the pelvis result from a combination of these mechanisms or from extreme force in one direction (e.g., a 70-mi/h motor vehicle crash). If they are open fractures, they carry a high mortality rate. Hemorrhage, intraabdominal injury, thoracic injuries, and head injuries are common, due to the magnitude of the injuring force. These patients typically present in frank hypovolemic shock and require immediate resuscitation.

Acetabular fractures result from one of two mechanisms. They are caused by indirect forces transmitted around the pelvic brim or from forces applied directly to the femur. Both forces cause disruption of the acetabular cup. The classification schemes for these fractures are beyond the typical scope of practice for the emergency physician. The major point of reference is the mechanism of injury; in addition, the presence and type of associated hip dislocation are important. Posterior acetabular fractures, which result from direct trauma to the flexed knee and hip, present with posterior hip dislocations. If the knee and thigh are flexed and the thigh is abducted, trauma to the knee is transmitted to the medial acetabulum, resulting in an ilioischial column fracture and a central hip dislocation.

When force is applied to the greater trochanter posteroanteriorly or lateromedially with the hip flexed, the acetabulum fractures transversely, also resulting in a central hip dislocation. If the hip is externally rotated and the injuring force strikes lateromedially, the anterior lip and iliopubic column of the acetabulum are fractured; the hip joint is usually maintained but may dislocate anteriorly. A history of significant injuring force and a typical lower extremity posture of dislocation should prompt consideration of acetabular fracture. Acetabular fractures are complicated by sciatic nerve injury and disruption of blood supply to the femoral head.

EMERGENCY DEPARTMENT EVALUATION

Once airway, breathing, and circulation are addressed, complete evaluation of the multiply injured patient may proceed. Pelvic injury must be excluded; this is particularly important if there is hemodynamic instability. Examination of the unresponsive patient should parallel that of the awake patient who specifically complains of symptoms in the pelvic region.

Whenever possible, a thorough history is obtained. Mechanism of injury and direction of forces are crucial details. In motor vehicle accident victims, a description of the vehicular damage is also useful. The ability to ambulate after the incident excludes unstable injuries but does not eliminate the possibility of stable fractures. Patients should be asked about the presence of back, buttock, pelvic, groin, perineal, hip, or thigh pain. Symptoms such as lower extremity numbness, paresthesias, or weakness are sought. Bladder and rectal sensation and function should be subjectively assessed in the conscious patient.

The physical examination of both the conscious and unconscious patient, symptomatic or not, begins with inspection over bony prominences for ecchymosis or abrasion. Perineal or scrotal hematomas (Destot sign) or blood at the anus or urethral meatus should be noted. Retroperitoneal bleeding may be apparent from the

Grey Turner sign (flank ecchymosis). Any evidence of open fracture is sought.

Palpation for tenderness and instability begins with the iliac crests, then progresses medially toward the symphysis. A “pelvic rock,” or exertion of pressure over the iliac wings, should detect instability, but this should be preceded by assessment for localized tenderness. The back examination should include the lower lumbar spine, both sacroiliac regions, and the coccyx. Abdominal, rectal, and scrotal or vaginal examinations are also necessary. The rectal examination must include an assessment of anal sphincter tone, prostate position and tenderness, evidence of bony intrusion into the rectum, and presence of blood; palpation of a fracture line or pelvic hematoma may be possible (Earle sign). The lower extremities are evaluated for pulses (by palpation or Doppler stethoscope), strength, sensation, and deep tendon reflexes. Leg-length discrepancy should be noted.

There are physical examination findings that are specific for certain types of injury. Pain due to an avulsion fracture is worsened by range of motion of the inserting muscle and direct tenderness to palpation over the involved bony prominence. Palpating over a Duverney fracture often yields false motion of the iliac wing. The FABER test is positive with pubic ramus fractures: Pain occurs when the ipsilateral foot is placed on the contralateral knee and the ipsilateral hip is flexed, abducted, and externally rotated.⁶ Any tenderness over the symphysis should prompt close study and measurement of the width of the anterior connection.

Radiographs are also obtained as part of the evaluation in both the conscious and unconscious trauma patient. In the unconscious victim, an anteroposterior radiograph of the pelvis is done routinely secondary to the patient's inability to contribute symptoms of pain on examination. Even in the conscious patient, empiric pelvic radiography remains standard practice; in one study, however, this policy is questioned for patients who are normotensive, alert, and sober and have no physical findings suggestive of pelvic, femoral, or lower urinary injury.⁷ The anteroposterior film has a reported accuracy of 88% in detecting ring instability.⁴ If the anteroposterior pelvic x-ray is suggestive or diagnostic of a fracture, or if the physical examination suggests instability or localized injury, further studies may be indicated.

Ring instability may be detected by fracture pattern or joint diastasis. The hemipelves should appear symmetric. The physician should look for sacroiliac (greater than 4-mm) and symphyseal (greater than 5-mm) widening. There should be careful evaluation for fractures of the iliac wings and pubic rami, as well as for avulsion fractures of the iliac spines and ischial tuberosities. Transverse fractures of the sacrum are frequently difficult to delineate and must be carefully sought. The arcuate lines of the neural foramina should be followed and examined for irregularity or asymmetry (Fig. 116.8). Acetabular fractures may also be difficult to recognize and can be found by following the iliopectineal and ilioischial lines (Fig. 116.9).

Figure 116.8. Anteroposterior x-ray of the sacrum. The arcuate lines (*highlighted*) that outline the sacral neural foramina should be symmetric and smooth. Sacral fractures are usually more evident on the lateral x-ray view. Any suspicion of fracture or disruption of the arcuate lines on the anteroposterior view should prompt further studies.

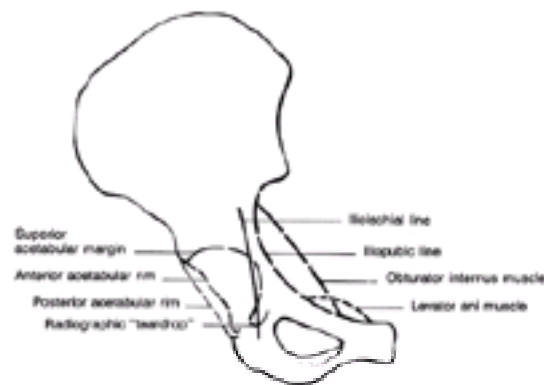

Figure 116.9. Iliopectineal and ilioischial lines.

Even though the standard anteroposterior pelvic radiograph will accurately assess pelvic stability in 88% of cases, other imaging modalities are useful for particular injuries.² If an acetabular, sacral, or sacroiliac fracture is suspected, adjunctive studies are often indicated; these areas are difficult to visualize solely by the anteroposterior radiograph secondary to position and overlying structures. A computed tomography (CT) scan usually demonstrates these areas clearly and is superior to plain films at delineating the sacrum and the axial relationships of the sacroiliac joint.² In a study by Berg et al.,² the anteroposterior pelvic radiograph missed posterior pelvic ring injuries of the sacrum, sacroiliac joints, and posterior ilium in 47% of cases. If a scanner is not available, other plain radiographs may be useful: Pelvic inlet views for the posterior arch, pelvic outlet or tangential views for the sacrum and sacroiliac complex, and Judet views for focusing on the acetabulum.

Associated injuries must also be addressed. Multiply injured patients should have blood counts, appropriate chemistry studies, and type and crossmatch performed in the emergency department. A pregnancy test is done on all women of childbearing age. All patients with detected pelvic injury should also have a urinalysis. A retrograde urethrogram (with cystogram, if indicated) should be done before Foley catheter insertion in patients with blood at the urethral meatus. Major trauma patients who are hypotensive, have a compromised sensorium, or have abdominal injuries or symptoms are assessed for concomitant intraperitoneal injury or hemorrhage. Diagnostic peritoneal lavage (performed by the open technique through a supraumbilical approach to minimize the possibility of inadvertently entering a pelvic hematoma¹) is performed, depending on the patient's stability, the physician's preference, and the institution's capability.

EMERGENCY DEPARTMENT MANAGEMENT

The initial management of a patient with possible pelvic trauma proceeds with the same ABCs of trauma care. With airway and breathing secured, circulation and hemorrhage become important considerations in these patients. *The only immediately life-threatening aspect of pelvic trauma is hemorrhage.* Unfortunately, such bleeding is typically internal, and the usual measures of quantification and suppression are difficult. There are four primary and often overlapping methods of managing hemorrhage from pelvic fracture: emergency department resuscitation, application of an external fixation device, open reduction and external fixation, and angiography with direct embolization of bleeding vessels. Any unstable trauma patient will receive emergency department resuscitation. The management method choices that follow will depend on the institution and its orthopedic surgeons.

Hypotensive patients with pelvic trauma should receive intravenous crystalloid through two large-bore peripheral lines. A central venous pressure monitoring line can be useful but is usually unnecessary. If the patient remains unstable after 3 to 4 L of crystalloid, type-specific or fully crossmatched blood is given. In addition, pelvic trauma with hypotension may be the final bona fide indication for the prehospital and emergency department use of the pneumatic antishock garment (PASG or MAST). Hemorrhage from pelvic fractures is lessened with immobilization and reapproximation of bony fragments; inflating all three compartments of the PASG may

accomplish this. The PASG may also tamponade bleeding from smaller vessels and exposed raw surfaces of cancellous bone.

There are many reports of experience with external fixation, operative fixation, and arteriography with embolization in the control of exsanguinating hemorrhage after pelvic fracture.^{1,3,8,10} No study has directly compared these modalities. External fixation is relatively rapid and can be performed in the emergency department. Internal fixation, although more definitive, is associated with the usual operative risk and the added consideration of loss of tamponade and sudden profound shock when the pelvic cavity is entered. Selective embolization is technically challenging and relatively time consuming and does not address venous blood loss, which may be significant. Angiographic embolization is, however, the currently recommended method for controlling arterial bleeding from pelvic fractures.^{1,3,8}

Pelvic fracture hemorrhage presents as a multispecialty challenge. The decision making regarding management modalities in the face of ongoing bleeding is shared among emergency physicians, surgeons, and orthopedists. The role of the emergency physician in the later stages of management is often limited, but he or she should be thoroughly familiar with the facility's and consultant's respective capabilities. Clinical picture and availability often dictate management choices and imaging modalities. While much has been written of the relative merits of CT and angiography for the detection and localization of pelvic hemorrhage, several facts remain apparent: First, not every facility has an angiography suite or interventional radiologist readily available, and second, CT scanning can detect pelvic hemorrhage with 90% accuracy and is less invasive to perform.^{1,3,8,10}

Lastly, pelvic fractures often present with associated injuries that must be managed accordingly. Hip dislocations must be reduced promptly to prevent neurovascular compromise. Urethral injuries may require placement of a suprapubic cystostomy. Abdominal injuries are generally addressed operatively, and genital injuries may require surgical or plastic reconstruction. Patients with open fractures or any penetrating pelvic trauma should receive tetanus prophylaxis and an empiric dose of a broad-spectrum antibiotic. Finally, the possible occurrence of fat embolism, and the often devastating pulmonary and cardiovascular consequences of such, must be remembered.

DISPOSITION

Patients with simple avulsion fractures or isolated stable fractures can be managed conservatively with bed rest, analgesia, and arrangements for physical therapy; many do not require hospital admission. Patients with more significant pelvic injuries must be assessed for related trauma and admitted. Extremes of age and overall physical condition are also important considerations. Patients with unstable fractures and multiple trauma usually require urgent or emergent operative intervention.

COMMON PITFALLS

- Remember that all unconscious patients with blunt multiple trauma require an anteroposterior pelvic radiograph.
- Use the history of the injuring mechanism to help predict the type and severity of pelvic injury.
- Always respect the hemorrhagic potential of unstable pelvic fractures. Vigorous fluid resuscitation, early blood transfusion, consideration of PASG application, and prompt orthopedic consultation are mandatory.
- Associated injuries to the intra- and retroperitoneal organs, the sacral nerves, and the pudendal blood vessels must be suspected and investigated as early as possible.

Injuries to the hip are a major cause of morbidity and mortality, a problem that has worsened, and will continue to worsen, as the population ages. Injuries to the hip are a major health hazard. For the elderly, as many as 37% of hip fractures result in death within 1 year, and half of these deaths are thought to be directly due to the fracture.⁶ Causes of hip fractures are primarily pathologic (from osteopenia) and due to falls (primarily a disease of the elderly), whereas motor vehicle crashes account for the majority of dislocations (primarily a disease of the young). The frequency of traumatic hip dislocations and proximal fracture–dislocations of the femur has declined with the use of seatbelts. Although this decline is encouraging, early recognition of hip dislocations and proximal femur fractures will minimize the likelihood of developing avascular necrosis of the femoral head. In traumatic hip dislocations, the incidence of associated osteoarthritis is 26%.^{1,7,10} For avascular necrosis, the incidence ranges from 8% to 30%, depending on the degree of displacement.⁷ The incidence of these complications can be minimized by prompt diagnosis, evaluation, and definitive treatment in the emergency department (ED).

Anatomically, the hip is an articulation between the femoral head and the acetabulum, joined together by the ligamentum teres and the capsular ligament of the hip joint. It is a very stable articulation, requiring violent injury to dislocate. Primary sources of blood flow for the femoral head are the retinacular branches of the circumflex femoral artery. These enter the femur in the region of the femoral neck, and fractures proximal to their entry can result in disruption of blood flow and cause avascular necrosis of the femoral head. The other source of blood for the femoral head comes from the artery of the ligamentum teres. Often, this artery is absent or vestigial, and its loss is rarely of clinical significance. Avascular necrosis of the femoral head is a common *early* complication of fracture of the femoral neck. It is identified on x-ray films as an increase in density in the region of the femoral head, thought to be new bone deposition onto necrotic spicules.

In addition to the capsule, the hip joint is reinforced by the hip abductor muscles (gluteus medius and minimus, obturator, gemelli, and piriformis) attached to the greater trochanter and flexor (iliopsoas), which is attached to the lesser trochanter ([Fig. 117.1](#)).

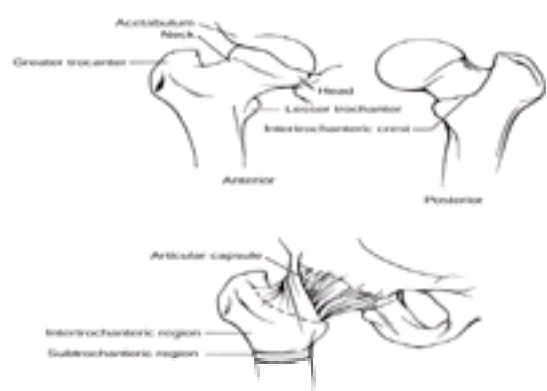

Figure 117.1. Anatomy of the hip. **(Top)** Anterior and posterior views of the femur. **(Bottom)** Division of the proximal femur.

HIP DISLOCATIONS

Posterior Hip Dislocations

Posterior hip dislocations are the most common type of dislocation and result from force applied to a flexed knee and hip. When the knee hits the dashboard during a motor vehicle crash, the hip is forcefully adducted and flexed while simultaneously pushed posteriorly. This is prevented by the use of a lap belt.

EMERGENCY DEPARTMENT EVALUATION

In posterior hip dislocations, the limb is flexed, adducted, and internally rotated, with limb shortening. If the patient is thin, the femoral head can often be palpated in the buttocks region ([Fig. 117.2](#) and [Fig. 117.3](#)). Examination of the leg should ensure vascular function (rarely compromised) and include neurologic evaluation for possible sciatic nerve injury. The sciatic nerve lies posterior to the femoral head, separated from it by the capsule and by the obturator and gemelli muscles. Up to 50% have an associated acetabular or femoral head fracture (discussion follows).

Figure 117.2. Posterior dislocation of the hip.

Figure 117.3. Posterior dislocation of the hip. **(A)** Mechanism of injury. The knee (1) strikes the dashboard. The thigh (2) is forced into flexion and adduction, and the femoral head is driven backward out of the acetabulum. **(B)** Ischial dislocation. The hip (1) is flexed. The hip is markedly adducted so that the knee (2) of the affected limb lies on the opposite thigh. The limb (3) is in extreme internal rotation. The greater trochanter and buttock (4) on the affected side are unusually prominent. **(C)** Iliac dislocation. As in **(B)**, the hip is flexed and is adducted (2). It is internally rotated (3). The affected extremity (4) appears shortened. The greater trochanter and buttock (5) on the affected side are unusually prominent. The knee (6) of the affected extremity rests on the opposite thigh.

EMERGENCY DEPARTMENT MANAGEMENT

Posterior dislocations optimally need reduction within 6 hours to minimize the risk for avascular necrosis,⁴⁹ which should be attempted in the ED (Fig. 117.4). Adequate analgesia and muscle relaxation must be obtained by using a short-acting narcotic (e.g., fentanyl) and a short-acting benzodiazepine (e.g., midazolam) with proper conscious sedation monitoring. After the patient is adequately relaxed, an assistant should apply pressure to the iliac crests, stabilizing the pelvis from lifting off the board. At this time, the physician should apply traction in line with the deformity and gently begin to flex the hip to 90 degrees. The reducing physician must stand on the gurney astride the patient. Successful reduction is often felt by a dull click. General anesthesia is occasionally necessary, and orthopedic consultation is always necessary. After reduction, the extremity should be placed in extension and neurovascular function of the extremity reassessed. Postreduction radiographs should be obtained. The patient should be admitted to the hospital and be kept from bearing weight on the extremity for 10 to 14 days.

Figure 117.4. Posterior dislocation of the hip: method of manipulative reduction. **(A)** The assistant makes downward pressure (1) on the anterior–superior iliac spine. With the knee flexed (2), the operator pulls on the limb in the line of deformity. **(B)** The assistant slowly brings the thigh (1) to 90 degrees of flexion. The assistant gently rotates the thigh internally and externally and rocks the thigh (2) backward and forward to disengage the head from the external rotator muscles and the posterior capsule. **(C)** The assistant relocates the femoral head by further internal rotation and extension of the thigh (3a), or external rotation and extension of the thigh (3b). **(D)** The assistant pushes firmly on the trochanter to direct the femoral head into the acetabulum while the limb is rotated and extended (4). Forceful rotation should be avoided, because it can readily fracture the femoral neck. If the reduction is not accomplished with two adequate attempts, open reduction is indicated.

Anterior Hip Dislocations

Anterior hip dislocations occur most commonly from a direct blow to the abducted hip. A distally applied force causes the femoral head to tear through the anterior capsule. Anterior dislocations may be classified as obturator, iliac, and pubic (Fig. 117.5). Obturator-type hip dislocations occur when the hip is abducted and in flexion. The pubic and iliac types occur most commonly when the hip is abducted and in extension.

Figure 117.5. Anterior hip dislocations. **(A)** Anterior obturator hip dislocation. **(B)** Anterior iliac hip dislocation. **(C)** Anterior pubic hip dislocation.

EMERGENCY DEPARTMENT EVALUATION

Careful neurovascular examination is mandatory, owing to the risk of arterial damage and venous thrombosis.⁸ Anterior obturator dislocations present as abduction, external rotation, and flexion of the involved extremity. Anterior iliac and pubic dislocations present as slight abduction, external rotation, and extension of the involved extremity (Fig. 117.6).

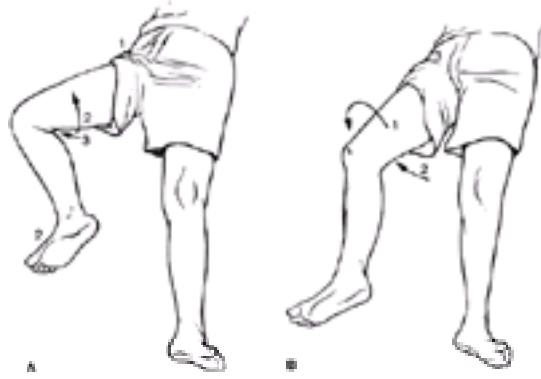

Figure 117.6. Anterior dislocations of the hip. **(A)** Obturator dislocation. The hip (1) is slightly flexed. The limb (2) is externally rotated. The thigh (3) is abducted. **(B)** Pubic dislocation. The extremity (1) is in severe external rotation (90 degrees). The extremity (2) is abducted only slightly (15 to 20 degrees), and it is slightly flexed. The femoral head (3) can readily be palpated in the inguinal region.

EMERGENCY DEPARTMENT MANAGEMENT

Anterior dislocations are best treated with closed reduction with the patient under general anesthesia. Emergent orthopedic consultation for early reduction is extremely important because of associated vascular injuries. This will minimize major sequelae, such as avascular necrosis of the femoral head.

COMMON PITFALLS

- Failure to look for associated acetabular, femur, and knee injuries (especially ligamentous) with hip dislocations; computed tomography (CT) or magnetic resonance imaging (MRI) may be necessary.
- Failure to obtain early closed reduction, which lowers the risk of avascular necrosis and posttraumatic osteoarthritis; less than 6 hours is ideal.
- Failure to realize that persistent pain after reduction may indicate the possibility of entrapment within the joint of neurologic or vascular components
- Failure to recognize sciatic nerve injury with posterior hip dislocation

HIP FRACTURES

Fractures of the hip are one of the common injuries seen in the ED, especially among elderly patients. It is estimated that 5% to 10% of those reaching their 80s will have a femoral neck fracture. The increasing elderly population could double the number of hip fractures seen over the next 20 years. A third of those over age 65 who live at home, and half of institutionalized individuals, are estimated to fall yearly. Morbidity in this age group is staggering, with a third dying within 1 year.⁶ Thirty percent of those who were independently ambulatory prefracture require permanent postinjury crutches or a walker, and 7% of them become permanently bedridden.² For the emergency physician, the diagnosis becomes the important step, as, almost invariably, these patients are repaired intraoperatively with an Austin-Moore-type femoral head prosthesis. The emergency physician should determine prior level of function, including the degree of independent ambulation, mental status, and any associated illnesses, as they are important factors in the ED and in the definitive management of these patients.

The term *hip fracture* refers to a fracture of the femur proximal to the subtrochanteric region. Hip fractures are broadly classified into six anatomic groups: femoral head and neck fractures, intertrochanteric fractures, subtrochanteric fractures, and isolated fractures of greater or lesser trochanters. Pertinent anatomy is shown in Figure 117.1.

Femoral Head Fractures

Isolated fractures of the femoral head are relatively uncommon. These fractures usually occur in conjunction with dislocations of the femoral head (unlike most other types of hip fractures). Three-fourths are due to motor vehicle crashes, generally in younger patients. As with dislocations of the hip, acetabular fracture may also be seen, and should be sought.

EMERGENCY DEPARTMENT EVALUATION

Femoral head fractures may not be noted on routine radiographs; additional studies, such as tomography, radionuclide scans, CT, or MRI may be required. Persistent pain in the absence of radiographic findings should prompt further investigation. In one report, one in seven changes in the femoral head noted after trauma, which were typically thought to be due to avascular necrosis, were actually due to impaction of the femoral head.³

These fractures may be subdivided into two types: single fragment (type I) and comminuted (type II). The site of fracture and the accompanying complications are also related to the type of dislocation associated with the fracture.⁵ Posterior dislocations are more likely to result in fracture of the inferior aspect of the femoral head and may have concomitant sciatic nerve injury. Anterior dislocations tend to result in fracture of the anterior femoral head and may have associated vascular injury.

EMERGENCY DEPARTMENT MANAGEMENT

Precise and early reduction are important to maximize range of motion and subsequent function and to minimize complications such as avascular necrosis or degenerative joint disease. Unfortunately, complications occur regardless of proper intervention and result in the need for prosthetic replacement. Urgent orthopedic consultation is mandatory.

Femoral Neck Fractures (Transcervical or Intracapsular Fractures)

These fractures occur below the femoral head and above the greater trochanter and are much more common than femoral head fractures. They are located within the joint capsule and include subcapital fractures (which occur through the fused epiphyseal plate). In the elderly, these fractures are pathologic, occurring with little or no trauma, while in younger patients they are usually the result of violent, unrestrained motor vehicle trauma. Osteoporosis is a major risk factor, making the injury four times more common in women than in men. Indeed, the fracture may sometimes occur due to angular or torsional forces placed on the neck before a fall.¹

EMERGENCY DEPARTMENT EVALUATION

Classifications of these fractures have been based on both patient and fracture characteristics. The system proposed by Garden is one of the most commonly used (Table 117.1). In type I, there is impaction or incomplete fracture. Type II is complete transcervical fracture with displacement. Type III is a complete fracture with partial displacement of the distal fragment, and type IV is fracture with total displacement or comminution. Ambulation does not imply absence of a fracture, because

patients with types I and II fractures commonly walk after these injuries. Individuals with types III and IV are unable to ambulate and usually present with a shortened, externally rotated extremity and an abducted hip.

Type	Definition
Type I	Impaction or incomplete fracture
Type II	Complete transcervical fracture with displacement
Type III	Complete fracture with partial displacement of the distal fragment
Type IV	Fracture with total displacement or comminution

TABLE 117.1. Garden Classification of Femoral Neck Fractures

Stress Fractures

Stress fractures represent a unique type of femoral neck fracture. They most commonly occur in young, athletic individuals, but also occur in those with pathologic bone, such as in rheumatoid arthritis, renal osteodystrophy, and chronic steroid use. They may be bilateral and are usually the result of repetitive abnormal stress on normal bone or repetitive normal stress on abnormal bone. The pain is often gradual in its onset. Ambulation is common, with weight-bearing pain. The usual signs of fracture are missing both clinically and radiographically. Bone scan and MRI is indicated in any high-risk individual who cannot bear weight. Treatment centers on the degree of the injury and the state of the underlying bone. The range is from resting the affected hip to prosthetic hip replacement.

EMERGENCY DEPARTMENT MANAGEMENT

Type I fractures may be nonoperatively managed, but patient compliance is mandatory, and the likelihood of complications make operative management the preferred modality (pinning, most commonly). Types II, III, and IV fractures require open reduction and internal fixation (compression screw and plate or Austin-Moore-type femoral head prosthesis). Early and precise anatomic reduction, within 12 hours, reduces the risk of avascular necrosis. Prompt recognition and orthopedic consultation in the ED may help minimize avascular necrosis and the other sequelae associated with these types of fracture.

Intertrochanteric Fractures

These are the most common type of hip fracture. They are usually extracapsular, and the vast majority are due to falls in the elderly (they are pathologic fractures). DeLee¹ found these to be four times as common as femoral neck fractures. X-ray findings usually show comminution, with only 20% composed of two pieces, 65% composed of three or four fragments, and 15% highly comminuted.²

EMERGENCY DEPARTMENT EVALUATION

Emergency diagnosis is usually straightforward. Any movement causes extreme pain, and the hip may be tender to palpation. The affected leg is shortened and externally rotated, and weight bearing is not possible. The diagnosis is usually confirmed radiographically with a single anteroposterior (AP) view of the hip. A lateral or groin view may be necessary to evaluate the degree of comminution.

The intertrochanteric fracture is extraarticular, but transarticular forces clearly play a major role in its occurrence. The fracture typically extends in a relatively straight line between the greater and lesser trochanters (Fig. 117.7). A variety of classifications are used to describe these fractures, and there is no universal agreement. As seen in Fig. 117.7, the Boyd and Griffin classification uses four categories. Type I is nondisplaced. Type II fracture lines parallel those in type I, but there is displacement. Types III and IV fracture lines run nearly perpendicular to types I and II. Type III is nondisplaced, whereas type IV is displaced. Another system uses stability and comminution as criteria. When obtaining orthopedic consultation, precise anatomic description may be more useful than a specific classification type.

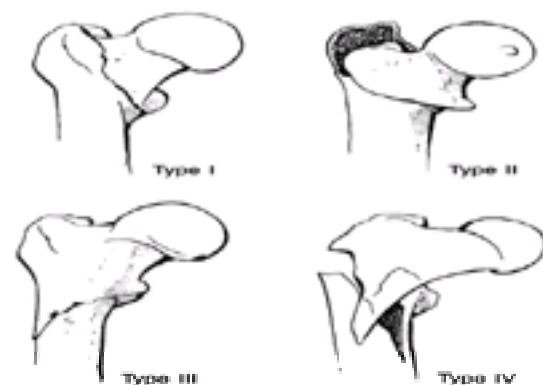

Figure 117.7. Boyd and Griffin classification of intertrochanteric hip fractures. (Adapted from Rockwood CA Jr, Green DP, Bucholz RW. *Rockwood and Green's fractures in adults*, 3rd ed. Philadelphia: Lippincott Co., 1991.)

EMERGENCY DEPARTMENT MANAGEMENT

Initial management consists of immobilization with sandbags or Buck's traction (2 to 4 kg). This helps to decrease blood loss until definitive therapy can be performed. Intravenous volume placement, with crystalloid or blood, may be necessary, because patients can lose 1 to 2 L of blood with these fractures. Many of these patients have concomitant chronic medical problems. These should be addressed, including the cause of the fall, and will help to establish whether the patient is an operative candidate. Laboratory evaluation should include the standard preoperative laboratory assessment, as well as other analysis necessary to ascertain the cause of the fall. This may include neurologic and cardiovascular evaluations. Avascular necrosis is an uncommon complication.

Operative repair has historically been considered safer than conservative therapy. This is due to the morbidity and mortality associated with extended immobilization. As a result, the treatment of choice is surgical (variety of procedures). Surgical reduction and fixation should be considered urgent rather than emergent, and all patients should have a thorough preoperative evaluation. Selected fractures may be managed by splinting, traction, or spica immobilization, as determined by the consulting orthopedist and the patient's underlying medical condition. Complications are common after these injuries and reflect the frail status of most of these patients; about a third of these patients will die within 1 year of injury.

Greater Trochanter Fractures

These injuries are quite uncommon. They occur as a result of direct trauma (generally adults, including the elderly), and in those with preepiphyseal plate fusion (ages 7 to 17), secondary to avulsion of the apophysis as a result of forceful muscular contraction. If due to direct trauma, they are rarely displaced and can be difficult to

see on routine radiographic views. Radiographic imaging frequently requires comparison views.

EMERGENCY DEPARTMENT EVALUATION

In both, tenderness to palpation is usually present over the greater trochanter. Patients are usually ambulatory, frequently with a limp. The fracture in adults, due to a direct blow, is usually comminuted without significant displacement. The epiphyseal avulsion type of injury is usually displaced but not comminuted.

EMERGENCY DEPARTMENT MANAGEMENT

Management varies from adduction splint and bed rest, to open reduction and internal fixation. In most instances, the prognosis is good, regardless of the method used. DeLee¹ recommends ORIF for greater than 1-cm displacement of either a large isolated fragment for the direct trauma (adult) type or the entire apophysis in the epiphyseal avulsion (youth) type.

Lesser Trochanteric Fractures

Lesser trochanteric fractures usually occur in the young, with 85% occurring before age 20.¹ They usually occur from forceful contraction of the iliopsoas muscle during strenuous activities. The lesser trochanter can be displaced up to 1 cm. This type of injury in an adult mandates a search for pathologic bone.

EMERGENCY DEPARTMENT EVALUATION

Patients will have pain and tenderness in the femoral triangle. There will be the inability to lift the affected extremity when in the sitting position if there is complete avulsion (Ludloff's sign). Radiographic imaging frequently requires comparison views.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment is usually bed rest, unless there is significant displacement. Some orthopedists favor nonoperative management, regardless of the degree of separation, because the outcome is uniformly good.¹

Subtrochanteric Fractures

Subtrochanteric fractures are defined as fractures occurring between the lesser trochanter and a point 5 cm (or 2 in.) distally. They account for one in ten hip fractures and are associated with more severe trauma, or are in pathologic bone (such as severe osteoporosis, Paget disease or cancer metastasis).

EMERGENCY DEPARTMENT EVALUATION

Clinical presentation is similar to that of intertrochanteric fractures. The forces of the muscles extending across this region frequently result in abduction, flexion, and external rotation. Young patients with these fractures are subject to violent forces; associated injuries are common and should be sought. Blood loss can be substantial in fractures of the midshaft femur, and these fractures fall into this subset. Subtrochanteric fractures may occur in combination with other hip fractures: Classification is varied and complex. Accepted anatomic description is best used when describing these fractures.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment involves immobilization, analgesia, volume replacement (if indicated), and timely orthopedic intervention. Associated neurovascular injuries should be identified. Prompt vascular surgery consultation should be obtained, if indicated. Operative reduction and fixation (usually some type of intramedullary nail) is used based on specific patient and fracture characteristics.

COMMON PITFALLS

- The ability to walk does not rule out fracture of the hip.
- Failure to evaluate an elderly patient with a history of a recent fall and a complaint of knee pain for hip fracture
- Failure to carefully examine patients with impaired mental status due to dementia, intracranial injury, or substance abuse for fractures
- Failure to evaluate young, athletic adults with pain in the femoral triangle for lesser trochanteric fracture
- Failure to realize that pain in the hip, in the absence of trauma, does not rule out fracture; radiographs should be obtained.

ACETABULAR FRACTURES

Acetabular fractures should be considered in both types of femoral head dislocations and, more commonly, in pelvic fractures. The force of injury applied to the femur from impact onto the dashboard is transmitted to the acetabulum.

EMERGENCY DEPARTMENT EVALUATION

There are four types of acetabular fractures. The posterior lip fracture is the most common and is associated with posterior hip dislocations. The transverse acetabulum fracture is best seen on AP view as it crosses the acetabulum. The third is the anterior fracture, which disrupts the arcuate or iliopubic line. The fourth is the ilioischial, or posterior, fracture. In type IV fractures, the entire posterior column (the bone extending from the ilium to the ischium) becomes separated from the pelvis. An occult acetabular fracture should be suspected when the patient gives a history of a recent fall, but the pelvic radiograph is normal. Always consider the use of oblique views to diagnose these fractures, as the first films generally do not visualize the injury. It is frequently necessary to consider CT scan, MRI, and nuclear medicine to image these patients' injuries.

EMERGENCY DEPARTMENT MANAGEMENT

Acetabular fractures are managed in consultation with the orthopedic surgeon. ED management involves immobilization, analgesia, volume replacement, if necessary, and identification of associated injuries.

COMMON PITFALLS

- Failure to look for acetabular fractures in patients with hip dislocations and inferior pubic rami fractures
- Failure to suspect occult acetabular fracture when the patient gives a history of a recent fall, the pelvic radiograph is normal, and there is persistent hip pain

ANATOMY

The knee is a synovial hinge joint with a complex architecture of bone, ligament, muscle, and cartilage ([Fig. 118.1](#)). The three bones that make up the knee are the distal femur, patella, and proximal tibia. The femoral condyles articulate with the proximal tibia (tibial plateau) to form the weight-bearing portion of the knee joint. The femoral condyles also articulate with the posterior portion of the patella in the trochlear groove. The patellofemoral articulation does not function in weight bearing; the patella provides protection to the femur, however, as well as improved stability and strength of the extensor mechanism. The proximal fibula is not part of the knee joint proper, although it does serve as the site of attachment of the lateral collateral ligament (LCL).

Figure 118.1. Anatomy of the knee.

The bony structures of the knee offer the joint little stability; the knee relies on fibrinous soft-tissue components for stability and proper function. Stability of the medial aspect of the knee is provided mainly by the medial collateral ligament (MCL). The MCL has a superficial and deep layer. The superficial portion originates from the medial femoral epicondyle and inserts on the medial aspect of the tibia just distal to the tibiofemoral joint and provides most of the resistance to valgus forces. The deep portion of the MCL helps stabilize the medial meniscus. The LCL protects the knee from varus stresses and originates from the lateral femoral epicondyle.

The cruciate ligaments are located within the intercondylar notch. The anterior cruciate ligament (ACL) originates from the posterior aspect of the lateral femoral epicondyle and inserts into the anterior tibia at the tibial spine. The posterior cruciate ligament (PCL) arises from the medial femoral condyle, crosses behind the ACL, and inserts on the posterior tibial spine. The ACL prevents anterior displacement of the tibia relative to the femur; the PCL helps prevent posterior displacement. Both cruciate ligaments also play a minor role in resisting varus and valgus rotation within the knee.

The menisci are cartilages positioned on the articulating surface of the tibia. They provide a contact surface between the tibia and femur and distribute and dissipate forces within the knee. The menisci also aid in stabilizing the knee by preventing abnormal motion of the tibia and femur. They have only peripheral vasculature, which is of clinical importance in the healing process following injury.

The muscles involved with normal knee function can be divided into extensors and flexors. Extension is primarily provided by the quadriceps muscles, composed of the vastus medialis, vastus intermedius, vastus lateralis, and rectus femoris. The tendons of these muscles combine to form the quadriceps tendon, which inserts into the superior patella and the medial and lateral retinaculum of the joint capsule. The tendon then becomes the patellar tendon, which connects the inferior portion of the patella to the tibial tubercle.

The hamstring muscles of the posterior thigh are the primary flexors of the knee. The four muscles of the hamstring are the semimembranosus, semitendinosus, and the two heads of the biceps femoris. The biceps femoris attaches to the proximal fibula. The semitendinosus and semimembranosus form the medial aspect of the hamstrings and insert into the tibia and medial joint capsule of the knee.

The major vascular structures around the knee pass posteriorly and are of extreme clinical importance. The popliteal artery is fixed proximally at the hiatus of the adductor magnus and distally at the tendinous arch of the soleus muscle.⁷ This tethering makes it susceptible to injury by traction forces, as seen with dislocations. The popliteal artery is also at risk of disruption by fractures or penetrating wounds. The collateral circulation is generally poor, so significant damage to the popliteal artery places the viability of the lower limb in jeopardy.

Proximal to the knee, the sciatic nerve separates into the tibial and peroneal nerves. The tibial nerve passes posteriorly and is therefore susceptible to the same mechanisms of injury as the popliteal artery. The peroneal nerve courses superficially around the lateral aspect of the knee to the proximal fibula. Because of its superficial location, the peroneal nerve may be injured in trauma involving less significant forces than those needed to affect the deeper tibial nerve.

EMERGENCY DEPARTMENT EVALUATION

The history is extremely helpful in directing the evaluation of a knee injury. The chief complaint, mechanism of injury, and the nature and duration of symptoms help differentiate acute trauma from chronic problems or reinjury.

The mechanism of injury is a key piece of the history. The force, direction, and placement of traumatic stresses, as well as the position of the knee at the time of injury, should be identified. Associated complaints, such as locking of the joint, effusions (and how quickly the fluid accumulated), popping sensations, and ability to ambulate, should be elicited. Any associated injuries, particularly to the hip and ankle, should be evaluated.

The physical examination begins with inspection of the knee and entire limb for obvious deformity, ecchymosis, erythema, edema, or cutaneous lesion. The presence of scars should be noted, as they may indicate previous trauma or surgery. Careful palpation will identify tenderness, crepitus, abnormal skin temperature, or the presence of an effusion.

At this point, if a fracture is suspected, obtain appropriate radiologic studies before performing extensive manipulation of the knee. Recently several clinical decision rules for the use of radiographs in the acutely injured knee have been developed. The Pittsburgh rules classify mechanism of injury (blunt trauma, falls), patient age (less than 12 years, greater than 55 years), and inability to walk (at least four weight-bearing steps) as predictors of fractures.¹⁶ The Ottawa knee rules identify five factors; the presence of any of them indicates that radiographs should be obtained. These are age greater than 55, tenderness at the head of the fibula, isolated tenderness of the patella, inability to flex to 90 degrees, and inability to transfer weight for four steps either immediately after the injury or in the emergency department (ED).¹⁷ Both sets of rules have been demonstrated to be highly sensitive in predicting the presence of fractures and may prove useful for the ED physician in the evaluation of an acute knee injury.

If radiographs are not indicated or are negative, continue assessment of potential injuries, using a systematic examination of the soft tissues, as well as determination of weight-bearing gait. When possible, the unaffected knee should be examined for comparison. Often, it is useful to examine the uninjured joint first to assess normal variability for the patient: Discrepancies between the patient's joints are more important than absolute laxity.¹⁵ Examining the uninjured knee also permits the physician to demonstrate the maneuvers that will be performed, ideally allaying the patient's fears and improving cooperation.

The presence of excessive tenderness and joint effusions may make the examination difficult. Effusions and tensing of the musculature secondary to pain may give the impression of more joint stability than is actually present. Therefore, although it is important to evaluate the patient acutely, it is often necessary in the ED to immobilize the injured knee and provide for a follow-up examination.

Specific Tests for Soft-Tissue Injuries

During each of the following tests, the patient should be as relaxed as possible. Explain the examination to the patient and compare the findings with those of the uninjured knee. If the patient cannot cooperate because of pain, appropriate analgesia or sedation may be necessary. In certain cases, it may be necessary to have the orthopedist perform these tests with the patient under general anesthesia.¹⁵

Collateral Ligaments

Examine the knee in both full extension and at 30 degrees of flexion ([Fig. 118.2](#)).¹⁵ Stabilize the tibia and femur with your hands while applying varus and valgus stresses to the knee, testing the stability of the LCL and MCL, respectively. With a first-degree sprain, there is no laxity at either extension or flexion. A second-degree sprain demonstrates some laxity in flexion (with a solid end point) but no laxity in extension. With a third-degree sprain, there is some laxity in extension and significant laxity in flexion, without a solid end point. Marked opening of the joint in both extension and flexion indicates the possibility of a cruciate ligament disruption in addition to the collateral ligament injury.¹⁵

Figure 118.2. Examination of the knee. (A) Valgus stress at 0-degree and 30-degree flexion, as viewed from the side. (B) Valgus stress at 0-degree flexion, as viewed from above. (C) Anterior drawer test. (D) McMurray test. (E) Apley test.

Cruciate Ligaments

The Lachman test is the best way to evaluate the ACL clinically.¹⁵ Position the patient supine; stabilize the tibia and femur with your hands and the knee flexed to 20 to 30 degrees. Then pull the tibia anteriorly. Excessive anterior displacement of the tibia relative to the femur and a lack of a distinct end point indicate an ACL rupture.

Although not as sensitive as the Lachman test, the anterior drawer test may also be utilized to evaluate the ACL. Flex the knee to 90 degrees with the foot flat on the stretcher in a neutral position and stabilized (see [Fig 118.2](#)). Place anterior force on the tibia. Significant displacement of the tibia anteriorly (compared with the unaffected knee) suggests ACL rupture.¹⁵ This test can also be performed with the foot in 15 degrees of external rotation (Slocum test) and 15 degrees of internal rotation.

Another test of ACL injury is the pivot shift. With the knee in full extension, the leg is lifted by the distal tibia. With an ACL rupture, the tibia is subluxed anteriorly in this position. Then apply a mild valgus force while the knee is carefully flexed to 20 to 40 degrees. At this point, the tibia jumps into a reduced position. Pain may

hinder the performance of this test in the acutely injured knee.⁸

The posterior drawer test, the reverse of the anterior drawer, is used to evaluate the PCL. Flex the knee to 90 degrees and secure the foot in a neutral position. Then apply posterior force to the tibia. If the tibia moves posterior to the femoral condyles, the test is positive, representing PCL injury.¹⁵

An alternative test of PCL injury is the posterior sag. Hold the knee in mild flexion with the thigh supported by a pillow and the foot secured. In this position, the tibia will displace posteriorly, or sag, if the PCL is ruptured.¹⁵

Meniscus

The McMurray test is used to identify meniscal injury. Hold the knee in one hand, the lower leg or foot in the other. Then apply internal and external rotation to the lower leg while flexing and extending the knee (see Fig. 118.2). Palpate the knee for catching or clicking sensations. Suspect a medial meniscal tear if clicking occurs as the leg is extended and externally rotated after being completely flexed. Clicking with internal rotation during extension is used to help identify a lateral meniscal injury. While a positive test does not guarantee a meniscal injury, it does suggest an intraarticular injury warranting further evaluation.⁶

Another test used to identify meniscal injury is the Apley test. Position the patient prone and flex the knee to 90 degrees. Apply upward force to the tibia while it is rotated and the knee is extended (see Fig. 118.2). Pain and clicking in the joint suggest a meniscal injury.¹⁵

Patellar Subluxation

The apprehension sign is seen with patellar subluxation. The knee is in extension and the examiner attempts to displace the patella laterally. With patellar subluxations, this manipulation is painful, and the patient, who is typically anxious and apprehensive about this maneuver, will contract the quadriceps.¹⁵

Other Tests

Plain radiographs are indicated in many knee injuries. Standard anteroposterior and lateral views should be supplemented with sunrise (skyline) and tunnel views to evaluate the patello-femoral joint and intercondylar notch, respectively.³ Plain films help diagnose fractures, effusions, dislocations, foreign bodies, and calcified loose bodies. Fluid-fluid levels seen on plain radiographs have traditionally been thought to represent lipohemarthrosis (fat floating on synovial fluid) and are thought to be an indication of an occult fracture. While not all fluid-fluid interfaces seen on plain films represent lipohemarthrosis, the presence of such a finding warrants further evaluation utilizing tomography, computed tomography (CT) scanning, or magnetic resonance imaging (MRI).¹⁰

Plain radiographs give little information on soft-tissue structures, but stress views and arthrography may be used to evaluate soft-tissue injuries. More recently, MRI scanning has become the test of choice for evaluating the soft tissues of the knee. Although more expensive than plain films, MRI scanning has many advantages over plain radiography. MRI scanning involves no ionizing radiation and clearly defines soft-tissue structures. It can also identify subtle injuries, such as bone contusions and occult fractures, not seen on plain films.¹⁰

Angiography, utilized to evaluate the presence of vascular injury, is indicated in the presence of any penetrating trauma in proximity to vascular structures. Furthermore, it is frequently indicated in the presence of a knee dislocation to rule out an occult injury to the popliteal artery.

Arthrocentesis and joint fluid analysis can be helpful in determining the etiology of a knee effusion. It may be difficult to differentiate hemarthrosis from an infective or inflammatory effusion clinically, particularly if the history is difficult to obtain. Analysis of the joint fluid may point to a diagnosis: For instance, an acute hemarthrosis may suggest an ACL tear, and the presence of lipid droplets in a bloody effusion may signify an occult fracture. The presence of white blood cells may indicate inflammatory or infectious processes. White counts in the range of 20,000 to 60,000 are associated with inflammatory processes; higher counts (greater than 100,000) usually represent infection.¹⁵

Further studies, such as Gram stain, cultures, crystal analysis, and glucose and protein determinations, are generally performed and provide clues to the etiology of the effusion. Some authors advocate arthrocentesis of acute hemarthrosis for pain relief; others, however, note that after evacuation of an acute hemarthrosis, it may quickly reaccumulate. Therefore, it may be preferable to utilize arthrocentesis in a diagnostic rather than a palliative role.

FRACTURES

Distal Femur

The distal femur is the lower third of the bone. Fractures in this area are typically described relative to the femoral condyles and are separated into supracondylar or intercondylar (Fig. 118.3). Distal femur fractures account for 4% to 7% of all femur fractures (31% if hip fractures are excluded). They are most often associated with high-energy trauma (e.g., knee to dashboard in high-speed motor vehicle crashes [MVCs]), but they may occur with less violent forces, particularly in the elderly.

Figure 118.3. Distal femur fractures. (A) Y-shaped intercondylar. (B) T-shaped intercondylar.

EVALUATION

The physical examination typically demonstrates a tender, edematous knee and distal femur. Obvious deformity may be present, and crepitus may accompany movement. If a fracture is suspected, the knee should be immobilized and radiographs obtained. Although neurovascular injuries are uncommon, the proximity of the femoral artery and peroneal nerves to the bone requires that the neurovascular status of the extremity be evaluated and documented. Differential diagnoses include patellar fractures, knee dislocations, and soft-tissue injuries with resulting effusions. Associated injuries, such as hip fractures and dislocations, acetabular fractures, knee dislocations, and proximal tibial fractures, should be suspected and evaluated.

Standard diagnostic tests include anteroposterior and lateral radiographs. Oblique views and tomography help evaluate intracondylar and intraarticular injuries. If vascular trauma is suspected, arteriography should be performed.

MANAGEMENT

Initial management includes immobilization, pain management, and evaluation of concomitant injuries. Early orthopedic consultation is indicated for definitive care

(skeletal traction or surgical repair).

Proximal Tibia

Tibial plateau fractures occur as a result of varus–valgus forces, from axial loads, or both. Fractures of the tibial plateau may cause a major impairment in the stability and function of the knee joint. The lateral portion of the tibial plateau is most commonly involved (approximately 80% of cases).³

EVALUATION

Clinical findings vary with the severity and type of fracture. There may be gross or only minimal deformity. The knee is usually swollen and tender. The potential for neurovascular injuries is much higher in proximal tibial fracture than in distal femoral fracture. The physician should maintain a high level of suspicion for such injuries and carefully evaluate neurovascular status.² The potential for the development of a compartment syndrome is also significant. Paresthesias and paralysis from compartment syndromes may be mistaken for a primary nerve injury. Injuries to the menisci, as well as to the collateral and cruciate ligaments, should be suspected. Deep venous thrombosis (DVT) is another common complication seen with tibial plateau fracture.¹

Diagnostic tests include plain radiographs, tomography, and CT scans. If a vascular injury is suspected, an arteriogram should be obtained. Doppler studies and venograms may be indicated to exclude DVT. If compartment syndrome is clinically suspected, compartment pressures should be measured.

MANAGEMENT

In addition to the standard management of immobilization and evaluation of other injuries, orthopedic consultation is indicated. Simple fractures may be treated with immobilization; depressed fractures require surgical reduction.

Tibial Spine Fractures

Fractures of the tibial spines generally represent avulsion injuries caused by trauma to the cruciate ligaments. Tibial spine fractures are more common in children, as their ligaments are stronger than their bone. The anterior spine is most commonly affected.⁴

EVALUATION

Clinical examination generally reveals a swollen, tender knee. Because there is a high correlation with ACL injuries, hemarthrosis is common. The most common diagnostic test needed is a plain radiograph. Fractures are usually seen on plain films, but MRI scanning or arthroscopy may be needed to identify associated injuries.

MANAGEMENT

Management involves immobilization and orthopedic referral. Some fractures may be treated nonsurgically, but if significant displacement is present, surgical intervention may be necessary.

Tibial Tuberosity

A fracture of the tibial tuberosity represents an avulsion injury caused by the patellar tendon. This uncommon fracture occurs with either strong flexion or extension of the knee against resistance. It most commonly occurs before closure of the epiphysis.⁴

EVALUATION

Examination reveals tenderness and possible deformity at the site of injury. As this is an extraarticular injury, joint effusion is rare. The differential diagnosis must include Osgood-Schlatter disease in adolescents. Osgood-Schlatter disease is a traction injury to the apophysis of the tibial tuberosity.¹¹ Although most common in boys ages 10 to 13, it may be seen in girls, usually ages 8 to 13.⁴ It is thought that repetitive trauma to the epiphysis results in incomplete separation of parts of the cartilaginous and chondroosseous portions of the tibial tuberosity.⁴ Diagnosis is based on the history and physical examination. The tubercle is painful, tender, and usually enlarged. Pain is exacerbated by extension of the knee, particularly against resistance.

The diagnosis of a tibial tuberosity fracture is generally made on plain radiographs. If Osgood-Schlatter disease is suspected, plain radiographs may be difficult to interpret, as fragments of the tuberosity may be a normal variant.⁴

MANAGEMENT

Tibial tuberosity fractures may require open reduction but are usually treated with immobilization.⁴ Osgood-Schlatter disease is treated with rest, sometimes plaster cast immobilization, and, rarely, surgical excision of loose ossicles to relieve symptoms.¹³

Patellar Fractures

Patellar fractures may result from direct or indirect forces. Direct forces, as seen with falls and MVCs, are most common. Less common are fractures resulting from severe tension placed on the patella by strong contraction of the quadriceps; the usual result is a transverse fracture, which may disrupt the extensor mechanism.

EVALUATION

Examination generally reveals pain and tenderness over the patella, inability to walk, and, commonly, a joint effusion. If the fracture is significantly displaced, a defect may be palpable. Diagnosis is generally made with plain radiographs. Tomograms and CT scans may identify an occult fracture. A bipartite patella may be confused with a fracture. Often, the margins of a bipartite patella are rounded, but in the setting of acute trauma, it may be difficult to differentiate from an acute fracture.³

MANAGEMENT

Therapy is based on the type of fracture, degree of separation, and condition of the extensor mechanism. Orthopedic referral is indicated. Simple fractures are treated with immobilization, but surgery may be indicated in severe cases. As with all fractures about the knee, posttraumatic arthritis is a significant complication.

DISLOCATIONS

Tibiofemoral Joint

Dislocation of the tibiofemoral joint is rare. It is generally associated with high-energy trauma but may be seen with low-energy forces (e.g., stepping in a hole, jumping on a trampoline).⁷ The dislocation is described as anterior, posterior, medial, lateral, or rotary based on the position of the tibia relative to the femur. For a dislocation to occur, significant trauma to the surrounding soft tissue is generally seen, including the collateral ligaments, cruciate ligaments, menisci, joint capsule, and

neurovascular structures.²

EVALUATION

Physical examination may be difficult. Some dislocations spontaneously reduce before the patient arrives at the ED. The patient may relate a history of abnormal position of the joint before reduction. Tenderness, swelling, joint effusion, and deformity may be present. Because of a high incidence of peroneal nerve and popliteal artery injury, specific attention should be devoted to this aspect of the physical examination.⁵ The absence of distal pulses highly correlates with significant vascular injury; the presence of pulses, however, does not eliminate the possibility of vascular damage.¹² Considering the common high-force mechanisms of injury and the potential for vascular damage, compartment syndrome is a significant potential complication.

Diagnosis is based on history, physical examination, and plain radiographs. CT scanning may be useful. MRI scanning will identify intraarticular injuries, but it is not commonly used in the acute setting.

For years, arteriography has been used in evaluating knee dislocations. If distal pulses are absent or abnormal, the need for arteriography is obvious. Recently, however, some have advocated the selective use of arteriography. These authors argue that although some patients with intact normal pulses may demonstrate arteriographic evidence of injuries, such as intimal tears, these lesions rarely need surgical intervention.^{7,18} Other authors suggest that arteriography is indicated in all patients² because of the devastating complications of missed injuries that can lead to limb ischemia and amputation.

MANAGEMENT

Emergency management involves rapid reduction of the dislocation, especially if vascular compromise is evident. It can be accomplished by longitudinal traction ([Fig. 118.4](#)). If the clinical status permits, intravenous sedation and analgesia may facilitate the reduction. The limb's neurovascular status must be reassessed periodically, particularly after manipulation. If the patient is stable, appropriate diagnostic tests and orthopedic and vascular surgery consultations should be quickly obtained.

Figure 118.4. Technique for reduction of knee dislocation.

Patella

The patella may be completely dislocated or subluxed from the intercondylar groove as a result of a direct blow or by hyperflexion of the knee joint. The patella almost always displaces laterally. This injury is common in adolescent girls.¹¹ The patient often reports previous episodes in which subluxations spontaneously reduced.

EVALUATION

The physical examination generally reveals an inability to extend the knee and obvious deformity. A joint effusion is commonly present. The subluxed patella may often reduce spontaneously. The apprehension sign may suggest this injury. Plain radiographs help confirm the diagnosis if it is not apparent on clinical examination. If the patella has spontaneously reduced, plain films will confirm proper placement and identify any bony injury. If subluxations are recurrent, plain films may assist in the evaluation of the anatomy of the patellofemoral joint and help direct further treatment.

MANAGEMENT

Emergency management of subluxations involves acute reduction. It is usually done by applying medial force to the patella while the knee is being extended. Appropriate sedation and analgesia are often necessary. Once reduced, the knee is immobilized and the patient treated with elevation, ice, and crutches. Complete dislocations often require surgical repair to decrease the incidence of recurrence or subluxation.¹⁴

SOFT-TISSUE INJURIES

Collateral Ligaments

The collateral ligaments protect the knee from varus and valgus stresses. The MCL is the most commonly injured ligamentous structure in the knee.¹¹ It is typically injured in sporting events when a direct valgus force is applied to the knee while the foot is relatively stationary. The LCL can also be injured, but injury to it is less likely to occur secondary to athletic events. LCL injuries are more commonly seen with falls and MVCs. MCL and LCL tears are associated with cruciate ligament injuries, with the LCL injury less likely to occur as an isolated event.¹¹

EVALUATION

The patient generally presents with tenderness along the distribution of the ligament. There is often a history of "popping" and abnormal bending of the knee. The physical examination should include the previously listed diagnostic tests, with varus and valgus forces applied to the knee at extension and 30 degrees of flexion. The presence of an associated effusion may complicate the examination, warranting a few days of elevation and immobilization prior to reexamination.

MANAGEMENT

Treatment is based on the severity of the injury. First- and second-degree sprains are treated with immobilization, ice, and crutches. Follow-up examination by an orthopedist is required to reevaluate the patient's progress and the need for further intervention (e.g., arthroscopy, surgical repair).

Cruciate Ligaments

Injuries to the cruciate ligaments are common with low-velocity trauma (e.g., football, basketball) as well as with high-energy forces. The patient usually reports a direct anterior or posterior blow to the knee. The cruciates can also be injured by rotational forces, usually in association with other soft-tissue trauma (e.g., collateral ligaments, menisci). The ACL is weaker than the PCL and is more commonly injured.¹¹

EVALUATION

The patient often presents with a swollen, tender knee. Seventy percent of patients presenting with an acute, traumatic hemarthrosis have a tear of the ACL. Because the cruciate ligaments are located deep in the articular surface and are associated with a high incidence of joint effusions, clinical diagnosis is often difficult.

Tests for ACL injuries include the Lachman, anterior drawer, and pivot shift tests. The Lachman test is the most sensitive. PCL stability is evaluated by the posterior drawer and posterior sag tests. Plain radiographs are of little value. MRI scanning is the best imaging test to evaluate the cruciate ligaments.

MANAGEMENT

Arthroscopy is used for both diagnosis and treatment. Definitive treatment is based on factors such as the patient's age, level of activity, and the severity of the injury. Initially, immobilization and orthopedic consultation are necessary.

Meniscal Tears

Meniscal injuries generally occur with a twisting force applied to the knee. The twisting may result from relatively minor forces, such as those produced when rising from a squatting position. Patients frequently complain of hearing a "snap" or "pop," which is common but not specific to meniscal injuries. Often, the patient reports locking of the knee, usually a result of a "bucket handle" tear of the meniscus, with a free central portion of the cartilage becoming lodged in the intercondylar notch. The medial meniscus is most commonly affected.

EVALUATION

The patient usually presents with a joint effusion. Unlike the hemarthrosis seen with an ACL rupture, the effusion accumulates much more slowly, generally over 12 to 24 hours. Pain is usually localized to the side of the knee where the tear is located. A decrease in the range of motion is often noted and may be related to the effusion or a loose body. Diagnostic tests include the McMurray and Apley tests. MRI scanning is very helpful in defining the anatomy of the meniscus and in pinpointing injuries.

MANAGEMENT

Arthroscopy is generally reserved for treatment, as the accuracy of the MRI is well documented. Initial treatment consists of immobilization, analgesia, and orthopedic referral. Definitive treatment is based on clinical evaluation. If symptoms persist, meniscectomy is generally performed arthroscopically.

Tendon Injuries

The extensor mechanism includes the quadriceps tendon, the patella, and the patellar tendon. Injuries to these structures, or with avulsion of the tibial tubercle, can disrupt the extensor mechanism. Disruption may result from high-energy or penetrating trauma, but is also seen with low-energy forces. Tendon ruptures associated with low-energy trauma commonly occur when the tendons are weakened (e.g., by gout, arthritis, infection, metabolic diseases, tenosynovitis, previous trauma). If the tendon is already weakened, rupture may occur with forceful contraction of the quadriceps.

Generally, the patellar tendon is least likely to rupture. The quadriceps tendon is more commonly ruptured, and this is usually seen in elderly patients. ⁹ The quadriceps tendon usually ruptures just proximal to the patella. The patellar tendon frequently ruptures at the insertion into the patella. ⁹

EVALUATION

The physical examination generally reveals a swollen, tender knee. A palpable deficit may be present. Tenderness is usually identified at the site of injury. To evaluate the tendons properly, the patient's ability to extend the knee fully against resistance must be tested. The diagnosis is usually suspected clinically; CT and MRI scanning may be used for definitive diagnosis of tendon ruptures.

MANAGEMENT

A complete rupture requires surgical repair. Incomplete ruptures necessitate orthopedic referral for definitive management.

Bursitis

Local inflammation and subsequent bursitis may be a complication of knee trauma. The bursae of the knee are illustrated in [Figure 118.5](#).

Figure 118.5. Bursae of the knee

EVALUATION

The physical examination often reveals a swollen, tender knee with a localized effusion that is warm to the touch. Other causes of knee swelling (hemarthrosis, infection) should be considered and evaluated. Arthrocentesis and joint fluid analysis are performed if an effusion is present.

MANAGEMENT

If bursitis is suspected, rest, ice, and nonsteroidal antiinflammatory medications are prescribed. The patient is referred to an orthopedist for follow-up.

COMMON PITFALLS

- Failing to examine the hip carefully. Knee pain is often referred from the hip, and knee trauma may precipitate hip injuries.

- Performing a soft-tissue examination in the face of joint effusion and muscle guarding. A period of immobilization and reexamination is indicated after the effusion resolves.
- Mistaking bipartite patella for a patellar fracture
- When evaluating the extensor mechanism, failing to examine the knee in full extension, against resistance
- Overlooking the possibility of proximal fibula fractures and dislocations resulting from ankle injuries
- Failing to consider Osgood-Schlatter disease in an adolescent with knee pain

LIGAMENTOUS INJURIES OF THE ANKLE

Ankle sprains are the most common sports-related injury,¹ and they comprise 75% of all ankle injuries. They are caused by eversion or inversion of the ankle, usually while the ankle is plantar flexed. More than 90% of all ankle sprains involve the lateral ligaments. Eversion injuries are much less common, often resulting in an avulsion fracture of the medial malleolus.

Ligaments stabilize the talus between the tibia and fibula. Three ligaments provide lateral ankle support: the anterior talofibular, the calcaneofibular, and the posterior talofibular. The anterior talofibular ligament is injured 90% of the time. The broad deltoid ligament supports the medial aspect of the ankle ([Fig. 119.1](#)).

Figure 119.1. Ligaments of the ankle.

EMERGENCY DEPARTMENT EVALUATION

The patient's history can help to differentiate the injury. Several important questions should be asked: How did the injury occur? Has the ankle been injured previously? Is the patient able to ambulate?

The injured ankle should be examined systematically, beginning with the unaffected areas. The ankle is inspected for swelling and ecchymosis. The entire extremity, including the hip and the knee, is palpated for tenderness. The patient's neurovascular status distal to the injury site, including dorsalis pedis and posterior tibial pulses and capillary refill, is assessed. The lateral and medial ligaments are palpated for tenderness. The proximal fibula and the base of the fifth metatarsal and the navicular bone are palpated to evaluate for an associated fracture.

Provocative Tests for Ankle Stability

The *anterior drawer test* evaluates the anterior talofibular ligament. With the ankle in a neutral position, the lower leg is immobilized with one hand. The physician's other hand holds the hindfoot in slight external rotation and distracts the hindfoot anteriorly. A positive test, greater than 1 cm anterior talar movement or the lack of a distinct end point, indicates anterior talofibular ligament disruption. The *talar tilt test* evaluates whether the ankle mortise opens up medially or laterally. With the ankle again in a neutral position, the ankle is inverted and everted while holding onto the hindfoot. If the talar joint opens as little as 5 degrees radiographically or there is greater than 10 degrees of difference between the injured and unaffected ankles, injury to the calcaneofibular ligament may have occurred. Pain elicited when the tibia and fibula are squeezed together 15 cm below the knee is a positive *squeeze test*; and may indicate interosseous membrane disruption. The calf should also be squeezed in all patients with an ankle injury (Thompson test; see section below, [Achilles Tendon Rupture](#)) to be certain an Achilles tendon rupture has not occurred.

Although the patient's pain and ankle swelling may limit the usefulness of provocative testing, such testing should be attempted in all patients.

Grading Ligamentous Injuries

Although grading remains controversial, it helps to establish criteria for treating ankle sprains. In a grade I injury, the ankle has localized swelling and tenderness, without loss of function or stability. A grade II injury involves more marked swelling and tenderness, as well as significant pain with weightbearing. The anterior drawer test may be positive. A grade III injury involves disruption of at least two of the lateral ligaments. The anterior drawer and talar tilt tests are often positive, and the patient will be unable to bear weight.

Radiographic Evaluation

Routine radiologic views of the ankle include an anteroposterior (AP) view to evaluate for talar shift and malleolar fractures, a mortis view to look for widening of the tibial–talar joint from ligamentous rupture, and a lateral view. Stiell and associates⁷ have developed criteria (the Ottawa rules) to assist in determining which patients with acute ankle or midfoot pain require radiographic evaluation. According to these criteria, ankle films are indicated if there is pain near the malleoli and either (1) an inability to bear weight (four steps) both immediately after the injury and in the emergency department or (2) bone tenderness at the posterior edge or inferior tip of the malleolus. Foot films are indicated if there is midfoot pain and (1) an inability to bear weight both immediately after the injury and in the emergency department or (2) bone tenderness over the navicular or base of the fifth metatarsal. Prospective and pooled trials have demonstrated the usefulness of these criteria in reducing the need for radiographic evaluation.^{3,5}

EMERGENCY DEPARTMENT MANAGEMENT

The goal of initial treatment is to minimize pain and ankle inflammation. Therapy should include the following, easily remembered by the acronym RICE: rest, ice, compression, and elevation. Instruct the patient to rest the ankle and to avoid activities that aggravate the injury. Cryotherapy, 20 minutes four times a day, and compression from an elastic wrap or ankle brace will help reduce pain and swelling. The patient should elevate the involved extremity whenever sitting or lying down.

Treatment of mild-to-moderate sprains centers around early mobilization.⁹ Early mobilization encourages stronger and faster soft-tissue healing and less muscle atrophy, inflammation, and inconvenience. Pneumatic compression braces and other marketed supports prevent recurrent ankle inversion or eversion but do not impede dorsiflexion or plantarflexion.

Although grade I and II sprains are treated with immobilization and protected weightbearing, grade III injuries may require cast immobilization for 3 to 6 weeks. All grade III ankle sprains should be splinted and immediately referred to an orthopedist for follow-up.

DISPOSITION

All ankle sprains can be discharged home with appropriate follow-up. Orthopedic or sports medicine consultation should be considered for all ankle sprains. Grade I and II sprains should be treated with compression, such as a pneumatic brace and early mobilization, including exercise recommendations. Referral to the patient's primary care physician or to a specialist within 7 days should be arranged if pain persists or if the patient has not returned to normal activity. Grade III sprains should be referred to an orthopedist within 1 to 2 weeks to change the splint to cast immobilization, if indicated. Other recommended reasons for orthopedic referral, according to Swain and Holt,⁸ include (1) a "pop" that is felt or heard, (2) prolonged recovery, (3) a history of several previous injuries, (4) medial ankle tenderness, or (5) a positive squeeze test or other stress test.

FRACTURES OF THE ANKLE

The ankle can be conceptualized as a closed "ring" surrounding the hindfoot. If this ring is disrupted in two or more places, instability occurs. A fracture of the ankle may indicate severe coexistent ligamentous disruption or dislocation, and a thorough neurovascular examination must be performed. The ankle should be properly splinted until such consultation is possible. Open fractures and neurovascular compromise necessitate emergent orthopedic consultation. Although not well supported in the literature, it is widely recommended that open fractures receive intravenous antibiotics. Stable, uncomplicated fractures should have outpatient follow-up within 7 days.

DISLOCATIONS OF THE ANKLE

Ankle dislocations require a large degree of force, owing to the bony anatomy of the ankle.⁴ They are commonly associated with ankle fractures. The talus most commonly dislocates posteriorly on the distal tibia.

EMERGENCY DEPARTMENT EVALUATION

Skin tenting and evidence of neurovascular compromise are indications for immediate reduction. In uncomplicated dislocations, radiographs should precede attempts at reduction.

EMERGENCY DEPARTMENT MANAGEMENT

The examining physician may require two assistants to perform closed reduction of ankle dislocations. For posterior dislocations, the first assistant flexes the knee to 45 degrees and applies countertraction over the calf. The second assistant pushes down on the front of the lower leg. The physician applies traction to the heel and forefoot, first plantarflexing the foot and then lifting the heel (Fig. 119.2). For anterior dislocations, the first assistant flexes the knee to 45 degrees and applies countertraction over the calf. The second assistant lifts up on the lower leg. The physician dorsiflexes the foot initially to disengage the talus and then pushes downward on the foot (Fig. 119.3). For lateral dislocations, the physician applies longitudinal traction to the foot, with one hand on the heel and the other on the dorsum of the foot. With assistants applying counteraction to the leg, the physician then manipulates the foot medially.

Figure 119.2. Technique of reduction of posterior dislocation of the ankle.

Figure 119.3. Technique of reduction of anterior dislocation of the ankle.

Most patients require open reduction and internal fixation to effect reduction of either anterior or posterior dislocations. If closed reduction is successful, a posterior splint should be initially applied and replaced with a short leg cast once swelling has decreased. The patient should be admitted. The patient should not bear weight on that extremity for approximately 6 weeks.

DISPOSITION

Dislocations or fracture–dislocations that cause neurovascular compromise require emergent reduction by the emergency medicine physician to restore proper anatomic alignment. It is important that such injuries be reduced prior to transferring the patient to another facility. Open injuries or fracture dislocations without neurovascular compromise require emergent orthopedic consultation for an attempt at closed reduction or open reduction and internal fixation, if needed. These injuries should be properly splinted prior to transfer. Closed fractures without neurovascular compromise and good anatomic alignment should be splinted, and arrangements should be made for orthopedic consultation within 48 to 72 hours.

MISCELLANEOUS ANKLE INJURIES

Other possible soft-tissue and bony injuries must also be considered. Injury to the deltoid ligament is usually accompanied by either a proximal fibula fracture (Maisonneuve fracture) or a disruption of the tibiofibular syndesmosis. These injuries are especially common with eversion injuries. Patients with a syndesmotic injury often prefer to walk on their toes, and the squeeze test will elicit pain. These injuries require proper splinting and orthopedic consultation within 48 to 72 hours.

Achilles Tendon Rupture

Rupture of the Achilles tendon may present somewhat similarly to an ankle injury. The patient may recall hearing a “pop” and subsequently being unable to bear weight on the leg. Achilles tendon rupture often affects middle-aged men involved in an athletic endeavor. The tendon rupture generally occurs at the narrowest portion of the tendon, about 5 cm above its calcaneal attachment. The left Achilles tendon ruptures more frequently than the right. Tendinitis or steroid injections may be risk factors for tendon rupture.

EMERGENCY DEPARTMENT EVALUATION

On examination, the patient may exhibit weakened plantarflexion. There may be an obvious defect in the tendon 2 to 6 cm proximal to its insertion on the calcaneus. Failure of the foot to plantarflex when the physician squeezes the calf, with the patient prone and the knee flexed to 90 degrees, indicates a positive Thompson test and probable Achilles tendon rupture.

EMERGENCY DEPARTMENT MANAGEMENT

Emergency department management consists of placing the leg in a posterior splint, with the foot in passive equinus. An orthopedist should be consulted.

DISPOSITION

Once this injury is properly splinted, orthopedic consultation should be accomplished within 48 to 72 hours, as there is evidence that early surgical repair of this injury results in a better outcome.

FOOT INJURIES

The foot is divided anatomically into the hindfoot, midfoot, and forefoot. The hindfoot includes the calcaneus and talus; the midfoot includes the navicular, cuboid, and cuneiforms; and the forefoot includes the metatarsals and phalanges. The Chopart joint separates the hindfoot from the midfoot, and the Lisfranc joint separates the midfoot from the forefoot ([Fig. 119.4](#)).

Figure 119.4. Bones of the foot.

Plantar Fasciitis

The plantar fascia extends from the os calcis to the flexor apparatus of the toes. Overuse, as from hill running or sprinting; poor arch support; and poor foot mechanics may contribute to cause inflammation and thus, plantar fasciitis.

PRESENTATION AND EMERGENCY DEPARTMENT EVALUATION

Patients with plantar fasciitis often note pain in the sole and heel of the foot that is worse in the mornings or when climbing stairs. Pain may be elicited by palpation of

the plantar fascia. Radiographic evaluation is usually not indicated unless the pain is localized, significant trauma has occurred, or a stress fracture is suspected.

EMERGENCY DEPARTMENT MANAGEMENT

The pain of plantar fasciitis subsides with rest, ice, and antiinflammatory drugs. Referral to an orthopedist, sports medicine physician, or physical therapist is appropriate to evaluate the patient for an orthotic device or exercise program.

DISPOSITION

Although crutches and decreased weightbearing are rarely indicated, consultation, as previously outlined, should be arranged within 1 to 2 weeks.

Turf Toe

Turf toe refers to a sprain of the great toe's metatarsophalangeal joint. Pushing off a severely dorsiflexed great toe causes the injury.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The area over the metatarsophalangeal joint is painful, swollen, and tender. Radiographic evaluation to rule out fracture may be indicated. A stiff-soled shoe that limits dorsiflexion at the metatarsophalangeal joint provides significant relief.

DISPOSITION

These patients respond well to rest, ice, and antiinflammatory agents. Orthopedic or sports medicine consultation may be needed if symptoms persist for more than 1 to 2 weeks.

Calcaneal Fractures

Calcaneal fractures account for 1% to 2% of all fractures. The calcaneus is the tarsal bone that is most often fractured. Calcaneal fractures occur in persons aged 30 to 50 years old, with men being affected five times more often than women. The calcaneus fractures under vertical compression. Typically, this occurs in a fall. These fractures are commonly (10%) associated with compression fractures of the dorsolumbar spine, and 25% are associated with other lower extremity fractures.

EMERGENCY DEPARTMENT EVALUATION

If a calcaneal fracture is suspected, three radiographic views of the heel should be obtained: AP, lateral, and axial. On the lateral radiograph, the angle formed by a line extending along the superior aspects of the os calcis and another line extending from the dome to the anterior tubercle, which is referred to as Böhler's angle, should be measured. A normal angle ranges from 20 degrees to 40 degrees. An angle of less than 20 degrees indicates a calcaneal fracture.

EMERGENCY DEPARTMENT MANAGEMENT

A minimum-to-severe disability may result from calcaneal fractures, and the degree of residual symptoms does not always correlate with the degree of subtalar joint disruption. Postinjury pain may result from a number of sources. These injuries are best managed in consultation with an orthopedic surgeon because of the potential for complications.

DISPOSITION

These injuries are best managed with emergent orthopedic consultation. They should be splinted, and the patient should do no weightbearing until such consultation can be accomplished.

Talus Fractures

Fractures of the talus are the second most common foot fractures. The talus fractures as a result of midfoot hyperdorsiflexion. Such a mechanism often occurs in motor vehicle accidents, when the foot is braced against the brake pedal. The tenuous blood supply to the talus makes it vulnerable to avascular necrosis when injured, especially if the fracture occurs through the neck.

Lisfranc Fracture–Dislocation

The midfoot is the least mobile portion of the foot, making it the most susceptible to direct trauma. A fracture–dislocation through the Lisfranc joint, usually involving a fracture of the second cuneiform with dislocation of the lateral four metatarsals, may result from a motor vehicle accident. Hyperdorsiflexion of the forefoot on the midfoot causes the forefoot to dislocate dorsally. Lisfranc fractures are rare (one in 55,000 per year), but delays in treatment, caused by a 20% rate of missed diagnoses, may result in significant morbidity.

PRESENTATION AND EMERGENCY DEPARTMENT EVALUATION

The foot is usually very swollen and painful. Ross and associates⁶ describe a consistent physical finding of a well-defined plantar ecchymosis in Lisfranc fractures. A fracture through the second metatarsal base may indicate disruption at a Lisfranc joint. The oblique radiograph may demonstrate widening between the first and second metatarsal bases, which suggests subluxation. In more subtle injuries, abduction stress radiographs may reveal disruption of the medial column line (a line tangential to the medial aspect of the navicular and medial cuneiform that should intersect the base of the first metatarsal).² [Figure 119.5](#) illustrates a Lisfranc dislocation.

Figure 119.5. Radiograph of a Lisfranc dislocation: **(a)** first metatarsal; **(b)** second metatarsal; **(c)** third, fourth, and fifth metatarsals, which have been dislocated laterally.

EMERGENCY DEPARTMENT MANAGEMENT

Most tarsometatarsal dislocations require open reduction and internal fixation to effect accurate reduction and stabilization. Closed reduction in the emergency department should be considered only when marked displacement and neurovascular compromise are present.

DISPOSITION

These injuries require splinting, no weightbearing, and emergent orthopedic consultation.

Fifth Metatarsal Fractures

The most common metatarsal fracture occurs through the base of the fifth metatarsal. Two distinct fractures may occur at the proximal end of the fifth metatarsal. An avulsion fracture by the peroneus brevis tendon results from plantarflexion and inversion of the foot. Another commonly seen fracture through the base of the metatarsal is a transverse fracture through the tuberosity. This fracture is common in athletes. Both of these fractures are relatively stable and can be treated conservatively with a hard-soled shoe, unless the fracture fragment is markedly displaced. A Jones fracture differs from the other two fractures in that it occurs at the metatarsal diaphysis distal to the tuberosity. Jones fractures have a higher incidence of nonunion or delayed union in comparison with avulsion fractures.

DISPOSITION

Orthopedic consultation should be obtained when a Jones fracture is identified, because athletic patients are usually managed operatively. In the nonathlete, this injury is treated with a walking cast for 4 to 6 weeks and then the wearing of a hard-soled shoe. Sports participation is avoided until a secure union is achieved. If nonunion or a recurrent fracture occurs, screw fixation is the preferred treatment.

Second and Third Metatarsal Fractures

Because of the stresses incurred while pushing off, the second and third metatarsals are particularly prone to stress fractures. Initial radiographs may not reveal the fracture line. Ra- diographs performed 2 to 3 weeks later will likely show cal- lus formation and periosteal reaction. If the fracture is not evident on follow-up films but symptoms persist, a bone scan should be considered. Radionuclide scanning is sensitive for stress fractures but not highly specific, because tumors and infections also result in positive scans.

DISPOSITION

Stress fractures require close orthopedic follow-up. Initial management includes cessation of any pain-producing activity, followed by a rehabilitation program and biomechanics evaluation.

Metatarsophalangeal and Interphalangeal Dislocations

In metatarsophalangeal dislocations, the phalanx commonly dislocates dorsal to the metatarsal. In interphalangeal dislocations, the distal phalanx may dislocate either volar or dorsal to the proximal phalanx. Dislocation is usually clinically evident, but radiographs should be obtained to rule out associated fracture. If no fracture is coexistent, the dislocation can usually be reduced by applying longitudinal traction in the direction of the dislocated phalanx with either dorsal or volar pressure ([Fig. 119.6](#)).

Figure 119.6. Technique of reduction of metatarsophalangeal dislocation of the great toe.

DISPOSITION

With successful reduction, the toe is “buddy-taped” to the adjacent toe for 3 to 4 weeks. If reduction is unsuccessful, the flexor tendon or joint capsule may be entrapped. Open reduction may be necessary.

COMMON PITFALLS

- Failure to palpate the base of the fifth metatarsal and navicular bone to evaluate for associated fracture when addressing ankle sprains
- Failure to evaluate for Maisonneuve fracture and syndesmotic injury with deltoid ligament injuries or ankle sprains
- Prolonged immobilization of grade I and II ankle sprains rather than early mobilization and exercises
- Failure to consider Achilles tendon rupture in the patient with “ankle pain”
- Failure to differentiate a Lisfranc fracture–dislocation from a simple metatarsal fracture
- Failure to differentiate a Jones fracture from a simple proximal fifth metatarsal fracture

[Common Pitfalls](#)
[Chapter References](#)

Replantation is defined as the reattachment of a completely amputated body part, while *revascularization* is the reconstruction of a partially or incompletely amputated part. With the advent of refined instrumentation and surgical techniques, success rates approaching 90% have been reported for both the replantation of complete amputations and the revascularization of partial amputations.¹⁶ As a result, emergency department physicians should consider all patients with complete amputations potential candidates for replantation, and all patients with partial amputations candidates for revascularization.

Partial and complete amputations occur equally often. Distal amputations are more common than proximal amputations. Sharp, guillotine-type injuries suffer less tissue destruction, devitalization, and contamination and heal better than crushing and degloving injuries. Most amputations and crush injuries of the extremities occur in patients between the ages of 20 and 40, with males predominating over females by a margin of 4:1.^{1,9} Up to 65% of these amputations are characterized as local crush wounds; the rest are divided between sharp injuries and diffuse crush wounds.

While advances in microvascular surgery have permitted surgical subspecialists to replant fingers, toes, extremities, ears, noses, penises, and virtually any musculoskeletal tissue, the media have propagated unrealistic expectations among the public about the success of replanting amputated body parts. The cost to the patient in dollars, repeated surgery, prolonged rehabilitation, and time lost from productive activity can be great. A replanted body part has little functional value to the patient if it is disfiguring or has unsatisfactory neurologic function, cold intolerance, or pain. Anticipation of good functional recovery has become the critical factor when considering revascularization of a severed body part. The cost of replanting a single distal phalanx may be excessive when disability and rehabilitation costs are included.⁸

Although the success rate in children is somewhat less than in adults, replanted limbs that remain viable have better return of function and usually have less pain and cold intolerance and better two-point discrimination than in adults. About 80% of continued longitudinal bone growth can be expected in children with replanted extremities.⁴

EMERGENCY DEPARTMENT EVALUATION

Indications for Replantation

While the final decision regarding microvascular repair rests with the surgical team and the patient, the emergency physician must be aware of the factors that influence the decision to perform replantation or revascularization ([Table 120.1](#)). There are no absolute indications for microvascular repair; however, general indications and contraindications are listed in [Table 120.2](#) . The decision to operate on patients with one or more relative contraindications is made on an individual basis. Contraindications are weighed by the treating surgeon and are considered when attempting to predict outcome. As a rule, even if the possibility of replantation seems remote, the treating emergency physician should manage the stump and amputated tissue as if they were suitable for replantation or revascularization.

Favorable Outcome	Poor Outcome
Young age	Elderly
Healthy	Systemic disease
Sharp injury	Diffuse crush injury
Short ischemic time	Long ischemic time
Appropriate ED care	Proximal injury
Motivated patient	Poorly motivated

TABLE 120.1. Predictors of Replantation Outcome

INDICATIONS
Young, healthy patient
Thumb or multiple digits
Sharp, guillotine injury
Upper extremity
RELATIVE CONTRAINDICATIONS
Single digit, except thumb
Avulsion injury
Prolonged ischemia
Gross contamination
Previous injury or surgery to part
Emotionally unstable
Lower extremity amputations
ABSOLUTE CONTRAINDICATIONS
Associated life threats
Severe crush injury
Unable to tolerate anesthesia or surgery

From Dalbey WC. Management of amputated part. In: Robert JR, Hodges JR, eds. Clinical procedures in emergency medicine. Philadelphia: WB Saunders, 1985.

TABLE 120.2. Indications and Contraindications for Replantation

Classically, the indications for replantation of upper extremity amputations include multiple digits, thumb, wrist or forearm, sharp amputations with minimum-to-moderate avulsion proximal to the elbow, single digits amputated between the proximal interphalangeal joint and the distal interphalangeal joint (distal to the flexor digitorum superficialis insertion), and amputations in children.¹⁶

Injuries to the distal phalanx less than 1 cm² may be allowed to heal by secondary intention. Granulation tissue and wound contraction will yield satisfactory functional and cosmetic results. Advancement flap skin grafts or pinch skin grafts may be used to cover larger wounds.

A solitary digit is less likely to be restored sufficiently to improve hand function (excluding the thumb) and is often not a candidate for replantation.² An exception is noted with amputations of digits distal to the insertion of the flexor digitorum superficialis (between the proximal interphalangeal and distal interphalangeal joints).

With amputations at this level of the middle phalanx, an undisturbed superficial flexor tendon will provide up to 82 degrees of proximal interphalangeal joint motion. ^{2,16}

Multiple-digit injuries, unlike single-digit amputations, mandate attempted repair to maximize functional recovery. Toe-to-hand transfers may improve opposition and grasping mechanisms for mutilating injuries of the hand involving the thumb or fifth digit. The thumb is the most important digit of the hand, and only the carpometacarpal joint is required to preserve functional opposition. ¹⁶ An injured thumb is usually replanted or revascularized. ⁶ Revision of the thumb amputation, pollicization of other digits, and toe-to-hand transfers may be acceptable alternatives if reimplantation is not an option. ^{6,12}

Proximal amputations at the metacarpal or wrist levels are associated with devastating loss of hand function; replantation often yields surprisingly good results. ² Amputations of the hand at the midpalm or carpal tunnel level may be successfully replanted up to 70% of the time. ^{9,18} Conversely, amputations proximal to the distal forearm and elbow are often complicated by severe avulsion or crush injury components, making them prone to muscle necrosis, infection, and functional failure. ¹⁶ Functional recovery is less satisfactory the more proximal the injury. Nevertheless, some surgeons have reported successful upper extremity replantation rates as high as 90%. ¹⁷

Traumatic amputations of the lower extremities are rare. Successful replantation of the legs has been performed with acceptable functional recovery. ³ Russian surgeons successfully replanted both lower legs of a 3-year-old girl that were severed in a mower accident. ⁵ Seven years after the injury, and after additional surgery to correct leg-length discrepancy, the girl enjoyed all of her usual activities.

Successful replantations of the penis, ears, nose, and avulsed scalp have been reported. ^{11,14,19} Cosmetic results are improved with the preservation of tissue. Penile replantation provides urethral competence in most cases, but sexual dysfunction is common.

EMERGENCY DEPARTMENT MANAGEMENT

Resuscitation and Initial Assessment

The initial evaluation and management of patients presenting with upper extremity amputations is aimed at stabilization of the patient and preservation of the limb and its components. ¹⁶ Patients with amputated limbs are treated with urgency. Although these injuries are dramatic, they cannot be allowed to distract the treating physician from more severe life-threatening injuries. Airway management, when indicated, and the placement of two large-bore intravenous lines are imperative. Hemodynamic instability is aggressively corrected with crystalloid solution or blood. Coexistent life threats are addressed before attention is directed toward the injured extremity.

Bleeding may be profuse in partially amputated limbs but minimal in guillotine-type injuries, owing to vessel retraction and spasm. Direct pressure and elevation are usually sufficient to control hemorrhage. The blind use of ligature, clamps, hemostats, or occlusive tourniquets must be avoided; these maneuvers may damage nerve tissue and blood vessels, rendering a limb unsuitable for replantation. If bleeding is uncontrollable, a blood pressure cuff placed on the proximal limb and inflated to 30 mm Hg above the systolic blood pressure may allow direct pressure and elevation to become effective.

The history explores the factors that will affect the decision to attempt replantation. The time and mechanism of injury, the inflicting agent, and the onset of cooling are noted. Medical history, last meal, allergies, tetanus status, and smoking history are recorded. Vocations, hobbies, handedness, lifestyle, and attitudes or religious beliefs toward replantation may influence the decision to amputate or replant.

Broad-spectrum antibiotics, such as first-generation cephalosporins, are given intravenously as soon as feasible. ¹⁰ Wound cultures may be obtained before starting antibiotics, if warranted. Preoperative laboratory studies are ordered and tetanus toxoid is given, if indicated.

Evaluation and Initial Care of the Limb

The stump and amputated part are irrigated with copious quantities of normal saline or lactated Ringer's solution to remove gross contaminants. No amputated part should be discarded until carefully inspected by the surgical team; a completely amputated body part, even if not suitable for replantation, may serve as a donor source for skin, bone, or vessel grafts. ¹⁶ Alcohol, povidone-iodine, or formaldehyde-containing solutions are avoided. The limb is handled as little as possible; exploration, debridement, and dissection are deferred to the microvascular surgeon. All constricting bands, tourniquets, and jewelry are removed. The proximal stump (as well as the amputated part, in the case of partial amputations) is evaluated for distal pulses, capillary refill, motor and reflex function, sensation, and two-point discrimination.

The absolute length of time an amputated limb can tolerate ischemia and still undergo successful replantation is unknown. The longer the ischemic time, the greater the likelihood of failure, particularly when rapidly necrosing muscle and connective tissue are involved. When amputated parts are preserved at or near room temperature, it is referred to as "warm ischemia," which may be tolerated for 6 to 8 hours. Cold preservation, or "cold ischemia," may extend the time an amputated part remains viable up to 12 to 24 hours. ¹³ Intracellular ATP is preserved and cellular acidosis delayed when tissue is cooled to 10°C, although no further benefit is gained by cooling amputated parts to 1°C. ¹⁵ One hour of warm ischemia is approximately equal to 6 hours of cold ischemia. ¹⁶ Cold ischemia has allowed amputated digits to be replanted 30 hours after injury. ⁹ The ischemic time is one of many factors that should influence the success of replantation surgery and should not be considered the sole predictor of viability (see [Table 120.1](#)).

Amputated tissue is wrapped in sterile, saline-moistened dressings and placed in a sealed plastic bag immersed in an "ice-and-water slurry" ([Fig. 120.1](#)). The tissue must not be placed directly on ice and must not be allowed to freeze. Partial amputations are more cumbersome but are also cooled when possible. Tissue bridges must not be divided, as they may carry enough venous or lymphatic drainage to make replantation possible. Partially amputated limbs are "splinted as they are found" ([Fig. 120.2](#)). Attempting to place the limb in the anatomically correct position may twist a neurovascular bundle 360 degrees, totally occluding any remaining blood flow. ⁹ The stump is also wrapped in sterile, saline-moistened dressings.

Figure 120.1. Replantation. Evaluate the patient's condition to ensure that he or she does not need to be resuscitated before transfer. **(A)** The wound should be rinsed with saline solution. *Do not scrub or apply antiseptic solution to the wound.* Apply dry sterile dressing, wrap in Kling or Kerlix for pressure, and elevate. **(B)** The amputated part should be rinsed with saline. *Do not scrub or apply antiseptic solution to the amputated part.* Wrap it in moist, sterile gauze or a towel, depending on size, and place it in a plastic bag or plastic container. **(C)** The part is then put in a container, preferably Styrofoam, and cooled by separate plastic bags containing ice.

Figure 120.2. Replantation. For a partial amputation: **(A)** Rinse with saline, place part(s) in a functional position, and apply dry sterile dressing. **(B)** Splint and elevate. **(C)** Apply coolant bags to the outside of the dressing. *Do not scrub or apply antiseptic solution to the wound.* Control bleeding with pressure. If a tourniquet is necessary, place it close to the amputation site.

After the initial stabilization of the patient is complete and the limb evaluated and dressed, radiographs of the entire extremity are obtained to define fractures.

DISPOSITION

Timely notification of the replantation team is the responsibility of the emergency physician. If transfer to another facility is required, arrangements must be completed by the time the patient is stable for transfer. It is prudent to treat every mangled or amputated limb as though it will be replanted or revascularized. The decision to perform microsurgery rests with the surgeon and the patient. Only after the surgeon has evaluated the extremity can a frank, thorough discussion about limb viability and functional recovery be entertained. It is inappropriate for the emergency physician to reassure the patient or the patient's family that limb salvage is possible or that replantation will be attempted.

COMPLICATIONS

Complications of microvascular reanastomosis are many and can be divided into early and late complications. ⁷ Ongoing ischemia requiring reexploration, reanastomosis, revision, debridement, or completed amputation can occur at any time during the postoperative period. Systemic acidosis, hyperkalemia, and rhabdomyolysis may be seen during major limb replantation when ischemic times are prolonged. Because muscle tolerates ischemia poorly and may swell after revascularization, replanted limbs containing large amounts of muscle may be subject to compartment syndrome. Systemic and local infection may occur due to the many factors that hinder wound healing. Late complications include scar contracture, tendon rupture or adhesion, poor or dysfunctional nerve regeneration, and osteomyelitis. Surgery resulting in a poorly functioning or frankly dysfunctional limb is the most feared complication. Sometimes, complete amputation with stump revision may be the best alternative.

COMMON PITFALLS

- Aggressively resuscitate the patient and address other life-threatening injuries first.
- Do not clamp or ligate blood vessels in the emergency department.
- Do not sever tissue bridges between the proximal stump and amputated part.
- Splint the stump and injured extremity to prevent further injury.
- Treat all amputated limbs as though they will be replanted or revascularized.
- Do not discard any body parts; consider all a possible donor source for skin, bone, and vessels.
- Rapidly cool, but do not freeze, amputated body parts.
- Give antimicrobial agents as soon as possible.
- Rapidly consult the microvascular surgeon to minimize total ischemic time.

CHAPTER 121

High-Pressure Injection Injuries of the Hand

Paul Blackburn

[Pathophysiology](#)
[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

To the unwitting physician, a high-pressure injection injury of the hand may at first appear innocuous, but clinical sequelae are devastating if the initial recognition or management is delayed or inadequate. The emergency physician can significantly diminish morbidity with prompt recognition, initiation of treatment, and immediate referral.

An injury of the industrial age, the first reported case by Rees in 1937 described a patient injured while working on the fuel-injection system of a diesel engine.²⁴ The clinical course described was classic: marked pain with edema of the digit, vascular compromise noted with a resultant amputation. As this type of machinery has entered numerous work environments, case reports and reviews have corroborated this clinical scenario and led to consensus concerning initial treatment. Few systematic studies of high-pressure injection injuries have been undertaken because of the low incidence of this type of injury in comparison with all hand injuries. However, the consensus among clinicians is that prompt recognition with aggressive treatment, including surgical debridement, is the only course that avoids a disastrous clinical outcome.^{2,9,11,15,20,23,26,27} and ²⁸

PATHOPHYSIOLOGY

It has been shown that a pressure of approximately 100 pounds per square inch (psi) is required to breach the skin.²⁵ The nozzle does not have to be in contact with the skin in order to cause injury. The pressures involved allow for injury even centimeters from the orifice.

Three types of industrial equipment (grease guns, spray guns, and diesel injectors) have accounted for most injection injuries.^{14,27} The air-compressed grease gun used to lubricate motor vehicles accounted for 57% of injuries in one review. Injection occurs as the operator uses a finger to wipe the plugged nozzle. The suddenly open orifice extrudes grease into the extremity at 5,000 to 10,000 psi. Hydraulic-pressured spray guns (3,000 to 7,000 psi) accounted for 18% of injuries. Spray guns are ubiquitous in industry and deliver fluids of varying viscosity: paints and lacquers, petroleum products, solvents (including paint thinner), animal vaccines, gases (Freon, oxygen), and semifluid mud, cement, and sand, for example. Diesel-fuel injectors accounted for 14% of cases reported. For diesel fuel to spontaneously ignite in the pressure chamber, the fuel must pass through an injector mechanism, which compresses the fuel between 2,000 and 12,000 psi. Injuries are most often sustained when the injection mechanism is being tested.^{15,24,27}

Numerous other types of pressure-related injuries may occur, and the hand need not necessarily be the only anatomic site involved. Defects of pneumatic hoses, valves from tractor greaseboxes, oil rig drilling and pipeline equipment, and hydraulic lines of sandblasters can lead to high-pressure injuries of other body parts.^{15,24} It should also be noted that some industrial equipment is capable of generating higher psi than the previously mentioned three examples.

The injury demographics are typical. It is an injury of the workplace, is usually due to operator inexperience or carelessness,¹³ and occurs most often with attempts to clean the pressure nozzle. Men between ages 16 and 65 are most commonly affected²⁶ on the nondominant hand. The most common site of injection is the distal volar surface of the index finger, followed by the distal volar long finger, then the palm.^{15,26} At the time of the injury, the patient may feel temporary stinging or no pain at all, which, unfortunately, may result in delay in seeking treatment.^{14,15,27}

Four factors determine the type and degree of high-pressure injection injury ([Table 121.1](#)).²³ The *type of material* is the most important element in determining the subsequent morbidity, owing to each material's propensity to create tissue inflammation and the resultant fibrosis that develops during healing. Paint and paint thinner create the greatest tissue inflammatory response and result in a high rate of amputation. Conversely, grease gun injuries do not create much inflammation. The morbidity from grease is due to eventual development of fibrosis, oleomas, and draining sinuses.^{12,15,20,26,28} It should be noted that both paint thinner and grease (and most injectates) are nearly bacteriostatic *in vivo*. Although infection is not usually a primary concern, empiric administration of broad-spectrum antibiotics is indicated.

Type of material
Amount of material
Location of injection site
Velocity of injection

TABLE 121.1. Factors Influencing the Type and Degree of High-Pressure Injection Injury

The *amount of material* injected determines tissue distention, compression, and mechanical distortion of blood flow. Simple compression of arterial and venous structures may impede venous outflow or arterial perfusion. Others feel that thrombosis and vasospasm are important components of vascular interruption.^{15,23,27} Whatever the precise etiology of impaired circulation, tissue viability is threatened, and necrosis with superimposed bacterial infection may occur.

The *location of the injection* determines the direction of injectate dispersion. Cadaveric studies using a mixture of turpentine and green-stained wax permitted controlled observation of the spread of materials.¹⁵ The substance under pressure travels in a direct line, with little lateral spread, until it encounters a resistance structure. Injection lateral to the bones of the finger leads to through-and-through penetration, with extensive spread around the dorsal surface. The fibrous tendon sheaths in the middle of a phalanx prevent direct penetration, and material travels laterally, encompassing the digital neurovascular bundles. However, at their thinnest area over the interphalangeal joints, the tendon sheaths allow penetration. If the sheath is penetrated, retrograde contamination may occur, including the radial and ulnar bursae if the thumb or little finger is involved.^{14,27} Isolated involvement of the thenar and hypothenar muscles (sparing the palm) can occur.²⁷ Palmar injection may involve deep structures if the aponeurosis is violated.

The *velocity* of the material injected does not lead to direct tissue damage, but determines the amount of material dispersion. While not a factor in creating direct tissue injury, broader spread of material will lead to more tissue damage.²³

CLINICAL PRESENTATION

The clinical appearance is determined by the time elapsed between injury and presentation. The clinical course can be divided into three stages: acute, intermediate,

and late.¹⁹ At the time of high-pressure injection, the patient may feel a stinging sensation at the site of penetration, or nothing at all. The examiner may note a small puncture wound, which may or may not have a droplet of the injected material at the site. Instantaneous swelling of the digit may be noted if sufficient material was injected.¹⁵

Within 1 to 2 hours, discoloration occurs, accompanied by increasing swelling, numbness, and pain. Within several hours, increased discoloration and swelling occur, accompanied by pain severe enough to be unrelieved by narcotics. This may appear similar to an infectious process, but conservative therapy consisting of antibiotics, elevation, and heat will doubtlessly prove catastrophic.^{15,27} Continued conservative treatment will almost certainly lead to the need for amputation of the affected part.²⁷

The *intermediate* stage is characterized by development of oleogranulomas, or oleomas around the site of injection, a foreign-body reaction to the injected material. The *late* stage is defined by ulceration of the oleomas, which discharge a sterile, amorphous material of grease and epithelium that may become secondarily infected. The skin becomes thickened and pitted, leading to functional disturbance and a poor cosmetic appearance. A possible late complication is squamous cell malignancy of the chronically irritated sinus tracts.¹⁵

In addition to the local effects, generalized constitutional symptoms may be present. Presumably because of the foreign material injected, the patient may develop a low-grade fever, leukocytosis, lymphadenitis, renal impairment, and blood chemistry alterations.^{15,16,27}

DIFFERENTIAL DIAGNOSIS

Taking a thorough history and performing a complete physical examination greatly limits the differential diagnosis. If the patient presents immediately following the injection, the puncture wound may not be evident, and a presumption of no injury might be inappropriately entertained. If a wound is noted, a mistaken clinical conclusion would be to treat it as a simple puncture wound. If the patient presents later in the acute stage, the appearance of the discolored and swollen involved part may mislead the physician to suspect an infectious condition.

EMERGENCY DEPARTMENT EVALUATION

The patient usually presents to the emergency department in significant pain within hours of the injury. Systemic manifestations are few. There may be abnormal vital signs: tachycardia or increased blood pressure due to pain, or low-grade fever.

The affected area must be meticulously inspected to find the site of injection in order to anticipate dispersion of injected material. The amount and location of swelling, tendon function, and joint range of motion are evaluated. The degree of vascular compromise, as assessed by discoloration, temperature, and capillary refill of the nailbed, is vital information for the consultant. Pulse oximetry of the affected part (with comparison with its contralateral partner) may give additional information.

Laboratory studies have little bearing on the emergency department evaluation and treatment. However, because of reports of temporary renal dysfunction from systemic absorption of injected material, urinalysis and baseline blood urea nitrogen and creatinine levels should be obtained.¹⁶ Drawing of routine preoperative studies may be considered. The clinician may consider the potential organ-specific toxicity of the material injected and add appropriate studies.

Plain films of the involved extremity are useful in determining the extent of the dispersed material and may help guide the extent of surgical debridement. Material can be dispersed a considerable distance from the site of penetration.²¹ Therefore, imaging to the elbow is mandatory. Some recommend imaging the entire upper extremity.²⁷

The x-ray appearance of injected substances may be characteristic ([Fig. 121.1](#)). The silica from sandblasting injuries is easily seen, as is the deposition of lead-based paint from a spray gun.^{21,27} The opacities of lead-based paint must not be confused with calcifications.²¹ Grease may appear as a radiolucency within the tissue and be mistaken for subcutaneous emphysema. Xeroradiography may better show the extent of grease injection.²¹ The use of magnetic resonance imaging has not been studied,^{23,27} nor has angiography.

Figure 121.1. Radiographic appearance of high-pressure injection injury of the digit. The extent of dispersal of the radiopaque material (lead-based paint) is demonstrated. (From Proust AF. Special injuries of the hand. *Emerg Med Clin North Am* 1993;11:770, with permission.)

EMERGENCY DEPARTMENT MANAGEMENT

Emergency department treatment must be rapid and definitive if a catastrophic outcome is to be avoided ([Table 121.2](#)). The time from injury to proper treatment is the prime determinant of prognosis.²⁶ Some authors feel that amputation is more likely if debridement is not done within 10 hours,²⁷ although others are of the opinion that there is no safe time window and all require urgent surgical decompression.¹⁸

1. Recognition of injury and physical examination
2. Plain films of the extremity
a. Consider preoperative lab draw
3. Broad-spectrum antibiotics, tetanus prophylaxis
4. Pain control
a. Opiates
b. Proximal nerve blocks as digital blocks are contraindicated.
5. Immediate surgical consultation
Use of steroids, heparin, and dextran is controversial.
Esmarch bandages and compressive dressings are contraindicated.

TABLE 121.2. Emergency Department Management of Injection Injuries

Emergency department care must include elevation of the extremity, administration of broad-spectrum antibiotics, tetanus prophylaxis, and general preparation for surgery. Empiric broad-spectrum antibiotics are indicated, even though most injected materials show antibacterial activity or are bacteriostatic. Pain control is

provided through opiates or proximal extremity (preferably brachial plexus) nerve blocks. Digital nerve blocks are absolutely contraindicated because of the additional fluid volume and tissue compression added to the already compromised digit.^{12,15,23,27,28} Warm soaks also are contraindicated. The increased blood flow into the extremity adds further volume and tissue compression.

Corticosteroid administration is controversial. Some argue that steroids are useful if an intense inflammatory response develops, if a delay in treatment has occurred, or if there is a systemic reaction.^{9,13} Others note that because wound infection is rarely a complication, and considering the high likelihood of poor outcome due to tissue inflammation, steroids (along with broad-spectrum antibiotics) should be administered to all.¹⁸ Data are currently insufficient to recommend the use of heparin or dextran.²³

The high-pressure injection injury is a true surgical emergency. Immediate surgical consultation is mandatory. The entire involved area must be operatively debrided and copiously irrigated with normal saline. Wounds are left open postsurgically, with Penrose drains in place to facilitate drainage. Wounds are closed at a later date, using split-thickness skin grafts. Early and aggressive treatment may preserve some function of a hand that otherwise would require amputation.²⁷ However, it must be noted that some advocate proceeding directly to amputation if there is vascular compromise.¹⁸ Reconstruction of the hand can occur at a later date.

The emergency physician should be made aware that there are case reports of conservative management of some injection injuries. One must be cognizant that the majority of reports involve gases,^{1,5,7,8,10,17,22} but isolated examples of water to the dorsum of the thumb⁶ and small volumes of nonirritating material (2-PAM chloride³) exist. In addition, the authors of a report relating to injection of veterinary vaccines notes that, with poultry vaccine (0.2 mL of injectate), the surgeon may attempt conservative or "minimally invasive" management. They go on to state that all other veterinary products must be treated entirely as high-pressure injections.⁴ One must take into account that this conclusion is based on a case series of four patients, two of whom had surgical procedures that involved opening and lavage of portions of the hand and the carpal tunnel.

Emergency physicians must realize that any decision concerning therapy beyond the initiation of treatment (antibiotics, tetanus prophylaxis, pain control, preparation for surgery) and surgical referral is not theirs to make. They must approach all high-pressure injection injuries in a similar fashion, with immediate surgical referral.

DISPOSITION

The only appropriate disposition for the patient with a high-pressure injection injury is immediate surgical consultation, with expectation of wide debridement and copious irrigation of all involved areas. Alteration from this course of action is solely the surgeon's determination.

COMMON PITFALLS

- The most common error is not to suspect or not to recognize the injury. The patient may have felt only a transient stinging sensation, and the entrance wound may be minuscule or absent. A drop of material may or may not be present at the injection site.
- Early after injury, the clinician may be faced with a puncture-like wound and a discolored, swollen, painful extremity. An infectious process may be considered if a thorough history is not obtained. Conservative treatment with antibiotics, heat, or localized incision and drainage will have predictably disastrous results.
- Digital blocks are absolutely contraindicated. The injected material has already compressed the normally nondistensible tissues of the finger. The added volume of local anesthetic will cause further compression of tissue and vascular compromise.
- Warm soaks increase blood flow to the compromised extremity and, like the added volume of injected local anesthetics, cause increased tissue compression.
- Esmarch or other compressive dressings to reduce swelling or create a bloodless field must be avoided. Their use serves only to distribute the injected material further throughout the tissue.

CHAPTER 122

Acute Compartment Syndrome

Steven C. Larson

[Pathophysiology](#)
[Clinical Presentation](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Common Pitfalls](#)
[Chapter References](#)

Acute compartment syndrome is the term used to describe the constellation of clinical symptoms and signs associated with a pathologic elevation in tissue pressure within anatomic “compartments” of the body.⁷ Left undiagnosed and untreated, this elevated pressure leads to muscle ischemia and death. Clinically, the result is the muscle contracture and deformity referred to as Volkmann’s ischemic contracture. In the late 1800s Richard von Volkmann described a progressive, posttraumatic muscle contracture (which had previously been attributed to neurologic injury) that he believed was secondary to the ischemia caused by trauma, swelling, and tight bandaging.⁶ Volkmann postulated,²²

. . . The paralysis is caused by the death of primitive muscle fibers deprived of oxygen. The contractile substance coagulates, falls into pieces, and is afterwards absorbed. The following contracture may be considered simply as a condition closely akin to rigor mortis, and indeed the limbs, if, as is usually the case, all muscles of a part are equally affected by the ischemia, assume the well known position as after death

Today, our understanding of acute compartment syndrome and Volkmann’s ischemic contracture is more detailed and sophisticated; and yet, at the core of the issue is a simple appreciation of anatomy. Basically, muscle groups and neurovascular structures are surrounded and encased in fascial sheaths, which create compartmentalized anatomic space. These compartments afford little room to accommodate swelling.²¹ When swelling occurs within this limited space or when externally applied forces such as constrictive dressings cause increased intracompartmental pressures, circulation is compromised. The resulting ischemia produces abnormal muscle function, followed by abnormal neurovascular function, and this process has come to be termed *compartment syndrome*. Matsen and associates¹² defined *compartment syndrome* as “a condition in which increased pressure within a limited space compromises the circulation and function of the tissues within that space.”

The incidence of compartment syndrome is unknown because of inconsistencies in diagnostic criteria, as well as the prophylactic fasciotomy often performed to prevent development of this syndrome.¹⁸ The disorder is most common in the calf or forearm, but the hand, foot, and upper portions of limbs may also be affected.⁸ In one study, the incidence of lower-limb compartment syndrome in adults was 6% in open fractures of the tibia and 1.2% in closed tibial fractures.^{1,25} Trauma associated with vascular injury markedly increases the likelihood of compartment syndrome. In another study, the incidence of compartment syndrome was 30% with arterial injuries and 14% with significant venous injuries.^{17,22} The incidence of compartment syndrome in children is not well documented.²²

PATHOPHYSIOLOGY

Two mechanisms produce acute compartment syndrome. The first is an increase in volume within a closed space. The second is a decrease in the size of a body space.⁶ Both of these events result in a rise in intracompartmental pressure, a prerequisite for the development of compartment syndrome.¹⁴ Clinically, elevated intracompartmental pressure may result from an increase in the contents of the compartment due to edema, hemorrhage, or intravenous fluid infiltration, or from a decrease in compartment size produced by constriction from casts, pneumatic garments, and eschar formation.^{4,18}

[Table 122.1](#) provides a complete list of etiologies. Trauma is the most common cause of compartment syndrome.^{3,13,18,19} Of traumatic events, fractures are the most common cause.¹³ In addition, pressure applied to a limb for prolonged periods, such as in the intoxicated patient whose body weight rests on the limb¹³ or in a patient undergoing a long operation in the lithotomy position,^{13,16} may precipitate a compartment syndrome.

INCREASED COMPARTMENT CONTENT
Infiltrated infusion
Swelling
• Vascular injury
• Coagulation defect
• Increased capillary permeability
• Reperfusion after ischemia
• Trauma
• Fracture
• Contusion
• Increased size of muscles
• Exertion
• Spasms
• Ischemia
• Tetany
• Burns
• Cuts
• Straddle
Increased capillary pressure
• Venous obstruction
Diminished venous osmolarity
• Hypertonic syndrome
INTENSELY APPLIED PRESSURE
• Casts, dressings, splints, pneumatic garment
• Lying on limb

TABLE 122.1. Common Etiologies of Compartment Syndromes Seen in Emergency Medicine

Although hemorrhage or trauma can lead to an abrupt rise in compartment pressures, the development of compartment syndrome is more often delayed and follows a period of ischemia.¹⁸ Ischemia may be local and related to increased tissue pressures,^{11,13,14} or it may result from factors that limit blood flow to the involved region, such as systemic hypotension, arterial injury, venous obstruction, or elevation of the extremity.^{13,14}

Compartment syndrome occurs in many locations, but it is most common in the anterior compartment of the leg ([Table 122.2](#)).²¹ It is not surprising that the extremities are most frequently involved. In the upper extremities and lower extremities, the arm, forearm, hand, thigh, leg, and foot all have muscle groups and neurovascular bundles surrounded by strong fascial boundaries. In addition, the extremities are frequently injured and are common sites for intravenous fluid administration, dialysis grafts, and catheterization procedures ([Fig. 122.1](#)).

Upper Limb Compartments	Lower Limb Compartments
Arm	Buttock
• Deltoid	• Clitoral
• Biceps	Thigh
Forearm	• Quadriceps
• Dorsal	Leg
• Volar	• Anterior
Hand	• Lateral
• Interosseous	• Superficial posterior
	• Deep posterior

TABLE 122.2. Common Locations of Compartment Syndromes

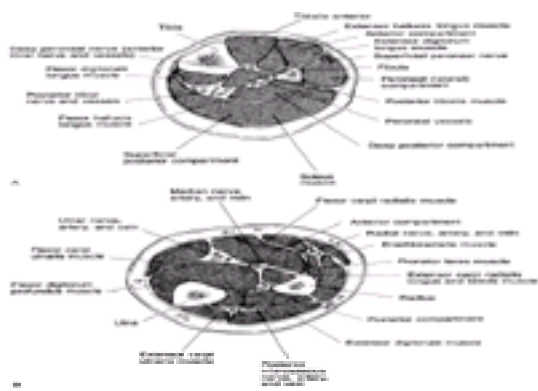

Figure 122.1. Compartments of the leg (A) and forearm (B).

Many theories have been proposed to explain the relationship between increased tissue pressure and decreased tissue perfusion. Experimental studies have shown an inverse linear correlation between muscle blood flow and compartment pressures in animals.¹⁴ Matsen argued that the “the increased tissue pressure in a given compartment decreases the overall arterial–venous pressure gradient by increasing local venous pressure.”²¹ A decrease in the arterial–venous pressure gradient decreases flow.¹⁴ This theory is currently widely accepted.^{4,14,19,24} The pressure within the compartment is not great enough to compress the major arterial structures; thus, pulses are usually present in acute compartment syndrome.²⁴

Newer pathophysiologic explanations for compartmental hypertension also take into account the “ischemia–reperfusion” theory for cellular injury. Essentially, ischemia results in the depletion of intracellular energy stores. Following reperfusion and the generation of toxic oxygen radicals, a cascade of pathophysiologic consequences results, including activation and adhesions of leukocytes and platelets, calcium influx, disruption of cellular membrane ion pumps, and transudation of fluid in the aggregate, producing both cellular swelling and edema formation.⁷

Regardless of the etiology, raised intracompartmental pressure results in venous outflow obstruction. The increasing capillary pressure worsens fluid transudation and cellular swelling, thus perpetuating a vicious cycle. Ultimately, when intracompartmental pressure equals capillary pressure, nutrient blood flow is reduced to zero.⁷

At rest, the normal compartment pressure approaches 4 to 8 mm Hg in the recumbent position.⁶ An absolute value for a compartment pressure at which cellular metabolism and subsequent tissue infarction occur is unclear. Elevated pressures ranging from 30 to 45 mm Hg have been considered indications for emergent fasciotomies.⁶ However, recent work suggests that such threshold pressure measurements are inadequately sensitive or specific for the diagnosis of compartment syndrome.⁷ The physiologic issues of greatest relevance are the arterial perfusion pressure and the interstitial pressure, which of course is a function of systemic arterial pressure.⁷

Heppenstall and colleagues⁵ demonstrated that “the threshold for cellular metabolic derangement in skeletal muscle subjected to increased tissue pressure was more closely associated with the difference between mean arterial blood pressure and compartment pressure than with the absolute compartment pressure alone.” They termed this difference *delta P* and noted that the lowest delta P at which a normal metabolic state could be maintained was about 30 mm Hg in normal muscle and 40 mm Hg in moderately traumatized muscle. Thus, these authors argue that compartment pressures must be viewed in relation to the amount of trauma sustained and the overall clinical picture.

The earliest symptoms of compartment syndrome are neurologic, relating to the fact that the tissue most sensitive to hypoxia is the nonmyelinated, type C sensory fiber that transmits fine touch and mediates symptoms such as paresthesias.⁷ Tissue hypoxic tolerance increases from nonmyelinated to myelinated nerves, skeletal muscle, and (most resistant to hypoxia) skin and bone.^{7,12,15,18} The length of time muscle and nerve can tolerate elevated pressure is unclear. Extrapolating from data related to acute arterial insufficiency, a 6-hour “grace period” appears to be the upper limit of successful revascularization before muscle injury is irreversible.^{6,7}

CLINICAL PRESENTATION

As in many clinical circumstances, the diagnosis of acute compartment syndrome is facilitated by the “prepared mind,” which takes into account the patient's history, symptoms, and clinical findings.⁷ The best possible outcome for acute compartment syndrome depends on early diagnosis and intervention. In the past, the “Five P's (pulselessness, pallor, paralysis, paresthesia, and pain) were advocated as clinical signs of a developing compartment syndrome. Unfortunately, these are late signs and symptoms associated with an established compartment syndrome, and fasciotomies performed utilizing these guidelines have been inconsistent in maintenance of limb function.⁶

The earliest and most important symptom of an impending acute compartment syndrome is the perception of pain “out of proportion” to the clinical findings on examination.^{3,12,13} and ^{14,18,21,24} Other important symptoms are those of distal motor and sensory dysfunction, characteristically weakness and paresthesias in the distribution of nerves passing through the compressed tissue compartments.⁷ There are, however, reports of compartment syndrome with little pain,¹³ and a substantial diagnostic dilemma is presented by the patient who is unconscious, intubated, intoxicated, paraplegic, or quadriplegic, or who, for some other reason, cannot sense or communicate sensations of pain.⁷

The most reliable clinical signs of compartment syndrome are weakness, pain on passive stretching of muscles, tenseness and pain on palpation of the involved compartment, and hypoesthesia in the distribution of nerves in the compartment ([Table 122.3](#)).^{3,4,12,13} and ^{14,18,21,24} These signs may be evident within 2 hours of the inciting event or may appear as late as 6 days after the injury.²¹ Increased pain on active movement or passive stretch of the muscles in the compartment is an early finding. Hypoesthesia is always a late finding.^{3,18} Both the two-point discrimination and light touch tests are more sensitive than the pinprick test.^{9,21} Pulses are most often present,^{3,4,12,13} and ^{14,18,21,24} and absence of pulses should widen the differential diagnosis to include arterial occlusion or injury.^{4,12,13} and ¹⁴ Other diagnoses must also be considered in the differential, including deep vein thrombosis, cellulitis, neuropraxia, osteomyelitis, tenosynovitis, and synovitis.¹⁴

Compartment	Partial Examination	Location of Tendons	Muscles Weakened	Sensory Loss
FOREARM				
Dorsal	Thumb and finger flexion	Dorsal forearm	Thumb and finger extensors	—
Volar	Thumb and finger extension	Volar forearm	Thumb and finger flexors	Ulnar and median nerves
HAND				
Interosseus	Adduction, abduction of metacarpophalangeal joints	Dorsum of hand between metacarpals	Interossei	—
LEG				
Anterior	Toe flexion	Anterior aspect of leg	Toe extensors and tibialis anterior	Deep peroneal nerve
Lateral	Toe inversion	Lateral aspect of leg over tibia	Peroneal muscles	Superficial and deep peroneal nerves
Superficial posterior	Toe dorsiflexion	Calf	Tibialis and gastrocnemius	—
Deep posterior	Toe extension	Dorsal medial leg between tibia, tibiotalar and tibia	Toe flexors and tibialis posterior	Posterior tibial nerve

TABLE 122.3. Compartment Syndromes and Associated Physical Signs

EMERGENCY DEPARTMENT EVALUATION

Laboratory studies are not helpful in diagnosing compartment syndrome. Hyperkalemia, elevated creatinine phosphokinase level, and myoglobinuria suggest muscle destruction, a nonspecific finding in compartment syndrome.^{13,14,18} The best diagnostic test is measurement of intracompartmental pressures.¹³ Elevated tissue pressure may occur before the onset of clinical signs and symptoms and may lead to early diagnosis.²⁵ In addition, measurement of pressures is extremely helpful in patients in whom examination is unreliable.^{10,12,17} Many techniques are available to measure pressures, including the needle manometer technique,^{13,21} the wick catheter method,^{13,14,24} and the portable Stryker hand-held monitor.^{13,14}

Normal intramuscular pressures may range from 0 to 8 mm Hg and may be as high as 20 mm Hg in the lower leg.^{14,18} There is no consensus as to an absolute pressure above which fasciotomy must be performed.^{5,13,14,18} Rorabeck and associates²⁰ suggest decompression at pressures above 30 to 35 mm Hg; Matsen,^{10,18} at pressures above 45 mm Hg; and Whitesides and colleagues,²³ when the intracompartmental pressure falls within 10 to 30 mm Hg of the diastolic blood pressure.¹⁴ Many authors emphasize that compartmental pressures should be evaluated only in conjunction with the diastolic pressure and clinical examination, and stress that both hypotensive and hypertensive patients may show different susceptibility to damage from elevated tissue pressures.^{5,10,23}

Transcutaneous Doppler measurement of tibial venous blood flow may be helpful in supporting the diagnosis of compartment syndrome in the anterior compartment of the leg. As tissue pressure exceeds venous pressure (normally 7 to 16 mm Hg), the tibial venous flow is reduced.¹⁸ Current trauma research utilizing near-infrared wavelength reflection to measure muscle oxyhemoglobin levels may prove useful in providing noninvasive, continuous monitoring, but further clinical studies are warranted.²

Nerve conduction studies may help to differentiate local nerve damage due to compartment syndrome from more proximal nerve injury, but are usually unavailable to the emergency physician in a timely manner.^{12,18} Arteriography may be required to evaluate the origins of ischemia.¹⁸ Intracompartmental pressure measurements remain the best objective test for possible compartment syndrome, but much value is placed on a thorough clinical examination.

EMERGENCY DEPARTMENT MANAGEMENT

The emergency physician must maintain a high index of suspicion and be knowledgeable about the clinical presentation of, and predisposing factors for, compartment syndrome. Management should include thorough, repeated clinical examinations, with special attention to the early signs and symptoms of compartment syndrome. Appropriate laboratory studies, including preoperative evaluation, should be sent. Any constrictive dressing, casts, or pneumatic garments must be removed as soon as possible and the limb placed in a neutral position, as elevation of the limb has been shown to be harmful.^{3,4,13} Circulation is aggressively supported with intravenous crystalloid and blood products, where indicated.¹³

Compartment syndrome is truly a limb-threatening condition. Surgical consultation should take place immediately. The definitive treatment of compartment syndrome is fasciotomy, which relieves pressure elevation within the compartment(s).^{13,14,18,24} Fasciotomy must be performed early, ideally less than 6 hours after the onset of symptoms.²¹ Other treatment, such as vasodilating drugs or sympathetic nerve blocks, have not been shown to be effective.¹⁴

Mannitol is controversial; recent data suggesting the important role of oxygen radicals in the pathogenesis of acute compartment syndrome has raised interest in the use of mannitol to scavenge toxic oxygen species (reducing ischemia–reperfusion injury) in addition to its known hyperosmolar capabilities (reducing tissue edema).⁷ Hyperbaric oxygen therapy has been used as an adjunct early in the course of a developing compartment syndrome, but in light of the “ischemia–reperfusion” theory, it remains debatable whether its use is indicated in an established acute compartment syndrome.¹⁴

COMMON PITFALLS

- Lack of clinical suspicion
- Failing to recognize early symptoms
- Attributing the signs and symptoms of compartment syndrome to other types of injury
- Failing to do a thorough extremity and neurologic examination, especially in intoxicated patients or in patients with an unreliable history

[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Blast injury is a general term used to describe the harmful effects produced by the sudden change in environmental pressure originating from an explosion. Blast injuries were first identified during World War II when aerial bombing of large cities produced many casualties.⁵ Blast injuries were also common among civilians during war conditions in Vietnam, Afghanistan, Lebanon, Croatia, and Bosnia.¹ In the United States, blast injuries commonly result from terrorist bombings and the rare civilian industrial accident.⁸ Injuries produced by explosions can be divided into four categories. Primary blast injuries are caused by the sudden change in environmental pressure as the explosion-produced shock wave passes by. Secondary blast injuries result from the victim being struck by flying debris. Tertiary blast injuries are sustained when the victim is hurled against a stationary object. Both secondary and tertiary blast injuries are due to the accelerative force imparted to loose objects by the shock wave. Although the duration of an explosion-produced shock wave is brief, the accelerative force is significant. For a 70-kg adult, a shock wave with a peak overpressure of 15 pounds per square inch (psi) produces an instantaneous acceleration of 450 ft per second squared or about 14 g. Miscellaneous blast injuries include exposure to dust, direct thermal burns, and burns from blast-ignited fires.

PATHOPHYSIOLOGY

There are four energy sources for explosions.

1. Mechanical (alternatively, hydraulic): Due to sudden structural failure of a pressurized container
2. Electrical: As an electrical arc passes through the air, intense heat is generated that produces a sudden increase in pressure.
3. Nuclear: Intense heat generated by the process of fission or fusion
4. Chemical
 - a. Diffuse reactants: Flammable gases or particulate matter mixed with air
 - b. Condensed reactants: Liquid or solid, which can be either low-order (e.g., black powder) or high-order (e.g., TNT) explosives

Chemical explosions are the most common cause of accidental or intentional blast injuries. Once ignited, a solid or liquid explosive undergoes a chemical decomposition into a gas. The space previously occupied by the explosive is now filled with gas under high pressure and temperature. This pressure is transmitted through the surrounding medium and propagates outward as a shock wave at speeds of 6 to 8 km/s. As measured at a position away from the explosion, the passing shock wave produces a rapid increase in environmental pressure to a peak above the ambient pressure (the peak overpressure), followed by a slow decline back to baseline. The peak overpressure can be very intense but brief, especially close to an explosion; at a distance of 10.2 m (33 ft), from 0.364 kg (0.8 lb) of TNT, the peak overpressure is about 45 kPa (6.5 psi), with a duration of about 2 ms.⁵

As the shock wave expands, the overpressure decreases, the duration lengthens, and the velocity of propagation diminishes. For free field air blast, the peak pressure of the shock wave falls off as the inverse of the distance from the explosion to the third power. This translates into a rough formula to use to the scaling factor in explosive science: For a bomb to produce twice the damage, it must be eight times as large. In denser media, such as water, explosions produce shock waves that have a much higher peak overpressure and a shorter duration, and propagate at a faster velocity than comparable explosions in air. In addition, the overpressure is less just below the surface than at greater depths. Parts of the body submerged to a greater depth are correspondingly more damaged than body parts submerged just below the surface or those that are above the surface.

If the explosion is contained within a closed space, reflections of the shock wave lead to greater overpressure, longer duration, and an increased incidence of primary blast injuries and death.¹²

Primary blast injuries are unique to this form of trauma. As the shock wave passes through biologic tissue, the injury is greatest at the interface between tissues of different densities, such as the lungs (which contain both blood and air), the tympanic membrane (which separates two air-filled cavities), and the bowel (which contains a slurry of solid and gas).¹⁴ The potential for primary blast injuries correlates with both the height and duration of the peak overpressure. The likelihood of primary blast injury can be illustrated for a specific clinical outcome (e.g., threshold for lung damage or 50% lethality [LD50]) by pressure-duration graphs. By the last 1960s, the Lovelace Foundation of Albuquerque, New Mexico, had assembled enough animal data to make an estimate of human tolerance to shock waves using pressure-duration graphs.¹⁰ The most vulnerable organ to primary blast injury is the tympanic membrane, followed by the lungs.¹⁴

The most common primary blast injury is a linear tear in the inferior portion of the tympanic membrane.⁶ Depending on the orientation of the external auditory canal in relation to the source of the shock wave, tympanic membranes may rupture at pressures as low as 2 to 5 psi. Explosions also commonly produce damage to the cochlea, which results in sensorineural hearing loss and tinnitus.⁶

In the lungs, primary blast injury produces a diffuse lung contusion; damage to the alveolar parenchyma leads to edema and hemorrhage into the interstitial and interalveolar spaces.¹⁴ The threshold for lung damage is about 15 psi of peak overpressure, and moderate-to-severe lung damage can be seen with 50 psi.⁵ Lacerations of the delicate parenchyma may occur in many locations, rupturing alveolar walls, tearing visceral pleura, and creating fissures between the alveolar spaces and the pulmonary veins. The latter allows air to enter into the pulmonary venous system, which can then travel to the left side of the heart and enter the systemic circulation. Systemic air emboli are the likely cause of sudden death, abnormal neurologic findings, and myocardial ischemia seen in some victims in the immediate postblast period.

Primary blast injury of the bowels requires even higher peak overpressures. Such injuries are relatively rare in air explosions, but are more common in water explosions, where the victim is completely or partially submerged. The most common injuries are serosal tears, subserosal and intramural hemorrhages, as well as bowel perforations, usually involving the ileocecal region.¹⁴

CLINICAL PRESENTATION

Casualty analysis of terrorist bombing incidents has found that secondary, tertiary, and miscellaneous injuries account for the vast majority of victims.^{9,12,13} The following principles are important to remember.

1. Terrorist explosions often occur within a populated and confined space, producing a large number of casualties.
2. The most common type of injury from terrorist bombs is superficial soft-tissue damage to exposed areas of the body from flying debris. The nonaerodynamic shape of most debris fragments means that they have marked air resistance and limited range for serious injury.
3. Serious injuries from terrorist bombings are usually major soft-tissue damage, flash burns, fractures, and eye injuries. Most of these victims are within 10 to 15 m of the source of the explosion.
4. While flash burns commonly injure exposed skin, the temperature content of gas is low and the duration of exposure is brief so that skin underlying clothing and the upper respiratory tract are rarely burned. However, burns and smoke from blast-ignited fires can, of course, be more damaging.
5. Other than tympanic membrane rupture, primary blast injuries are uncommon and account for less than 10% of the victims in open-air explosions but up to 38% in closed-space (e.g., bus) explosions.^{9,12}

A triad of hypotension, bradycardia, and apnea has been observed in experimental animals exposed to moderate thoracic blast injury.⁷ The first two responses—hypotension and bradycardia—have been observed in human victims immediately after the explosion.

The clinical presentation of patients with primary blast injuries is usually the result of damage to the ears, lungs, brain, and bowel. The most common respiratory symptoms are dyspnea, chest pain, and hemoptysis. Physical examination will disclose rales, rhonchi, and, occasionally, the presence of a pneumothorax or pneumomediastinum. Frothy, blood-tinged sputum is seen in severe cases. Radiographic progression of pulmonary injury can occur during the first 48 hours after the explosion, corresponding to the clinical development of respiratory failure.

Tympanic membrane rupture usually presents with decreased hearing occasionally accompanied by bleeding into the external auditory canal. Perforations are usually small and located in the inferior portion of the membrane.^{6,11} The degree of associated conductive hearing loss is related to the size of the perforation. Sensorineural hearing loss can occur from damage to the sensory structures in the cochlear basal membrane.¹⁵

Concussion with amnesia is common in blast-injured victims. Focal neurologic findings usually result from cerebral air emboli. If the victim was exposed to underwater blast, concussion of the spinal cord may present as lower extremity weakness, paralysis, or paresthesias lasting from seconds to minutes.

Bowel injuries are more common in victims exposed to underwater explosions, compared with those exposed to air blasts. Clinical symptoms include acute abdominal pain, tenderness, nausea, vomiting, and an urge to defecate.

Systemic air emboli may be difficult to detect, and the diagnosis depends on clinical suspicion. Definite diagnosis of systemic air emboli can be made if air emboli are visualized in retinal vessels or on computed tomography of the brain. Air embolism usually develops immediately or very soon after the explosion. However, delayed cases can occur when positive-pressure ventilation is initiated in patients with pulmonary blast injury.

DIFFERENTIAL DIAGNOSIS

The key to diagnosis is to obtain a history of injury associated with an explosion. Finding a tympanic perforation may be a clue to potential blast injuries, but the absence of tympanic membrane perforation does not exclude potential blast injury. Nonexplosive blast injury to the ear can occur from a blow that seals the external auditory meatus and causes a sudden increase in air pressure.³ Tympanic membrane perforations and conductive hearing loss are common. Such perforations almost always heal with improvement in the conductive hearing loss.

EMERGENCY DEPARTMENT EVALUATION

Initial evaluation is similar to that of any multiple trauma victim, with initial evaluation of the ABCs, followed by the secondary survey and ongoing monitoring, including vital signs, electrographic monitoring, and pulse oximetry. The focus of the examination is the detection of primary blast injury, which may be obscured by secondary and tertiary injury. After the primary and secondary patient assessments, further examination is directed toward identifying emergent life-threatening arterial emboli. A chest radiograph is indicated because of pulmonary susceptibility to primary blast injury. Radiographic injuries seen with primary blast injury include pneumothorax, pneumomediastinum, hemothorax, subcutaneous emphysema, pulmonary interstitial emphysema, interstitial infiltrates, and alveolar edema.

Laboratory studies should be ordered if clinically indicated, but routine arterial blood gas analysis is particularly useful. In blast-injured patients, the arterial blood gas may be the first sign of lung damage, preceding radiographic changes.

All patients exposed to blast explosions need to be observed to exclude delayed manifestations of primary blast injuries. For patients with only soft-tissue injuries, the observation period can be as short as the time it takes for evaluation of such injuries in the emergency department or treatment center.

EMERGENCY DEPARTMENT MANAGEMENT

Evaluation, resuscitation, and ongoing management should proceed as it would for any other victim of multiple trauma in both the prehospital setting and the emergency department. For prehospital personnel, it is important that the scene be secured and declared safe before approaching the victims. Accurate triage is an important determinant of survival for critically injured casualties from terrorist bombings and industrial accidents. High-flow oxygen should be administered, because injury to the lungs may not be initially recognized and hypoxemia may develop insidiously. Because excessive fluid accumulation may occur in damaged lungs, fluid resuscitation should be carefully monitored to avoid exacerbation of pulmonary insufficiency.

For victims with systemic air emboli, hyperbaric oxygen therapy is the treatment of choice. It can be dramatically effective for cerebral air emboli, even up to 12 hours after the acute event. Although unproved, the Trendelenburg position is sometimes advocated to reduce embolization to the brain. However, experimental models and anecdotal reports find no clear benefit to this position, as compared with the standard and supine position for assessment and treatment of the trauma patient.

Primary blast lung injury requires careful management.² For trauma patients with respiratory failure, the standard approach is endotracheal intubation and positive-pressure ventilation. However, positive-pressure ventilation in patients with blast-injured lungs may produce or exacerbate pneumothorax, increase the alveolar-to-pulmonary vein pressure gradient, and potentiate systemic air embolization. The immediate use of mechanical ventilation during the first 2 hours in a dog model of blast-injured lungs produced increased air embolism and mortality. In addition, general anesthesia is poorly tolerated in patients with primary blast injury during the first 24 to 48 hours; therefore, regional or spinal anesthesia should be used, if possible. Intravenous fluid management needs to be carefully monitored, and pulmonary artery and arterial catheters may be required to manage fluids appropriately. For patients with severe pulmonary blast injuries, a regimen of volume-controlled, synchronized, intermittent, mandatory ventilation with small tidal volumes and permissive hypercapnia (PaCO₂ 57 mm Hg) appears beneficial.¹⁶

Abdominal blast injury is managed just like that of any other blunt-force trauma to the abdomen. Lacerations, abrasions, fractures, and burns resulting from secondary and tertiary blast injury can be managed the same as trauma caused by other mechanisms. Fragments generated by small explosions (e.g., from a hand grenade) tend to produce wounds with little damage and can usually be managed without extensive wound exploration and fragment removal.⁴ However, high-velocity fragment wounds (e.g., from a terrorist bomb incident) should have as many fragments excised as possible and the wound left open for delayed primary closure.

Tympanic membrane perforation has a high rate of spontaneous healing, especially if it is small and marginal in location.¹¹ For large and central perforations, immediate paper patching has been advocated.¹¹ If a perforation (large or small) does not heal after 10 months, tympanoplasty should be performed. In general, the external auditory canal should be kept clean and dry; there is no need for routine irrigation or use of topical solutions. One potential long-term sequela to bear in mind is the development of cholesteatoma. The ruptured tympanic membrane can distribute small pieces of keratinizing squamous epithelium throughout the middle ear and mastoid sinuses, viable fragments of which may grow into a mass of keratinous debris known as a cholesteatoma. Cholesteatoma may lead to varying degrees of sensorineural or conductive hearing loss and may erode into surrounding structures.

DISPOSITION

Blast injuries that result in multiple trauma require consultation with the hospital trauma service or referral and transfer to the regional trauma center. If systemic air embolism is suspected, urgent consultation with a hyperbaric specialist is required for definitive therapy. Patients with signs of blunt-force trauma and those with tympanic membrane rupture should be observed for occult injuries during the first 24 hours. Outpatient management is acceptable for patients who were a distance from the blast origin and received relatively minor lacerations, abrasions, fractures, or burns.¹³

Patients with serious blast injuries should be transferred to a regional trauma center. Those with suspected systemic air embolism may require transfer to a hyperbaric therapy facility. If air transport is used, pressurized aircraft or flights at low altitude are important to prevent further exacerbation of air emboli or pneumothoraces from barometric changes during flight.

COMMON PITFALLS

- Accurate triage at the scene is an important determinant of survival for critically injured victims of explosions.
- The tympanic membrane should always be checked as an indicator of the potential for primary blast injuries to the lungs.
- The most lethal problem in blast injuries is air emboli affecting the brain or the heart. Symptoms suggestive of cerebral emboli or myocardial ischemia need to be carefully addressed for this potential.
- Positive-pressure ventilation poses a significant risk of worsening pneumothorax or producing systemic air embolization.

Trauma is the most frequent cause of nonobstetric maternal and fetal death during pregnancy.¹⁵ The incidence of trauma in pregnancy is 7% to 8%.¹ Diagnosis and treatment follows the same general guidelines as for the nonpregnant trauma victim. The initial treatment must be directed toward stabilizing maternal hemodynamics. However, due to the altered anatomy and physiology of the gravid female, several critical differences exist. Knowing these differences and applying this knowledge in the critical minutes following trauma will have an important impact on the life and health of both mother and fetus.

PHYSIOLOGY AND ANATOMY OF PREGNANCY

Pregnancy is a high-flow, low-resistance state of cardiovascular homeostasis ([Table 124.1](#)). Heart rate increases until the end of the second trimester, when it plateaus at 10 to 15 beats above baseline. Meanwhile, systolic and, to a greater degree, diastolic blood pressures decrease 5 to 15 mm Hg during the first and second trimesters, returning to prepregnancy baseline levels during the third trimester. Cardiac output increases 40% by the end of the first trimester and persists at this level, causing a systolic flow murmur in 90% of pregnant women. By the third trimester, there is increased vascular congestion in the pelvis and a 50% decrease in the velocity of venous flow in the lower limbs associated with a 10-mm Hg increase in venous pressure.³ These changes predispose the gravida to deep vein thromboses, as well as increased bleeding with lower extremity trauma.

System	Change	Effect	Normal	1st Trimester	2nd Trimester	3rd Trimester
Cardiovascular	Heart rate		70–80	100–110	100–110	100–110
	Systolic blood pressure		110–120	90–100	90–100	110–120
	Diastolic blood pressure		70–80	50–60	50–60	70–80
	Cardiac output		5 L/min	6–7 L/min	6–7 L/min	6–7 L/min
Respiratory	Tidal volume		500 mL	700 mL	700 mL	700 mL
	Functional residual capacity		1,200 mL	1,000 mL	1,000 mL	1,000 mL
Hematologic	Hemoglobin		12–16 g/dL	10–12 g/dL	10–12 g/dL	10–12 g/dL
	Hematocrit		37%–47%	33%–37%	33%–37%	33%–37%
Renal	Glomerular filtration rate		120 mL/min	150 mL/min	150 mL/min	150 mL/min
	Renin		Low	High	High	High
Gastrointestinal	Gastric emptying		Normal	Delayed	Delayed	Delayed
	Small intestine motility		Normal	Delayed	Delayed	Delayed
Urologic	Bladder capacity		400 mL	500 mL	500 mL	500 mL
	Uterine blood flow		50 mL/min	500 mL/min	500 mL/min	500 mL/min

TABLE 124.1. Anatomic and Physiologic Changes in Pregnancy

The diaphragm is gradually pushed up 3 to 4 cm, causing the QRS axis on the electrocardiogram to shift an average of 15 degrees to the left. Other pregnancy-related electrocardiographic changes include Q waves in leads III and aVF and flattened or inverted T waves in lead III.

Elevation of the diaphragm causes a 25% decrease in functional residual capacity, resulting in decreased maternal oxygen reserve. Pulmonary function is further compromised by increased oxygen consumption. Starting in the first trimester, stimulation of the medullary respiratory center by progesterone gradually increases minute ventilation by up to 50% (a result of increased tidal volume). This is accompanied by a 10-mm Hg increase in P O₂, a 10-mm Hg decrease in PCO₂, and a compensatory decrease in bicarbonate to about 19.5 mEq/L, producing a net slight respiratory alkalosis.

Progesterone also causes smooth muscle relaxation in the gastrointestinal tract, which leads to decreased motility and decreased gastroesophageal sphincter competence, producing a greater risk of aspiration.

Urologic changes begin at the end of the first trimester. The bladder becomes hyperemic and rises out of the pelvis, and the ureters dilate and become laterally displaced.

After the third month, the uterus is no longer protected by the pelvis. Uterine blood flow increases tenfold by term. The uterine vascular bed has no autoregulatory capability and is completely dependent on maternal blood pressure for perfusion.

Several hematologic changes accompany pregnancy. A 50% increase in blood volume, accompanied by only a 20% to 30% increase in red blood cell mass, results in a 3% to 6% drop in hematocrit. The white blood cell count increases to 12,000 to 18,000/μL by the second trimester and may increase to 25,000/μL with stress. Neutrophils predominate. The prothrombin and partial thromboplastin times are somewhat shortened. Coagulation factors rise gradually and, by the third trimester, exceed fibrinolytic activity.

The fetus has a higher hemoglobin concentration than the mother, and fetal hemoglobin has a greater affinity for oxygen. As a result, fetal oxygen consumption does not decrease until oxygen delivery decreases by 50%.²¹ This allows the fetus to tolerate brief periods of maternal hypoxia and hypoperfusion. Furthermore, late in pregnancy, the fetus is capable of the mammalian diving reflex by which blood can be redistributed to the heart and brain.²¹

PREHOSPITAL CARE

The best outcome is ensured by prevention of maternal hypoxia and hypotension. The airway should be aggressively managed and supplemental oxygen liberally utilized. A low threshold for volume replacement should exist. Maternal blood loss of 30% to 35% can cause a 10% to 20% decrease in uterine blood flow without a detectable change in maternal vital signs.²⁷ After the twentieth week, transport should be done, with the patient in the left lateral decubitus position or with the right hip elevated. If the patient is fully immobilized, the backboard should be tilted 15 degrees to the left. This will help keep the uterus off the descending aorta and inferior vena cava and prevent a number of adverse hemodynamic effects collectively known as the supine hypotension syndrome ([Fig. 124.1](#)). Uterine compression of the inferior vena cava can cause up to a 30% decrease in cardiac output, due to decreased preload.³ Maternal hypotension resulting either from this or from hypovolemia leads to uteroplacental insufficiency, increased risk of placental abruption, and possible cardiopulmonary arrest.¹² If possible, vasopressors should be avoided,

because they decrease uterine blood flow. Pneumatic antishock garments (PASGs) are not well studied in pregnancy. Their use is controversial and generally contradicted, although there has been some support for their role as an adjunct to stabilize pelvic fractures in patients in extremis in the first trimester.

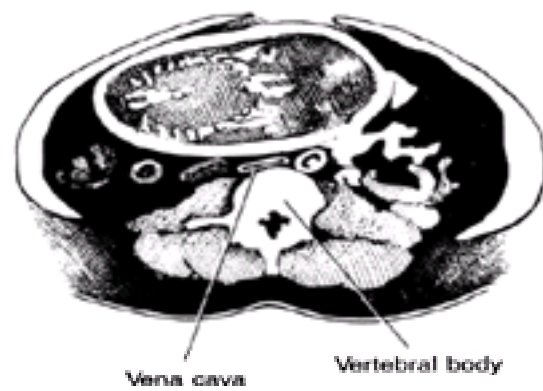

Figure 124.1. Cross section of the lower abdomen in a supine pregnant patient. Note the vena caval compression against the vertebral body.

Transport should proceed without delay and with early notification of the receiving hospital, so that all involved services and resources can be mobilized.

EMERGENCY DEPARTMENT EVALUATION

An appropriate patient history should determine the date of the last menstrual period, estimated date of delivery, problems with present and previous pregnancies, ultrasound results, and time of last fetal movement. Initial evaluation and therapy must be directed primarily at the case of the mother and should not be delayed or compromised because of pregnancy. Fetal survival is largely dependent on maternal condition and resuscitation. After the primary survey has been completed, uterine size is estimated, bearing in mind that if the fundus is above the umbilicus, fetal age is probably more than 20 weeks and there is potential viability. Uterine tenderness, irritability, contractions, and fetal movement should be sought. Fetal heart rate is auscultated. A careful speculum examination is performed if no frank bleeding exists. Abdominal examination is less reliable, due to the blunted response to peritoneal irritation caused by stretching of the abdominal wall. ^{27,30}

Monitoring is the best way to determine the functional and anatomic viability of the fetal-placental unit. External cardiotocographic monitoring should be instituted as soon as is practical. Contractions may portend abruption or the start of labor. Fetal tachycardia (rate greater than 160) or bradycardia (rate less than 120) or loss of accelerations, and particularly late or prolonged decelerations, may represent fetal distress or occult maternal shock. Real-time ultrasonography provides important information about fetal age and movement, amniotic fluid volume, and the position and integrity of the placenta.

Radiation is potentially hazardous to the fetus throughout pregnancy. This is particularly true in the first 7 weeks following conception, during organogenesis, when the fetus is sensitive to radiation's teratogenic, growth-retarding and postnatal neoplastic effects. It is reassuring, however, that significant risk is unlikely with exposures of less than 10 rads³⁰ (Table 124.2). If the fetus is outside the radiographic field, radiation dose is limited to that delivered by leak and scatter. The dose drops off rapidly with fetal distance from the radiographic field. Appropriate radiographs are obtained as necessary for the proper care of the patient, without delay, but the pelvis is shielded and care taken to minimize the dose of radiation to the lower abdomen. ^{27,30}

Cervical spine	<1 mrad
Chest	1-3 mrad
Abdomen	200-500 mrad
Pelvis	200-500 mrad
Lumbar spine	600-1,000 mrad
Hip/femur	100-450 mrad
CT head/chest with shielding	<1,000 mrad
CT abdomen	3,000 mrad
CT pelvis	3,000-9,000 mrad

TABLE 124.2. Estimated Radiation Dose to Fetus Per Radiograph

EMERGENCY DEPARTMENT MANAGEMENT

The evaluation and resuscitation of the seriously, or potentially seriously, injured pregnant trauma patient often benefit from a multidisciplinary team approach. In addition to the emergency physician and nursing staff, trauma surgeons and, when available, physicians and nurses from obstetrics and gynecology, pediatrics or neonatology, and possibly anesthesia may offer specific expertise. The first priorities are airway, breathing, and circulation. Hypoxia, acidosis, and alkalosis all decrease uterine blood flow and oxygen delivery to the fetus. Oxygen saturation is kept greater than 90%. ³⁰ Extra care is warranted during intubation because of smaller maternal oxygen reserve and increased risk of aspiration. Hemodynamics should be maximized using standard protocols for crystalloid and blood infusion, with central venous monitoring as needed. Vasopressors are withheld until appropriate fluid resuscitation is accomplished. The supine hypotension syndrome is avoided by proper patient positioning.

Maternal head trauma is managed as in the nonpregnant patient. If there is a history of a seizure before the accident, eclampsia must be considered in the differential diagnosis. Hyper-tension may be masked by hypovolemia.

In late pregnancy, if a chest tube is necessary to manage thoracic injury, it should be placed one to two interspaces higher than usual to avoid the elevated diaphragm present at this stage of pregnancy.

Pelvic fractures may prove especially serious in the pregnant patient, due to increased pelvic vascularity and the proximity of the fetus. There is a 25% incidence of associated fetal death,²⁶ due to shock, abruption, and direct fetal injury.

Tetanus prophylaxis may be given without fetal ill effects. Antibiotics considered safe to use in pregnancy include penicillins, cephalosporins, and erythromycin (except the estolate salt).

The risk of thromboembolic disease in the third trimester and immediately postpartum is five to six times that of the general population. ³ Subcutaneous heparin or pneumatic compression devices may be used for prophylaxis.

Disseminated intravascular coagulation is associated with several sequelae of trauma in pregnancy, including abruptio placentae, amniotic fluid embolism, and fetal death in utero. Baseline coagulation studies, including prothrombin time and partial thromboplastin time, fibrinogen level, and fibrin split products, should be obtained in any gravid patient sustaining significant trauma.

Anesthesia is safe as long as adequate oxygenation and perfusion are maintained. ³⁰ Laparotomy risks for the mother are not increased with pregnancy, and labor and abortion will not be precipitated,^{3,8,27} although uterine manipulation should be minimized. When contemplating the need for emergent cesarean section, one should

first consider the mother's ability to tolerate the procedure and then weigh the risk of fetal distress against the risk of immaturity. Survival with normal development has been achieved at 22 weeks.³¹ By 24 weeks, 50% survival can be achieved, but morbidity remains high.¹⁵

In the event of cardiopulmonary arrest, rapid airway access should be gained and aggressive fluid resuscitation ensured. One member of the team should be assigned to deflect the uterus to the left. The fetus should be monitored. Defibrillation, lidocaine, and bretylium tosylate are safe to administer. After a few minutes of unsuccessful resuscitation with standard cardiopulmonary resuscitation, and if not already performed for other indications, one should consider a perimortem emergent cesarean section.^{14,17}

Based on knowledge of fetal and maternal physiology and a review of case reports, one study recommends that perimortem cesarean delivery be initiated after 4 minutes and completed within 5 minutes of unsuccessful cardiopulmonary resuscitation.¹¹ These reports document decreased fetal survival as time from maternal death to delivery increases. If not already accomplished, simultaneous open cardiac massage and aortic cross-clamping (after delivery of the fetus) should be considered. A midline incision is made from the epigastrium to the pubis. The uterus is vertically incised from the fundus to the bladder reflection. An anterior placenta is incised as necessary and the cord promptly clamped and cut. Successful outcome depends on the interval between maternal death or arrest and fetal delivery, cause of maternal death, fetal age, and extent of direct fetal injuries. In addition, the ability to provide immediate and adequate neonatal resuscitation is imperative. No physician has been found liable in performing this operation, and there is unanimous consensus among legal authorities that, regardless of outcome, judgment would not be found against this physician.¹¹

BLUNT TRAUMA

The most common causes of blunt trauma during pregnancy are motor vehicle crashes, falls, and direct assaults. Motor vehicle injuries account for the majority of severe obstetric trauma.³² However, direct assaults, including cases of domestic violence, are likely underreported.^{18,23,28} Falls occur more frequently in women at greater than 20 weeks' gestation, due to pelvic laxity and imbalance. Most cases involving minimum-to-mild trauma have good maternal and fetal outcomes; however, instances of abruption and fetal death have been reported in cases of minimal maternal injury. Maternal death is most often due to head injury or hemorrhagic shock. The most common causes of fetal death are maternal death (fetal mortality greater than 90%) and maternal shock (fetal mortality approaches 80%), followed by significant maternal injury, placental abruption, and direct fetal injury.¹⁵ Fetal deaths are not uncommon, however, even when maternal injuries are not life-threatening.

As in the nonpregnant trauma victim, the most frequently injured abdominal organs are the spleen, liver, and kidney. Bowel injuries are less frequent. Diaphragm and serious retroperitoneal injuries occur more often.

EMERGENCY DEPARTMENT EVALUATION

Diagnostic peritoneal lavage is safe and accurate with the supraumbilical open technique.²¹ Indications for lavage and criteria for a positive lavage are similar to those for the nongravid trauma patient. Ultrasound has the potential to evaluate both mother and fetus and, in experienced hands, can identify hemoperitoneum and injuries to the spleen, liver, and kidney (Fig. 124.2). Computed tomography (CT) is not well studied in pregnancy, and the additional dose of radiation must be considered. However, CT may be indicated to evaluate the retroperitoneal space due to the increased risk of significant retroperitoneal hemorrhage following lower abdominal and pelvic trauma in pregnant women.

Figure 124.2. Cross section of the upper abdomen in a pregnant trauma patient. Crowding and upper displacement of the small intestine may increase the likelihood of missing mesenteric and hollow viscus injuries.

EMERGENCY DEPARTMENT MANAGEMENT

Patients with significant blunt abdominal trauma are admitted to the hospital and managed as inpatients. Fetal monitoring is indicated. Operative indications are the same as in the nongravid patient.

Pregnant patients with minor injuries, who are beyond 20 weeks of gestation, should undergo observation and fetal monitoring.³⁰ The optimal length of in-hospital observation and fetal monitoring remains controversial, with suggestions ranging from 2 to 48 hours.^{5,20} Fetal heart rate and uterine contractions and patterns are evaluated, along with any evidence of vaginal bleeding, rupture of membranes, or uterine tenderness. If this period of evaluation does not reveal significant findings, and if the mother is otherwise stable and the mechanism of injury was not significant, the patient can likely be discharged home. Any abnormal findings warrant admission and further evaluation. If discharged, the mother should be instructed to record fetal movements over 1 week and return to the hospital immediately for a nonstress test if she notes fewer than four fetal movements per hour or any bleeding, preterm labor, rupture of membranes, or uterine or abdominal pain. Serial ultrasound evaluations and monitoring should be scheduled for a few days after the trauma and periodically for the remainder of the pregnancy.

SPECIAL CONSIDERATIONS

Placental abruption occurs in 1% to 5% of minor trauma and in 40% to 50% of major trauma.^{21,30} It is initiated by a direct blow or deceleration force and may be propagated by increased amniotic fluid pressure or elevated pressure in the vena cava. The clinical consequences are proportional to the amount of placenta involved.

Clinical signs and symptoms of abruption include vaginal bleeding, abdominal cramps, contractions, uterine tenderness, and fetal distress. It is important to note, however, that abruption may be present in the absence of vaginal bleeding in up to 20% of cases. In some cases, up to 2 L of blood can be sequestered in uterine tissue without external bleeding. Ultrasound may fail to identify abruption in up to 50% of cases; often, cardiotocographic monitoring is more sensitive. Pearlman and associates²⁰ detected all abruptions in the first 4 hours of monitoring. Fewer than four contractions an hour ensured a good outcome in all cases. Abruption of less than 25% is consistent with fetal survival but may induce premature labor. A 50% or greater abruption uniformly results in fetal demise. The maternal death rate is less than 1%.¹⁵

Heavy vaginal bleeding, evidence of coagulopathy, and fetal distress are indications for cesarean section. Management of mild abruption is controversial and is determined by the obstetric consultant.

Uterine injury is common. Contractions are the most frequently seen obstetric problem caused by trauma. Any damage to the myometrium or placenta can cause contractions. Ninety percent will stop spontaneously.²⁰ The use of tocolytics in the setting of trauma is controversial: Tocolysis has been successfully employed,³¹ but many researchers believe that regular uterine contractions after trauma suggest abruption until proven otherwise.^{1,20}

Rupture of membranes can lead to early labor or infection. Obstetric consultation should be obtained and the patient should undergo observation and fetal monitoring in labor and delivery.

Uterine rupture is devastating but, fortunately, rare. It is associated with major trauma, especially fractures of the anterior pelvic ring.

The clinical presentation of uterine rupture is usually dramatic and may include shock, severe abdominal pain, difficulty palpating the fundus, and easily palpable fetal parts. Diagnosis is readily confirmed with ultrasound. Treatment is immediate cesarean section. Fetal mortality is nearly 100%.

Fetal injuries are minimized in blunt trauma by the cushioning provided by the uteroplacental unit. Fetal injuries, when they do occur, usually involve intracranial hemorrhage and skull fracture secondary to maternal pelvic fractures when the fetal head is engaged. The nonvertex fetus may sustain intracranial trauma even in the absence of significant maternal trauma, presumably due to deceleration forces.³⁰

PENETRATING ABDOMINAL TRAUMA

Penetrating abdominal trauma is rare during pregnancy: Gunshot wounds are more common than stab wounds. In late pregnancy, the gravid uterus is the most commonly injured intraperitoneal structure with penetrating trauma.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Controversy regarding evaluation and management may be divided into two broad categories: injuries above the fundus and those below the fundus.

Gunshot wounds above the fundus, or suspicious for intraperitoneal violation, require exploration. Management of upper abdominal stab wounds remains somewhat controversial. Local wound exploration can frequently exclude peritoneal penetration. Because the bowel is displaced superiorly, and there is a high incidence of reported bowel injury with stab wounds during pregnancy, most of the literature supports mandatory exploration when peritoneal penetration cannot be excluded.^{24,26,27} Recommendations for exploration are based on the lack of sensitivity of diagnostic peritoneal lavage in picking up bowel injuries, the delayed peritoneal response to these injuries, the difficulty in clinically evaluating the pregnant abdomen, and the fact that diagnostic peritoneal lavage has not been specifically studied for stab wounds in pregnancy (see [Fig. 124.2](#)).

Although there has been support for selective observation of gunshot wounds to the uterus,⁹ most now agree that these wounds should be explored.^{24,26,30} The viable fetus should be delivered by cesarean section to decrease the risk of delayed death from fetal and placental injury. The dead fetus should be left in utero,^{9,10,27} sparing the mother unnecessary blood loss and operating time. Labor proceeds uneventfully despite the injured uterus and laparotomy scar.^{10,26,27} If labor does not ensue in a few days, it can be induced.¹⁰ Lower abdominal contents are relatively shielded from stab wounds by the gravid uterus. Stab wounds to the uterus are more controversial, with advocates of both mandatory surgery^{24,27} and diagnostic peritoneal lavage–guided observation under certain circumstances.^{26,30} There have been no reported maternal deaths with uterine stab wounds, but the incidence of fetal injury is very high.²⁴ Any sign of fetal distress on external fetal monitoring warrants immediate cesarean section for a potentially viable fetus.

BURNS

Pregnancy does not affect maternal outcome in burns.² Fetal survival is related to gestational age and the extent of burn. In the first trimester, there is high fetal wastage, while premature labor is common in the third trimester.²⁶ Pregnancy is usually unaffected by a less than 20% total body surface area (TBSA) burn. Burns between 20% and 50% TBSA show increasing risk of fetal loss and premature labor, as well as maternal complications and death. With a more than 50% TBSA burn, there are few maternal or fetal survivors. Burn criteria for inpatient versus outpatient management do not differ in the pregnant patient. The fetus should be monitored continuously in all cases of moderate-to-severe burns. Hemodynamic monitoring is the best guide to fluid replacement.²⁶ Silver sulfadiazine should be used sparingly in the last trimester, due to the risk of kernicterus.⁶ Delivery of the fetus should be considered at the first sign of septic shock or other significant burn complications, due to the high risk of abortion.²

ELECTRICAL INJURIES

Reports of electrical injury by household current are rare in pregnancy. Lieberman and coworkers¹⁶ reviewed six cases. No maternal morbidity was noted, but two mothers noticed decreased fetal movements and experienced stillbirths within 1 week of injury. One exposure resulted in intrauterine growth retardation and, later, stillbirth. The remaining three cases had normal outcomes, but two of these were complicated by oligohydramnios. Regardless of how minor the exposure, women should seek medical care and carefully monitor fetal movements for the remainder of their pregnancy.

Pierce and associates²² reviewed 12 cases of pregnant lightning-strike victims. No maternal deaths resulted, but one cardiac arrest was successfully resuscitated. There were five immediate fetal deaths, one from uterine rupture. Three strikes resulted in spontaneous labor; all victims were at greater than 34 weeks' gestation. Five infants were normal at birth. This review by Pierce et al. would suggest that lightning causes either an immediate problem or no problem at all.

PREVENTING MORBIDITY FROM MOTOR VEHICLE ACCIDENTS

The use of three-point restraints can significantly reduce both maternal and fetal morbidity and mortality from motor vehicle accidents.²⁵ The lap belt should be worn snug and low over the anterior iliac spines. The shoulder belt should be worn above the gravid uterus without touching the neck. The pregnant woman should sit upright and use the headrest.

FETAL–MATERNAL HEMORRHAGE

Fetal–maternal hemorrhage (FMH), or the occurrence of fetal bleeding into the maternal circulation, occurs in 2% to 8% of normal pregnancies.¹⁵ The incidence is believed to increase to 8% to 30% of pregnant women involved in trauma.^{21,30} The incidence and extent of bleeding is likely higher with more significant trauma; however, the relationship is not linear.

All Rh-negative trauma victims should receive 300 µg of Rho(D) immune globulin (RhIG or RhoGAM) no more than 72 hours after trauma to prevent Rh sensitization. This covers hemorrhages up to 30 mL. Larger hemorrhages are quantitated using the Kleihauer-Betke test or similar techniques. An additional 300 µg of RhoGAM is given for each additional 30 mL of hemorrhage. Kleihauer-Betke testing may also be useful in guiding intervention for other complications of FMH, such as fetal and neonatal anemia.

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism is occasionally associated with trauma and abruption. Amniotic fluid and debris enter the maternal venous circulation and lodge in the lung.

This is a clinical diagnosis based on sudden dyspnea, hypoxia, and hypotension. The chest radiograph is consistent with pulmonary edema or adult respiratory distress syndrome. Disseminated intravascular coagulation develops in 30%.

Treatment is supportive and includes oxygen, maximizing hemodynamics, and correcting coagulopathy. Mortality is 80%.

COMMON PITFALLS

- Failure to diagnose pregnancy in the trauma patient
- Failure to appreciate the anatomic and physiologic changes of pregnancy in interpreting physical, laboratory, and radiologic data
- Failure to aggressively treat maternal hypovolemia and hypoxia
- Neglecting proper patient positioning
- Inadequate fetal monitoring
- Failure to obtain indicated radiographic studies
- Failure to consider and treat FMH
- Failure to appreciate the increased risk to the fetus with maternal burns, carbon monoxide exposure, and electrical shock
- Delay in performing perimortem cesarean section during maternal cardiopulmonary arrest
- Delay in assembling the appropriate multidisciplinary team

[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

In 1992, more than 1 million Americans sustained thermal burns; of these, at least 75,000 were hospitalized and 5,500 died.³ Over the past decades, major strides have been made in burn care. These include improvements in fluid management, infection prevention, surgical management (in the form of early excision),¹⁵ and nutritional support. Survival has significantly improved: In 1952, half of patients with a 50% burn survived; by 1996, the same survival rate was seen in those with a 70% burn.¹⁵ Patients now die of respiratory complications or sepsis rather than of “burn shock.”

Fifty percent of burn patients are younger than 20 years old, and 30% (of all burn patients) are younger than 10 years old.²⁰ The median age of burn patients is 22 years, and males predominate.¹⁷ Interestingly, in one study,² 75% of drug-positive and 58% of ethanol-positive fatalities were aged 21 to 50 years. Ninety-three percent of burns occur in the home, with more than half due to flames.

For patients older than 65 years, burns are the fourth leading cause of death (they represent 28% of fire-related deaths in all age groups). Mortality is directly proportional to the extent of injury and patient age.¹⁵ With a 15% burn, the mortality is 50%, while for a 30% burn, it is 75%; 50% burns are generally fatal.

Elderly patients have a poorer prognosis than do younger ones. Their burns are generally more extensive because of slow reaction time and thin skin. Their thin skin regenerates poorly, particularly in donor sites.¹⁵ When two or more preinjury health problems are present, there is a higher incidence of complications and death. The most common site of infection is the lower respiratory tract.⁶

PATHOPHYSIOLOGY

Burns threaten the ability of the skin, the largest organ of the body, to prevent water and heat losses and to be a barrier to infection. Damage occurs sequentially: The initial direct cellular injury is followed by later injury from continued dermal ischemia.²⁰ Three concentric zones have been proposed: (1) the central zone of coagulation closest to the heat source (where there is irreversible death and avascularity); (2) the zone of stasis, where injury can continue for 24 to 48 hours if not arrested (blood flow is impaired secondary to the release of local mediators)²²; and (3) the zone of hyperemia, or minimal injury, which will recover unless there is another insult.¹⁰

The amount of penetration through the epidermis and the dermis also determines the extent of injury. Damage to the integrity of the epidermis and to the capillary membrane causes patients with significant burns to lose fluids, with most lost in the first 8 to 12 hours. Capillary integrity is generally restored by 24 hours. Dermal burns may damage or destroy the sensory, vascular, and endocrine functions of the skin.

The severity of thermal injuries is determined by several factors: the character and temperature of the agent, the duration of exposure, and the character of skin at the site of injury.¹⁴ The type of agent involved helps to determine the potential severity. Scalds tend to be more superficial, while chemical and electrical burns are very deep. An exposure of 40°C will not injure the skin. At temperatures in excess of 40°C, the higher the temperature and the longer the period of exposure, the greater the damage that is produced. Associated inhalation injury, trauma, and the presence of preexisting medical problems put the patients at increased risk. Burns tend to be deeper where the skin is thinner. Patients younger than 3 years and older than 65 years appear to be particularly at risk.⁴ It has also been shown that intoxication at the time of the injury is an important predictor of complications in adult patients.¹¹ Chronic alcoholics have a higher mortality rate, die of smaller burns than do nonalcoholics, and have longer hospital stays.¹³

PREHOSPITAL CARE

The patient should be removed from the scene and any flames extinguished. Jewelry and clothing should be removed or cut away. Embedded material may remain until hospital evaluation. No topical agents should be applied during transport, just clean sterile sheets or dressings to cover the burns. If there is any suspicion of inhalation injury, 100% oxygen should be given by facemask. Place large-bore intravenous lines for burns greater than 15% total body surface area (TBSA); run them wide open unless transport time is prolonged. With prolonged transport, it is possible to administer excessive fluids with lines running wide open. As such, total fluids infused should be carefully tracked and titrated to the patient's response. Transport to the receiving facility should occur as expeditiously as possible. In areas where a burn center is nearby and easily accessible by ground transport, the American Burn Association advises that patients with significant burns be taken there rather than to the closest facility, unless the patient is in near arrest.¹

EMERGENCY DEPARTMENT EVALUATION

Information that needs to be expeditiously obtained includes (1) the circumstances of the injury, (2) the specific agent or agents involved, (3) the anatomic location and extent and depth of the burns, (4) the possibility of inhalation injury, (5) factors that may affect long-term prognosis (such as age), and (6) previous medical problems. A rapid determination needs to be made in the emergency department, if it was not made in the prehospital environment, as to the level of expertise that will be required to manage the patient appropriately.

Evaluation of the percentage of burn can be done a number of ways. The “rule of nines” is the most popular and consists, in the adult patient, of assigning 9% TBSA to each of the following: the head, each upper extremity, and each half of each lower extremity. The front and back of the torso are 18% TBSA apiece, and the genitalia are 1% TBSA (Fig. 125.1). Superficial partial-thickness burns are not included in this system.¹⁴ This evaluation is good for a rough estimate but can lead to overestimation and inappropriate transfer. In children, as the proportion of body surface areas changes with growth, an age-appropriate Lund and Browder chart should be used. The Lund and Browder chart is more accurate in all age groups and should be used after the initial resuscitation is completed. A third method designates the palm of the patient's hand as approximately 1% TBSA.

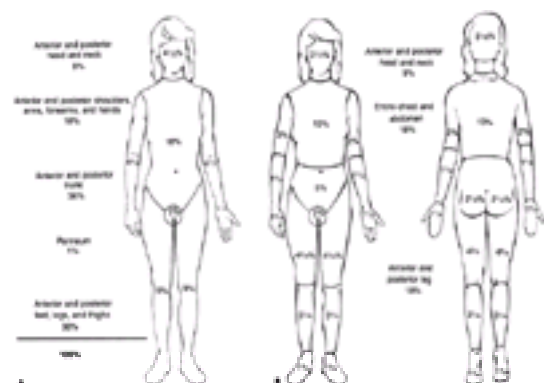

Figure 125.1. Methods to evaluate the percentage of burn. **(A)** Rule of nines. **(B)** Lund and Browder chart.

The full extent of the burn is categorized as minor, moderate, or major ([Table 125.1](#)).¹ A minor burn encompasses less than 15% TBSA in adults (less than 10% in children and the elderly) and less than 2% TBSA full-thickness. These patients can be managed as outpatients. A moderate burn covers 15% to 25% mixed partial- and full-thickness in adults, 10% to 20% in children and those older than age 40 years, and less than 10% TBSA full-thickness. A major burn covers more than 25% TBSA in adults, more than 20% in children and patients older than age 40 years, and 10% TBSA full-thickness. Patients with inhalation injury, high-voltage injury, associated fractures, or major trauma, as well as patients at high risk because of underlying medical problems, are also considered to have major burns.

Minor Burns	Moderate Burns	Major Burns
Outpatient	Inpatient	Burn Center
First degree <10% TBSA Second degree <15% TBSA Third degree <2% TBSA	Second degree 15%-25% Third degree <10%	Second degree >25% Third degree >10% All listed below*

TBSA, total body surface area.
*Burns of hands, face, eyes, ears, feet, or perineum; inhalation burns; electrical burns; those associated with major trauma and in poor-risk patients (previous medical illness, head injury, cerebrovascular accident, psychiatric illness, closed space injury).

TABLE 125.1. American Burn Association Grading System

Estimation of the depth of the burn is often difficult in the first few hours. Repeated evaluations must be done at least daily. The designation of first-, second-, and third-degree burns has been replaced by that of superficial partial-thickness, deep partial-thickness, and full-thickness burns. Very superficial burns (first-degree), such as those from sunlight or very short flash, involve the superficial epidermal layers. They are erythematous, are painful, lack blisters, are sensate, and heal without scars.

Second-degree burns have been divided into superficial and deep partial-thickness burns. Superficial partial-thickness burns, from scalds or short flashes, involve the full epidermis and cause varying levels of destruction in the dermis but spare important structures. They are red, blistered, weeping, and painful, and they generally heal without scarring in 3 weeks. Deep partial-thickness burns are usually caused by flames, oil, or grease; involve deeper areas of the dermis; and also spare dermal structures. Such burns may have, in addition to blisters, areas that are waxy and dry, and they can be difficult to distinguish from full-thickness burns. In fact, they can be converted to full-thickness burns by coincidental trauma or infection. They usually scar on healing.

Full-thickness burns caused by flames, scalds, and chemical and electrical contact destroy dermal structures (third-degree) or underlying tendons, muscle, and bone (fourth-degree). The skin appears white or charred, is inelastic, and exhibits thrombosed vessels. The patient notes no pain on palpation. These wounds will scar with contracture.¹⁸

Laboratory evaluation should include a complete blood cell count; determination of electrolytes, glucose, blood urea nitrogen, and creatinine; urinalysis (including myoglobin when suspected); arterial blood gas analysis; measurement of carboxyhemoglobin level; and type and screen and coagulation studies. An electrocardiogram and a chest radiograph should be obtained.

EMERGENCY DEPARTMENT MANAGEMENT

The ultimate philosophy of burn management is to “do no harm.”⁴ A sterile environment should be provided to decrease the risk of secondary infection. The patient's airway, breathing, and circulation (ABCs) are attended to primarily. If available, an additional provider should be designated to place cool, sterile compresses on all burned areas. This treatment retards the process of cell death by inhibiting the release of toxic metabolites in cells in the zone of stasis, preventing leukocyte adhesion and increasing perfusion to the burned area.²⁰ Ice causes vasoconstriction and can worsen the extent of the burn; it should not be applied.⁹

As with all emergency patients, the physician should consider the ABCs as part of the initial assessment. If there has been associated trauma, immobilize the neck until a cervical spine injury has been ruled out. Until a good history about the circumstances of the injuries is obtained, significantly burned patients should be given humidified 100% oxygen by a nonrebreathing mask.

With severely burned patients, an expeditious decision must be made regarding potential airway damage. Intubation should be performed *before* the airway is lost. Intubation must be performed immediately in unconscious patients with a history of prolonged smoke or fire exposure in a confined space and in those with a high clinical probability of airway edema (stridor, increasing respiratory distress, hypoxia despite 100% oxygen, high carbon monoxide level, and poor peak flow). Nasotracheal intubation may be attempted in the awake, cooperative patient who is still breathing; otherwise, rapid-sequence orotracheal intubation should be performed. Performing emergency surgery to open an airway, particularly if the neck is burned, places the patient at great risk for later infection. After intubation, the head should be elevated 30 degrees to decrease edema and increase venous return. Many patients may require positive end-expiratory pressure to keep the distal airways open; begin with 5 cm H₂O. Bronchodilators may be effective if secretions or particulate inhalation leads to bronchospasm. Concurrent carbon monoxide exposure may require hyperbaric oxygen therapy.

In the more stable patient, whose clinical examination is suggestive of the potential for airway damage (burned nasal hair, carbonaceous deposits in the pharynx and sputum), immediate nasolaryngoscopy or bronchoscopy is warranted. If no injury is present, the patient may not need admission to the intensive care unit.¹⁵ Early airway visualization may be negative, however, despite severe injury.

If the patient is in severe respiratory distress and has sustained circumferential burns to the chest, an immediate escharotomy may be necessary. Incision should be made in the anterior axillary line connected by a third incision in the form of an inverted V ([Fig. 125.2](#)).⁴ The lower respiratory tract can be further evaluated in the inpatient environment with xenon scans, but there is a high incidence of false-positive results. If patients exhibit persistent acidosis despite adequate fluid resuscitation, normal carbon monoxide level and, absent other major injuries, the possibility of cyanide toxicity should be addressed.

Figure 125.2. Escharotomy sites.

Place two large-bore intravenous lines through unburned skin, if possible. Crystalloid remains the intravenous fluid of choice for the first 24 hours. Calculation of fluid requirement should begin at the time of the burn, *not* when the patient arrives in the emergency department. Most institutions managing burns of greater than 15% TBSA use the Parkland formula (4 mL/kg of lactated Ringer's solution × percentage TBSA burn) as an estimate of the total fluid required during the first 24 hours: One half is given during the first 8 hours, and the remainder during the next 16 hours. Because lactated Ringer's solution has 80 to 100 mL/L of free water, additional maintenance fluids are not necessary in the adult.¹² In certain cases, patients have increased fluid requirements: inhalation or electrical injury, escharotomies, delayed resuscitation, or associated trauma.²² Some authors have recommended the use of hypertonic saline, particularly in patients with underlying cardiac disease, pulmonary hypertension, and renal disease. After 24 hours, the fluid is changed to dextrose 5% in water, and colloids may be given to replace plasma volume deficiency.⁹ Some burn units start fresh-frozen plasma for burns greater than 50%, elderly patients, and those with inhalation injury at 8 to 10 hours after the burn.²² Neither of these has been demonstrated to improve patient outcome, while colloid has been associated with increased lung water and decreased glomerular filtration rate, and hypertonic saline has been associated with renal failure and death.

In elderly patients who have more than 5% burns, it is recommended to give intravenous fluids at 3 mL/kg/TBSA burn. In some pediatric burn centers, the fluid resuscitation formula is based on body surface area rather than on weight, with D5LR being used as the fluid.²² Such formulas are established as guidelines; fluid management should be guided by pertinent clinical parameters, including pulse rate, blood pressure, capillary refill time, urine output, and mental status. Urine output is a very sensitive indicator of adequate resuscitation in the first 24 hours and should be 0.5 to 1.0 mL/kg/h.

A sinus tachycardia that develops within a few hours of a large burn injury is considered a desirable physiologic response, and patients who do not develop it have a higher mortality.⁹ Base deficit may also be used very effectively to monitor the appropriateness of resuscitation.⁸

Hemodynamic monitoring is frequently used; however, central venous pressure monitors are not necessary routinely during the first 24 hours, except in those patients who require twice the usual amount of fluid or in those who have cardiac disease. Patients with deep burns (including electrical burns), associated trauma, or inhalation injuries will generally require more fluid resuscitation. Intravenous lines should be changed every 3 days because of the risk of suppurative thrombophlebitis.

Patients with electrical injuries should be carefully monitored for 24 hours if there was loss of consciousness at the scene or any evidence of arrhythmias in either the prehospital phase or the emergency department.

All clothing should be removed as soon as possible. If clothing adheres tightly to the skin, however, forcible removal can inflict even more damage. Many synthetic materials significantly increase the skin temperature while burning. Application of topical ointment may facilitate later removal.⁹ Hypothermia can contribute to coagulopathy, decrease circulation to the wound, and, if less than 33°C, can actually increase metabolic rate.¹⁴ Hypothermia should, therefore, be prevented during resuscitation.

Patients who have sustained a burn greater than 25% should have a nasogastric tube placed. These patients will develop an ileus secondary to splanchnic vasoconstriction.²⁰ This ileus usually resolves by 24 to 48 hours: Most burn units begin enteral feedings as early as the first day postburn to satisfy caloric needs,²² regulate the microflora of the gastrointestinal tract, and maintain the integrity of the mucosal barrier.⁷

A Foley catheter should be placed in patients with severe burns (greater than 20%).²² A majority of patients with deep burns and electrical injuries will filter the hemochromogens hemoglobin and myoglobin into the urine.¹² If myoglobinuria is present, additional fluid resuscitation may be necessary to prevent acute tubular necrosis and resultant renal failure. Mannitol and bicarbonate may also be employed to maintain urine output and prevent precipitation of pigments, respectively.¹²

If tetanus prophylaxis is not up to date, it should be given. Tetanus toxoid is usually sufficient, but if there is any doubt as to primary immunization status, tetanus immunoglobulin should also be administered, and the patient will require the remainder of the immunization series at appropriate intervals.

Pain can be severe, particularly in patients with partial-thickness burns; full-thickness burns tend to be painless because nerve endings have been destroyed. All pain medication should be given intravenously in small, frequent aliquots, titrated to pain relief, after fluid resuscitation has been accomplished; otherwise, the vasodilatory effect of the narcotics may negatively affect the patient's blood pressure. Intramuscular pain medications may have erratic absorption. Morphine remains the narcotic of choice. Fentanyl and nitrous oxide are acceptable alternatives. If the patient is extremely anxious, and is not hypoxic or hypovolemic, small doses of intravenous diazepam or lorazepam may be used.

Escharotomy may be indicated on extremities in the case of distal pain, paresthesias, decreased pulses, or cyanosis, suggesting the development of a compartment syndrome. The most reliable way of checking arterial flow is by an ultrasonic flow meter.¹⁴ Compartment pressure measurement can be helpful, if it is readily available. Incisions should be made on the radial and ulnar borders of the arm and forearm and along the midaxial lines of the digits. Incisions are made on the medial and lateral borders of the lower extremities. Escharotomy may lead to significant soft-tissue bleeding, which may require electrocautery to control (see [Fig. 125.2](#)).

Burns are at risk for infection for several reasons: The skin no longer serves as a barrier to microorganisms, the exudate from the burn is an ideal culture medium, the host's immune system is impaired, and many sick patients require the performance of invasive procedures. Antibiotics made a great difference in mortality with their discovery in the 1940s. At first, gram-positive organisms, such as group A *Streptococcus*, predominated, and penicillin G was often given prophylactically. Indiscriminate parenteral antibiotic use over the ensuing decades, however, has tended to select out resistant gram-negative organisms, such as *Pseudomonas*. This selection occurs in the gastrointestinal tract, where antibiotics overwhelm the normal mucosal anaerobes and allow the overgrowth of gram-negative organisms and yeast.⁷ As a result of this process, systemic antibiotics are generally not given prophylactically at this time. Topical antimicrobials, such as 1% silver sulfadiazine, and aggressive early excision of eschar are used to prevent the development of infection. If a patient returns to the emergency department with burns that appear infected, admission may be warranted.

If the patient is to be transferred, no wound care (except for emergency escharotomy) should be performed unless discussed with the accepting burn center. The burns should be covered with cool, sterile compresses (small areas) and then sterile drapes. Cooling produces vasoconstriction, appears to reduce histamine release and thromboxane B₂ and kinin formation, and stabilizes mast cells. Transfer should not be delayed by burn debridement. If the patient's burns are such that hospitalization is not necessary, they should be irrigated with sterile saline and cleaned with mild soap. Necrotic skin should be sharply debrided, and broken blisters should be unroofed and debrided. Blisters over joints and large blisters should be debrided. Some controversy exists about the management of small intact blisters in compliant patients: Some authorities believe that the intact blister provides protection for the new skin; others believe that the fluid contains toxic products of the inflammatory reaction (e.g., thromboxane) and recommend debridement of bullae larger than 2 cm,¹⁴ or sterile aspiration of the fluid²⁰ to improve normal neutrophil function, to decrease production of arachidonic acid metabolites, and to allow normal fibrinolytic processes to occur.²¹ Shaving hair (except the eyebrows) 3 to 4 in. from the wound border has also been recommended by some.¹⁴

Outpatient management can be summarized by the five C's: cut, cool, clean, chemoprophylaxis, and cover. The ideal burn dressing is one that is inexpensive, safe, and painless; prevents infection; promotes rapid wound healing; promotes functional and cosmetic results; and requires infrequent dressing changes that can be done at home.¹⁶ For very superficial, small burns, some use only nonadherent dressings with simple antibiotics, such as bacitracin,¹⁶ or no antibiotics at all. The final covering is absorbent gauze and stockinette, which is changed twice daily while the burn weeps and once daily thereafter.

For the remainder of outpatient burns, topical antibiotic ointments are applied after cleansing. The most commonly used topical therapy is silver sulfadiazine, which is broad spectrum and nontoxic. It does have a 5% to 7% incidence of allergic reaction,¹⁷ however, and is expensive. It should not be used in pregnant patients or nursing mothers and should not be used on the face because of staining. Mafenide, Furacin, and silver nitrate are not used in the outpatient setting.

The burn is then covered with a nonadherent dressing and, finally, a gauze dressing. Dressing changes must be done twice a day while the burn weeps. Each time, the old silver sulfadiazine should be completely washed off. Several trials have compared synthetic occlusive dressings (Biobrane, DuoDerm, OpSite, and Inerpan) with silver sulfadiazine. These dressings were found to have a decrease in the frequency of dressing changes, better compliance, and marginally faster healing, but none was found to produce superior healing.⁵

Outpatient management of burns of the face and neck consists of the use of bacitracin ointment, no dressing, and thrice-daily washing.¹⁰ In an interesting study from

India,²⁴ 100% of burns treated with pure unprocessed honey healed in 15 days, compared with 50% healing in the same time period with boiled potato peel. Separate dressings should be used for each finger. The hand should be immobilized in the position of function (wrist extension, metapalangeal flexion, interphalangeal extension),¹⁸ which is opposite of the position assumed by the burned hand.²⁵ Ideally, the extremity should be elevated and joints must be exercised, particularly in the case of burns that cross joints.²³ Patients should be cautioned that burned skin is sun-sensitive for up to a year,¹⁸ and that they should protect the skin by using SP25 sunning agents and, in the case of head and neck burns, by also wearing a hat. Aspirin should not be used for pain control, because antiplatelet effects may worsen blood loss if skin grafting becomes necessary.⁵

If a deep burn heals untreated, new collagen is formed randomly, with a piling up of excessive tissue and hypertrophic scar formation. Two approaches exist for the management of deep partial- and full-thickness burns: early excision and grafting versus delayed grafting after the eschar separates.²⁵ The former approach appears to be the most accepted at the present time. When wounds are greater than 60%, use of growth hormone has decreased donor-site healing.²²

DISPOSITION

Most patients who sustain minor burns can be managed as outpatients. Burns should be rechecked within 24 to 48 hours. Beyond that period, further management depends on the mechanisms available in an individual's particular setting. Some emergency departments manage their own follow-up burn care. Patients with deep partial-thickness or full-thickness burns should be referred to a plastic surgeon or other burn-care specialist in 2 to 4 days for consideration of skin grafting and physical therapy. Hospitalization should be considered, even for minor burns, in those patients who are immunocompromised, including the very young and the old, and in those with poor home situations or possible abuse.

Recommendations for transfer to a burn center are as follows: any person with a burn of more than 20% TBSA; patients older than 50 years or younger than 10 years with a burn greater than 10% TBSA; patients with full-thickness burns greater than 5%; patients with burns to the face, hands, feet, perineum, or major joints; patients with electrical or chemical burns or associated inhalation injuries; patients with multiple trauma; and patients with circumferential injuries of the chest or extremities.⁹ A BURN PLAN is a simple acronym (airway, breathing, urine output, resuscitation, nasogastric tube, pulses, lines, accurate documentation, and notify unit) that is used to ensure documentation and communication of all required treatment and information.⁹ In making the decision to transfer a patient to a higher level of care, an important question must be asked: Can the patient tolerate the evacuation? In transfers up to 150 miles, a helicopter can be used; greater distances require fixed-wing aircraft.

A flowsheet containing a complete record of initial findings, ongoing resuscitation, and patient response by appropriate clinical parameters, consultations, and the results of pertinent laboratory, radiologic, and other testing should be maintained on any significantly burned individual. A copy of this record must accompany all transferred individuals.

COMMON PITFALLS

- Failure to calculate fluid requirements from the time of the burn
- Using the pulse to determine if an extremity is compromised
- Waiting too long to intubate a patient with a compromised airway
- Overestimating or underestimating the size of the burn
- Using blood pressure as a guide to fluid requirements and not adjusting fluid resuscitation by physiologic parameters such as urine output

Strangulation injuries are broadly categorized as either hanging, manual ligature strangulation (choking), or throttling. Hanging is the most common form of strangulation injury. Hanging occurs when pressure is exerted on the neck by an external force, usually a rope, with the degree of external force increased by the weight of the victim. In complete hanging, the point of suspension is placed over the occiput. In manual ligature strangulation or choking, the ligature is tied around the victim's neck and the weight of the body is not used to increase the pressure on the neck structures. In throttling, the force is applied to the victim's neck by the assailant's hand or arm.

EPIDEMIOLOGY

Adult

Hanging and strangulation injuries are quite common in the United States and the rest of the world. Among all suicide deaths reported in the United States in 1989, 4484 were due to hanging or strangulation. Hanging was the most common mechanism of suicide after firearms and poisonings.³³

In a recent article, a disturbing increase in frequency of suicides by hanging was found in young Australians.⁵ Among all deaths by hanging in Western Australia during the 1988–1992 period, 88% occurred in males.⁷ There was one homicide, 14 cases were thought to be accidental, and the remainder were suicides. Alcohol was the most commonly detected drug at autopsy. In one-third of the cases, there was a positive history of psychiatric illness. An increasing number of hangings was reported in a review of methods of suicide in Denmark over a 70-year period.² In developing countries, hanging is frequently the most common mechanism of suicide.^{16,23,35}

The elderly are particularly at risk for suicide by hanging.^{21,27,32} Psychiatric inpatient populations are also at risk for suicide, with hanging noted to be the method of choice. Nearly half of these suicides occur outside of the hospital setting.²⁸ Prison inmates are also at increased risk, with reported rates of death from hanging up to nine times higher than in the general population.²⁴

Pediatric

Causes of strangulation injuries vary in pediatric populations relative to age. Infants are often strangled intentionally by cords, or unintentionally by clothing becoming tangled in cribs. Strollers as causes of accidental strangulation have also been reported.⁴ Toddlers to early-school children tend to be injured by window cords, plant holders, or looped rope swings. Older children and adolescents are at risk for strangulation during play and by suicide.^{6,9,10,14} A number of potentially dangerous sleeping environments at risk for accidental strangulation in infants and toddlers have been identified,^{3,26} which include large spaces between bed sides and wall, beds with plastic bed covers, and co-sleeping with adults.

Special Cases: Autoerotic

Autoerotic asphyxiation is defined as induction of hypoxia by hanging or strangulation in an attempt to achieve sexual arousal. Autoerotic behavior is associated with significant mortality rates.⁸ Mortality estimates are two to four deaths per million in the United States and one to two deaths per million in Scandinavian countries.^{18,30} Fatalities resulting from autoerotic behavior are most commonly encountered in males 12 to 25 years of age.^{8,13} Individuals engaged in such behavior often use a number of safety devices, which include a slipknot to loosen the ligature, knives to cut cords, and more involved self-rescue mechanisms that are activated if a person faints. However, these safety devices frequently fail, leading to significant morbidity and mortality.⁸

PATHOPHYSIOLOGY

Bony Injuries

It is estimated that as many as 16,000 judicial hangings have occurred in the United States.¹⁹ In classic judicial hanging, no injury to the spinal cord, spine, or base of skull was usually noted. Death resulted from asphyxiation. With longer judicial drops, disjuncting of second and third cervical vertebrae occurred, with resulting hangman's fracture.²⁵ Associated spinal cord injury was usually seen in such cases.²² Some evidence suggests that the frequency of neck fractures increases with longer hanging time.²⁵ Decapitation, as a result of extreme distracting force leading to cervical spine fracture in conjunction with complete severance of other neck structures, has also been reported.²⁹ Decapitation appears to occur with longer drops and when single-twist ropes are used.

Injuries to Vascular Structures

Almost all strangulation causes obstruction of venous flow, with resultant petechial hemorrhages seen on the neck surface. Significant injury to deep vascular structures may also occur. The vertebral arteries are most commonly injured. Injuries to the bifurcation of the common carotid arteries are less frequently encountered.¹⁹ Most injuries are intimal tears. Vascular injuries often lead to cerebral anoxia, which causes most immediate deaths in hanging victims. Autonomic nervous system instability, secondary to stimulation of deep neck vascular structures, also contributes to immediate mortality as a result of profound bradycardia.^{20,22}

Injuries to Laryngotracheal Apparatus

Injuries to the laryngotracheal apparatus in strangulation victims are common; however, most such injuries are rarely life-threatening. They are usually observed in drops from longer heights and when the ligature is tied lower down the neck. Injuries to the thyroid cartilage occur almost 50% of the time, whereas injuries to the hyoid bone occur in 20% of strangulations. Cricoid cartilage injuries are uncommon.¹⁹ Interestingly, one series failed to document any injuries to the laryngotracheal structures.¹² Injuries to the laryngotracheal apparatus are less common in the pediatric population, secondary to increased flexibility of the larynx in this age group.³¹

Pulmonary Sequelae

Immediate and delayed pulmonary complications following near-fatal hanging are routinely encountered.¹⁵ The pathophysiology of such injuries is multifactorial. Patients often develop pulmonary edema or pneumonia. Adult respiratory distress syndrome following near-fatal hanging has also been reported. Pulmonary edema may be secondary to the increased airway pressures produced with inhalation against a closed airway, or due to neurogenic causes. Aspiration pneumonias are also common. Iatrogenic volume overload from overly aggressive resuscitation may also occur.

Neurologic Sequelae

Both immediate and delayed neurologic sequelae have been documented. Case reports document patients whose neurologic function continued to deteriorate, resulting in death. Deaths secondary to global hypoxic encephalopathy or vascular intimal tears, with resultant, later cerebral infarction, have been recorded.^{11,17} Reports also document patients who completely recover, with no long-term sequelae, despite the presence of agonal respirations and posturing on presentation to the emergency department.³⁴

NATURAL HISTORY AND PROGNOSIS

The natural history of strangulation victims is unpredictable. The degrees of injury seen vary from minor injuries to superficial neck structures to life-threatening pulmonary, airway, and neurologic sequelae. Immediate neurologic prognostication is of little value. Patients who fail to resume spontaneous breathing and circulation with first aid measures appear to carry a worse prognosis.¹⁴ In one study, 22 of the 24 hanging patients who died experienced either prehospital or emergency department cardiopulmonary arrest. In the same study, all treated patients who died required intubation prior to death.¹

CLINICAL PRESENTATION

A wide variety of clinical presentations are encountered in strangulation victims. Patients often present with severe cyanosis. Grunting respirations may be observed, and patients may exhibit severe stridor. Tachypnea is common. Subcutaneous emphysema is more common in victims of throat injuries. The presenting neurologic status can vary widely from complete normalcy to unconsciousness and posturing. Ligature marks and subconjunctival and facial petechiae are usually present.

EMERGENCY DEPARTMENT MANAGEMENT

As with any potentially severe injury to the neck structures, airway management is a first priority. The method of endotracheal intubation chosen depends on the clinician's experience. Any approach to airway control in a strangulation victim must presume that a cervical spine injury exists. As such, in-line stabilization of the cervical spine during intubation is mandatory. Once the airway is adequately controlled, the use of positive end-expiratory pressure should be considered because of the high incidence of pulmonary complications associated with the initial injury. In hypotensive patients, fluid resuscitation may result in delayed pulmonary edema and adult respiratory distress syndrome. The cervical spine should continue to be immobilized at all times, despite the fact that associated spine injuries are uncommon. Radiographic investigation of the cervical spine and the soft tissues of the neck is indicated. In the face of neurologic deterioration, intracranial pressure monitoring should be employed. Gentle hyperventilation, as well as osmotic and nonosmotic diuresis, may be utilized in the presence of increased intracranial pressure.

Once immediately life-threatening injuries are addressed, a detailed history should be obtained. The distance of fall, estimated time to initiation of rescue efforts, condition of the patient at the scene, and response to initial resuscitation are particularly important predictors of outcome. Evidence of associated suicidal injuries, including ingestions, should be sought.

DISPOSITION

All strangulation victims should be admitted for at least a 24-hour observation period to an area where adequate monitoring for potential airway, pulmonary, and neurologic sequelae is available. The airway should be secured via endotracheal intubation if transfer is deemed necessary. Early neurosurgical and/or otolaryngologic consultation should be considered if severe neurologic and/or laryngeal injuries are suspected. In conscious patients, psychiatric consultation should be obtained. "One-to-one" patient supervision, to prevent further attempts at self-destructive behavior, is mandatory in all intentional hanging victims.

COMMON PITFALLS

- Attempting to predict outcome based on the initial condition
- Failure to control airway in a timely fashion
- Failure to institute early, aggressive positive end-expiratory pressure
- Failure to maintain cervical spine immobilization
- Failure to consider early neurosurgical and otolaryngologic consultation
- Failure to consider early psychiatric consultation
- Failure to institute precautions against further attempts at self-destructive behavior
- Failure to definitively control the airway via endotracheal intubation prior to transfer of the patient to another facility
- Premature discharge (especially in hanging victims who are incarcerated)

Trauma in the elderly is a growing concern. The elderly (above age 65 years) have increased in number and now make up about 12% of our population ([Fig. 127.1](#)). They are expected to represent 13% of the U.S. population by the year 2005. ²⁸ In 1990, a staggering 977,000 elders required care for fractures. ²⁵ The elderly account for 25% of hospitalizations for trauma and 25% of all trauma costs. ²¹ Unfortunately, when the elderly are injured, they are more likely to suffer complications and to die than their younger counterparts, and they exhibit different injury patterns. ^{12,24}

Figure 127.1. Percentage increase of elderly population, 1920–2050. (Redrawn from Eliastam M. Elderly patients in the emergency department. *Ann Emerg Med* 1989;18:1222.)

PATHOPHYSIOLOGY

Many elderly patients seem to function very well, but the aging process limits the physiologic reserve needed to respond adequately to injury. The following is an overview of the physiologic derangements of aging that increase the morbidity and mortality of trauma in this group.

Cardiovascular

Functional losses in the cardiovascular system result from a loss of normal elasticity and changes in tissue collagen. As the heart and pericardium stiffen, resting cardiac output and stroke volume begin to fall. ^{6,9} This effect may progress to overt congestive heart failure in up to 10% of patients over age 75 years. ⁷ Although the resting heart rate often does not change, fibrosis of the conduction system and the loss of specialized conduction cells impede the heart's ability to increase its rate when necessary. ⁵ Also, aging is often accompanied by the development of atherosclerotic coronary disease. The combination of fixed coronary artery lesions, decreased cardiac compliance, increased wall tension, and the inability to raise heart rate limits myocardial oxygen delivery. Because cardiac output often needs to increase after injury or blood loss, these patients are at risk for developing myocardial ischemia. Ischemia, in turn, may further impair cardiac output. The accompanying increase in pulmonary pressure also tends to decrease cardiac output. Dysrhythmias may also occur, further complicating the situation.

Many elderly patients are on prescription medications that tend to limit the heart's ability to respond to stress (i.e., beta blockers, calcium channel blockers, clonidine). Afterload-reducing agents and diuretics may limit preload, thereby decreasing blood pressure under stress. Diuretic-induced electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia), as well as medications such as digoxin and theophylline, may precipitate dysrhythmias.

The changes in the vascular system are similar to those in the heart. Loss of compliance tends to make vessels more easily injured by shearing forces, producing vascular rupture, occlusion from intimal disruption, or aneurysm formation. ^{6,22}

Pulmonary

As the lungs age, they undergo numerous changes, none of them helpful. The same loss of elasticity that impedes the cardiovascular system tends to occur in the lung. As the lungs stiffen, forced vital capacity and maximal expiratory flow are reduced. Residual volume rises and vital capacity decreases as the total lung capacity does not change. These alterations, combined with a decrease in lung surface area due to emphysematous changes (remarkably common in the elderly), contribute to a decrease in ventilation. ²⁷ As perfusion does not change, ventilation–perfusion mismatch occurs, characterized by a fall in P_{O_2} .

Loss of elasticity also occurs in the muscle and connective tissue of the chest wall. Combined with osteoporosis of the ribs (discussion follows) and the pulmonary parenchymal changes, this condition makes the elderly much more prone to rib fractures and pulmonary contusion, which may occur even with seemingly minor forces. These patients often require mechanical ventilation; thus, these injuries may prove lethal.

Renal

With aging, kidneys lose both structure and function due to a loss of both glomeruli and nephrons, in both number and function. Renal blood flow falls secondary to decreases in cardiac output and the development of renal artery atherosclerosis. Progressive fibrosis occurs in the remaining parenchyma. All of this produces the well-recognized decrease in creatinine clearance that accompanies aging. ¹³ We lose an estimated 8 to 10 mL/min of creatinine clearance per decade of life after the 20s. Diminution of renal function is characterized by an inability to concentrate urine, as the kidneys cannot retain free water.

Serum creatinine and urine output are two of the clinical tools often used to estimate renal function, but this is potentially disastrous in the elderly. Older patients progressively lose lean muscle mass, so they do not produce as much creatinine. The loss of concentrating ability means they may continue to produce seemingly adequate amounts of dilute urine, even in the face of significant hypovolemia. Patients with an impaired myocardium may also not make adequate amounts of urine in response to a fluid challenge, again making urine output an unreliable indicator of intravascular volume. Because these normally reliable indices cannot be used in the elderly, our approach must be changed, especially when we use nephrotoxic agents, such as antibiotics, or contrast agents.

Osteoporosis

Osteoporosis is present to some degree in almost every elderly patient. The loss of histologically normal bone produces a significant loss of bone strength, making these bones much more susceptible to fractures. Osteoporosis accounts for an estimated 1.5 million fractures in the United States every year.^{4,15} The most common osteoporotic fractures in the elderly are vertebral compression fractures and fractures of the wrist, hip, pelvis, and skull.

Osteoporotic fractures have tremendous clinical implications. Fractures often require operative fixation, subjecting the elderly patient to myriad postoperative complications. Nonoperative therapy puts the patient at risk for skin breakdown, pulmonary embolus, and pneumonia. Narcotics used to treat pain may cause marked decreases in mental status. A seemingly straightforward fracture may carry substantial morbidity and mortality in the elderly patient.

Central Nervous System

The central nervous system undergoes substantial changes with aging. The brain progressively loses volume, and the dura becomes more tightly adherent to the skull, limiting the occurrence of epidural hematoma. The smaller brain is allowed more angular movement in the skull. This increased space could potentially protect the brain from contusions, but the loss of volume also stretches the parasagittal bridging veins, making them prone to rupture. This stretching makes the elderly patient particularly prone to the development of subdural hematoma. The increased space around the brain can also hold a remarkable amount of blood before the hematoma produces clinical signs. Neurotrauma is second only to shock as a predictor of death in the traumatized elderly patient.¹²

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Traumatized elderly patients present a special problem for the emergency physician. Because of the inability of the elderly patient to respond to injury, seemingly minor trauma can result in major complications; preventing these complications requires alert, accurate assessment.

Trauma in the elderly, as in younger patients, is classified by mechanism of injury. When an elderly person is traumatized, the emergency physician must rapidly determine that a medical emergency did not lead to the traumatic event (i.e., syncope, seizure). Falls are a common consequence of such medical emergencies in elderly patients, as are motor vehicle crashes.

Falls are relatively insignificant in younger people but are a source of considerable morbidity and mortality in older patients, in part because 50% of these individuals fall repeatedly.²⁶ The careful emergency physician must evaluate an elderly person who has fallen not only for potential injuries, but also for the underlying factors causing the fall. The causes of falls are divided into three categories: environmental (chairs, stairs, rugs), gait disturbances, and medical problems unrelated to gait. Clearly, these etiologies are interrelated. For instance, nocturia and urinary or fecal incontinence are common in the elderly. The urgency to avoid soiling oneself, combined with postural hypotension, an unsteady gait, and a slippery rug, may result in a fall. In patients older than 85 years, 20% of such falls occur in nursing homes.²⁶

A host of common medical problems may manifest as syncope, near-syncope, dizziness, or vertigo, and can lead to falls. [Table 127.1](#) and [Table 127.2](#) outline the most common etiologies and the minimum evaluation needed to rule them out. Many of these etiologies are immediately life-threatening.

ATLS protocol
Cardiac monitoring (continue for at least 24 h)
Transcutaneous oxygen saturation monitoring
Rapid glucose assessment (give D50W if equivocal)
Arterial blood gas analysis
CBC, serum electrolytes, glucose, BUN, creatinine
Serum calcium, magnesium, phosphorus (low levels promote seizures)
12-lead ECG (should be performed serially to help rule out myocardial infarction)
Consider serum cardiac enzymes
Consider naloxone (Narcan) administration if mental status is altered and there is no evidence of head injury
Give i.v. or i.m. thiamine (100 mg)
Careful history and physical examination, particularly neurologic
Consider head CT scan, particularly if no obvious cause for the fall is identified

TABLE 127.1. Emergency Department Evaluation of the Patient Who Has Fallen

Focal/partial seizures
Generalized seizure
Medications

^aCommon causes of syncope, near-syncope, dizziness, and seizures.

TABLE 127.2. Internal Causes of Falls Unrelated to Gait^a

It is unacceptable to learn that a patient is hypoglycemic 2 hours after he or she arrives at the emergency department, when a serum glucose value finally returns from the laboratory. It is equally unacceptable to send to radiology an unmonitored patient having bouts of ventricular tachycardia. It is safest to assume that an elderly person who has fallen is hypoglycemic, is having dysrhythmias, has multiple chronic medical problems, is on a host of medications, and has simultaneously suffered a stroke, myocardial infarction, or pulmonary embolus.¹⁹

Falls need not be an inevitable consequence of aging, and the elderly person who has fallen is not necessarily doomed to do so repeatedly. Rubenstein and associates¹⁶ demonstrated the value of assessing falls in the elderly. They performed a randomized study in which patients were given routine care or a detailed postfall study (detailed physical examination, environmental assessment by a nurse practitioner, laboratory studies, electrocardiogram, and 24-hour Holter monitoring). The probable cause of the fall, risk factors, and therapeutic recommendations were then passed on to the patient's primary physician. At the end of a 2-year follow-up period, the intervention group had 26% fewer hospitalizations, a 52% reduction in hospital days, 9% fewer falls, and 17% fewer deaths.

Referrals from the emergency department to gerontologists, neurologists, physiatrists, and social workers may be of significant benefit to an elderly person who has fallen but who does not require admission. Caregivers can decrease a person's risk of future falls by identifying people at high risk for falls, modifying their environments, aiding the hearing and vision, improving their footwear, and getting them to exercise the legs and trunk to improve strength.

Motor vehicle crashes are another source of tremendous morbidity and mortality in the elderly. Although the number of miles driven each year decreases with advancing age, the risk of crash involvement increases significantly. Many of the etiologic factors responsible for falls should also be considered in the elderly crash victim. Crashes among the elderly are more likely to involve intersections, traffic sign violations, right-of-way decisions, and two-car accidents than are those in younger drivers, and are more often fatal.^{8,10,21} This fact suggests that there are real problems with cognitive and perceptual functions, as well as impaired reaction

times. Dementia, attention deficits, sensory and motor slowing, loss of motor strength, arthritis, decreases in peripheral vision, prescription drug use, and concurrent medical conditions all contribute to the increased crash rate per mile seen in the elderly. ¹⁴

All of these impairments also put elderly pedestrians at risk for being hit by a motor vehicle. ²³ They do not readily perceive threats or react to them. They have lost their ability to evade an onrushing accident. In particular, the elderly have difficulty at crosswalks. Add to their problems kyphoscoliosis (restricting upward gaze at traffic lights and signs), decreased hearing, and a slow gait, and one can see why the crosswalk is too often an insurmountable obstacle. ¹⁵ Of motor vehicle accidents in general, elderly pedestrians struck may have the highest morbidity and mortality rates.

Finally, the elderly patient's injury may have been intentionally inflicted. Emergency physicians must maintain the same grim alertness for elder abuse that they do for child and spousal abuse. The abuse may be obvious (penetrating trauma, burns, or head injuries) or subtle (poor hygiene, dehydration, weight loss, or unexplained bruising). Because it can escape notice, elder abuse is often unrecognized and, therefore, underreported. Dementia, fear of abandonment, and cultural mores may cause the elderly patient to deny the abuse. ² The elderly are also at increased risk to be the victims of violent robbery. ²¹

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The principles governing the emergency department evaluation and management of traumatized geriatric patients are identical to those for younger patients. Follow the usual guidelines for trauma management, ³ with some modifications for elderly patients. The two most important differences are that no one is stable, and every minute counts.

Some elderly trauma victims are obviously in extremis at the time of initial evaluation. These badly injured patients almost always die, particularly if they have suffered a head injury. ¹² Of more concern are patients who have sustained a significant mechanism of injury but seem relatively stable at the initial evaluation.

One group of patients is at high risk for dying or developing significant complications after the injury ([Table 127.3](#)). Although the patient is relatively normotensive in the emergency department, the combination of soft-tissue injury, long-bone fractures, and head injuries produces tissue oxygen deficits that the elderly patient has trouble meeting. If these oxygen delivery deficits are not met in a timely fashion, the patient develops an oxygen debt that cannot be repaid, and he or she will expire early from heart failure or late from multiorgan failure. ²⁰ Failing to recognize this oxygen debt is one of the main reasons for the high mortality rate in the traumatized elderly patient. Invasive monitoring can be extremely helpful in guiding resuscitation in these patients. ¹⁸

Pedestrian vs. motor vehicle mechanism
Initial systolic blood pressure <130 mm Hg
Acidosis (pH <7.35)
Multiple long-bone fractures
Head injury

TABLE 127.3. High-Risk Geriatric Patients

Because many emergency departments cannot yet provide this level of critical care monitoring, the period of time elderly trauma victims spend in the emergency department must be minimized. When Scalea et al. ²⁰ cut the time from emergency department presentation to intensive care unit monitoring from 5.5 to 2.2 hours in this high-risk group, survival rose from 7% to 53%. The initial period in the emergency department is the window of opportunity, a window that closes when poor oxygen delivery is not addressed.

Therefore, emergency department diagnostics must be limited to only those that are necessary. Evaluation should begin with a rapid primary survey. If there is any question about airway integrity, it is controlled by means of endotracheal intubation, as the injured elderly patient will often not tolerate even transient hypoxemia. Remember to check for dentures in the elderly patient with airway obstruction or pending intubation. Also, remember that the increased presence of arthritis in the cervical spine further prohibits neck extension during intubation attempts. ¹⁷

The history is of significant importance in the elderly patient, as current medical problems or medications may significantly affect the patient's presentation, response to injury, and response to therapy. The patient's family or physician or emergency medical service personnel may provide vital information regarding the injury, the patient's current level of functioning, and the patient's medical problems, medications, and use of alcohol or drugs.

Limit initial radiographs to films of the cervical spine, chest, and pelvis. Evaluate the abdomen by ultrasound (which is much quicker than computed tomography [CT] scanning) or by CT scanning. ¹¹ Long-bone films that cannot be obtained as stat portables may need to be deferred, and obvious fractures splinted. Only patients with clinically serious head injuries (markedly depressed mental status or lateralizing neurologic signs) may need to have head CT scanning emergently.

Patients then undergo invasive monitoring. Unless an intensive care unit bed is immediately available, initiate invasive monitoring in the emergency department or trauma resuscitation area. Although a detailed description of hemodynamic optimization is beyond the scope of this chapter, general guidelines are that fluid and blood are used to optimize preload; inotropes are used to increase oxygen delivery further if it remains inadequate after volume loading. Scalea et al. ^{19,20} successfully used dobutamine and amrinone. These agents are also vasodilators and do not markedly increase myocardial oxygen demand as they increase cardiac output. Augment oxygen delivery until oxygen consumption plateaus and the serum lactate level normalizes. ¹

This approach may seem radical to some, but it follows the basic principles of trauma resuscitation. The clinician has not adequately evaluated the "C" of the ABCs of the primary survey until the patient is invasively monitored. Unfortunately, no noninvasive measures, especially the normally followed signs (i.e., vital signs, urine output, central venous pressure), are adequate to determine the adequacy of tissue oxygen delivery. Hypotension is a late sign of shock and a grim prognostic indicator of survival in the elderly. ²⁹

Early, aggressive trauma care increases survival in the elderly. ¹⁹ It is risky to assume that a normotensive, traumatized, elderly patient in the high-risk group is stable. Multiple organ failure and death may occur from unrecognized, inadequate cardiovascular response to injury. Although complete skeletal surveys are necessary to complete the trauma evaluation, they almost never affect the immediate treatment plan and almost always take much longer than planned. The same is true for studies such as precautionary head CT scans or the evaluation of microscopic hematuria. These are of lower priority than invasive monitoring and should be deferred until the patient's cardiovascular status has been clearly optimized.

Because the elderly have such limited cardiac reserve, a rapid search for all sources of blood loss is mandatory. In addition to loss from abdominal trauma, the elderly are at risk for blood loss from all other injuries. As with younger patients, fractures—in particular, pelvic fractures—can be the source of significant blood loss. The loss of tissue turgor that accompanies aging may limit the tamponade effect that the skin and connective tissue provide in younger patients, which puts the elderly patient at an even higher risk for blood loss at fracture sites. As coronary artery disease limits myocardial oxygen delivery, even at rest, the consequences of anemia may be devastating in the elderly patient. Elderly trauma patients should be transfused more liberally than their younger counterparts, because the blood's oxygen-carrying capacity may be more critical to myocardial oxygen delivery, and crystalloid administration may reduce volume overload, in this setting of diminished compliance of the ventricles.

Because hematocrit determinations require time for equilibration, they are inaccurate in determining acute blood loss. Scalea et al. ^{19,20} and ²¹ routinely empirically

transfused elderly patients at high risk for blood loss, such as those with multiple fractures (particularly pelvic), without waiting for a fall in the hematocrit.

Figure 127.2 outlines one basic strategy for the management of the injured elderly patient.

Figure 127.2. Algorithm showing management strategy used for the injured elderly.

DISPOSITION

Due to the complexities inherent in the management of elderly trauma patients, the trauma surgeon, orthopedist, neurosurgeon, and intensivist must be involved early in their care. Good communication is essential to maximize functional outcome in these difficult patients. All patients in the high-risk group require invasive monitoring and, therefore, admission to the intensive care unit. Elderly patients suffering falls should be evaluated for the need for cardiac monitoring, either in the coronary care unit or in the telemetry department. Transfer criteria for traumatized elderly patients are the same as for their younger counterparts, with one caveat. Because significantly injured elderly patients require invasive monitoring, transfer to a level I trauma center should be considered, particularly if those resources are unavailable at the referring institution.

Despite the best efforts, some elderly patients do not return to their preinjury levels of functional activity. A number of markers for poor outcome in this population have been described, including (1) a Glasgow Coma Score greater than or equal to 7, (2) age greater than 75 years, (3) severe head injury, (4) presence of shock on admission, and (5) the development of sepsis during the admission for the traumatic event. However, early, aggressive resuscitation and evaluation are essential to limit long-term disability.²⁶ Referring the elderly person who has fallen to a gerontologist or rehabilitation specialist may help prevent recurrent falls.

COMMON PITFALLS

- “Stable vitals” do not necessarily mean a stable patient.
- Do not delay hemodynamic monitoring and optimization for nonurgent studies (e.g., distal extremity x-rays) in patients in the high-risk group.
- Do not rely on urine output to guide resuscitation.
- Do not rely on central venous pressure measurements to guide resuscitation (except early in the resuscitation, when finding a low central venous pressure can be helpful).
- Delaying transfusion can lead to the development of an unrecoverable oxygen debt. Elderly patients should be transfused early.
- Allowing a period of observation to see how an elderly patient responds risks closing the window of opportunity.

ACKNOWLEDGMENT

The authors wish to acknowledge the contribution of Lewis Kohl and Thomas M. Scalea, who wrote the previous version of this chapter.

[Chapter References](#)

The real and potential clinical applications of ultrasonography in the emergency department (ED) setting have greatly expanded over the past decade, and no discussion of its clinical applications will remain current for more than a few years. Ultrasound (US) provides real-time information about anatomic structures and cardiac activity, provides guidance for invasive procedures, and localizes areas of pain. It has been incorporated into the clinical practice of a number of specialties outside of radiology, by virtue of its ability to provide immediate clinical information to the assessing physician at the patient's bedside.

Over the past decade, the use of US by emergency physicians has become increasingly widespread, and there is a growing body of literature describing its use by emergency medicine (EM) physicians in a variety of clinical contexts. It is still not routinely incorporated into the practice of most EM physicians, and so this chapter attempts to address the role of US for physicians with and without ultrasonographic capabilities in their ED.

BASIC PRINCIPLES OF ULTRASOUND

For clinicians either requesting a US or performing one on a patient, there are some basic principles of physics and instrumentation that must be appreciated. US imaging uses sound waves to provide images of structures within the body. The sound waves are nonionizing forms of energy that are propagated in waves of variable frequencies. The sound waves are emitted from the transducer with frequencies typically ranging from 2.5 to 10 million hertz (MHz).

The sonographer selects the desired frequency by choosing a transducer or probe that is designed to emit sound waves at a given frequency. Higher frequencies improve image resolution; lower frequencies allow greater penetration and visualization of deeper structures. In general, the sonographer will select a high-frequency probe for superior resolution of a superficial structure such as a subcutaneous foreign body or vein, and a low-frequency probe for imaging of larger subjects or retroperitoneal structures such as the aorta. For most routine imaging in the ED, a range of 3.5 to 5.0 MHz will visualize most intraabdominal structures, with higher frequencies (7.5 to 10.0 MHz) reserved for endovaginal and subcutaneous imaging and testicular and vascular structures.

The ability of a US machine to visualize a structure is dependent on a number of variables, specifically the body habitus of the patient, the ability of the organ and surrounding tissues to transmit sound waves, and, finally, the skill of the sonographer. The limitations of sonography are usually due to inability to obtain good-quality images. Simply stated, if you cannot see the organ or cavity in question well, you cannot accurately interpret the image.

It is always more difficult to obtain high-resolution images on larger patients, because lower frequency waves are needed to penetrate deeper structures. For example, the obese individual in whom you suspect an abdominal aortic aneurysm (AAA) may be better screened with abdominal computed tomography (CT), owing to the difficulty of obtaining good-quality images of retroperitoneal structures with US.

Image resolution of specific organs is greatly affected by the fluid content of the organ and surrounding structures. Fluid transmits sound waves well, and organs containing fluid (e.g., blood, bile, urine) or those adjacent to fluid-filled structures will usually be readily visualized. One of the reasons the gallbladder is so easily visualized by US is its proximity to the liver, which is filled with blood, and the fact that the gallbladder is filled with bile. Conversely, air and bone transmit sound waves poorly, and images containing or adjacent to air-filled or bony structures may be difficult to image well. For this reason, US is a less reliable tool to use for imaging intraabdominal structures because of gas contained within the bowel.

TERMINOLOGY

It is important that clinicians appreciate the terminology used to describe images, in order to interpret radiology reports and, in addition, to describe their own findings when performing bedside US. Images are described with respect to the orientation of the transducer beam to the organ being imaged. When the transducer is aligned in a sagittal or cephalad–caudad orientation, this is termed a *long-axis* or *longitudinal view*. When the transducer is rotated 90 degrees from the longitudinal view, a *transverse view* of the organ is obtained. When the transducer beam is aligned to separate the body into anterior–posterior (AP) sections, the image is described as a *coronal view*.

The US machine has a number of controls that allow the sonographer to modify the image and the signal. Through manipulation of these variables, the signal that returns to the transducer can be altered to obtain optimal images. Images are usually obtained while in *B-mode (brightness) scanning*. The B mode electronically converts US signals to intensity-modulated dots on the display screen. B-mode scanning provides a real-time cross-sectional image. *M-mode (motion) scanning* is a one-dimensional display of motion, usually of the walls and valves of the heart. It takes a one-dimensional signal from the B-scan image and displays it over time.

Gain refers to the echo signal that is received by the transducer. Increasing the gain is roughly equivalent to turning up the volume of a radio, and it increases the number of incoming signals. Too much gain can result in increased scatter and generation of artifacts. Because the strength of the returning image is often attenuated as the depth of imaging is increased, the *time gain compensation control (TGC)* is often used to create a more uniform image. Gain at varying depths can be increased or decreased without affecting overall gain.

Echogenicity refers to the ability of the organ being imaged to reflect sound waves. *Hyperechoic*, *hypoechoic*, and *anechoic* describe the relative echogenicity of a structure or space. Stones and calcified structures are hyperechoic, appearing bright or white on the screen. Hypoechoic structures have a higher fluid content, are less reflective, and appear darker on the screen. Fluid-filled areas are echo-free, or anechoic, and appear dark or black on the screen.

Artifacts are commonly encountered, which can produce either misleading or clinically relevant imaging effects, depending on the artifact and the clinical scenario. *Shadowing* is an artifact that results from a highly echogenic structure blocking further transmission of the beam to distal structures. The image on the screen will reveal a relatively hypoechoic area, compared with surrounding tissues, immediately beyond a brightly reflective structure. The classic example of this is a stone or calculus, either biliary or renal ([Fig. 128.1](#)). When searching for stones, the shadow may be the only clue to their presence, particularly when the stones are small.

Figure 128.1. Posterior shadowing: A stone within the renal pelvis (*large arrow*) casts a posterior shadow (*small arrow*).

Lateral cystic shadowing results from bending of the signal when it comes in contact with a large curved structure ([Fig. 128.2](#)). It can be easily misinterpreted as posterior shadowing, except that it can be made to “disappear” by altering the direction of the signal. *Enhancement* refers to the fact that structures that lie below a fluid-filled structure appear brighter than objects in the near field. This phenomenon is due to the disparity in attenuation that occurs when adjacent signals pass through tissue or fluid. Those that pass through tissue are attenuated and appear “dimmer.” Those that pass through fluid are enhanced and appear brighter when they make contact, compared with the shadows from the surrounding structures ([Fig. 128.3](#)).

Figure 128.2. Lateral cystic shadowing: This transverse cystic image reveals a lateral cystic shadowing artifact (*arrows*). This is caused by refractive defocusing of the sound beam on the edges of the cystic structure (gallbladder).

Figure 128.3. Posterior acoustic enhancement: These transverse views of the bilateral axillae reveal a fluid-filled structure in the right that is consistent with an abscess (*arrows*). The contralateral side (**left**) is examined for comparison. The bright distal echoes are secondary to posterior acoustic enhancement. This enhancement artifact helps in differentiating solid from fluid-filled masses.

Sonographers frequently make use of this artifact to obtain high-quality images of deep structures, and refer to it as an *acoustic window*. A classic example is imaging of the female pelvis, where a full bladder provides an ideal acoustic window for the pelvic organs.

CLINICAL USES OF ULTRASOUND

Evaluation of the Patient with Suspected Cholelithiasis

The role of ultrasonography is to screen those patients presenting with right upper quadrant or epigastric pain for gallstones and evidence of cholecystitis. The predictive value of history, physical examination, and laboratory studies for cholecystitis are poor, particularly in the elderly and diabetic patient. ^{18,20} Ultrasonography can accurately identify those patients with acute cholecystitis as the cause of their symptoms, and is complementary to hepatobiliary scanning in distinguishing between acute and chronic cholecystitis.

The gallbladder is uniquely suited for evaluation with ultrasonography because of its location beneath the liver, which serves as an ideal acoustic window. The normal gallbladder appears as a thin-walled, fluid-filled structure located adjacent to the liver. It is best evaluated when the patient has been fasting for at least 6 hours, because the postprandial gallbladder will be contracted and difficult to evaluate. A number of ED examinations will be suboptimal due to insufficient fasting periods and may need to be repeated at a later time.

Gallstones appear as a brightly echogenic structure located within the dependent portion of the gallbladder. The stones do not transmit sound waves, and so the image generated is the reflection of the sound waves from the surface of the stones and the posterior shadowing that results from their reflection. The shadow is quite distinct and may be the only visible sign that a stone is present ([Fig. 128.4](#)). The presence of gallstones does not always mean that they are the cause of the patient's symptoms, and the sonographer should note whether the stones are mobile or fixed by imaging the patient in more than one position. Mobility can be ascertained by turning the patient onto the left side and seeing if the stones move. A stone that does not move, particularly when located in the neck of the gallbladder, suggests that it is impacted and likely to be the cause of the patient's symptoms.

Figure 128.4. Gallstone: There is a hyperechoic stone (*large arrow*) in the dependent portion of the gallbladder, with a posterior shadow (*small arrow*). There is no thickening of the gallbladder wall or fluid around the gallbladder.

Stones are not always readily visualized, owing to large body habitus, nonfasting states, or location of the stone within the biliary tree. In this situation, the sonographer can use other aspects of the examination to suggest the presence of stones. A large, distended gallbladder, greater than 4 cm in diameter in the transverse view, is suggestive of an obstructing stone in the gallbladder neck or cystic duct. The common bile duct in non-disease states is usually difficult to image, located adjacent and anterior to the portal vein. A duct that is easily visualized and measures greater than 4 mm in internal diameter should be considered obstructed.

The most useful clinical finding is the presence or absence of the sonographic Murphy sign. Application of pressure with the US probe directly over the gallbladder should elicit pain if the patient's symptoms are due to gallstones. The absence of this important sign should lead the clinician to consider alternative causes of the patient's pain, even when gallstones are visualized.

The ultrasonographic diagnosis of acute cholecystitis is based on the presence of stones, a positive ultrasonographic Murphy sign, and one or more signs of gallbladder obstruction or inflammation. These may include thickening of the gallbladder wall (greater than 3 mm, but usually in excess of 4 mm), fluid around the gallbladder (pericholecystic fluid), intramural gas, or a tense, distended gallbladder ([Fig. 128.5](#)). These findings are highly suggestive of acute cholecystitis when supported by the appropriate clinical presentation.

Figure 128.5. Acute cholecystitis: There are two stones within the gallbladder, in addition to thickened gallbladder walls (*arrows*).

The sensitivity of US alone for revealing changes consistent with cholecystitis has been reported as approaching 90%, but the specificity is closer to 50%.²⁰ Gallbladder wall thickening is seen in a number of other conditions, including hepatitis, congestive heart failure, renal disease, and ascites. The gallbladder will also appear enlarged and may be tender to palpation in other conditions that cause nausea, vomiting, and epigastric pain. Because of these confounding features, the US examination must be interpreted in the appropriate clinical context.

Evaluation of the Patient with Blunt or Penetrating Thoracoabdominal Trauma

US is routinely incorporated into the clinical practice of many traumatologists and EM physicians when evaluating patients with blunt and penetrating thoracoabdominal trauma. The ultrasonographic examination of the traumatized patient has been standardized to include a minimum of four views. These are (1) the subcostal view of the heart, which rapidly assesses the pericardial space for fluid and cardiac wall motion; (2) the right upper quadrant view, which visualizes the right costophrenic angle and Morison's pouch for fluid within the pleural space and peritoneum, respectively; (3) the left upper quadrant, which visualizes the left costophrenic angle and potential space between the left kidney and spleen for fluid within the pleural space and peritoneum, respectively; and (4) the suprapubic view, which looks for fluid within the retrovesicular space ([Fig. 128.6](#)).

Figure 128.6. Trauma scan: This illustration demonstrates probe positioning to obtain the four quadrant views of the chest, abdomen, and pelvis.

In the hands of experienced sonographers, it is comparable to CT and direct peritoneal lavage (DPL) in detection of free intraperitoneal fluid, with sensitivity and specificity ranges of 80% to 95% and 96% to 99%, respectively.^{11,14,15} The diagnostic sensitivity is improved with increasing sonographer experience, increased number of views, placing the patient in a supine position, and repeating negative examinations after short periods of observation.

It has also been shown to be comparable to chest radiographs in the detection of hemothorax.⁹ The sensitivity and specificity for detection of hemoperitoneum for pediatric patients are similar those for adults, with superior ability to detect specific organ injury due to their small body size and minimal subcutaneous fat.^{4,8} Ultrasonography is limited in its inability to detect fluid (blood) within the retroperitoneal space, and injuries to specific organs, particularly the pancreas and bowel. When injuries to these regions are suspected, CT is a superior imaging modality.

There are relatively few contraindications to US. Massive obesity and subcutaneous emphysema may limit the sonographer's ability to obtain high-quality images. The presence of ascites will compromise the clinical interpretation of free fluid, and may result in a falsely positive study. Prior abdominal surgery can limit the free flow of

fluid within the peritoneal or pleural cavities. It is the initial study of choice in traumatized pregnant patients, particularly with respect to its ability to rapidly assess fetal viability.

The role of US in assessing the traumatized patient has evolved into a screening examination performed shortly after arrival. It can rapidly detect free fluid within the pericardial sac, pleural space, and peritoneal cavity ([Fig. 128.7](#), [Fig. 128.8](#) and [Fig. 128.9](#)). For the low-risk individual, US is an excellent screening tool for intraperitoneal bleeding when combined with close clinical monitoring and serial examinations. In the moderate- or high-risk patient, it rapidly identifies acute bleeding and the need for emergent laparotomy. For patients who can be stabilized in the ED, CT scanning provides important additional information about parenchymal, retroperitoneal, and hollow viscus injury.

Figure 128.7. Intraperitoneal fluid: This image demonstrates free fluid within the peritoneal cavity. Fluid is seen as a black anechoic stripe in Morison's pouch (*arrows*), which is the potential space between the liver and the kidney.

Figure 128.8. Pleural effusion: This right upper quadrant view reveals a pleural effusion. There is loss of the mirror image artifact above the diaphragm (*D*), and a wedge of lung (*small arrow*) can be seen within the fluid (*F*). The liver (*L*) and kidney (*K*), in addition to Morison's pouch (*hollow arrow*), are seen in this view. There is no fluid in Morison's pouch.

Figure 128.9. Pericardial effusion: This is a subcostal view of the heart, revealing a large circumferential pericardial effusion. The pericardial fluid is represented by the black, anechoic area (*arrows*) between the brightly echogenic pericardium and the myocardial wall.

The Patient with Suspected Kidney Stone

The typical patient with ureteral colic is between the ages of 20 and 50 years and presents with acute onset of flank pain, vomiting, and hematuria. The choices of imaging studies available to evaluate such a patient include plain abdominal radiographs, intravenous urography (IVU), helical CT, and ultrasonography. Which study, or combination of studies, used is dependent on the ability of each study to answer the following questions: (1) Is this the correct diagnosis, (2) what is the likelihood of this stone's passing spontaneously, and (3) what are the risks to the patient?

The advantage of bedside ultrasonography is that it is quick and noninvasive and does not expose the patient to ionizing radiation or contrast. The sonographic diagnosis of kidney stones relies on the fact that most symptomatic stones cause some degree of obstruction, which can be seen as hydronephrosis ([Fig. 128.10](#)). Rarely can the sonographer visualize the stone itself. The sensitivity of ultrasonography for detecting hydronephrosis, when present, is over 90%. When combined with plain radiographs of the abdomen, ultrasonography has a sensitivity for diagnosing stones that approaches 100%.²

Figure 128.10. Hydronephrosis: This is a longitudinal view of the right kidney. There is moderate hydronephrosis, which is seen as separation of the pelvic calyces by fluid (*arrow*).

There are a number of important caveats to this statement. The first is that approximately one-fourth of patients with obstructing stones have no evidence of hydronephrosis on presentation. Repeat examination after a period of hydration and observation greatly increases the sensitivity of the ultrasonographic examination.

Second, not all hydronephrosis is due to kidney stones, and approximately 20% of patients with suspected renal colic do not have stones. Commonly encountered confounding disorders include extrinsic compression of the ureters due to tumor, urologic tumors, papillary necrosis, congenital abnormalities of the genitourinary system, polycystic kidney disease, and processes causing obstruction or impaired emptying of the bladder. Ultrasonography is inferior to CT or IVU in identifying many of these alternative causes of hydronephrosis.

Finally, ultrasonography cannot describe the amount of functional impairment secondary to the stone or predict the likelihood that the stone will pass spontaneously. Stone size is the major determinant of whether the stone will pass spontaneously, and the degree of hydronephrosis seen on US correlates poorly with either stone size or extent of obstruction. Both CT and IVU can offer superior information regarding the anatomy of the genitourinary system in addition to functional information regarding the level and degree of obstruction.

So, what is the role of ED ultrasonography? Most EM physicians with access to bedside US have found that in the patient with a classic presentation, the presence of unilateral hydronephrosis is a reassuring adjunct to their clinical impression. When combined with a KUB radiograph showing a calcification on the side of the hydronephrosis, the diagnosis of kidney stones can be made with excellent accuracy. Many of these patients can be safely discharged from the ED and scheduled for either IVU or CT at a later time. In those patients with normal examinations, either the US examination should be repeated after a period of hydration, or an alternative imaging modality (CT or IVU) chosen, if clinically indicated. In patients with contraindications to either contrast or radiation, ultrasonography remains the initial study of choice.

When alternative causes of flank pain, such as an AAA, are clinically suspected, ultrasonography can also be a useful initial screening tool. Negative studies should be followed up with a more definitive imaging study, such as CT or magnetic resonance imaging (MRI), if AAA is clinically suspected, or CT or IVU when renal calculus remains the primary clinical diagnosis.

First-Trimester Bleeding

US is invaluable in the evaluation of the patient with vaginal bleeding or pain in the first trimester of pregnancy. The primary goal is to rapidly identify those patients with ectopic pregnancy, and, secondarily, to assess fetal viability. Emergency physician use of bedside pelvic ultrasonography has been shown to significantly improve detection of ectopic pregnancies on initial presentation to the ED.¹⁰

Two sonographic techniques exist for imaging of pelvic structures. The transabdominal approach utilizes a low-frequency probe (2.5 to 3.5 MHz), and the endovaginal method employs a higher frequency, endocavitary probe (5.0 to 7.5 MHz). The two techniques of imaging the pelvis are complementary, with advantages and limitations directly related to the principles of high- versus low-frequency sonography. The transabdominal approach offers an overall view of the uterus and pelvis and is the best technique for identifying free fluid within the pelvis. The higher frequency, endovaginal probe provides a detailed, high-resolution view of the uterus, ovaries, and cul-de-sac.

Most ED-based protocols focus on using US to confirm the *presence* of an intrauterine pregnancy (IUP) in the patient with pain or bleeding in the first trimester. Endovaginal imaging has greatly enhanced the ability to visualize an IUP within 5 weeks of gestation. The first sonographic indicator of pregnancy is the gestational sac at 4.5 to 5.0 weeks; however, the yolk sac is the earliest *reliable* sign of an IUP (Fig. 128.11). A fetal pole can be seen adjacent to the yolk sac, and as early as 6 weeks the presence of embryonic cardiac activity can be readily visualized.

Figure 128.11. Intrauterine pregnancy with yolk sac and fetal pole: This is a transvaginal view of an intrauterine gestational sac with fetal pole (*large arrow*) and yolk sac (*small arrow*).

When there is no evidence of an IUP on US, subsequent clinical management depends on the quantitative beta human chorionic gonadotropin (beta-hCG) and the presence or absence of high-risk clinical findings. If the serum beta-hCG is above the discriminatory zone, the patient has an ectopic pregnancy until proven otherwise. A discriminatory zone is a cut-off level for serum beta-hCG above which an IUP should be seen.⁷ The actual value may vary by institution, with a conservative discriminatory level for endovaginal imaging being 2,000 mIU/mL (IRP). Ectopic pregnancies have been seen on US at levels below 1,000 mIU/mL, and clinical management should not be based solely on the quantitative hCG.¹

There is a spectrum of sonographic findings of ectopic pregnancy. A very early extrauterine pregnancy may have the appearance of an echogenic (or tubal) ring surrounding a hypoechoic area. Other sonographic findings include an empty extrauterine gestational sac, a ruptured ectopic with hemoperitoneum, or a mass within the adnexa. A true or definite ectopic pregnancy (defined as a thick, brightly echogenic structure outside of the uterus with a gestational sac containing a fetal pole or yolk sac) is seen in less than 5% of all patients with ectopic pregnancies¹⁰ (Fig. 128.12). The presence of an abnormal adnexal mass, free cul-de-sac fluid, and severe adnexal tenderness with probe pressure are additional worrisome findings, irrespective of the beta-hCG.

Figure 128.12. Ectopic pregnancy: This is an endovaginal view of a right adnexal ectopic pregnancy with a gestational sac (*large arrows*) and fetal pole (*small arrow*). The uterus is seen to the right of the image, with a small amount of endometrial fluid (*hollow arrows*).

In view of the spectrum of sonographic findings in the diagnosis of an ectopic pregnancy, it is an appropriate initial approach to *rule in* an IUP. If an IUP is not visualized and the beta-hCG is greater than the discriminatory zone or there are additional clinical or sonographic findings suggestive of an ectopic pregnancy, obstetric or radiologic consultation is indicated.

Potential pitfalls in the sonographic diagnosis of ectopic pregnancy include (1) failure to image patients with low beta-hCG levels, (2) failure to determine the exact location of a gestational sac, (3) mistaking an ectopic pregnancy for a corpus luteum cyst or bowel, and (4) misdiagnosing an advanced ectopic (interstitial) pregnancy as an IUP. The best way to avoid these potential pitfalls is to scan the entire pelvis, even when an IUP is identified.

When the pregnancy is determined to be intrauterine, sonography can be helpful in determining viability. One of the best indicators of fetal viability is the presence of embryonic cardiac activity. The rate of spontaneous abortion is very low (2% to 4%) if normal embryonic cardiac activity is observed. Sonographic findings suggestive of a nonviable pregnancy include (1) an irregular gestational sac, (2) a gestational sac greater than 25 mm on transabdominal US or greater than 16 mm on endovaginal US without a yolk sac or embryo, (3) an embryo that measures over 5 mm in length without a heart beat, and (4) abnormal echogenic material within the uterine cavity. The lack of embryonic cardiac activity after 8 weeks (as determined by crown rump length) is highly indicative of embryonic demise.

The presence of maternal anatomic abnormalities may occur in 10% to 15% of women with recurrent spontaneous abortion. These anatomic abnormalities include a bicornuate or septate uterus and leiomyomas, all of which are readily identified on US. Other entities that can be diagnosed with US in patients with pelvic pain, bleeding, and a positive pregnancy test include retained products of conception and hydatidiform moles.

The Nonpregnant Patient with Pelvic Pain

The nonpregnant female patient presenting with pelvic pain is a common ED complaint. The differential diagnosis is broad and includes tuboovarian abscesses (TOAs), ovarian cysts, torsion, and masses such as fibroids and teratomas. US is the primary diagnostic imaging tool used to differentiate among these disorders. Uterine fibroids are common and appear as moderately echogenic masses distorting the shape of the uterus. A degenerating fibroid can often be the source of severe lower abdominal pain, and will appear as a heterogeneous mass with fluid filled areas within or adjacent to the uterus.

Ovarian cysts are frequently seen on routine pelvic scanning. When accompanied by the presence of tenderness with palpation of the probe or pelvic fluid, the diagnosis of a leaking or ruptured cyst becomes likely. Complex ovarian masses may be noted on US, and may be due to a TOA or tumor. Although ovarian neoplastic disease is beyond the scope of this discussion, consultation with gynecology is recommended to determine further evaluation and treatment. If an ovarian torsion is suspected, endovaginal color flow sonography is recommended to determine intrinsic ovarian arterial flow.

In the evaluation of *right-sided* pelvic pain, it is important to remember that the appendix can occasionally be seen on US. In appendicitis, the appendix appears on US as a noncompressible tubular structure with a diameter greater than 7 mm. An appendicolith, which appears as a highly echogenic structure with distal shadowing, may be seen within the distended appendix. US is not the ideal screening examination for suspected appendicitis, especially when the clinical suspicion is either very high or low. In those cases, the patients should undergo either exploratory laparotomy or CT scanning. For borderline cases, ultrasonography may reveal a nonappendiceal cause of the patient's symptoms, particularly those due to gynecologic disorders.

The Patient with Suspected Deep Venous Thrombosis

The diagnosis of an acute deep venous thrombosis (DVT) often is clinically challenging because the clinical signs and symptoms are unreliable. US is the imaging modality of choice in the evaluation of suspected lower extremity DVT. Even when the study reveals no clot, it can identify other etiologies of a swollen lower extremity, such as pseudothrombophlebitis or Baker's cyst. The examination is performed with the patient in the supine position and the leg turned slightly outward. The reverse Trendelenburg position allows blood to pool into the leg veins. Most scanning is performed in the transverse orientation. The vein is compressed in the transverse orientation and repeated in increments of 1 to 2 cm. The sonographer should use only the force needed to bring the walls together. The walls must touch completely for the test to be diagnostic.

The common femoral vein should be imaged first, and is easily identified distal to the inguinal ligament. The greater saphenous vein takes off from the common femoral vein. The course of the common femoral vein extends distally under the superficial femoral artery and then divides into the superficial and deep femoral veins. Imaging should include the popliteal vein and popliteal fossa, which is territory for a Baker cyst. A large Baker cyst may cause swelling of the lower extremities by either compression of the deep veins or rupture of the cyst itself.

The best-studied diagnostic criterion for an acute DVT is loss of vein wall compressibility. Arteries are noncompressible and pulsatile. The presence of echogenic material within a noncompressible vein is further supportive evidence of a thrombus. An acute DVT is usually found centrally in the lumen. When the thrombus is obstructing, the vein is usually large and easily imaged proximate to the obstruction. Color flow imaging is helpful in distinguishing a partially obstructed vein from a total obstruction. Emergency physicians can perform color flow Doppler US to diagnosis acute DVT with reasonable accuracy.⁶ Potential pitfalls include (1) the edematous leg, (2) obesity, and (3) nonvisualization of a venous segment containing clot. Negative or nondiagnostic studies should be followed up with definitive imaging studies (venography, MRI) if there is a high clinical suspicion for DVT.

The Patient with a Pulsatile Abdominal Mass

US is a highly accurate imaging procedure for patients with an AAA. For the patient with a symptomatic AAA due to acute expansion or leakage, timely diagnosis and early surgical consultation are crucial. Ultrasonography has clear advantages over other imaging modalities as an initial screening tool when this diagnosis is clinically suspected. It can be performed at the bedside, obviating the need to take a potentially unstable patient out of the department. If a normal-sized aorta is visualized through its entire abdominal course, it is unlikely that this is the cause of a patient's symptoms. When performed immediately on arrival in the ED in patients with suspected AAA, US can rapidly confirm the diagnosis and shorten times to surgical consultation.¹⁷

The normal sonographic appearance of the abdominal aorta is that of a tapering, echogenic, and pulsatile vessel just left of midline in longitudinal orientation. It can be distinguished from the inferior vena cava by its posterior course along the lumbar spine, lack of change with respiration (sniff test), and echogenic walls. The aorta should be scanned in its entirety from the diaphragm to the bifurcation. The proximal common iliac arteries should be viewed if an aneurysm is present.

The most accurate measurement is in the AP diameter, with measurement made from outer wall to outer wall. The abdominal aorta should be no larger than 3 cm in diameter, and the aorta should taper proximate to the iliac bifurcation to a diameter of 1.0 to 1.5 cm. Loss of this taper, which is often the earliest sign of AAA, or a diameter greater than 3 cm is diagnostic of AAA. Thrombus is often noted within the lumen of the aneurysm (Fig. 128.13). Approximately 90% of AAAs are infrarenal. Identification of a normal sized aorta within 2 cm (distal) of the origin of the superior mesenteric artery should exclude involvement of the renal arteries. Potential pitfalls include (1) bowel gas obscuring the abdominal aorta; (2) tortuosity of the aorta, in which case, oblique views are often helpful; (3) obesity; and (4) failure to identify a mural thrombus.

Figure 128.13. Abdominal aortic aneurysm: This is a transverse image of a large AAA with mural thrombus (arrow). The spine is well outlined posteriorly.

The role of bedside US is to confirm or exclude the presence of AAA. US is not useful in making the diagnosis of dissection or rupture, and alternative imaging studies should be obtained when these complications of AAA are suspected. For those patients with hemodynamic instability and AAA on US, the diagnosis of rupture can be inferred, and urgent surgical consultation is indicated. Approximately one-fourth of all aneurysms will rupture intraperitoneally, and a rupture can be seen on bedside sonography as free intraperitoneal fluid.

ULTRASOUND-ASSISTED PROCEDURES

US-assisted procedures include identification and localization of abscesses and foreign bodies and identification and staging of hematomas, paracentesis, pericardiocentesis, and joint aspiration, as well as vascular access.¹⁶

Abscess

US may assist in determination and localization of an abscess, depending on the stage of the process. A variety of echogenic patterns have been described, including an anechoic, hypoechoic, or hyperechoic mass or diffuse echogenicity with no demonstrable mass. The presence of posterior acoustic enhancement is very helpful diagnostically in the determination of an abscess or liquid-filled mass versus a solid mass (see [Fig. 128.3](#)).

Foreign Body

Emergency physicians are commonly faced with the problem of extracting soft-tissue foreign bodies that are complicating wounds, and US may have a role in identification and removal.¹⁶ Foreign bodies as small as 0.5 mm can be readily identified on US, with wooden foreign bodies (acutely) best visualized, then glass, plastic, and metal. Secondary signs, such as hematoma, abscess formation, or air trails (acutely), may assist in localization.

Hematomas

Hematomas can be sonographically identified and staged. The initial appearance is hypoechoic. After several hours, a fluid level appears and the echogenic clot will be in the dependent portion of the hematoma. Within several days, the fluid appears anechoic. Hematoma formation is the hallmark of muscle rupture.

Nontraumatic Intraperitoneal Fluid

US can readily identify and localize intraperitoneal fluid collections. Ascites may be loculated, depending on the presence of adhesions. US may provide assistance in localizing the optimum approach to fluid collections prior to paracentesis. In addition, patient positioning and the effects of abdominal palpation may be viewed. In a similar manner, pleural fluid can be identified prior to and following aspiration.

Pericardiocentesis

Blind pericardiocentesis is often accompanied by complications, with an associated mortality of up to 6%. Echocardiography-guided pericardiocentesis is now performed routinely in many EDs and is considered the procedure of choice for removal of hemodynamically significant pericardial effusions. Under US guidance, the site of needle entry is the point at which the largest amount of fluid is closest to the body surface, without injuring vital structures. The left chest wall has become the preferred site of needle entry instead of the subcostal approach.¹⁹ A 3.5- to 5.0-MHz transducer held in the subcostal position is recommended. The probe is held under a transparent plastic surgical sheet, thus allowing US imaging and a sterile field.

Joint Aspiration

Joint aspiration is routinely performed in the ED. US can identify joint effusions and demonstrate enhanced patient positioning for fluid aspiration¹⁶ ([Fig. 128.14](#)). In addition, US can demonstrate the presence of synovial proliferation, especially in inflammatory arthritis, and predict success or failure of joint aspiration.

Figure 128.14. Knee joint effusion: This transverse suprapatellar view of the knee reveals a large joint effusion. The patella is well outlined inferiorly.

Central Vein Cannulation

US-assisted internal vein catheterization in the ED has been described as particularly useful in patients with no visible or palpable anatomic landmarks. US has been associated with an increased rate of successful internal jugular cannulation in at least one prospective trial.³

SUSPECTED SEPTIC, HEMOPHILIC, OR INFLAMMATORY ARTHRITIS

US has proven accuracy in the determination and characterization of joint effusions and hence in the diagnoses of septic, hemophilic, or inflammatory arthritis. It can detect as little as 1 mL of intraarticular fluid and is more sensitive than blind aspiration. Although not commonly performed in the ED, imaging of the joints has distinct clinical promise. Large joints are readily imaged with a variety of sonographic windows. The affected joint is identified and compared with the normal side by use of the split-screen function on the US machine. The most commonly utilized probe for this application is a linear array probe (5 to 10 MHz).

Simple joint effusions are typically anechoic or hypoechoic in appearance (see [Fig. 128.14](#)). In septic arthritis, the fluid frequently has a hypoechoic appearance, with internal echoes in addition to synovial irregularity and joint capsule thickening. However, a septic arthritis cannot be ruled out solely based on the sonographic appearance. Hemarthrosis can be difficult to distinguish from a simple effusion. Lipohemarthrosis has the sonographic appearance of a two-layer effusion, with the superior layer being fat and the inferior layer blood.

CARDIAC APPLICATIONS

One of the more useful clinical applications of US is the assessment of the patient who presents with acute hemodynamic instability or pulseless electrical activity (PEA). PEA is defined as the absence of a discernible pulse in the presence of electrical activity observed on a cardiac monitor. The causes are multifactorial and can be broken down into those that compromise cardiac filling (hemorrhage, pneumothorax, and tamponade) and those that are due to poor myocardial contractility (cardiogenic shock). The resuscitation efforts depend on the physician's interpretation of history and physical findings on presentation, which are often unreliable and

nonspecific.

Immediate application of US can quickly sort out these very distinct clinical entities. When performed by EM physicians, the use of echocardiography has been shown to reduce time to identification and treatment of clinically significant pericardial effusions due to trauma and cardiac rupture, with significant improvements in overall mortality.^{12,13} Bedside sonography can not only assist in differentiation among the various causes of PEA⁵, but also allow the clinician to continuously assess the response, or lack of response, to interventions. The sonographer typically utilizes a subcostal or long-axis parasternal view. The benefit of the subcostal view is that it can be performed simultaneously while other chest procedures and tests are being performed. Both views rapidly identify a large pericardial effusion and grossly assess vigor of cardiac wall motion (see [Fig. 128.9](#)). The parasternal long-axis view provides superior views of the left ventricle wall, valve motion, and posterior pericardium.

Clinically significant pericardial effusions are easily visualized with ultrasonography. The pericardial sac is a fibrous, echogenic structure that surrounds the heart, and there is normally a small amount of pericardial fluid within the dependent portion of the sac. Greater amounts of fluid are easily seen as an anechoic space between the pericardium and the heart. Small amounts of fluid usually collect in the dependent portion of the heart, but clinically significant effusions are circumferential. In large effusions, there may be echogenic material due to fibrin or clot formation within the pericardial space. The presence of fluid alone does not indicate tamponade physiology. The echocardiographic diagnostic criteria for tamponade are often subtle and not within the purview of most EM sonographers. The most important finding is the presence of a large circumferential effusion, a hyperdynamic heart, and collapse of the right atria and ventricle during diastole.

Other clinically significant findings that can be helpful in guiding therapy include the inability to visualize the heart, suggesting the presence of air within the pleural space, as in a pneumothorax. The presence of a hyperdynamic heart without fluid in the pericardial sac leads the clinician to search for signs of hemorrhage and suggest volume resuscitation as an initial step. A large, dilated right ventricle in the setting of hypotension and hypoxia is suggestive of a large pulmonary embolus.⁵ Poor or absent cardiac contractility indicates a primary cardiac cause and suggests the need for inotropic therapy. Bedside sonography can provide immediate confirmation of the patient's response to resuscitative measures. Patients with poor or absent cardiac activity have a poor prognosis, and lack of response to therapy can support termination of resuscitative efforts.

If a primary cardiac cause of instability cannot be readily identified, US can be used to search for other potential reversible causes, specifically evidence of acute blood loss. Fluid within the pleural cavity can be identified with excellent sensitivity,⁹ and often before the chest radiograph can be performed. Large amounts of free fluid within the peritoneal cavity may indicate spontaneous splenic rupture or ruptured ectopic pregnancy. Identification of a large aortic aneurysm in the setting of hypo-tension suggests a leaking aneurysm, and surgery should be consulted immediately. Fluid above or below the diaphragm can appear as pericardial fluid, and the sonographer should make all efforts to confirm the location of the fluid. The subcostal view will not show fluid within the pleural space. Fluid within the peritoneal cavity will not follow the contours of the heart, and imaging from a number of positions will usually clarify its location.

The limitations of US are largely related to operator experience, patient body habitus, and suboptimal imaging conditions—the sonographic imaging is usually being performed in the midst of a major resuscitative effort. Identification of clinically significant pericardial effusions and a gross assessment of cardiac wall motion can be readily achieved under these conditions. Further clinical information regarding cardiac wall motion, valve function and chamber size, and aortic caliber should be performed only by those with sufficient imaging experience.

SUMMARY

The clinical applications for US within the ED will continue to expand as both experience and technology improve. EM physicians will play an increasingly central role in the performance and interpretation of examinations used to answer discrete and directed clinical questions. In particular, EM physicians are uniquely positioned to play a key role in the performance of ultrasonographic examinations in those clinical situations that require immediate assessment, such as patients with acute instability, both traumatic and atraumatic. EM physicians performing US for less urgent situations must work collaboratively with the radiologists, cardiologists, and other subspecialists with ultrasonographic expertise in their institution to ensure that this exciting technology is being used to ensure both rapid and expert patient care.

The modern era of cardiopulmonary resuscitation (CPR) has been marked by the development of closed-chest cardiac massage, artificial respiration, and electrical defibrillation into a practical set of techniques for the treatment of patients in cardiac arrest. After its introduction in 1960, closed-chest CPR was shown to be successful in resuscitating approximately 25% of patients from in-hospital cardiac arrests. However, it was soon realized that the vast majority of patients suffered cardiac arrest outside a hospital and that most patients who die of myocardial infarction succumb to arrhythmias within the first hour after the infarction. The concept of extending treatment into the community was developed in the 1970s. Pioneering studies in Belfast, New York, Seattle, and other cities demonstrated that emergency medical services (EMS) providing advanced cardiac life support (ACLS) by trained paramedics could significantly improve resuscitation and survival in patients suffering cardiac arrest. Thus an effective approach to cardiac arrest required the development of new concepts for bringing emergency care into the community.^{6,15}

Improvements in the treatment of patients in cardiac arrest have generally come by evaluating cardiac arrest as a systems problem that requires new solutions beyond the traditional medical model. Advances have come with community solutions such as the development of an out-of-hospital community emergency medical care system and the training of laypersons to deliver CPR.¹⁶ More recently, the development of the automatic external defibrillator further extends the possibilities for community treatment. Public-access defibrillation holds the promise of providing early defibrillation in the community by trained persons, such as security guards and flight attendants, prior to the arrival of the EMS medics.^{6,15,16}

BASIC CARDIOPULMONARY RESUSCITATION

The function of basic CPR is to provide some blood flow to vital organs until more definitive treatment, such as defibrillation, can be initiated. There has been some debate about the efficacy of CPR in the resuscitation of patients in cardiac arrest. Although studies from one city with a rapid-response EMS system have failed to show the benefit of layperson CPR in the resuscitation of victims of cardiac arrest, other studies from several cities have demonstrated that the earlier CPR is applied, the better is the outcome.^{6,15} It is important to remember, however, that CPR itself usually does not resuscitate patients from cardiac arrest. CPR must be accompanied by the early institution of advanced life support.

The importance of early defibrillation is emphasized by the concept of “phone first,” in which laypersons are taught to activate the EMS system before CPR is started in adults in cardiac arrest.¹⁵ This concept recognizes the importance of getting the defibrillator to the scene as soon as possible. The standard technique of CPR includes chest compression and ventilation. It is designed to provide some blood flow to vital organs until more definitive therapy, such as defibrillation, is available.

There has also been much debate about the mechanism of blood flow during closed-chest compression. Some authorities believe that the thorax acts as a pump when the chest is compressed and that pressure gradients are generated between the intrathoracic and extrathoracic structures. Other authorities believe that the heart itself is compressed during chest massage and that pressure gradients are developed between intracardiac and extracardiac structures. If the mechanism of blood flow during CPR were known, techniques could be developed to increase blood flow to vital organs. For example, if the thorax-pump mechanism of blood flow predominates, techniques that maximize thoracic pressure differences, such as simultaneous ventilation and compression, or abdominal binding, might improve cardiac output during CPR. On the other hand, if the heart acts as the pump during chest compression, one could improve cardiac output by increasing the number of chest compressions per minute. Although studies investigating these alternative forms of CPR have yielded encouraging results in specific laboratories or animal models, there are not yet enough data in humans to determine which mechanism of blood flow predominates. There may even be a dimorphic population, meaning that thorax compression may predominate in some persons and cardiac compression in others.

Thus far, no alternative CPR techniques have yielded improved resuscitation or survival rates in clinical studies. Therefore, the standard technique of CPR has changed little over the past decade.

Airway

In approaching the victim of cardiac arrest, one must assess unresponsiveness, activate the system for initiating advanced life support, and position the patient on the floor or a backboard to assess the airway. The tongue may fall back and obstruct the airway. Rescuers may open the airway by using the head tilt–chin lift maneuver (Fig. 129.1). The rescuer places backward pressure on the patient’s forehead while lifting the chin anteriorly. This maneuver pushes the tongue and epiglottis forward, removing the obstruction.

Figure 129.1. Opening the airway. (Top) Airway obstruction produced by tongue and epiglottis. (Bottom) Obstruction is relieved by head tilt–chin lift. (Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Guidelines for cardiopulmonary resuscitation and emergency cardiac care, I: introduction.

The head tilt–chin lift maneuver should not be used if neck injury is suspected for any reason. In patients with possible neck injury, the jaw thrust maneuver is used. Pressure applied to the angles of the mandible moves the jaw anteriorly, opening the airway.

Breathing

Once the airway is open, the rescuer looks, listens, and feels for an exchange of air. If the patient is not breathing, mouth-to-mouth respirations are administered by pinching the victim's nostrils and blowing slowly into the mouth for two breaths. The rescuer watches for the rise and fall of the chest during ventilation. The patient receives ten to 12 breaths per minute, with each ventilation lasting 1.5 to 2.0 seconds. Slow ventilations, with time for complete exhalations, may result in less gastric distention and less potential for regurgitation and aspiration. The patient should be intubated and ventilated with oxygen as soon as it is practical in the ACLS sequence. After endotracheal intubation, the rescuers do not need to pause between compressions for ventilation to be given.

Obstructed Airway

If the rescuer has optimally positioned the jaw, chin, and tongue and still cannot detect adequate air exchange, one must be concerned about an obstructed airway. The Heimlich maneuver, or subdiaphragmatic abdominal thrust, is the recommended procedure for clearing the obstructed airway of a foreign body (Fig. 129.2). The rescuer's hand is positioned between the patient's xiphoid and navel, and several quick thrusts are administered in an attempt to relieve the foreign-body obstruction. In the unconscious victim, the Heimlich maneuver may be accompanied by attempts to visualize the foreign body in the pharynx and by finger sweeps to remove the foreign body. Complications of the Heimlich maneuver include regurgitation, aspiration, and traumatic injury to the abdomen. ¹⁵

Figure 129.2. (Top) Administration of Heimlich maneuver to *conscious* victim of foreign-body airway obstruction. **(Bottom)** Administration of Heimlich maneuver to *unconscious* victim of foreign-body airway obstruction. (Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Guidelines for cardiopulmonary resuscitation and emergency cardiac care, I: introduction. JAMA 1992;268:2172.)

Circulation

The rescuer determines pulselessness through palpation of the carotid. If no pulse is detected, chest compressions should be instituted. After placing the victim on a backboard or firm surface, the heel of the hand is placed on the lower half of the sternum and depressed 1.5 to 2.0 in. The recommended compression rate is 80 to 100 times per minute. ¹⁵ The duration of compression should be 50% of the entire compression–release cycle. A 5:1 ratio of compression to ventilation is used when there are two or more rescuers. When there is only one rescuer, the ratio should be 15 compressions to two ventilations. ¹⁵

Closed-chest compression can provide 10% to 30% of normal cardiac output. The key hemodynamic parameter that predicts whether resuscitation will be successful is the aortic diastolic pressure. Animal studies have shown that if an aortic diastolic pressure of 40 mm Hg can be generated during CPR, there is an excellent chance of successful resuscitation, presumably because it is during diastole that the coronary arteries are filled.

Mechanical resuscitators are commercially available that deliver standard American Heart Association chest compression and ventilation. These resuscitators have been shown to produce pressures comparable to manual CPR. Once applied, the resuscitators deliver standard CPR throughout the resuscitation effort, freeing personnel to perform ACLS.

Alternative Cardiopulmonary Resuscitation Techniques

A number of alternatives to the standard CPR technique have been proposed, based on theoretical advantages in achieving higher cardiac output during CPR. Although many of the techniques have shown promise in laboratory investigations and limited clinical studies, none has yielded improved survival from cardiac arrest when compared with standard CPR. The most promising techniques include interposed abdominal compression CPR (IAC-CPR), active compression–decompression CPR (ACD-CPR), simultaneous ventilation compression CPR (SVC-CPR), and high-frequency CPR.

IAC-CPR involves compression of the abdomen by a second rescuer during the relaxation phase of chest compression. IAC-CPR has been shown to improve the aortic systolic and diastolic pressure, as well as cardiac output and myocardial perfusion pressures, when compared with standard CPR in experimental models. Clinical studies comparing IAC-CPR with standard CPR have shown some promise. ¹³ The technique requires an additional rescuer, however, and compression of the abdomen may predispose to complications such as abdominal injury and aspiration if used in patients with unprotected airways. The role of IAC-CPR needs to be defined by future clinical studies.

ACD-CPR makes use of a suction device that is applied to the anterior thorax and creates negative intrathoracic pressure during the relaxation phase of CPR. Studies in experimental models and humans in cardiac arrest have demonstrated improvement in some hemodynamic parameters but not in others. Clinical trials of the device have demonstrated mixed results. ⁴

SVC-CPR attempts to use the entire thorax as the pump to produce forward blood flow. Chest compression is applied at full inspiration to maximize the gradient between intrathoracic and extrathoracic structures. A newer circumferential vest CPR has shown improved hemodynamics in limited clinical trials. ⁸ High-frequency or rapid-compression-rate CPR has been shown in experimental models to improve cardiac output, myocardial perfusion pressures, and 24-hour survival compared with standard CPR. Clinical studies are limited, but there is some evidence for improved hemodynamics using rapid manual compression rates. ⁹

Other studies have questioned the role of ventilation as a standard part of layperson CPR. In experimental models of cardiac arrest, chest-compression-only CPR provides outcomes comparable to conventional CPR. While professional health-care providers will continue to provide ventilation with basic life support, further clinical trials are needed before any recommendations can be made regarding the option of chest-compression-only CPR for lay rescuers. ²

Studies evaluating these alternative techniques of CPR appear to show benefits in some groups of patients but not in others. One explanation may be that certain physiologic characteristics may be more important in some subsets of patients than in others. For example, patients who are obese or have large anterior–posterior chest diameters probably receive no direct cardiac compression during standard CPR but might benefit from techniques designed to take advantage of the thorax mechanism of forward blood flow, such as SVC-CPR. Patients with a thin body habitus, for whom cardiac compression may be the primary mechanism of forward blood flow, might benefit from techniques such as rapid-compression-rate CPR. It may be that the use of one standard method of CPR for all patients in cardiac arrest

is inappropriate. At the present time, however, these alternative techniques of CPR should be considered experimental.

ADVANCED CARDIAC LIFE SUPPORT

Because the recommended treatment protocols are based on the patient's underlying rhythm, it is important that electrocardiographic (ECG) monitor leads be placed early and followed throughout the resuscitation attempt. If the patient is in ventricular fibrillation, immediate defibrillation is recommended even before CPR, intubation, and other interventions. As soon as possible, the patient is endotracheally intubated and an intravenous line is placed. Peripheral lines may be placed in the antecubital area, or central lines through the internal or external jugular veins. Peripheral lines should not be placed in the lower half of the body, because external chest compression results in retrograde blood flow through the vena cava (because there are no valves in the inferior vena cava).¹⁵

Defibrillation

Early defibrillation is the one intervention that has been repeatedly shown to be efficacious for patients in pulseless ventricular tachycardia or ventricular fibrillation. The longer the patient remains in fibrillation, the more likely it is that defibrillation and resuscitation will be unsuccessful.^{6,15} It is the current passing directly through the heart that allows defibrillation. Current is directly related to the energy set on the defibrillator and inversely related to the transthoracic impedance. The transthoracic impedance can be minimized by attention to several factors, including position of the defibrillation paddles, firm pressure on the paddles, the use of conductive material between the skin and paddles, employing sets of shocks (pairs or triplets), and coordinating the shock with the end-expiratory phase of ventilation.¹⁵

A precordial thump generates 0.5 to 1.0 joule of energy. Rarely, when applied early to a patient in cardiac arrest, a precordial thump can convert ventricular fibrillation to a perfusing rhythm; pulseless ventricular tachycardia may be converted to a perfusing rhythm in 11% to 25% of cases. However, a thump can also convert ventricular tachycardia to a more malignant dysrhythmia, such as ventricular fibrillation, asystole, or pulseless electrical activity (PEA). The precordial thump may be used for patients with witnessed cardiac arrest while another rescuer is preparing the defibrillator. It should, however, never delay the definitive treatment—electrical defibrillation.

The automatic external defibrillator (AED) is capable of analyzing the rhythm of a patient in cardiac arrest and shocking the patient per ACLS protocols. Semiautomatic external defibrillators analyze the rhythm and advise the rescuer to attempt defibrillation through the sensing electrodes.¹⁹ These devices extend the capability of EMS systems to reach victims of cardiac arrest earlier. Rescue workers and even spouses of high-risk patients can be trained to operate the AED. Some communities have trained basic emergency medical technicians (EMTs) in the recognition of ventricular fibrillation and the use of defibrillators, providing for early defibrillation in communities in which paramedics cannot respond to cardiac arrests within a few minutes.¹⁵ AEDs have also been advocated for use by other professionals who may come in contact with patients in cardiac arrest. These include security guards, airline flight attendants, and police officers in situations in which EMS responders might not be immediately available. The use of AEDs might help some communities solve the difficult issue of prompt defibrillation. The place of public access defibrillation in community EMS systems remains to be determined by future clinical studies and individual community needs and resources.

Pressor Agents

Epinephrine, a mixed α - and β -adrenergic agent, is the pressor drug of choice for patients in cardiac arrest.¹⁵ Epinephrine increases peripheral vascular resistance and raises aortic diastolic pressure, thus augmenting coronary blood flow. It also increases cerebral blood flow during cardiac arrest. The recommended dose is 1 mg initially, with repeated doses every 3 to 5 minutes,¹⁵ but the optimal dose has not been established. Although there is some evidence that higher doses of epinephrine may increase myocardial and central nervous system blood flow, several outcome studies have failed to demonstrate any difference in survival to hospital discharge with standard-dose compared with high-dose epinephrine.³ In fact, there is some evidence that high doses of epinephrine may result in worse neurologic outcome.^{1,7} Thus, after the initial 1-mg dose, subsequent doses may be higher based on the treating physician's discretion. Epinephrine can also be given through the endotracheal tube; the dose is two to two and one-half times the intravenous dose. Vasopressin is a potent vasopressor that has been shown to improve cardiac as well as cerebral blood flows in cardiac arrest. The role of vasopressin as an alternative to epinephrine is being investigated in larger clinical trials.¹²

Acid–Base Abnormalities

The optimal treatment of acidosis during cardiac arrest is hyperventilation. The role of bicarbonate administration is controversial. The patient in cardiac arrest develops lactic acidemia from poor tissue perfusion, but lactic acid does not accumulate significantly until relatively late in the course (20 or more minutes of total arrest time). Many patients in cardiac arrest also develop a venous respiratory acidosis because they are unable to transport CO_2 to the lungs where it may be excreted.²⁰ This CO_2 readily crosses membranes and may worsen intracellular and central nervous system acidosis. If bicarbonate is given to a patient in cardiac arrest, CO_2 is generated by the buffering of metabolic acids and PCO_2 increases locally. Thus, bicarbonate may actually worsen the acid–base status. In addition, overzealous administration of bicarbonate can produce alkalosis and hyperosmolarity, both of which are associated with a poor prognosis. Clearly, however, there are patients in cardiac arrest in whom aggressive treatment with bicarbonate can be life-saving. These include patients with hyperkalemia and those with tricyclic antidepressant overdose. In addition, patients with other drug overdoses and those with preexisting metabolic acidosis may benefit from early treatment with bicarbonate. Arterial and central venous blood gases may be useful in assessing acid–base status and the advisability of administering bicarbonate for patients in cardiac arrest.

Antiarrhythmic Agents

No studies have shown that antiarrhythmics improve survival from cardiac arrest. Many of the antiarrhythmic agents raise the fibrillation threshold, however, and are thus useful in preventing recurrent ventricular fibrillation in patients who have been successfully defibrillated. Antiarrhythmic agents that may be beneficial in the treatment of patients in ventricular fibrillation include amiodarone, lidocaine, bretylium, magnesium sulfate, and procainamide. Amiodarone may be an important drug for the treatment of patients in persistent ventricular fibrillation or pulseless ventricular tachycardia resistant to electrical defibrillation. In one study,¹¹ it improved the rate of return of spontaneous circulation and admission to the hospital for patients with out-of-hospital ventricular fibrillation unresponsive to electrical defibrillation. Studies assessing the effects of amiodarone on the rate of discharge from the hospital and on long-term survival will determine the place of amiodarone in ACLS algorithms. Lidocaine has been used in the treatment of patients in cardiac arrest for many years. In clinical studies, no difference in overall resuscitation or survival has been seen when lidocaine and bretylium are compared in patients with ventricular fibrillation. In general, when antiarrhythmic agents are administered, they should be followed by immediate attempts at electrical defibrillation so that the sequence of drug-shock-drug-shock is maintained.

Atropine

Atropine may be useful in some patients with asystolic cardiac arrest who have an excess of parasympathetic stimulation. Studies in the prehospital use of atropine have shown improved resuscitation rates but not improved overall survival in patients in asystolic arrest.¹⁷ Atropine is also useful in patients with symptomatic bradycardia.

Pacemakers in Cardiac Arrest

The wide adoption of transcutaneous cardiac pacing has extended the availability of pacemakers to many patients. Transcutaneous pacing capability is often a feature of newer defibrillators. Pacing is indicated in patients with hemodynamically unstable bradycardia and may also be useful for overdrive pacing patients with tachycardia unresponsive to pharmacologic therapy. Although the successful use of pacing for patients in asystolic cardiac arrest has been reported anecdotally, most studies have failed to show significant improvements in resuscitation rates. Thus, pacemakers cannot be recommended for routine use in asystolic cardiac arrest. If pacing is used in the management of patients in cardiac arrest, however, it should be applied early.

GUIDELINES FOR CARDIAC ARREST

Guidelines for the treatment of patients in cardiac arrest have been developed by the American Heart Association.¹⁵ They are updated every few years; clinicians should be aware of the updated versions. Although the ACLS treatment for patients in cardiac arrest is based on the ECG monitor rhythm, the clinician must always consider the etiology of the arrest in developing a treatment plan. Cardiac arrest is the end point of a physiologic process that results in the loss of circulation or

ventilation. Etiologies such as respiratory failure, asthma, medication toxicity, hypovolemia, pulmonary embolism, sepsis, trauma, acute myocardial infarction, anaphylaxis, metabolic abnormalities, and others may be treated specifically while going through the ACLS algorithm. ¹⁰

Patients in cardiac arrest present with either ventricular fibrillation–pulseless ventricular tachycardia (Fig. 129.3), asystole (Fig. 129.4), or PEA (Fig. 129.5). Treatment modalities have been classified by a consensus of experts based on the scientific evidence of their efficacy and safety, as follows:

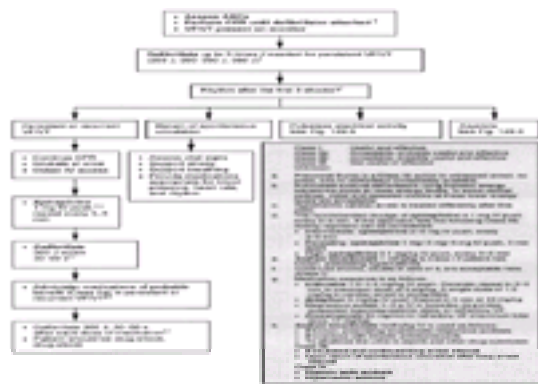

Figure 129.3. Ventricular fibrillation–pulseless ventricular tachycardia (VF/VT) algorithm. (1997–99 Handbook of emergency cardiovascular care for healthcare providers. American Heart Association, Dallas, 1997.)

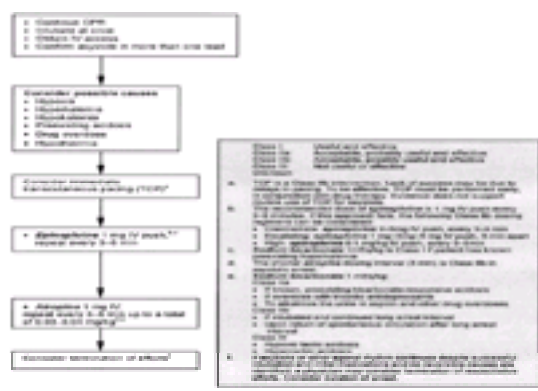

Figure 129.4. Asystole algorithm. (1997–99 Handbook of emergency cardiovascular care for healthcare providers. American Heart Association, Dallas, 1997.)

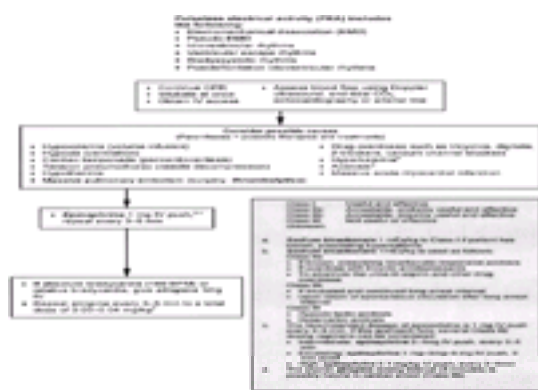

Figure 129.5. Pulseless electrical activity (PEA) algorithm. (1997–99 Handbook of emergency cardiovascular care for healthcare providers. American Heart Association, Dallas, 1997.)

- Class I: Definitely helpful
- Class IIa: Acceptable, probably helpful
- Class IIb: Acceptable, possibly helpful
- Class III: Not indicated, may be harmful

Ventricular Fibrillation and Pulseless Ventricular Tachycardia

The key to the treatment of patients with ventricular fibrillation or pulseless ventricular tachycardia is to remember that successful resuscitation depends on electrical defibrillation. All other treatments, including CPR, intubation, and drugs, are merely attempts to prepare the patient for successful defibrillation. Defibrillation should be attempted with up to three shocks as soon as the diagnosis is made. ¹⁵ Shocking the patient several times in a row decreases the transthoracic impedance and increases the chances for successful defibrillation. If defibrillation attempts are unsuccessful, CPR is initiated, the trachea is intubated, and an intravenous line is placed as soon as possible. Epinephrine is the first recommended pharmacologic agent; repeat doses should be given every 3 to 5 minutes until defibrillation is successful. Each administration of drug should be followed by attempts at electrical defibrillation. Antiarrhythmic drugs may be useful in preventing refrillation once the patient has been electrically defibrillated. Lidocaine is frequently given as the first antiarrhythmic agent. In the future, amiodarone may be the first antiarrhythmic drug recommended. If this is ineffective, treatment with bretylium, magnesium sulfate, and procainamide may be considered. Treatment with bicarbonate should be initiated if there is any clinical suspicion of hyperkalemia, tricyclic antidepressant, or preexisting acidosis. ¹⁵

Asystole

The asystolic patient has a poor prognosis for resuscitation. However, because some patients who appear to be asystolic are actually in fine ventricular fibrillation, the diagnosis of asystole must be confirmed by checking for a straight-line rhythm on three leads. If there is any suspicion that ventricular fibrillation is present, one should proceed with defibrillation as in the ventricular fibrillation protocol. For asystole, one must consider possible causes such as hypoxia, drug overdose, hypothermia, and electrolyte imbalance. As noted previously, transcutaneous pacing has not generally been efficacious for patients in asystole. If it is used in selected patients, however, it should be applied early in the treatment protocol. Pharmacologic treatment of asystole involves the use of epinephrine to improve myocardial and cerebral blood flow during CPR, and atropine to antagonize parasympathetic stimulation. ¹⁵

Pulseless Electrical Activity

PEA describes a situation in which there is an electrical rhythm other than ventricular tachycardia or fibrillation, but no palpable pulses. This condition may be due to true electromechanical dissociation (EMD), in which the heart muscle itself is not contracting despite the presence of electrical activity. True EMD has a very poor prognosis. However, PEA may also be due to states of severely decreased flow, so patients must be evaluated for cardiac and extracardiac causes of severe shock. Bedside ultrasonography may allow the treating physician to determine whether the heart is beating and whether pericardial fluid is present. Alternatively, the placement of an arterial line can be used to differentiate severe shock states from true EMD. In cases in which these modalities are not available, the clinician must consider causes such as hypovolemia, hypoxia, cardiac tamponade, tension pneumothorax, hypothermia, pulmonary embolism, drug overdose, acidosis, and

electrolyte imbalance. A thorough reevaluation of the respiratory system is also critical. This may involve reintubation of the patient or confirmation of endotracheal tube placement both visually and with capnometry. The possibility of pneumothorax should be evaluated by listening to breath sounds bilaterally; if necessary, needle decompression can be performed to rule out a tension pneumothorax. Pericardiocentesis may help to identify cardiac tamponade if bedside ultrasonography is not available. Arterial blood gases may be particularly useful in patients with PEA to determine oxygen and acid–base status. Empiric treatment with a fluid bolus while evaluating for acute blood loss from gastrointestinal hemorrhage, ruptured aortic aneurysm, or other causes for hypovolemia may also be useful. Once extracardiac causes of EMD are ruled out, treatment recommendations include epinephrine to improve myocardial and cerebral blood flow during cardiac arrest, and atropine if the ECG shows bradycardia.

Initiating and Discontinuing Resuscitation Efforts

CPR should be instituted for all patients in cardiac arrest, except in two circumstances:

1. The patient made it clear, while competent and informed, that he or she did not want resuscitation efforts to be instituted.
2. Successful resuscitation would be futile because the patient has clear signs of irreversible death, such as rigor mortis, dependent lividity, or decapitation.

Emergency physicians and paramedics are obligated to respect patients' wishes regarding resuscitation. In most cases, these wishes may be known through documentation on advance directives. Many EMS communities throughout the United States have developed a standardized “do not attempt resuscitation” (DNAR) form that patients and their physicians can fill out, documenting their wishes, and present to paramedics. Portable or prehospital DNAR orders are likely to become more commonplace over the next decade and should be respected by emergency health-care professionals.

Once undertaken, resuscitation efforts are generally continued until it is clear that the patient is not responding to them. The longer the patient remains in cardiac arrest without response, the worse the prognosis for survival. There is, however, no definitive time interval that can predict the impossibility of survival after cardiac arrest. Indeed, special circumstances, such as hypothermic arrest in a child, may dictate prolonged resuscitation efforts. Thus, clinicians must use their judgment in going through the ACLS protocols and determining unresponsiveness to resuscitation.

INVASIVE CARDIOPULMONARY RESUSCITATION

Studies in animal models have shown that techniques of invasive CPR, such as open chest CPR and cardiopulmonary bypass, and the use of direct mechanical assist devices improve hemodynamics, resuscitation, and the chances of surviving cardiac arrest. It has also been demonstrated that when invasive CPR is applied late in the treatment protocol (after more than 15 to 20 minutes of total arrest time), there is no improvement in resuscitation. At the present time, however, these techniques should be used only in the context of well-defined experimental protocols and should not be used as last-ditch efforts for patients who do not respond to standard ACLS protocols.

QUALITY OF RESUSCITATION EFFORTS

How well CPR is performed and ACLS delivered does make a difference in the outcome for patients in cardiac arrest. Unfortunately, the performance of CPR is frequently not optimal.¹⁸ Ideally, the quality of resuscitation efforts might be best assessed by monitoring pressures during CPR so that the diastolic pressure gradient could be maximized, but this is clearly impractical except under special circumstances. The use of capnometry to monitor end-tidal CO₂ levels during CPR gives clinicians a noninvasive assessment of the cardiac output generated by CPR.¹⁴ The quality of resuscitation efforts should also be assessed retrospectively by systematically tracking key variables and the outcome of resuscitation efforts in both the in-hospital and out-of-hospital setting.⁵

PROGNOSIS

The prognosis for survival of cardiac arrest depends on many factors. These include patient variables such as the etiology of the arrest and comorbid diseases, arrest variables such as initial rhythm, and system variables such as time to CPR and defibrillation.⁵ None of these variables, by themselves or in combination, can accurately predict survival or neurologic outcome. However, it has been demonstrated in several studies that the longer the patient remains in cardiac arrest, the poorer the chances for successful resuscitation.⁹

The presenting rhythm is the most important factor in overall prognosis. Rhythms that are amenable to treatment with electrical defibrillation (ventricular tachycardia and ventricular fibrillation) have a relatively good prognosis, whereas asystole and EMD usually have poor outcomes. Resuscitation success for patients in ventricular fibrillation depends on the time elapsed before the patient is defibrillated; the longer the patient remains in ventricular fibrillation, the less likely is successful defibrillation.^{6,15} In units where staff are prepared to treat cardiac patients for ventricular arrhythmias promptly, successful defibrillation is nearly universal.
