ANSWERS TO CASE STUDY QUESTIONS

Case Summary: This trauma patient had surgery to repair bone fractures. After surgery, his WBC count was elevated with a predominance of bands. The platelet count and hemoglobin were also below the reference range for his age and sex. Although a bacterial infection was suspected based on the CBC, cultures were negative. Despite the high WBC count and shift to the left, there were no toxic changes of the leukocytes. After further review, it was determined that Dennis had Pelger-Huët anomaly. The bands were actually mature neutrophils whose nucleus failed to segment.

Question:

1. What results, if any, are abnormal?

Explanation:

The white blood count and number of bands are elevated.

Question:

2. What is the most likely reason for these results?

Explanation:

The most likely reason for an elevated white count and left shift on a trauma patient who has had emergency surgery is a bacterial infection acquired either from the original trauma or during surgery. Leukocytosis without toxic changes present or a shift to the left may occur in post-surgical patients.

Question:

3. Given the leukocyte morphology and cultures, what additional condition must now be considered?

Explanation:

Because the cultures are all negative and there are no other indications of a reactive process, such as toxic granulation, Döhle bodies, or vacuoles, it is unlikely the patient has an infection. Pelger-Huët anomaly is a benign inherited condition in which the neutrophils have hyposegmentation. The nuclei are shaped like dumbbells or wire-rimmed eyeglasses and have very condensed chromatin.

Question:

4. Explain the clinical significance of the nuclear anomaly described in this patient.

Explanation:

Pelger-Huët anomaly is benign, and the neutrophils appear to function normally. The greatest significance of this disorder is that it be recognized and cells not mistakenly identified as bands leading to an incorrect diagnosis of infection. In this case, the patient had additional tests (the cultures) performed that probably were not necessary had the condition been diagnosed previously.

Question:

5. Why is the white count elevated?

Explanation:

Pelger-Huët does not typically present with leukocytosis unless it is accompanied by another condition. The white count is probably increased due to tissue damage from the accident trauma and/or the surgery. Also, although the patient's hemoglobin is only low normal, it is likely that a young previously healthy man had a higher value before the accident. He could have lost blood from the accident and/or during the surgery. Acute blood loss and surgery are associated with leukocytosis.

ANSWERS TO CHECKPOINTS**Checkpoint! 1**

Calculate the absolute number of each cell type. Is each of these relative and absolute cell counts normal or abnormal?

Answer

Neutrophils— $0.60 \times 5.0 = 3.0 \times 10^9/L$

Lymphocytes— $0.35 \times 5.0 = 1.8 \times 10^9/L$

Monocytes— $0.05 \times 5.0 = .25 \times 10^9/L$

All of the cell counts are normal. If the total leukocyte count and the relative differential percents are normal, the absolute counts are also normal.

Checkpoint! 2

How can CML be distinguished from a leukemoid reaction?

Answer

The white cell count is usually higher and there are more immature cells in CML. Eosinophils and basophils are often elevated in CML but not in leukemoid reaction. Other cell counts (red and platelet) are more likely to be abnormal in CML. The LAP (low in CML and high or normal in leukemoid reaction) and Philadelphia chromosome (positive in CML) can be helpful. Patient demographic and symptoms follow: CML is usually a disease of middle age adults and presents with systemic symptoms such as enlarged spleen and nodes and bone pain due to bone marrow expansion; leukemoid reaction from a reactive process usually presents with fever or symptoms related only to the primary condition.

Checkpoint! 3

What is the difference between a leukemoid reaction and a leukoerythroblastic reaction?

Answer

A leukemoid reaction occurs when a leukocytosis with a shift to the left in circulating granulocytes occurs. It is a transient condition that happens in response to a stimulus-like infection or inflammation. A leukoerythroblastic reaction is characterized by a shift to the left in granulocytes and nucleated RBCs in the peripheral blood. The total WBC count can be increased, normal, or decreased. It is found in myeloproliferative conditions and leukemia.

Checkpoint! 4

How can the correct white count be determined when neutrophils clump in the presence of EDTA?

Answer

If neutrophils clump in the presence of EDTA, the blood for the white count and differential must be collected by a method without

its presence. Manual or automated counts can be performed using fingerstick or capillary collection. Blood collected in a different anticoagulant also may be used for selected tests. Heparin provides an accurate white cell count, but the erythrocytes are distorted. Citrate can be used if corrections are made for the dilutional effects of the increased volume of anticoagulant in a blue top tube.

Checkpoint! 5

Describe the difference between hypersegmented neutrophils, hyposegmented neutrophils, and pyknotic nuclei. In what conditions is each seen?

Answer

Hypersegmented neutrophils have six or more nuclear segments and are associated with megaloblastic anemia. Hyposegmented neutrophils are mature cells with one or two nuclear segments and are associated with Pelger-Huët anomaly and some leukocyte malignancies. Be aware that bands, metamyelocytes, and myelocytes have one or two segments as well but are immature cells. Pyknotic nuclei are smooth nuclear fragments seen when the cell is dying. Disintegrating cells can be seen in blood but more often are found in infectious body fluids.

Checkpoint! 6

Explain how you can distinguish if toxic granulation and vacuoles are due to the patient's condition or to artifact.

Answer

Toxic granulation and vacuoles are associated with infection. Thus, you should correlate these findings with other signs of infection. A high WBC count and a shift to the left may be present in an infectious state. The patient's history may also be important. A comparison to other blood smears stained with the same stain is helpful if it is suspected that the large dark granules are due to precipitated stain. If due to staining artifact, the toxic granulation is present on other blood smears as well. The time the blood was collected should be checked; blood stored in EDTA might show vacuoles in PMNs.

Checkpoint! 7

Why is the basophil and eosinophil count important when assessing the benign or neoplastic nature of a disorder?

Answer

Basophils and eosinophils are rarely increased in benign disorders but are commonly increased in neoplastic disorders. Evaluated together with other hematologic data and the patient's clinical history, the eosinophil and basophil count may provide important clues to the disorder assessment.

Nonmalignant Lymphocyte Disorders

Sue S. Beglinger, M.S.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Identify the infectious agent and describe the clinical symptoms and corresponding leukocyte differential in infectious mononucleosis.
2. Describe and recognize the reactive morphology of lymphocytes found in infectious mononucleosis.
3. Relate the heterophile antibody test to infectious mononucleosis.
4. Given a differential and leukocyte count, calculate an absolute lymphocyte count and differentiate it from a relative lymphocyte count.
5. Identify reactive cell morphology associated with viral infections and compare it with normal lymphocyte morphology.
6. Describe clinical symptoms of disorders in which a leukocytosis is caused by lymphocytosis.
7. State the complications associated with CMV infections.
8. Identify absolute and relative lymphocytopenia and lymphocytosis, and list conditions associated with these abnormal counts.
9. Explain the pathophysiology of HIV infections and describe how it affects lymphocytes.
10. Describe the abnormal hematological findings associated with AIDS.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Assess and resolve/explain conflicting results between peripheral blood morphology and serologic tests in suspected Epstein-Barr virus (EBV) infection.
2. Describe the pathophysiology of infectious mononucleosis.
3. Assess and correlate antibody titers found in infectious mononucleosis with respect to the various EBV viral antigens.
4. State the pathophysiology of toxoplasmosis infections, and explain the resulting lymphocytosis.
5. Differentiate benign lymphocytic leukemoid reactions from neoplastic lymphoproliferative disorders by laboratory results and characteristics of cell morphology.
6. Define the pathophysiology of CMV infections, and give clinical findings associated with it.
7. In *Bordetella pertussis* infections, propose the cause of lymphocytosis and recognize laboratory features associated with it.

OBJECTIVES—LEVEL II (continued)

8. Assess a patient case using the CDC AIDS case surveillance criteria and recommend appropriate laboratory testing.
9. Explain the cytopenia, identify the defect, and recognize the laboratory features in congenital qualitative disorders of lymphocytes.
10. Evaluate a case study from a patient with a lymphoproliferative disorder and conclude from the medical history and laboratory results the most likely diagnosis for the disorder.

KEY TERMS

Acquired immune deficiency syndrome (AIDS)
 AIDS-related complex (ARC)
Bordetella pertussis
 Cytomegalovirus (CMV)
 Epstein-Barr virus (EBV)
 Heterophile antibodies
 Immunosuppressed
 Infectious lymphocytosis
 Infectious mononucleosis
 Lymphocytic leukemoid reaction
 Opportunistic organisms
 Severe combined immunodeficiency (SCID) syndrome
 Toxoplasmosis
 Viral load

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review this material before starting this unit of study.

Level I

- ▶ Describe normal and reactive lymphocyte morphology; identify the distinguishing characteristics of T and B lymphocytes.
- ▶ Calculate absolute cell counts; summarize the relationship between the hematocrit and hemoglobin.
- ▶ Define *antigen* and *antibody*, and describe their roles in infectious and noninfectious diseases; summarize the immune response.

Level II

- ▶ Describe the process of T and B lymphocyte differentiation and the function of each subtype; summarize the structure and function of each of the immunoglobulins; describe the immune response.
- ▶ Describe the structure and function of the hematopoietic organs and tissue.
- ▶ Give the principle and application of direct antiglobulin tests in diagnosis of immune mediated anemia.

**CASE STUDY**

We will refer to this case study throughout the chapter.

Heidi, a 54-day-old female, was admitted to the hospital because of recurrent respiratory distress and failure to gain weight. She was born prematurely at 35 weeks gestation by urgent Cesarean section. Her mother was immune to rubella and had negative serologic tests for syphilis. Consider why the lymphatic system should be evaluated in this child and the possible etiology of repeated respiratory problems.

OVERVIEW

This chapter discusses benign conditions associated with quantitative and qualitative alterations in lymphocytes. Infectious mononucleosis and other acquired disorders characterized by lymphocytosis are described. A discussion of lymphocytopenia and immune deficiency states, both acquired and congenital, follows. Emphasis is on the laboratory features that allow the diseases to be diagnosed and differentiated from neoplastic lymphoproliferative disease.

INTRODUCTION

Evidence of disease, especially infectious disease, can be observed by finding abnormal concentrations of lymphocytes and/or reactive lymphocytes on a peripheral blood smear. This finding helps direct the physician's subsequent workup of the patient and aids in the initiation of appropriate therapy. Most disorders affecting lymphocytes are acquired and are characterized by a reactive lymphocytosis. Some acquired disorders result in a lymphocytopenia that can compromise the function of the immune system. In acquired disorders affecting lymphocytes, the change in lymphocyte concentration and morphology is a reactive process. In contrast, in congenital disorders involving lymphocytes, the primary defect is within the lymphocytic system.

► **LYMPHOCYTOSIS**

Lymphocytosis, an increase in lymphocytes, can result from a relative or absolute increase in lymphocytes. Absolute lymphocytosis occurs in adults when the lymphocyte count exceeds $4.8 \times 10^9/L$ and relative lymphocytosis is present when the lymphocyte differential exceeds 35–45% (differs with race). An absolute lymphocytosis can occur without relative lymphocytosis and a relative lymphocytosis can occur without absolute lymphocytosis. The lymphocyte concentration in children is normally higher than in adults and varies with the child's age (Table B, inside front cover). Lymphocytosis can occur without a leukocytosis.

Lymphocytosis is usually a self-limiting, reactive process that occurs in response to an infection or inflammatory condition. Both T and B lymphocytes commonly are affected but their function remains normal. Occasionally, viral infections can cause functional impairment of the lymphocytes yielding both a qualitative disorder and quantitative changes.

Once lymphocytes are stimulated by an infection or inflammatory condition, they enter various states of activation, resulting in a morphologically heterogeneous population of cells on stained blood smears (Figure 1■). These activated cells can appear large with irregular shapes and cytoplasmic basophilia, and granules and vacuoles can be seen. The nuclear chromatin usually becomes more dispersed. Cells with these features of activation are commonly referred to as *reactive* or *atypical lymphocytes*. Occasionally, intense proliferation of lymphoid elements in the lymph nodes and spleen occurs, causing lymphadenopathy and splenomegaly, respectively.

T lymphocytes normally compose about 60–80% of peripheral blood lymphocytes. Thus, increases in the concentration of T lymphocytes are more likely than increases in B

lymphocytes to cause changes in the relative lymphocyte count. Absolute lymphocytosis is not usually accompanied by leukocytosis except in infectious mononucleosis, infectious lymphocytosis, *Bordetella pertussis* infection, cytomegalovirus infection, or lymphocytic leukemia. A relative lymphocytosis secondary to neutropenia that occurs in a variety of viral infections is more commonly found. The absolute lymphocyte count is calculated as:

$$\text{Absolute lymphocyte count } (\times 10^9/L) = \% \text{ lymphocytes} \times \text{WBC count } (\times 10^9/L)$$

It is important to differentiate benign conditions associated with lymphocytosis from neoplastic (malignant) lymphoproliferative disorders (Table 1★). The presence of heterogeneous reactive lymphocytes, positive serologic tests for the presence of specific antibodies against infectious organisms, and absence of anemia and thrombocytopenia favor a benign diagnosis. This section includes a discussion of the more common disorders associated with a reactive lymphocytosis.

★ **TABLE 1**

Conditions Associated with Lymphocytosis

Benign (Nonmalignant) Conditions	Neoplastic Conditions
Infectious mononucleosis	Acute lymphoblastic leukemia
<i>Bordetella pertussis</i> infection	Chronic lymphocytic leukemia
Toxoplasmosis	Hairy cell leukemia
Persistent polyclonal B cell lymphocytosis	Heavy chain disease
	Multiple myeloma
Viral infections	Waldenstrom's macroglobulinemia
Chicken pox	
Coxsackie virus

Tertiary syphilis	
Congenital syphilis	
Brucellosis	
Endocrine disorders	
Thyrotoxicosis	
Addison's disease	
Panhypopituitarism	
Convalescence of acute infections	
Immune reactions	
Inflammatory diseases	

■ **FIGURE 1** Forms of stimulated lymphocytes from a case of infectious mononucleosis. There are two immunoblasts (one o'clock and eight o'clock) and a reactive lymph (three o'clock). (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

CASE STUDY (continued from earlier in this chapter)

Admission CBC on Heidi was WBC: $7.6 \times 10^9/L$; Hct: 0.55 L/L; Plt: $242 \times 10^9/L$; and differential: 84% segs, 2% bands, 4% lymphocytes, 8% monocytes, and 2% eosinophils.

1. Does this patient have a leukocytosis or leukopenia?
2. Does this patient have an abnormal lymphocyte count? Explain.

INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis is a self-limiting lymphoproliferative disease caused by infection with **Epstein-Barr virus (EBV)**. EBV usually affects young adults; the peak age for infection is 14–24 years. In children from lower-income groups, infection usually occurs before 4 years of age; in more affluent populations, peak infection incidence occurs during adolescence. About 80–90% of adults have had exposure and possess lifelong immunity. Not considered highly contagious, the disease is transmitted through saliva, hence, the nickname *kissing disease*.

Cellular immunity (the function of T lymphocytes) is important in limiting the growth potential of EBV-infected B lymphocytes. Immune-compromised individuals are at increased risk of serious infection. EBV-associated B cell tumors and lymphoproliferative syndromes can occur in transplant patients and patients with acquired immune deficiency syndrome (AIDS).¹ These patients have severe T lymphocyte immunodeficiency. Male children with a rare X-linked lymphoproliferative syndrome, lacking a T lymphocyte response, are unable to limit EBV infection of B lymphocytes. As a result, a fatal polyclonal B lymphocyte proliferation occurs.²

EBV Pathophysiology

EBV attaches to B lymphocytes by means of a specific receptor designated CD21 on the B lymphocyte membrane surface.¹ This also is the receptor for the C3d complement component. The virus infects resting B lymphocytes as well as epithelial cells of the oropharynx and cervix. The binding of the virus to the lymphocyte activates the lymphocyte, causing it to express the activation marker CD23.³ CD23 is the receptor for a B lymphocyte growth factor. Once internalized, the virus is incorporated into the B lymphocyte genome, instructing the host cell to begin production of EBV proteins. These viral proteins are then expressed on the cell membrane. Thus, EBV-infected cells express markers of activated B lymphocytes as well as viral markers. The viral genome is maintained in the lymphocyte nucleus and passed on to the cell's progeny. This results in EBV-immortalized B lymphocytes and possible latent infection.

Acute EBV infection is controlled by a complex, multifaceted cellular immune response. In the first week of illness, a polyclonal increase in immunoglobulins occurs. During the second week, however, the number of immunoglobulin se-

creting B lymphocytes decreases, presumably resulting from the action of suppressor T lymphocytes. Activated cytotoxic cells that resemble activated killer cells are present early in the course of the disease. These cells are neither EBV specific nor HLA restricted (virus nonspecific). Cytotoxic T lymphocytes inhibit the activation and proliferation of EBV-infected B lymphocytes and participate in the cell-mediated immune response. The majority of the reactive lymphocytes seen in the peripheral blood are the suppressor-cytotoxic T lymphocytes.

Clinical Findings

Prodromal symptoms include lethargy, headache, fever, chills, sore throat, nausea, and anoxia. The classic triad presentation of symptoms are fever, pharyngitis, and lymphadenopathy² (Table 2). Children younger than 10 years of age have mild disease and can be asymptomatic.⁴ The cervical, axillary, and inguinal lymph nodes are commonly enlarged. Splenomegaly occurs in 50–75% of these patients, and hepatomegaly occurs in about 25%. Occasionally, jaundice can develop. Hematologic complications that can occur during or immediately after the disease include autoimmune hemolytic anemia, thrombocytopenia, agranulocytosis, and (very rarely) aplastic anemia. The disease is usually self-limiting, resolving within a few weeks.

Laboratory Findings

Hematologic findings provide important clues to diagnosis in infectious mononucleosis. Serologic tests can confirm the diagnosis.

Peripheral Blood During active viral infection, an intense proliferation of lymphocytes occurs within affected lymph nodes. The leukocyte count is usually increased ($12\text{--}25 \times 10^9/L$), primarily due to an absolute lymphocytosis. Lymphocytosis begins about 1 week after symptoms appear, peaks at 2–3 weeks, and remains elevated for 2–8 weeks.⁵ Lymphocytes usually constitute more than 50% of the leukocyte differential. The platelet count is often mildly decreased, but concentrations of less than $100 \times 10^9/L$ are rare.

★ TABLE 2

Summary of Typical Clinical and Laboratory Findings in Infectious Mononucleosis

Clinical Findings	Laboratory Findings
Lymphadenopathy	Leukocytosis
Fever	Lymphocytosis
Lethargy	Peripheral blood smear
Sore throat	>20% reactive (atypical) lymphocytes
Splenomegaly	Immunoblasts present
	Heterophile antibodies present
	Positive antigen tests for EBV

■ **FIGURE 2** Two reactive forms of lymphocytes from a case of infectious mononucleosis. Note the cytoplasmic vacuoles and cytoplasmic basophilia and irregular shapes. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

Various forms of reactive lymphocytes (>20%) can be found in the peripheral blood (Figure 2■). Typical cells are irregular in shape and have large amounts of spreading cytoplasm with irregular basophilia. Other reactive cells may have deep blue cytoplasm and vacuoles. Immunoblasts are usually present early in the disease. Plasmacytoid lymphocytes and an occasional plasma cell also can be found. When present, immunoblasts should be distinguished from leukemic lymphoblasts to prevent a misdiagnosis. The chromatin pattern of leukemic lymphoblasts is usually finer than the reticular chromatin of immunoblasts. In addition, immunoblasts generally have a lower N:C ratio with more abundant, sometimes vacuolated, cytoplasm. Another important criterion that helps differentiate infectious mononucleosis from leukemia is the morphologic heterogeneity of the lymphocyte population characteristic of viral infections whereas in leukemia, there is usually a homogeneous population.

Other diseases associated with a reactive lymphocytosis can be confused with the blood picture of infectious mononucleosis. These include cytomegalovirus infection, viral hepatitis, and toxoplasmosis.

Bone Marrow Bone marrow aspirations in EBV infection are not indicated, but when performed show hyperplasia of all cellular elements except neutrophils.

Serologic Tests Serologic tests (tests based on antigen/antibody reactions) are used to differentiate this disease from similar more serious diseases (i.e., diphtheria, hepatitis). The blood of patients with infectious mononucleosis contains greatly increased concentrations of transient **heterophile antibodies** that agglutinate sheep or horse erythrocytes, but are not specific for EBV.^{6,7} (A heterophile antibody will react with antigens that are common to multiple species.) Antibodies specific for EBV can be identified by absorbing the nonspecific heterophile antibodies from the serum with guinea pig antigen and testing the absorbed serum with horse erythrocytes. The infectious mononucleosis IgM antibodies react with horse erythrocytes. Positive agglutination between treated serum and horse erythrocytes indicates EBV infection. A negative result usually indicates infection by some other virus. The level of antibody occasionally is not yet high enough to be detected; therefore, the test should be repeated a week later if patient symptoms continue.

Rapid, specific, and sensitive slide agglutination or solid phase immunoassay tests are available to test for the presence of infectious mononucleosis heterophile antibodies. The infected individual produces antibodies specific for the viral capsid antigen (VCA) of EBV at various stages of infection which can be detected earlier than the heterophile antibodies. VCA-IgM rises first followed by VCA-IgG which, when present, signals the development of immunity.⁷ Antibodies to EBV nuclear antigens (EBNA) rise during early convalescence and persist together with VCA-IgG (Table 3★). Thus, the presence of EBNA excludes an acute infection.

A patient with all clinical manifestations and peripheral blood findings of infectious mononucleosis occasionally does not have a positive heterophile test (heterophile-negative syndrome). In 10–20% of adult cases and in 50% of children younger than 10 years of age, the test is negative in the presence of EBV infection. In other cases, the heterophile-negative syndrome is caused by a non-EBV viral infection. The likely causative agent is cytomegalovirus; however, toxoplasmosis, hepatitis, and drug intoxication also should be considered. Antibody responses might not be detected in **immunosuppressed** individuals (those in whom the immune response is suppressed either naturally, artificially, or pathologically).⁷

Other laboratory tests can be abnormal depending on the presence or absence of complications. Hepatitis of some degree is common and can be a severe complication. An increase

★ TABLE 3

Antibodies to EBV That Are Found in Infectious Mononucleosis

Stage of Infection	Heterophile Antibodies	VCA-IgM (titer)	VCA-IgG (titer)	EBNA (titer)
Acute (0–3 months)	Present	>1:160	>1:60	Not detected
Recent (3–12 months)	Present	Not detected	>1:160	>1:10
Past (>12 months)	Present	Not detected	>1:40	>1:40

VCA = viral capsid antigen; EBNA = EBV nuclear antigen

in both direct and indirect bilirubin fractions and an increase in serum liver enzymes are common findings in the presence of hepatitis. A rare complication of infectious mononucleosis is hemolytic anemia. The anemia appears to be due to cold agglutinins directed against the erythrocyte i-antigen.

Therapy

Because the disease is normally self-limited, therapy is supportive. Bed rest is recommended if fever and myalgia are present. Strenuous exercise should be avoided for several weeks, especially if splenomegaly is present. Antibiotics are not useful except in the presence of secondary infections.

Checkpoint! 1

A patient with lymphocytosis, showing reactive lymphocyte morphology with large, basophilic cells, fine chromatin, and a visible nucleolus has a negative infectious mononucleosis serologic test. What is a possible cause for this altered lymphocyte morphology?

TOXOPLASMOSIS

Toxoplasmosis is the result of infection with the intracellular protozoan *Toxoplasma gondii*. This obligate parasite can multiply in all body cells except erythrocytes. The infection can be congenital or acquired. Congenital infection, the most serious, results from placental transmission of organisms from the parasitized mother to the fetus. Congenital infection can cause abortion, jaundice, hepatosplenomegaly, chorioretinitis, hydrocephalus, microcephaly, cerebral calcification, and mental retardation. Acquired infection can be asymptomatic or cause symptoms resembling infectious mononucleosis. Infection in children and adults is acquired by ingestion of oocysts from cat feces or from inadequately cooked meat. Toxoplasmosis seropositivity is more common in rural children than urban children.⁸ Molecular tests for *Toxoplasma gondii* DNA are available but are not yet FDA approved.

Laboratory findings assist in diagnosis. There is a leukocytosis with a relative lymphocytosis, (more rarely) an absolute lymphocytosis, and an increase in reactive lymphocytes. Most reactive cells are similar to lymphoblasts or lymphoma cells. The heterophile antibody test is negative. Biopsy of lymph nodes shows a reactive follicular hyperplasia and can play an important role in diagnosis. Diagnosis of an active infection is established by confirming a rising titer and seroconversion of antibodies to *Toxoplasma gondii*. Immunologically compromised hosts have a more severe infection. The most common hematologic complication is hemolytic anemia, which can be severe.

CYTOMEGALOVIRUS

Infection with the herpes-group virus **cytomegalovirus (CMV)** can be the result of congenital or acquired infection. Infection in neonates occurs when organisms from the infected mother cross the placenta and infect the fetus. The

newborn demonstrates jaundice, microcephaly, and hepatosplenomegaly. Only about 10% of infected infants exhibit clinical evidence of the disease. The most common hematologic findings in neonates are thrombocytopenia and hemolytic anemia.

Acquired infection is spread by close contact, blood transfusions, and sexual contact. The disease occurs in immunosuppressed individuals, in patients with malignancy, in patients after massive blood transfusions, and in previously healthy adults. It is the most common viral infection complicating tissue transplants and is a significant cause of morbidity and mortality in immunocompromised patients.⁹ However, recent advances in treatment with anti-viral drugs and immunosuppressive therapy have dramatically decreased the incidence of CMV complications in organ transplantation.¹⁰ Infected adults present with symptoms similar to those of infectious mononucleosis except pharyngitis is absent. Many cytomegalovirus infections are subclinical or cause mild flu-like symptoms.

Laboratory findings include a leukocytosis with an absolute lymphocytosis. Many of the lymphocytes are reactive, but the heterophile agglutinin test is negative. Hepatic enzymes are usually abnormal. Diagnosis is confirmed by demonstrating the virus in the urine or blood using a viral DNA (molecular) assay or by a rise in the cytomegalovirus antibody titer (except in immunocompromised patients).

CMV is thought to infect neutrophils, which serve as a means of transporting the virus to other body sites. The virus appears to suppress cell-mediated immune function and induce formation of autoantibodies that have lymphocytotoxic properties.¹¹ A decrease in circulating T helper lymphocytes and an increase in T suppressor/cytotoxic lymphocytes occurs.

INFECTIOUS LYMPHOCYTOSIS

Infectious lymphocytosis, previously considered an infectious, contagious disease of young children, is now referenced as the reactive immune response associated with several viruses that infect children. The most common viruses are the adenovirus and coxsackie A virus and sometimes *Bordetella pertussis*. EBV and CMV are not implicated.¹² Leukocytosis and lymphocytosis occur in the first week of illness and subsequently return to normal. The lymphocytes are small and appear normal rather than reactive.

BORDETELLA PERTUSSIS

Infection from *Bordetella pertussis* (whooping cough) causes a blood picture very similar to that of infectious lymphocytosis (Figure 3 ■). The leukocyte count typically rises to $15\text{--}25 \times 10^9/\text{L}$ but may reach $50 \times 10^9/\text{L}$. The rise in leukocytes is caused by an absolute lymphocytosis, although neutrophils also can be increased. Granulocytes may show toxic changes. The lymphocytes are small cells with condensed chromatin and indistinct nucleoli.

■ **FIGURE 3** Lymphoproliferation due to *Bordetella pertussis* (whooping cough). Note the numerous small lymphocytes with condensed chromatin. This self-limiting peripheral blood picture must be distinguished from that of CLL. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

Laboratory diagnostic methods include culture, serology, and PCR.¹³ Culture is the gold standard and is specific but not sensitive. The advantage of culture is that it allows antibiotic sensitivity testing and epidemiological typing. Serologic diagnosis is based on demonstrating antipertussis toxin antibodies and has high specificity. It is preferred for older children and adults who present after a prolonged coughing illness. A PCR commercial test approved by the Food and Drug Administration is not available; current tests in development have problems with variable sensitivity and specificity between laboratories. It is most useful in acutely ill infants.

Pertussis toxin stimulates lymphocytosis-promoting factor (LPF) produced by the bacteria that recruits lymphocytes into the peripheral circulation and blocks their migration back into lymphoid tissue, causing accumulation of lymphocytes in the blood. LPF interferes with lymphocyte function and appears to influence T helper cells.¹³ Rapid peripheral lymphocytosis is accompanied by decreased cellularity of the lymph nodes. A recent study immunophenotyped the lymphocytes from a neonate with pertussis.¹⁴ Results showed that the increase in lymphocytes was due to T lymphocytes with a normal CD4 to CD8 ratio. However, a dramatic loss of L-selectin expression by these T cells occurred. This could prevent the homing of T cells to lymphoid tissues and explain the buildup of lymphocytes in the peripheral blood.

Whooping cough infections rose 400% between 1990 and 2001 in the adult population, suggesting that childhood vaccinations do not yield lasting immunity. Studies show that 20–30% of adults with a cough that lingers 6–8 weeks are positive for *Bordetella pertussis*. While the infections cause a lingering cough in adults, passing it on to infants can be fatal.¹⁵

PERSISTENT LYMPHOCYTOSIS

Persistent lymphocytosis is a rare disorder found in young to middle-aged females who are heavy smokers. It is characterized by a persistent polyclonal B cell expansion¹⁶ The disorder is often asymptomatic and found by chance on a routine blood analysis. Symptoms can include fever, fatigue, weight loss, recurrent chest infections, or generalized lymphadenopathy. Hematologic findings are normal except for lymphocytosis and the occasional presence of binucleated lymphocytes. There is a polyclonal increase in serum IgM but low IgG and IgA levels. Bone marrow examination reveals lymphocytic infiltrates. Patients have a benign course.

OTHER DISORDERS ASSOCIATED WITH LYMPHOCYTOSIS

Other disorders accompanied by a reactive lymphocytosis are listed in Table 1. The lymphocytic reactions in these disorders are characterized by an increased relative lymphocyte count with the presence of reactive or immature-appearing lymphocytes (**lymphocytic leukemoid reaction**). An absolute lymphocytosis is found occasionally. Many of the lymphocytes are large reactive cells with deep blue cytoplasm, fine chromatin, and cytoplasmic vacuoles (Figure 4 ■). Reactive cells are usually nonclonal T lymphocytes and large granular lymphocytes. In some viral infections, lymphocytosis is preceded by lymphocytopenia and neutropenia. As the infection subsides, plasmacytoid lymphocytes can be found (Figure 5 ■).

In some cases, a lymphocytic leukemoid reaction resembles chronic lymphocytic leukemia (CLL). Bone marrow aspiration, however, shows minimal (if any) increase in lymphocytes in a lymphocytic leukemoid reaction. In contrast to

■ **FIGURE 4** An immunoblast found in a patient with a viral infection. This cell must be distinguished from a leukemic lymphoblast. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

■ **FIGURE 5** A plasmacytoid lymphocyte. Note the deep basophilic cytoplasm and eccentric nucleus. These cells are associated with infectious states. Note also the neutrophil with toxic granulation. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

CLL, adenopathy, and splenomegaly are usually absent. In addition, patients with a lymphocytic leukemoid reaction are usually young, whereas in CLL the patients are usually older adults.

PLASMACYTOSIS

Plasma cells are not normally found in the peripheral blood. They can be present, however, with intense stimulation of the immune system as occurs in some viral and bacterial infections and in disorders associated with elevated serum gamma globulin. They are commonly found in rubeola infections. Circulating plasma cells also can be found in skin diseases, cirrhosis of the liver, collagen disorders, and sarcoidosis. Most often the presence of plasma cells is associated with the neoplastic disorders, plasma cell leukemia, and multiple myeloma.

▶ LYMPHOCYTOPENIA

Some disorders are associated with a lymphocytopenia, which occurs in adults when the absolute lymphocyte count is less than $1.0 \times 10^9/L$. In children less than 5 years old, the lower normal range varies, but it is higher than in adults (Table B, inside front cover). Generally, lymphocyte counts less than $2 \times 10^9/L$ are abnormal in this population. When the lymphocyte count is decreased, there could be an impaired ability to mount an immune response, resulting in immunodeficiency.

Lymphocytopenia results from decreased production or increased destruction of lymphocytes, changes in lymphocyte circulation patterns, and other unknown causes

★ **TABLE 4**

Conditions Associated with Lymphocytopenia

- Malnutrition
- Disseminated neoplasms
- Connective tissue disease (e.g., systemic lupus erythematosus, SLE)
- Hodgkin's disease
- Chemotherapy
- Radiotherapy
- Corticosteroids
- Acute inflammatory conditions
- Chronic infection (e.g., tuberculosis, TB)
- Congenital immune deficiency diseases
- Acquired immune deficiency diseases
- Acute and chronic renal disease
- Stress

(Table 4★).¹⁷ Corticosteroid therapy causes a sharp drop in circulating lymphocytes within 4 hours. The decrease is caused by sequestration of lymphocytes in the bone marrow. Values return to normal within 12–24 hours after cessation of therapy. Acute inflammatory conditions, including viral and bacterial infections, also can be associated with a transient lymphocytopenia. Carcinoma of the breast and stomach with an associated lymphocytopenia is a poor prognostic sign. Systemic lupus erythematosus is frequently associated with a lymphocytopenia presumably caused by autoantibodies produced against these cells. Chemotherapeutic alkylating drugs for malignancy, such as cyclophosphamide, cause the death of T and B lymphocytes in both interphase and mitosis. Malnutrition is the most common cause of lymphocytopenia. Starvation causes thymic involution and depletion of T lymphocytes. Both congenital and acquired immune deficiencies are associated with lymphocytopenia.

Irradiation causes a prolonged suppression of lymphocyte production. T helper lymphocytes are more sensitive to radiation than are T suppressor lymphocytes. It appears that small daily fractions of radiation are more damaging to lymphocytes than periodic large doses. With periodic radiation, the lymphocytes can renew during periods of nonradiation. Aggressive treatment of hematologic malignancies with chemotherapeutics or ionizing radiation can lead to immunodeficiency by depleting short-lived, antibody-forming B lymphocytes.

✓ **Checkpoint! 2**

Why is lymphocytopenia a concern if there is no accompanying leukopenia?

CASE STUDY (continued from earlier in this chapter)

Heidi weighed 2 pounds 1 ounce at birth. Tests for CMV and toxoplasma infections were negative. At 4 days of age, she was transferred to a special facility for feeding and growth monitoring. She developed a diaper rash that failed to respond to many measures. No thrush was found. At 44 days, she developed pneumonia from coagulase-negative staphylococci that responded to antibiotics. Her WBC count was $12.3 \times 10^9/L$ with a differential of segs 42%, bands 5%, lymphocytes 1%, monocytes 28%, eosinophils 23%, and basophils 1%.

3. What is the absolute lymphocyte count?
4. What possible causes exist for these opportunistic infections?

IMMUNE DEFICIENCY DISORDERS

Immune deficiency disorders are characterized by impaired function of one or more of the components of the immune system, T, B, or NK lymphocytes. In some disorders, the numbers of these cells also can be reduced. This results in an inability to mount a normal adaptive immune response. These disorders are characterized clinically by an increase in infections and neoplasms and can be subgrouped as acquired or congenital.

Acquired immune deficiency syndrome (AIDS) is an infectious disorder characterized by lymphocytopenia. Due to the frequency with which this disorder is encountered in the clinical hematology laboratory, it is discussed in more detail next and is followed by a discussion of the congenital immune deficiency disorders.

Acquired Immune Deficiency Syndrome

Acquired immune deficiency syndrome (AIDS) is a highly lethal immune deficiency disease first described in 1981.¹⁸ The disease is caused by infection with a retrovirus, human immunodeficiency virus type I (HIV-1). Advances in HIV treatment with combination antiretroviral therapy delay progression to AIDS and death for people infected with HIV.¹⁹

AIDS is defined by the occurrence of repeated infections with multiple **opportunistic organisms** and an increase in malignancies, especially Kaposi's sarcoma, in individuals infected with HIV. Patients infected with HIV progress through three recognized stages: an asymptomatic carrier stage, an **AIDS-related complex (ARC)** stage (mild symptomatic stage), and finally, symptomatic AIDS with one of the AIDS-defining clinical conditions (discussed later).²⁰

Transmission of the virus is through sexual intercourse or contact with blood and blood products. The disease occurs primarily in certain high-risk groups: those who participate in unprotected sexual intercourse with high-risk or infected individuals, homosexual and bisexual men, prostitutes, intravenous drug abusers, Haitians, and hemophiliacs. Although it is most common in men, women who have had sexual relations with someone at high risk of HIV infection

also are at risk as are infants born to HIV-infected mothers. Infant infection can be perinatal or occur at birth.

Surveillance HIV Case Definition In 1982, the Centers for Disease Control and Prevention (CDC) in the United States developed a case definition of AIDS for surveillance purposes. It is revised periodically as more is learned about the disease.^{21,22} It was proposed that AIDS case definition should be as comprehensive as possible because many countries will grant social benefits or access to medical care only if HIV-infected patients have a diagnosed AIDS-defining illness²³ (Table 5).

TABLE 5

Clinical Conditions Included in the Centers for Disease Control and Prevention Surveillance Case Definition for HIV Infection

Candidiasis of bronchi, trachea, or lungs
Candidiasis, esophageal
Cervical cancer, invasive
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus disease (other than liver, spleen, or nodes)
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy, HIV related
Herpes simplex: chronic ulcer(s) (>1 month's duration) or bronchitis, pneumonitis, or esophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi's sarcoma
Lymphoma, Burkitt
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
<i>Mycobacterium avium</i> complex or <i>M. kansasii</i> (disseminated or extrapulmonary)
<i>Mycobacterium tuberculosis</i> , any site (pulmonary or extrapulmonary)
<i>Mycobacterium</i> , other species or unidentified species, disseminated or extrapulmonary
<i>Pneumocystis carinii</i> pneumonia
Pneumonia, recurrent
Progressive multifocal leukoencephalopathy
<i>Salmonella</i> septicemia, recurrent
Toxoplasmosis of brain
Wasting syndrome due to HIV
Bacterial infections, multiple or recurrent*
Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex*

*only among children <13 years old
(From Appendix B from *MMWR*, 41, No. RR-17, December 1992.)

However, AIDS case surveillance alone does not accurately assess the HIV epidemic. To more accurately reflect the trends in HIV infection, the CDC recommends surveillance not only for AIDS but also for HIV infection.¹⁹ This surveillance expansion helps to identify populations with newly diagnosed HIV infection and aids in efforts to prevent HIV transmission. In 2008, the Council of State and Territorial Epidemiologists (CSTE) developed a revised case definition of HIV infection intended for public health surveillance.²⁴ The revised criteria apply to adults and children over 18 months of age and combine the HIV case definition, HIV classification system, and AIDS case definition into a single case definition for HIV infection. This revised case definition for HIV infection requires laboratory-confirmed evidence of HIV infection. CSTE, in cooperation with pediatricians, also described the criteria for a negative diagnosis for children <18 months old born to HIV-infected mothers. The child does *not* meet the criteria for HIV/AIDS diagnosis if antibody tests or virologic tests are negative after 4–6 months of age and the child does not have an AIDS-defining condition. The reader is directed to the primary source for details.²⁴

Laboratory evidence of HIV infection includes positive serologic HIV antibody tests, positive HIV nucleic acid tests, and positive HIV cultures.¹⁹ Almost all children born to HIV-infected mothers have anti-HIV IgG antibodies at birth due to placental transmission of maternal antibodies. However, only 15–30% are infected with HIV. Thus, anti-HIV IgG tests are not reliable until after 18 months in this population. In these cases, HIV nucleic acid detection tests performed after the infant is at least one month of age are almost always positive if the virus is present.¹⁹

Immune-compromised patients without one of the AIDS-defining clinical conditions but with milder symptoms, including weight loss, fever, lymphadenopathy, thrush, chronic rash, and intermittent diarrhea, are included in the ARC category.

Pathophysiology The etiologic agent of AIDS has been identified as the retrovirus, HIV-1. This virus selectively infects helper T lymphocytes by binding to the CD4 antigen that is part of the T lymphocyte receptor (TCR), causing rapid, selective depletion of this lymphocyte subset. Cytolysis of these CD4 lymphocytes results in lymphocytopenia. Once in the cell, HIV sheds its viral coat and uses reverse transcriptase to make a DNA copy of the viral RNA. Viral DNA is then integrated into the host cell DNA where the virus replicates. Monocytes and macrophages also have the CD4 antigen and are infected but are not destroyed by the virus.

Cell-mediated immunity and humoral immunity are abnormal. Cell-mediated immunity declines as CD4 T-lymphocyte-helper function for monocytes, macrophages, and other T lymphocytes declines.²⁵ Humoral responses are exaggerated with polyclonal B lymphocyte proliferation and increased immunoglobulin production.²⁶ The B lymphocytes, however, are incapable of responding to signals that trigger resting B lymphocytes.

Laboratory Findings Multiple hematologic abnormalities are found in AIDS, including leukopenia, lymphocytopenia, anemia, and thrombocytopenia (Table 6). Leukopenia is usually related to lymphocytopenia, although neutropenia also can be present.²⁷ Lymphocytes can include reactive forms. Mild to moderate anemia is present in the majority of HIV-infected individuals and worsens as the disease progresses.²⁸ Macrocytosis (MCV>110 fL) occurs in up to 70% of patients 2 weeks after receiving zidovudine.²⁹ Antierthrocyte antibodies can be found in up to 20% of patients with hypergammaglobulinemia. These antibodies react like polyagglutinins and cause a positive direct antiglobulin test (DAT, Coombs' test). Immune thrombocytopenia, indistinguishable from idiopathic thrombocytopenic purpura (ITP), is common. (ITP is characterized by immune destruction of platelets, causing a thrombocytopenia.)

Disease Monitoring The severity of CD4 lymphocytopenia and concentration of plasma HIV-1 RNA copies correlate with the severity of disease.^{20,30} The normal CD4-to-CD8 ratio in peripheral blood is about 2:1. In AIDS, this ratio reverses progressively and permanently due to destruction of the CD4 T lymphocytes. The CD4 T lymphocyte count is performed at initial diagnosis and measured periodically to monitor disease progression. AIDS (Stage 3 HIV infection) is defined by a CD4+ lymphocyte count of <200/ μ L or a CD4+ lymphocyte concentration <14% of total lymphocytes.²⁴ In addition, the **viral load** also is monitored by measuring the number of copies of HIV-1 RNA.³⁰

Therapy No cure for AIDS currently exists. Treatment with zidovudine (azodithymidine, AZT) and protease inhibitors appear to lengthen the time between HIV seropositivity and the onset of AIDS.³¹ Surveillance studies between 1992 and 1997 determined that careful follow-up and new antiviral treatments decreased the incidence of opportunistic infections in over one-half of the patients on the case definition list.³²

Health care workers with occupational exposure (e.g., needle-stick injury) to HIV should receive immediate anti-retroviral therapy.³⁰ CDC recommends initiation of anti-retroviral therapy within 2 hours of a needle-stick injury from a potential HIV source. Combination therapy should consist of two or more antiretroviral drugs and continue for 4 weeks. Laboratory evaluation for adverse effects should be considered after 2 weeks. Health care workers with questions about postexposure prophylaxis (PEP) should contact the CDC PEpline at 1(888)HIV-4911.

Common Laboratory Findings in HIV Infections

- Leukopenia
- Anemia
- Macrocytosis
- Thrombocytopenia
- Decreased CD4 counts
- Positive molecular tests for HIV-1 RNA

✓ Checkpoint! 3

Why does infection with HIV result in an increased chance for opportunistic infections?

Other Acquired Immune Deficiency Disorders

Some disorders are characterized or accompanied by functional abnormalities of lymphocytes. The lymphocyte count can be normal but in many cases is decreased. Acquired defects of either T or B lymphocytes can result in serious clinical manifestations. Some inflammatory states can transiently impede the response of T lymphocytes to antigen. These include idiopathic granulomatous disorders and malignancy. Severe infection by one microorganism sometimes impedes the ability of T lymphocytes to react to other infectious organisms. Starvation or severe protein deficiency can severely affect the functional ability of the T lymphocyte.

Congenital Immune Deficiency Disorders

Congenital disorders are usually characterized by a decrease in lymphocytes and impairment in either cell-mediated immunity (T lymphocytes), humoral immunity (B lymphocytes), or both (Table 7). In contrast to the reactive morphologic heterogeneity of lymphocytes associated with acquired disorders, lymphocytes in congenital disorders are usually normal in appearance. The functional impairment of the immune response is often apparent from birth or a very young age.

Severe Combined Immunodeficiency Syndrome
Severe combined immunodeficiency (SCID) syndrome includes a heterogeneous group of disorders result-

ing in major qualitative immune defects involving both humoral and cellular immune functions. These disorders have diverse genetic origins with different inheritance patterns and varied severity in clinical manifestation. Most are inherited as sex-linked or autosomal-recessive traits, but sporadic forms have been reported. About 75% of individuals with SCID are males because the most common form of SCID is an X-linked disorder.

Both the T and B lymphoid lineages are functionally deficient. Subgroups of SCID are now defined on the basis of which lymphocytes are absent. If only the T cells are absent, it is termed $T^-B^+NK^+$ SCID; if both T and B cells are absent, $T^-B^-NK^+$ SCID; and in those patients (usually with the most severe lymphopenia) where all three are absent, $T^-B^-NK^-$ SCID. Because of the need for T cell help in generating an antibody response against protein antigens, peripheral blood B lymphocytes, even when present, are unresponsive to mitogens, and immunoglobulin production decreases. However, these B lymphocytes respond normally when incubated with normal T lymphocytes *in vitro*.²⁶ The absolute lymphocyte count is variable but often decreased to less than $1.0 \times 10^9/L$. Lymphocyte counts in SCID patients can be normal in the neonate, especially if they are able to generate B cells and NK cells, but usually eventually develop a profound lymphopenia.

Lymph node examination reveals a lack of plasma cells, B lymphocytes, and T lymphocytes. No lymphoid cells are found in the spleen, tonsils, or intestinal tract. The bone marrow also is deficient in plasma cells and lymphocyte precursors.

Frequent recurrent infections, skin rashes, diarrhea, and a failure to thrive are characteristic findings in infants with

★ TABLE 7

Laboratory Findings in Selected Immunodeficiency Disorders

Disorder	Immunoglobulins	B lymphocytes	T lymphocytes	Inheritance
SCID (X-linked) $T^-B^+NK^+$ SCID	↓ IgG, IgE, IgA; N IgM	↓ or normal (number)	Mature T lymphs absent	X(q13.1—q21.1) (γ -chain of IL-7 R)
Autosomal recessive $T^-B^+NK^+$ SCID	↓ IgG, IgE, IgA; N IgM	↓ or normal (number)	Mature T lymphs absent	JAK3 (19p13.1); IL-7 α -chain (5p13); ZAP-70 (2q12)
$T^-B^-NK^+$ SCID	↓ IgG, IgM, IgA, IgE	Mature B cells and plasma cells absent	Mature T lymphs absent	ADA (20q13.11) PNP (14q13.2) RAG-1, RAG-2
$T^-B^-NK^-$ SCID Reticular dysgenesis	↓ IgG, IgM, IgA	Mature B cells and plasma cells absent	Mature T lymphs absent	Etiology unknown
Wiskott-Aldrich syndrome	↓ IgM; N/↑ IgA; ↑ IgE; N/↑ IgG	Normal	Progressive ↓	Sex-linked; X(p11.3—p11.22)
DiGeorge syndrome	Normal	Normal	↓	Gene deletion; del(22)(q11)
X-linked agammaglobulinemia	↓ IgG, IgM, IgA	↓	Normal	Sex-linked; defects at X(q21.3—q22)
Ataxia-telangiectasia	N/↑ IgM; N/↓ IgG; N/↓ IgA; ↓ IgE	Normal	Normal	Autosomal recessive; 11q22—q23

↓ = decreased; ↑ = increased; N = normal; ADA = adenosine deaminase; PNP = purine nucleoside phosphorylase; RAG = recombination activating gene.

this disorder. Death related to overwhelming sepsis usually occurs within the first 2 years of life if untreated. Bone marrow transplantation or gene therapy are the only options for successful treatment.

Sex-Linked SCID. Classic sex-linked (X-linked) SCID is the most common form of inherited severe combined immunodeficiency, accounting for ~45% of cases. This form of SCID (a $T^+B^+NK^+$ SCID) has been mapped to the long arm of the X chromosome (Xq13.1—q21.1) and was originally associated with a loss-of-function mutation in the gene for the γ -chain of the IL-2 receptor. Because the γ -chain also is an essential subunit of the receptors for IL-4, IL-7, IL-9, and IL-15, cytokine regulation by all of these cytokines is impaired. IL-7/IL-7R signaling is required for T cell development and, in its absence, there is failure of T cell lymphopoiesis. Thus X-linked SCID is characterized by absent T lymphocytes and a hypoplastic thymus. B lymphocytes are normal or even increased in number but are functionally abnormal due to lack of T helper function, and immunoglobulin levels are severely depressed. Family history is important in determining the mode of inheritance of SCID, although a negative family history of the disease does not rule out an X-linked disease. Up to one-third of the cases present as a spontaneous mutation.^{24,32}

Females who carry the abnormal X-linked SCID gene have normal immunity. These carriers can be detected by molecular assays for mutations in the γ -chain locus using cells other than lymphocytes. The normal mature female cell population is mosaic with one or the other X chromosome inactivated. In female SCID carriers, however, only lymphocytes carrying normal X chromosomes are found rather than the expected mixture of cells with normal and abnormal X chromosome inactivation. It has been found that random X chromosome inactivation occurs in these carriers, but the gene product of the mutant-X chromosome does not support lymphocyte maturation. Thus, lymphocytes with the mutant X chromosome fail to develop, and the only lymphocytes found in carriers have the active normal X chromosome.

Checkpoint! 4

Would you expect female carriers of X-linked SCIDs to be more susceptible to infection than the normal population? Why or why not?

Autosomal SCID. The autosomal forms of SCID exhibit severe deficiencies of both T and B lymphocytes. The most common form, found in about 50% of autosomal-recessive SCID (15% of all SCID patients), is due to an adenosine deaminase (ADA) deficiency.^{34,35} The adenosine deaminase gene is located at chromosome 20q13.11. Both point mutations and gene deletions have been associated with an ADA deficiency. Another enzyme deficiency, purine nucleoside phosphorylase (PNP), is the cause of ~2% of SCID cases. The

gene for PNP is located at chromosome 14q13.1. Both of these enzymes degrade purines. Without the enzyme, accumulation of toxic DNA metabolites (deoxyadenosine triphosphate/dATP and deoxyguanosine triphosphate/dGTP) occurs, inhibiting normal T and B cell development. In both cases, the result is a $T^+B^-NK^+$ type of SCID. Other defects include a deficiency of MHC class II gene expression, interleukin-2 (IL-2) deficiency, mutations in the *RAG-1* and *RAG-2* genes (which catalyze VDJ recombination), and defective assembly of the T lymphocyte receptor/CD3 complex.²⁶

CASE STUDY (continued earlier in this chapter)

All of Heidi's immunoglobulin levels were decreased. T and B lymphocyte counts were severely decreased. The peripheral blood smear showed anisocytosis, poikilocytosis (schistocytes), polychromatophilia, and 2 nucleated RBCs/100 WBCs. Her thymus was not detectable on chest films.

- Is this child more likely to have a congenital or acquired immune deficiency?
- If she has a congenital immune deficiency, is it more likely she has X-linked or autosomal SCIDs?
- Are the lymphocytes more likely to be morphologically heterogeneous or homogeneous? Why?
- What confirmatory test is indicated?

Wiskott-Aldrich Syndrome Wiskott-Aldrich syndrome (WAS) is a sex-linked recessive disease characterized by the triad of eczema, thrombocytopenia, and immunodeficiency resulting in recurrent infections. About two-thirds of affected children have a family history of the disease; one-third reflects a spontaneous mutation. Most children die before 10 years of age due to infection or bleeding. Those who survive longer can develop neoplasms of the histiocytic, lymphocytic, or myelocytic systems.

Laboratory findings play an important role in the diagnosis of WAS (Table 8). There is progressive decrease in thymic-dependent immunity and depletion of paracortical areas in the lymph nodes leading to abnormal lymphocyte function. The absolute numbers of helper and suppressor T lymphocytes and their ratio is normal to variable. Typically, CD8 T lymphocytes are decreased, but numbers vary over time for individuals. Circulating B lymphocyte concentrations are normal, but antibody production is abnormal.³⁶ Serum IgM levels are decreased, but IgE and IgA levels are increased. IgG concentrations are usually normal.

One of the most consistent findings is low or absent levels of circulating antibodies to the blood group antigens.³⁶ This is due to the inability of these children to produce antibodies to polysaccharide antigens. This T-lymphocyte-independent phenomenon suggests that there is an intrinsic B lymphocyte abnormality.

★ TABLE 8

Laboratory Features in Wiskott-Aldrich Syndrome

- Platelets: decreased concentration; small size
- Lymphocytes: decreased or normal concentration; T lymphocytes variable; B lymphocytes usually normal
- Immunoglobulin: IgM decreased, IgE and IgA increased, IgG normal/increased
- Antibodies to blood group antigens absent
- PCR detects WAS gene mutation

A low platelet count with abnormal bleeding in the neonatal period is one of the first clinical signs of WAS. Patients have a severe thrombocytopenia ($<70,000/\text{mm}^2$) with small sized platelets.³⁵ Bleeding times are abnormal, but the prothrombin time and activated partial thromboplastin time are normal, indicating the coagulation factor proteins are adequate. Megakaryocytes in the bone marrow are normal or increased in number. Genetic mutations involve the WAS gene on the short arm of the X chromosome between Xp11.3 and Xp11.22. Females are carriers; affected males cannot pass the deficiency to their male children. PCR techniques detect 98% of affected males and are the primary diagnostic tests when WAS is suspected.³⁵ Molecular analysis using restriction fragment length polymorphisms reveals that female carriers have selective inactivation of the WAS X chromosome rather than random inactivation of paternal or maternal X chromosomes. This nonrandom inactivation pattern is found in the carrier's T and B lymphocytes, granulocytes, monocytes, and megakaryocytes, indicating all hematopoietic cells in WAS express the defect.

Therapy includes treatment for bleeding and infection. Splenectomy usually results in correction of the platelet count and significantly reduces the risk of bleeding complications. Bone marrow transplantation has been used with some success.

 **Checkpoint! 5**

What laboratory findings suggest WAS in a child, and how is the diagnosis confirmed?

DiGeorge Syndrome DiGeorge syndrome is a congenital immunodeficiency marked by the absence or hypoplasia of the thymus, hypoparathyroidism, heart defects, and dysmorphic facies. Hypocalcemia is typical, and the presenting symptom can be seizure due to hypocalcemia. There is usually a decrease in peripheral blood T lymphocytes as well as a decrease in the cellularity of the thymic-dependent regions of peripheral lymphoid tissue. The low lymphocyte count is related to a decreased number of CD4 lymphocytes. T lymphocyte function varies. Those children with a hypoplastic thymus may be able to produce enough lymphocytes with

normal function to maintain immunocompetence. B lymphocytes are normal in number and function, and immunoglobulin levels are normal. Infants exhibit increased susceptibility to viral, fungal, and bacterial infections that are frequently overwhelming. Death occurs in the first year unless thymic grafts are performed.

Cytogenetic studies on these children reveal a deletion within chromosome 22q11.³⁷ This defect also is found in a parent of a child with DiGeorge syndrome in 25% of the cases.

Sex-Linked Agammaglobulinemia Sex-linked (X-linked) agammaglobulinemia (Bruton's disease) is inherited as a sex-linked disease characterized by frequent respiratory and skin infections with extracellular, catalase-negative, pyogenic bacteria. Molecular analysis has revealed that the genetic defect is on the long arm of the X chromosome (q21.3—q22).²⁶ More than 90% of patients have a loss-of-function mutation of a tyrosine kinase gene named *Bruton tyrosine kinase (BTK)*. The genetic mutation results in a block in B lymphocyte maturation at the pre-B-lymphocyte stage. The variable and constant regions of the IgM immunoglobulin chain fail to connect. Peripheral blood lymphocyte counts are normal as are T lymphocytes; there is, however, a decrease in B lymphocytes and an absence of plasma cells in lymph nodes. The serum concentrations of IgG, IgM, and IgA are decreased or absent. Cell-mediated immune function is normal. Monthly injections of gamma globulin are effective in preventing severe infections.

Female carriers of this disease have normal immunity. All of their B lymphocytes carry the paternal, normal X chromosome. This suggests the normal X chromosome confers a growth advantage to the normal cells.

Ataxia-Telangiectasia Ataxia-telangiectasia (AT) is inherited as an autosomal-recessive disease that results from mutations in the ataxia-telangiectasia mutated gene (ATM) at chromosome 11(q22—q23). The ATM protein is involved in the repair of DNA double-stranded breaks. The disease is characterized by progressive neurologic disease, immune dysfunction, and predisposition to malignancy. Affected individuals are ataxic and develop telangiectasias in childhood or adolescence. Telangiectasia is a vascular lesion formed by a dilation of a group of blood vessels that appears as a red line or radiating limbs (spider). Chronic respiratory infection and lymphoid malignancy are the most common causes of death.

These patients have a defect in cell-mediated immunity with hypoplasia or dysplasia of the thymus gland and depletion of thymic-dependent areas in the lymph nodes. B lymphocyte function also is abnormal. Lymphocytopenia with a reversed CD4:CD8 ratio exists along with deficiencies in IgA, IgG and IgE. IgM levels are increased. Cytogenetic analysis reveals excessive chromosome breakage and rearrangements in cultured cells and clonal abnormalities of chromosome 7 or 14.³⁸

SUMMARY

Lymphocytes mount an immune response in inflammatory or infectious states. In these states, the lymphocyte morphology often includes various reactive forms, immunoblasts, and possibly plasmacytoid cells. Quantitative changes in the total lymphocyte concentration occur, which can be either increased or decreased. Although the lymphocyte induces an immune response to eliminate foreign antigens, the cell itself also can serve as the site of infection for some viruses that use lymphocyte membrane receptors to attach to and invade the cell.

Infectious mononucleosis is a common self-limiting lymphoproliferative disorder caused by infection with EBV. Laboratory diagnosis of this disorder includes serologic testing for heterophile antibodies and identification of reactive lymphocytes on Romanowsky-stained blood smears.

AIDS is a disease caused by infection of the CD4 lymphocyte with the retrovirus HIV-1. The virus suppresses the immune response by replicating within and destroying CD4 lymphocytes. CD4 lymphocyte levels and viral loads monitor the disease's progression. Antiviral treatments in combination with protease inhibitors slow the progression of the disease process. This disease has no cure.

Congenital qualitative disorders of lymphocytes include a wide variety of immunodeficiency disorders. Either the T or B lymphocyte or both can be affected. These are usually very serious defects with most affected individuals succumbing to the disease in childhood. Diagnosis involves genetic tests. Bone marrow transplant is the only treatment in many cases.

REVIEW QUESTIONS

LEVEL I

- The infectious agent in infectious mononucleosis is: (Objective 1)
 - CMV
 - HIV
 - EBV
 - Toxoplasmosis gondii*
- Large reactive (atypical) lymphocytes with dispersed chromatin and irregular cytoplasmic membranes are associated with: (Objective 2)
 - infectious lymphocytosis
 - infectious mononucleosis
 - cytomegalovirus infection
 - hepatitis
- Which of the following best describes the lymphocytes seen in viral infection? (Objective 5)
 - large cells with high N:C ratio, immature nucleus, and vacuoles
 - small cells with high N:C ratio and vacuolated cytoplasm
 - large cells with deep basophilic cytoplasm and decreased N:C ratio
 - large cells with immature nuclei and high N:C ratio
- The CD4:CD8 ratio of T lymphocytes in a patient with AIDS is: (Objectives 9, 10)
 - 2:1
 - increased
 - decreased
 - equal
- The type of antibodies found in infectious mononucleosis that are used to confirm a diagnosis are: (Objective 3)
 - heterophile antibodies
 - cold agglutinins
 - PIG antibodies
 - HIV antibodies

LEVEL II

Use this case study for questions 1–3.

A 39-year-old male was seen at the clinic with complaints of nagging cough, weight loss, diarrhea, and low-grade temperature. Results of physical examination showed lymphadenopathy, congested lungs, and increased heart rate. Slight splenomegaly and hepatomegaly were noted. A CBC and flow cytometry studies were ordered. Histologic examination of sputum with Gomori's methenamine silver nitrate stain revealed *Pneumocystis carinii*.

Laboratory Data:

Erythrocyte count	3.86 × 10 ¹² /L	
Hb	13.6 g/dL (136 g/L)	
Hct	0.41 L/L	
Platelet count	104 × 10 ⁹ /L	
Leukocyte count	2.8 × 10 ⁹ /L	
Differential		
Segmented neutrophils	68%	Monocytes: 10%
Lymphocytes	21%	Eosinophils: 1%
Positive for HIV-1 antibodies		

- What clinical condition does this patient have? (Objectives 8, 10)
 - congenital immune deficiency
 - infectious mononucleosis
 - ARC
 - AIDS
- Which lymphocytes are periodically counted to monitor the disease? (Objective 8)
 - infected B lymphocytes
 - CD4 T lymphocytes
 - CD8 T lymphocytes
 - natural killer lymphocytes

REVIEW QUESTIONS (continued)

LEVEL I

6. The HIV-1 virus infects what type of lymphocyte? (Objective 9)
 - a. B lymphocyte
 - b. suppressor T lymphocyte
 - c. CD4+ T lymphocyte
 - d. CD8+ T lymphocyte
7. A 2-year-old child has a total leukocyte count of $10 \times 10^9/L$ and 60% lymphocytes. Which of the following best describes the child's blood count? (Objectives 4, 8)
 - a. absolute lymphocytosis
 - b. relative lymphocytosis
 - c. normal lymphocyte count for the age given
 - d. absolute lymphocytopenia

Use this case study for questions 8–10.

A 19-year-old female college student went to student health complaining of lethargy and a sore throat over the last two weeks. Physical exam shows pharyngitis, lymphadenopathy, and splenomegaly with a total leukocyte count of $11 \times 10^9/L$ and 70% lymphocytes (50% of lymphs are reactive).

8. She probably has: (Objective 1)
 - a. HIV
 - b. hepatitis
 - c. X-linked SCIDS
 - d. infectious mononucleosis
9. Her absolute lymphocyte count is: (Objective 4)
 - a. $10 \times 10^9/L$
 - b. $11 \times 10^9/L$
 - c. $5.5 \times 10^9/L$
 - d. $7.7 \times 10^9/L$
10. The best description of this patient's leukocyte count is a(n): (Objectives 4, 8)
 - a. relative lymphocytopenia
 - b. relative neutrophilia
 - c. absolute lymphocytosis
 - d. absolute neutrophilia

LEVEL II

3. Which laboratory test is used to follow this patient's disease? (Objective 8)
 - a. HIV-1 viral load
 - b. throat swab
 - c. serologic test for heterophile antibody
 - d. PCR for genetic mutations
4. A clue to differentiating the lymphocytes of infectious mononucleosis from those found in neoplastic lymphocytic disorders is that in neoplastic disorders, the lymphocytes are: (Objective 5)
 - a. morphologically similar
 - b. heterogeneous morphologically
 - c. not increased
 - d. reactive
5. A 17-year-old male has a sore throat and lymphadenopathy. He is lethargic and has a temperature of 99.5°F. Laboratory tests reveal a leukocyte count of $13 \times 10^9/L$ with 65% lymphocytes, most of which are reactive. The heterophile antibody test is positive, the VCA-IgM titer is 1:640, VCA-IgG titer is 1:120, and EBNA is not detectable. What is the most likely explanation for these results? (Objectives 3, 10)
 - a. acute EBV infection
 - b. EBV infection within the last 3–12 months
 - c. EBV infection more than a year ago
 - d. no EBV infection present now or in the past
6. In female carriers of sex-linked, severe combined immunodeficiency gene, the lymphocytes carry: (Objective 9)
 - a. a normal X chromosome in the T lymphocytes
 - b. the mutant X chromosome in T and B lymphocytes
 - c. the mutant X chromosome in T lymphocytes
 - d. the mutant X chromosome in 50% of T lymphocytes
7. *Bordetella pertussis* infection is characterized by: (Objective 7)
 - a. positive heterophile antibody test and lymphocytosis
 - b. lymphocytopenia and reactive lymphocytes
 - c. lymphocytosis with normal appearing lymphocytes
 - d. lymphocytosis with reactive lymphocytes
8. Occasionally, a patient who has been exposed to EBV shows clinical symptoms and reactive lymphocytes but has a negative serologic test. This could be due to: (Objective 1)
 - a. infection with a parasite
 - b. infection with *Bordetella pertussis*
 - c. infection with syphilis
 - d. early infection with no detectable antibody
9. Documentation and surveillance for AIDS in patients includes those who are positive for: (Objective 8)
 - a. HIV viral DNA
 - b. EBV viral RNA
 - c. heterophile antibodies
 - d. any bacterial infection

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

10. Which of the following nonmalignant conditions is associated with a lymphocytosis? (Objectives 5, 7, 9)
- whooping cough
 - AIDS
 - X-linked immunodeficiency syndrome
 - SCIDS

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Heidi has had recurrent infections since birth. Her WBC was normal but there was an absolute lymphocytopenia. Further investigation suggested an immune deficiency disorder and led to additional laboratory tests. These tests revealed high levels of erythrocyte adenosine and deoxyadenosine indicating a deficiency in adenosine deaminase. This deficiency occurs from a gene deletion resulting in an autosomal inherited severe combined immunodeficiency. Normal immune function is restored when (1) toxic metabolites are cleared, (2) a normal adenosine deaminase gene is inserted into the patient's lymphocytes, or (3) the patient has a bone marrow transplant.

Question:

1. Does this patient have a leukocytosis or leukopenia? Explain.

Explanation:

No, she does not have a leukocytosis or leukopenia. The WBC count is within normal range.

Question:

2. Does this patient have an abnormal lymphocyte count? Explain.

Explanation:

The absolute lymphocyte count = $7.6 \times 10^9/L \times 0.04 = 0.304 \times 10^9/L$. This is abnormally low because the reference range at this age is $2.5\text{--}16.5 \times 10^9/L$.

Question:

3. What is the absolute lymphocyte count?

Explanation:

At 54 days, the absolute lymphocyte count is only $12.3 \times 10^9/L \times 0.01 = 0.123 \text{ lymphocytes} \times 10^9/L$, a condition of lymphocytopenia.

Question:

4. What possible causes exist for these opportunistic infections?

Explanation:

Two causes of immunodeficiency are suspected with opportunistic infection and severe lymphocytopenia: (1) AIDS and (2) severe combined immunodeficiency syndrome.

Question:

5. Is this child more likely to have a congenital or acquired immune deficiency?

Explanation:

A congenital immune deficiency is more probable as the child has had recurrent infections and lymphocytopenia since birth.

Question:

6. If she has a congenital immune deficiency, is it more likely she has X-linked or autosomal SCIDS?

Explanation:

Autosomal SCIDS is more likely. Females who carry the abnormal X-linked SCIDS gene have normal immunity. Only normal X chromosomes are found in the lymphocytes of females who carry the abnormal X-linked SCIDS gene.

Question:

7. Are the lymphocytes more likely to be morphologically heterogeneous or homogeneous? Why?

Explanation:

They are more likely homogeneous. The congenital immune deficiency disorders are characterized by normal appearing lymphocytes, but the lymphocytes are either defective or decreased in concentration or both. Heterogeneous lymphocytes are normally reactive lymphocytes. They are stimulated by infectious agents.

Question:

8. What confirmatory test is indicated?

Explanation:

A test to determine a decreased adenosine deaminase level or increased purine metabolites of deoxyadenosine triphosphate and deoxyguanosine triphosphate confirm an enzyme deficiency.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

A patient with lymphocytosis showing reactive lymphocyte morphology with large, basophilic cells, fine chromatin, and a visible nucleolus has a negative infectious mononucleosis serologic test. What is a possible cause for this altered lymphocyte morphology?

Answer

Causes of reactive lymphocyte morphology are other viral infections, particularly hepatitis or cytomegalovirus, and reactions to drugs or toxoplasmosis. If the patient is under 10 years of age, the child may not produce heterophil antibodies in increased quantities and thus yield a negative serologic test when infected with EBV. Some adults do not produce a positive serologic test either even though they are infected with EBV.

Checkpoint! 2

Why is lymphocytopenia a concern if there is no accompanying leukopenia.

Answer

A decrease in lymphocytes impairs the body's immune response and makes the patient more susceptible to disease.

Checkpoint! 3

Why does infection with HIV result in an increased chance for opportunistic infections?

Answer

HIV-1 gains access to cells through the CD4 protein receptor on the cell surface. Some T lymphocytes, monocytes, and macrophages express this receptor. Once in the cell, it destroys the T lymphocyte, compromising the cell-mediated immune system and allowing opportunistic infections to cause disease.

Checkpoint! 4

Would you expect female carriers of X-linked SCIDS to be more susceptible to infection than the normal population?

Answer

No, all of their lymphocytes have the normal X chromosome activated.

Checkpoint! 5

What laboratory findings suggest WAS in a child, and how is the diagnosis confirmed?

Answer

Thrombocytopenia, lack of blood group reverse typing, decreased IgM levels but increased IgE and IgA levels suggest WAS. Diagnosis for WAS is substantiated by flow cytometry and molecular analysis. A positive PCR test revealing the gene mutation confirms the presence of the disease.

Introduction to Hematopoietic Neoplasms

Shirlyn B. McKenzie, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define and differentiate the terms *neoplasm* and *malignant* and identify hematopoietic disorders that can be included in each category.
2. Compare and contrast the general characteristics of the myelodysplastic syndromes (MDS), myeloproliferative disorders (MPD), and acute and chronic leukemias.
3. Name and describe the classification systems used for MDS, MPD, and the leukemias.
4. List the various methods used to categorize the leukemias.
5. Compare and contrast the laboratory findings of the acute and chronic leukemias and myeloid and lymphoid leukemias.
6. Differentiate proto-oncogenes and oncogenes and summarize their relationship to neoplastic processes.
7. Correlate patient age to the overall incidence of the hematopoietic neoplasms.
8. Explain the usefulness of immunological techniques, chromosome analysis, molecular analysis, and cytochemistry in the diagnosis and prognosis of hematopoietic neoplasms.
9. Predict the prognosis and survival rates of the hematopoietic neoplasms.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Explain how proto-oncogenes are activated and the role that oncogenes and tumor suppressor genes and their protein products play in the etiology of hematopoietic neoplasms.
2. Describe the effects of radiation on the incidence of leukemia.
3. Differentiate between the acute and chronic leukemias based on their clinical and hematologic findings.
4. Reconcile the use of chemotherapy for treatment of leukemia.
5. Compare and contrast treatment options for the hematopoietic neoplasms including possible complications.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Etiology/pathophysiology
- ▶ Epidemiology
- ▶ Clinical findings
- ▶ Hematologic findings
- ▶ Hematopoietic neoplasm classification
- ▶ Laboratory procedures for diagnosing and classifying neoplasms
- ▶ Prognosis and treatment of neoplastic disorders
- ▶ Summary
- ▶ Review questions
- ▶ References

■ OBJECTIVES—LEVEL II (continued)

6. Name the leukemogenic factors of leukemia and propose how each contributes to the development of leukemia.
7. Compare and contrast laboratory features of MDS, MPD, and acute leukemia (AL), and justify a patient diagnosis based on these features.
8. Define the principles of, explain the applications of, and select appropriate cytochemical stains for bone marrow evaluation.
9. Select laboratory procedures appropriate for confirming cell lineage and diagnosis in hematopoietic neoplasms.
10. Explain the role of epigenetics in cancer.
11. Define *cancer stem cell* and explain its similarities to the hematopoietic stem cell (HSC).

KEY TERMS

Acute lymphocytic leukemia (ALL)
 Acute myeloid leukemia (AML)
 Aleukemic leukemia
 Auer rods
 Benign
 Cancer-initiating cell
 Cancer stem cells
 Chronic lymphocytic leukemia (CLL)
 Chronic myelogenous leukemia (CML)
 Consolidation therapy
 Cytogenetic remission
 Epigenetics
 French-American-British (FAB)
 Hematologic remission
 Induction therapy
 Leukocyte alkaline phosphatase (LAP)
 Leukemia
 Leukemic hiatus
 Leukemic stem cell
 Lymphoma
 Maintenance chemotherapy
 Malignant
 Minimum residual disease (MRD)
 Molecular remission
 MPO
 Myelodysplastic syndromes (MDS)
 Myeloproliferative disorders (MPD)
 Neoplasm
 Nonspecific esterases
 PAS
 Specific esterases
 Tartrate resistant acid phosphatase (TRAP)

BACKGROUND BASICS

The information in this chapter serves as a general introduction to the hematopoietic neoplasms. To maximize your learning experience you should review these concepts before starting this unit of study.

Level I

- ▶ Summarize the origin and differentiation of the hematopoietic cells.
- ▶ Describe the morphologic characteristics of the hematopoietic cells.
- ▶ Define *oncogenes* and *proto-oncogenes*.

Level II

- ▶ Describe the actions of growth factors and oncogenes.
- ▶ Summarize the cell cycle and identify factors that affect it.
- ▶ Describe the normal structure and function of the bone marrow, spleen, and lymph nodes.

CASE STUDY

We will refer to this case study throughout the chapter.

Agnes, a 72-year-old female, was seen by her physician for a persistent cough and fatigue. She had always been in good health and played golf regularly. Upon examination, she was noted to be pale and had slight splenomegaly. A CBC revealed the WBC was $83.9 \times 10^9/L$. Consider possible explanations for this test result and select reflex tests that should be performed.

► **OVERVIEW**

This chapter provides a general introduction to the neoplastic hematopoietic disorders. It discusses oncogenesis including how oncogenes are activated and their association with hematopoietic disease. This is followed by a description of how neoplasms are classified and characterized according to cell lineage and the degree of cell differentiation, morphology, cytochemistry, immunophenotype, and genetic abnormalities. The etiology and pathophysiology of the leukemias are examined with general clinical and laboratory findings. Finally, prognosis and treatment modalities are considered for the disorders.

► **INTRODUCTION**

Neoplasm (tumor) literally means “new growth.” Neoplasms arise as a consequence of dysregulated proliferation of a single transformed cell. Genetic mutations in the transformed cell reduce or eliminate the cell’s dependence on external growth factors to regulate proliferation.

Neoplasms are either malignant or benign. **Benign** neoplasms are formed from highly organized, differentiated cells and do not spread or invade surrounding tissue. *Malignancy* means “deadly” or “having the potential for producing death.” A **malignant** neoplasm is a clone of abnormal, anaplastic, proliferating cells, which often have the potential to metastasize. Only malignant tumors are correctly referred to as cancer. Although cancer is actually a malignancy of epithelial tissue, common use of the term includes all malignant neoplasms. A benign neoplasm can be premalignant and progress with further genetic mutations to a malignant neoplasm.

Neoplasms of hematopoietic cells in the bone marrow are phenotypically grouped as lymphoid or myeloid. Both groups include benign (pre-malignant) and malignant neoplasms. The pre-malignant myeloid neoplasms include the **myeloproliferative disorders (MPD)** and **myelodysplastic syndromes (MDS)**. (Figure 1 ■) The pre-malignant

■ **FIGURE 1** The spectrum of granulocytic proliferation disorders ranges from benign to malignant processes. Benign granulocyte proliferation is usually a reactive process. Myeloproliferative disorders, myelodysplastic syndromes, and acute myeloid leukemia (AML) are neoplastic clonal stem cell defects characterized by autonomous proliferation of hematopoietic cells. (Adapted from McKenzie, S. Chronic myelocytic leukemia. *Tech Sample*. H-4 Chicago, ASCP; 1990.)

lymphoid disorders include the chronic lymphoproliferative disorders and plasma cell disorders. The lymphoid and myeloid malignant bone marrow neoplasms are collectively known as **leukemia**. Malignant cells may or may not circulate in the peripheral blood. The term *leukemia* is used when abnormal cells are seen in both the bone marrow and peripheral circulation. If the abnormal cells are found only in the bone marrow, the term **aleukemic leukemia** is used.

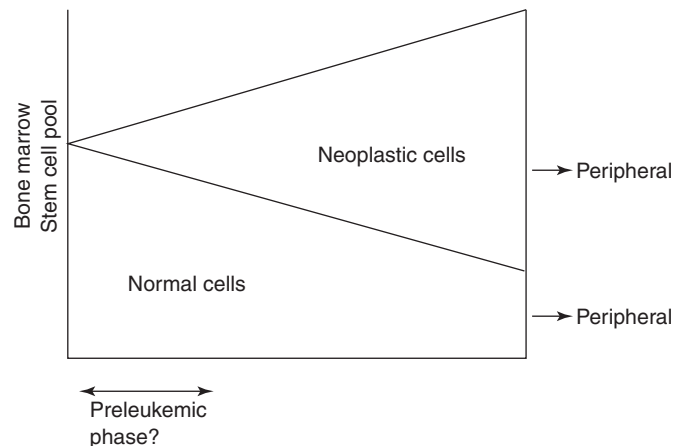

Abnormal proliferation of lymphoid cells sometimes occurs within the lymphatic tissue or lymph nodes. These solid tumors are referred to as **lymphoma**. If the lymphoma affects the bone marrow and the lymphoma cells are found in the peripheral circulation, the leukemic phase of *lymphoma* is present.

Failure of normal hematopoiesis is the most serious consequence of malignant neoplasms. As the neoplastic cell population increases, the concentration of normal cells decreases, resulting in the inevitable cytopenias of normal blood cells (Figure 2 ■). If the neoplasm is not treated, the patient usually succumbs to infections secondary to granulocytopenia or bleeding secondary to thrombocytopenia.

The next section briefly discusses these major groups of hematopoietic neoplasms.

LEUKEMIAS

The two broad groups of leukemia are myeloid and lymphoid, which are based on the origin of the leukemic stem cell clone. If myelocytic cells or other cells derived from the common myeloid progenitor cell (CMP) predominate, the disease is called *myelogenous leukemia*. If lymphoid cells predominate, the disease is termed *lymphocytic leukemia*. These two groups are further classified based on the aggressiveness of the illness and degree of differentiation of the leukemic

■ **FIGURE 2** Clonal expansion of neoplastic cells in the bone marrow in leukemia over a period of time.

★ TABLE 1

Comparison of Acute and Chronic Leukemias

	Acute	Chronic
Age	All ages	Adults
Clinical onset	Sudden	Insidious
Course of disease (untreated)	Weeks to months	Months to years
Predominant cell	Blasts, some mature forms	Mature forms
Anemia	Mild–severe	Mild
Thrombocytopenia	Mild–severe	Mild
WBC	Variable	Increased

cells: (1) acute, an aggressive disease (**acute myeloid [myelogenous or myelocytic] leukemia, AML; acute lymphoid [lymphoblastic or lymphocytic] leukemia, ALL**); and (2) chronic, a less aggressive form (**chronic myelogenous leukemia, CML; chronic lymphocytic leukemia, CLL**) (Table 1 ★).

In acute leukemia, there is an apparent gap in the normal maturation pyramid of cells with many blasts and some mature forms but an apparent decrease in intermediate maturational stages. This is referred to as the **leukemic hiatus**. The mature cells seen in the bone marrow and peripheral blood arise from proliferation of the residual normal hematopoietic stem cells (HSC) in the bone marrow. The apparent excess of blasts reflect primarily proliferation of the abnormal malignant clone, which fails to undergo maturation. Eventually, the immature neoplastic cells fill the bone marrow and spill over into the peripheral blood, producing

leukocytosis. In the laboratory, the diagnosis of acute leukemia is suggested when examination of the peripheral blood smear reveals the presence of many undifferentiated or minimally differentiated cells (Figure 3 ■). Chronic leukemias are characterized by leukocytosis and although blasts may be present in the peripheral blood, there is a predominance of more mature cells (Figure 4 ■).

Subtypes of acute leukemia (ALL, AML) can be identified based on morphologic, cytochemical, immunologic, and genetic criteria of the malignant cells. Acute leukemias involving the granulocytic, monocytic, erythrocytic, or megakaryocytic cell lines are classified as subtypes of acute myeloid leukemia (also known as *acute nonlymphocytic leukemia, ANLL*) because these cell types develop from the common myeloid progenitor cell, CMP. The ALL group can be subtyped based on immunophenotype of the neoplastic lymphoid cell, as T or B cell neoplasms.

In the past, chronic leukemias were commonly classified as a distinct group of hematopoietic disorders. More recently, they have been grouped with other chronic neoplastic stem cell disorders, MPD, MDS, and chronic lymphoproliferative disorders. The bone marrow in chronic leukemias typically exhibits an accumulation of differentiated lymphocytic (CLL) or myelocytic (CML) elements (<20% blasts). The differential count of the bone marrow and of peripheral blood is similar with all stages of maturation present but with a predominance of the more mature forms.

✓ Checkpoint! 1

A patient has 50% monoblasts in the bone marrow. Which of the four major types of leukemia—AML, CML, ALL, or CLL—does he have?

■ FIGURE 3 Acute myelocytic leukemia. Note the large number of myeloblasts with no mature granulocytes present. (Wright stain, 1000×, PB).

■ FIGURE 4 Chronic myelogenous leukemia. Note the large number of granulocytic cells in various stages of granulocytic maturation including blasts, metamyelocyte, bands and segmented neutrophils. (Wright stain, 1000×, PB).

MYELOPROLIFERATIVE DISORDERS

The MPDs are characterized by a hypercellularity of the bone marrow and erythrocytosis, granulocytosis, and/or thrombocytosis in the peripheral blood due to unregulated cell proliferation. One cell line is usually more prominent than the others, a feature used to subgroup these clonal stem cell disorders. Acquired abnormalities of tyrosine kinases or other proteins involved in cell cycle signaling are commonly found in these disorders. The MPDs are found most often in adults.

MYELOYDYSPLASTIC SYNDROMES

The MDS are characterized by a hypercellular, dysplastic bone marrow and peripheral blood cytopenias with variable dysplasia of the various lineages. The peripheral blood cytopenias are the result of ineffective hematopoiesis and increased apoptosis. The transformed neoplastic cell is thought to be the pluripotential HSC. The MDS are subgrouped based on percentage of blasts, presence or absence of ringed sideroblasts, and number of cytopenias and dysplastic cell lines. These disorders are found most commonly in the elderly.

MYELOYDYSPLASTIC SYNDROMES/ MYELOPROLIFERATIVE DISORDERS

This group of disorders is characterized by the proliferative features of MPD and dysplastic features of MDS. They are subgrouped by lineage of the involved neoplastic cell.

▶ ETIOLOGY/PATHOPHYSIOLOGY

Hematopoietic neoplasms are believed to occur as the result of a somatic mutation of a single hematopoietic stem or progenitor cell. Evidence for the clonal evolution of neoplastic cells comes from cytogenetic studies. More than 50% of individuals with leukemia show an acquired abnormal karyotype in hematopoietic cells whereas other somatic cells are normal. Using these specific cytogenetic markers, normal and malignant cells can be demonstrated to populate the marrow simultaneously. In untreated leukemias and during relapse, the leukemic cells dominate whereas during remission, only normal cells can usually be detected. The MPD, MDS, and lymphomas are also associated with nonrandom genetic abnormalities.

The cell in which a genetic mutation(s) occurs can be a committed lymphoid or myeloid progenitor cell (CMP, CLP) or a more primitive precursor cell that has the potential of differentiating into either lymphoid or myeloid cells, the hematopoietic stem cell (HSC), or the multipotential progenitor cell (MPP).¹ The cell from which the cancer originally

arises is sometimes called the *cell of origin* or the **cancer-initiating cell** (Figure 5 ■). A hallmark of hematologic malignancies is the capacity for unlimited self-renewal of the cancer initiating cell, which is also a characteristic of normal HSC. Normal MPP, CMP, and CLP do not have the self-renewal capacity. Because malignant cells share the capacity for self-renewal with the HSC, it would seem logical that the HSC was the source of the transforming (mutation) event. However, if more restricted progenitor cells acquired or reactivated the self-renewal program(s), they could be the cancer-initiating cells.² Many of the signaling pathways that play a role in cancer cell proliferation have been shown to regulate normal stem cell development.^{1,2}

Studies in the field of cancer cell biology over the past several years have resulted in the hypothesis that **cancer stem cells** exist.^{1,2} Most cancers are not truly clonal but

■ **FIGURE 5** Clonal evolution of a neoplasm from a single transformed (mutated) cell (the “cell of origin”). The genetic mutation(s) that transform a normal hematopoietic precursor cell to a malignant cell can occur at either the hematopoietic stem cell (HSC) or committed progenitor cell (CMP, common myeloid progenitor) stage, producing the leukemic “cell of origin.” If the cell of origin is the CMP, the mutations must include the re-acquisition of the capacity for self-renewal (broad curved arrow). If the mutation(s) also results in a block to terminal differentiation (⊥), the resulting malignancy will be acute myeloid leukemia (AML). Residual “normal” HSC and CMP in the marrow will still be capable of producing mature granulocytes.

consist of heterogeneous cell populations. Only a small subset of cells within a tumor is capable of extensive proliferation *in vitro* (in colony-forming assays) and *in vivo* (in transplantation models). These cancer stem cells are believed to be rare cells with infinite proliferative potential that drive the formation and growth of tumors. In leukemias, identification of the leukemic stem cell (LSC) for each type of leukemia has become a major focus of research.

The mutation(s) resulting in malignant transformation can often be identified as a chromosome alteration (abnormal karyotype) when cells in mitosis are studied. When chromosome studies are normal, aberrations in DNA at the molecular level occasionally can be found. The mutation leads to a survival and/or proliferation advantage over normal cells and to the neoplastic expansion of the affected stem cell and its progeny. In acute leukemia, this unregulated proliferation is accompanied by an arrest in maturation at the blast cell stage.

✓ Checkpoint! 2

A 62-year-old male presents with an elevated leukocyte count, mild anemia, and a slightly decreased platelet count. His physician suspects leukemia. Explain why the erythrocytes and platelets are affected.

ONCOGENES

Until recently, the actual pathogenic mechanisms of neoplasms remained obscure. Enormous progress in our understanding of the pathogenesis of these disorders has been made in the last several decades.

In 1976, J. Michael Bishop and Harold Varmus of the University of California, San Francisco, discovered that normal cells contain genes that can cause cancer/tumors if they become altered or activated.³ These altered cell genes that cause tumors are referred to as *oncogenes* (*onco* means “tumor”), and the normal unaltered cellular counterparts of oncogenes are known as *proto-oncogenes*. Proto-oncogenes can become activated to oncogenes as a consequence of gene mutation, gene rearrangement (translocations, inversions, deletions), and gene amplification. This alters gene expression or activity/structure of its protein product. In the normal cellular state, proto-oncogenes direct cellular growth, proliferation, differentiation, or apoptosis by encoding proteins that are involved at every level of growth regulation. When altered, these genes are capable of inducing and maintaining cell transformation.

The protein products encoded by proto-oncogenes include:

- Growth factors
- Growth factor receptors
- Proteins involved in signal transduction
- Transcription factors (nuclear)

When a proto-oncogene is activated to an oncogene, either a qualitative or quantitative change occurs in the gene's protein product. Protein changes include increased protein activity, unregulated protein control and increased protein production. These changes allow cells to proliferate without the normal controls.

Another type of gene recognized as playing a role in neoplastic transformation of cells is the anti-oncogene, or tumor-suppressor gene (TSG). The TSG products function by suppressing cellular proliferation and, hence, neoplastic transformation. For example, they can trigger apoptosis if DNA cannot be repaired, or they can block the progression of the cell cycle if DNA is damaged. In terms of oncogenic potential, these genes are considered recessive because one copy is usually sufficient to provide a reasonable amount of normal functioning protein to keep cell growth in check. Mutations to both copies, however, eliminate the block and facilitate tumor growth. Recently, a number of tumor-suppressor genes have been shown to be associated with malignancy when only a single mutated allele was present, indicating that for these TSG, haploinsufficiency (loss of one copy of the gene) can be tumorigenic.

ROLES OF ONCOGENES AND TUMOR-SUPPRESSOR GENES IN NEOPLASIA

Neoplasia is a multistep process that involves a series of progressive changes. Both oncogenes and TSG play a role in this process. Activation of an oncogene or loss of a TSG is only one step in tumor development. Alterations of multiple oncogenes and TSGs acting together probably are necessary for a malignant neoplasm to develop. This concept of multiple genetic mutations helps explain the high incidence of leukemia in nonhematopoietic disorders associated with hereditary genetic mutations such as Down syndrome. In these conditions, the genetic mutation associated with the nonhematopoietic disorder can be one of the first of multiple steps leading to malignancy. Thus, these individuals are at a higher risk of developing a neoplasm. Some benign neoplasms progress to more malignant disorders as additional genetic mutations occur over the course of the disease. For instance, myelodysplasia and chronic leukemia often evolve to acute leukemia as progressive genetic abnormalities occur.

The role of oncogenes and TSGs in the pathogenesis of neoplasms continues to be investigated. Oncogenes have been identified at the breakpoints of chromosomal aberrations that are commonly present in specific types of leukemias and lymphomas. Chromosome breaks and translocations appear to activate these genes and result in the aberrant expression of the protein product (Table 2★). Also, breaks and translocations *within* a gene sequence can produce a hybrid (fusion) gene and a new protein product. For example, the balanced translocation between chromosomes in chronic myelogenous leukemia (CML) 9 and 22 results in

★ TABLE 2

Common Genetic Abnormalities in Hematopoietic Neoplasms (for a more complete listing see Tables 38-6, 38-7, 38-8)

Malignancy	Genetic Abnormality	Involved Genes	Product/Activity
Myeloid neoplasm			
CML	t(9;22)	<i>BCR/ABL</i>	Fusion protein/tyrosine kinase
PV	9p (V617F mutation)	<i>JAK2</i>	Increased tyrosine kinase activity
AML-M2	t(8;21)	<i>ETO/AML1</i>	Fusion protein/transcription deregulation
AML-M3	t(15;17)	<i>PML/RAR-α</i>	Fusion protein/transcription deregulation
CMMoL	t(5;12)	<i>PDGFRB/TEL</i>	Fusion protein/activation of signal transduction pathways
B cell neoplasm			
ALL	t(9;22)	<i>ABL/BCR</i>	Fusion protein/increased tyrosine kinase activity
Pre-B ALL	t(1;19)	<i>E2A/PBX1</i>	Fusion protein/transcription dysregulation
CLL	t(14;19)	<i>IGH/BCL3</i>	Deregulated expression
Lymphomas			
Burkitt lymphoma	t(8;14)	<i>MYC/IGH</i>	Transcription deregulation
Mantle cell lymphoma	t(11;14)	<i>BCL1/IGH</i>	Transcription deregulation
T cell lymphoma	t(8;14)	<i>MYC/TCR</i>	Transcription deregulation
Mixed lineage leukemia	11q23	<i>MLL</i>	Fusion protein/transcription deregulation

CML = chronic myelogenous leukemia; AML = acute myeloid leukemia; PV = polycythemia vera; CMMoL = chronic myelomonocytic leukemia; ALL = acute lymphoblastic leukemia; CLL = chronic lymphocytic leukemia

the formation of a *BCR-ABL* fusion gene that results in synthesis of an abnormal tyrosine kinase (TK) protein.⁴ This protein is constitutively activated and involved in cell cycle signaling and increased resistance to apoptosis. Consequently, the cell is in a continual state of proliferation. As the molecular basis of malignant disorders is disclosed, as in CML, therapy is becoming more targeted. Imatinib (Gleevec), the first-line drug therapy for CML, competitively binds to and prevents cell signal transduction by the mutant *BCR-ABL* kinase. It is not a cure, but it inhibits the TK activity of the aberrant protein.

ACTIVATION OF ONCOGENES

From studies on laboratory animals, several factors have been proposed as playing roles in the activation of oncogenes: (1) genetic susceptibility, (2) somatic mutation, (3) viral infection, and (4) immunologic dysfunction (Table 3).

Genetic Susceptibility

Strong evidence suggests that hereditary factors and abnormal genetic material have important leukemogenic effects. A number of individuals who have congenital abnormalities associated with karyotypic abnormalities have a markedly increased risk of developing acute leukemia. Each of these genetic events has the potential to activate proto-oncogenes or eliminate the function of a TSG. The best known of the genetic abnormalities associated with leukemia is Down syndrome.^{5,6}

Various other congenital disorders also are associated with an increased risk for leukemia; these include Fanconi anemia, Klinefelter syndrome, Bloom syndrome, Wiskott-Aldrich syndrome, and Blackfan-Diamond syndrome.

★ TABLE 3

Factors Proposed to Play a Role in Leukemogenesis

Factor	Example
Genetic susceptibility	Down syndrome
	Fanconi anemia
	Klinefelter syndrome
	Bloom syndrome
	Wiskott-Aldrich syndrome
	Blackfan-Diamond syndrome
	Xeroderma pigmentosum
	Li-Fraumeini syndrome
Somatic mutation	Radiation
	Chemicals
	Drugs
Viral infection	Retroviruses—HTLV-I, II, V, HIV-1
Immunologic disorders	Wiskott-Aldrich syndrome
	Bruton's type X-linked agammaglobulinemia
	Ataxia telangiectasia
	Immunosuppressive therapy

Further evidence supporting the association of genetic factors with the occurrence of leukemia comes from family studies in which increased incidence has been reported in family groups.^{7,8}

Somatic Mutation

A somatic cell mutation is an acquired change in the genetic material of cells other than those involved in reproduction. Mutations in the chromosome near proto-oncogenes likely play a role in the development of neoplasms. More than 50% of patients with leukemia can be demonstrated to have acquired abnormal karyotypes. As data accumulated from cytogenetic studies, specific, consistent mutations have been found in certain subgroups of hematopoietic neoplasms.⁹

Radiation, some chemicals, and drugs can cause chromosome mutations. Ionizing radiation has long been recognized as capable of inducing leukemia, which is evident from observations of human exposure to radiation from nuclear reactions, therapeutic radiation, and occupational exposure to radiation. An increase in leukemia has been observed after treatment with alkylating agents and other chemotherapeutic drugs used in treatment of many kinds of malignancy. The only specific chemical implicated in causing leukemia other than those used as medications is benzene.

Viral Infection

Retroviruses have been shown to cause leukemia in laboratory animals, and a few malignancies can be traced to a viral infection of cells in humans.¹⁰ Retroviruses contain a reverse transcriptase that allows them to produce a DNA copy of the viral RNA core. The DNA can then be copied to produce more viral cores or can be incorporated into the host cell's nuclear DNA. The strongest support for the existence of a leukemogenic virus in humans comes from the isolation of several human retroviruses known as *human T cell leukemia/lymphoma virus* (HTLV-I, II, V) and *human immunodeficiency virus* (HIV-1) from cell lines of patients with mature T cell malignancies.¹¹ Exactly how viruses induce leukemia is unclear, but it is suspected that the incorporation of the viral genome into host DNA can lead to activation of proto-oncogenes.

Immunologic Dysfunction

An increased incidence of lymphocytic leukemia has been observed in both congenital and acquired immunologic disorders. These disorders include the hereditary immunologic diseases Wiskott-Aldrich syndrome, Bruton's type X-linked agammaglobulinemia, and ataxia telangiectasia. An association between long-term treatment of patients with immunosuppressive drugs (e.g., renal transplant) and leukemia also has been observed. Possibly, a breakdown in the cell-mediated immunologic self-surveillance system and/or deficient production of antibodies against foreign antigens leads to the emergence and survival of neoplastic cells.

Miscellaneous Factors

Certain hematologic diseases appear to pose a leukemogenic risk. The development of leukemia sometimes appears to be related to the treatment used for the primary disease, but in other patients no such relationship can be found. The highest incidence of acute leukemia is found in individuals with other neoplastic disorders, such as MPD and MDS,¹² prompting some hematologists to use the word *preleukemia* for these disorders. Additional genetic mutations (or epigenetic alterations, see below) occur as the preleukemic disease progresses to the frank malignancy, leukemia. Other hematopoietic diseases with an increased incidence of leukemia include paroxysmal nocturnal hemoglobinuria (PNH), aplastic anemia, and multiple myeloma. It is interesting to note that all of these hematologic disorders are considered stem cell disorders in which the primary hematologic defect lies in the myeloid or lymphoid progenitor cells or in the pluripotential stem cells.

No single factor is responsible for the activation of oncogenes that result in hematopoietic neoplasms, but the malignancy is produced by a variety of etiologic factors including genetic factors and environmental exposures.^{13,14} The cause probably varies from patient to patient, and some individuals could be more susceptible than others to oncogene activation.

EPIGENETICS AND MALIGNANCY—SILENCING OF TUMOR SUPPRESSORS

Research in the past two decades has revealed that genetic changes (mutations either at the molecular level or chromosomal alterations) and epigenetic changes both contribute to the development of a malignancy.¹⁵ **Epigenetics** is defined as the heritable (i.e., stable from one cell generation to the next during mitosis) changes in gene expression not due to changes in DNA sequence. Epigenetic alterations involve chemical modifications of the DNA polynucleotide chains (e.g., CpG methylation) or the nuclear histone proteins (acetylation, methylation, phosphorylation). These chemical changes alter the configuration of the chromatin, affecting its packaging and accessibility for transcription within the nucleus.¹⁶ The best understood epigenetic modifications are DNA methylation and histone deacetylation, both of which result in gene silencing. Although gene silencing plays an important role in normal cellular differentiation, silencing can become dysregulated in various disease processes including cancer. Epigenetic events resulting in altered gene expression, particularly silencing genes involved in regulating cell growth and differentiation, can result in a cellular growth advantage, progressive uncontrolled growth, and the development of a cancer. Many cancers are associated with epigenetic silencing of TSG (i.e., p16, Rb, p53), which play a major role in tumorigenesis.^{15,17,18}

✓ Checkpoint! 3

Does a 3-year-old child with Down syndrome have an increased risk of developing leukemia? Why or why not?

► EPIDEMIOLOGY

The Leukemia and Lymphoma Society predicted that in the year 2008, about 44,270 new cases of leukemia would be reported in the United States.¹⁹ Most cases occur in older adults with more than half occurring after age 67.

Approximately 50% of all leukemias are diagnosed as acute. Although some difference in the incidence of the acute leukemias exists between countries and regions of countries, the differences are not great. However, all leukemias are more prevalent in Jews of Russian, Polish, and Czech ancestry than in non-Jews. Acute leukemia also is more common in whites than in blacks.

Of particular interest is the incidence and morphologic variation of leukemia among age groups (Table 4). Although acute leukemia occurs at all ages, peak incidence occurs in the first decade, particularly from the ages of 2 to 5 followed by a decreasing incidence in the second and third decade. Thereafter, the incidence begins to increase, rising steeply after age 50. The cellular type of leukemia occurring at these peak periods differs significantly. Most childhood acute leukemias are of the lymphoid type, whereas those occurring in adults are typically myeloid in origin. Chronic leukemias are rare in children. Most chronic myelogenous leukemias occur in young to middle-aged adults, and chronic lymphocytic leukemia is found primarily in older adults. MPD and MDS occur most often in middle-aged to older adults.

► CLINICAL FINDINGS

Failure of normal hematopoiesis is the most serious consequence of hematopoietic neoplasms. The most frequent symptoms are related to erythropenia, thrombocytopenia, or

neutropenia. The major clinical problems are anemia, infection, and bleeding episodes occurring as frank hemorrhages, petechiae, or ecchymoses. Bone pain due to marrow expansion and weight loss are also common complaints. Physical examination can show hepatosplenomegaly and, occasionally, lymphadenopathy. Organomegaly is more common in chronic leukemias than in the acute forms.

Although the disease originates in the bone marrow, neoplastic cells can infiltrate any tissue of the body, especially the spleen, liver, lymph nodes, central nervous system, and skin. The lesions produced vary from rashes to tumors. Skin infiltration is most commonly found in AML, particularly those with a monocytic component. Central nervous system (CNS) involvement is common in ALL of childhood. Chloromas, which are green tumor masses of immature leukocytes, are associated with AML and CML. They are usually found in bone but can be found throughout the body. The green color, which fades to a dirty yellow after exposure to air, is responsible for the descriptive name given to this unique clinical finding. Presumably, the green color results from the myeloperoxidase content of the malignant cells.

► HEMATOLOGIC FINDINGS

Cell counts and morphology are variable in the hematopoietic neoplasms (Table 5). A normocytic (occasionally macrocytic) normochromic anemia is usually present at diagnosis. If not present initially, it invariably develops during progression of the disease.

Thrombocytopenia is usually present at diagnosis in acute leukemia. Thrombocytosis is a common initial finding in MPD. The platelet count in MDS is variable. In both MPD and MDS, however, the platelet count decreases with progression of the disease. Platelet morphology and function also can be abnormal. Large hypogranular forms are common, and circulating micromegakaryocytes occasionally are present.

The leukocyte count can be normal, increased, or decreased. More than 50% of patients with AML do not have a significant leukocytosis at diagnosis. However, if left untreated, leukocytosis eventually develops. On the other hand, in the chronic myeloproliferative and lymphoproliferative neoplasms, leukocytosis at diagnosis is a prominent finding. Normal or decreased leukocyte counts are typical in MDS. Regardless of the leukocyte count, an increase in immature precursors is found in most cases. Blasts are especially prominent in the acute leukemias. Unique pink-staining granular inclusions called **Auer rods** can be found in the blast cells and promyelocytes of some acute myeloid leukemias. These Auer rods are believed to be formed from fused primary granules. When AML is suspected, the finding of Auer rods can help establish the diagnosis because these inclusions are not found in ALL.

TABLE 4

Age Groups Typically Found in Acute and Chronic Leukemias

ALL	Children 2–5 years old
CLL	Adults >50 years old
AML	Adults
CML	Adults

 **TABLE 5**
Characteristic Hematologic Findings in Acute Leukemia (AL), Myelodysplastic Syndrome (MDS), and Myeloproliferative Disorders (MPD)

Neoplasm	Leukocytes	Platelets	Bone Marrow	Other
AL	Normal or increased Blasts present	Decreased	Hypercellular, >20% blasts	Auer rods in AML
MDS	Normal or decreased Blasts may be present	Variable	Hypercellular, <20% blasts	Dysplastic
MPD	Increased Shift to left but predominance of mature forms	Usually increased	Hypercellular, <20% blasts, (occasionally hypocellular)	
MDS/MPD	Increased blasts and other immature forms	Usually decreased	Hypercellular, <20% blasts	Dysplastic

The bone marrow is hypercellular, although occasionally normocellularity or hypocellularity is found. Reticulin is increased, often worsening with progression of the disease. Blasts are usually increased. The cutoff of <20% blasts is used to differentiate MPD and MDS from AL.

Maturation abnormalities are commonly present in all three cell lines. Megaloblastoid erythropoiesis can be prominent but is unresponsive to vitamin B₁₂ or folic acid treatment.

Because of the intense increase in cell turnover, other laboratory tests reflecting cell destruction could be abnormal. An increase in uric acid, which is a normal product of nucleic acid metabolism, is a consistent finding in all types of leukemia. The rate of excretion can increase to 50 times normal. Serum lactic dehydrogenase (LD) levels appear to correlate closely with the concentration of leukemic cells. Isoenzyme studies reveal that the LD is derived from immature leukocyte precursors. Muramidase (lysozyme) is a lysosomal enzyme present in monocytes and granulocytes. The serum and urine muramidase concentration in leukemia is highly variable and is related to the cellular type. The highest concentrations are found in neoplasms with a monocytic component.

 **Checkpoint! 4**

Why is the finding of Auer rods an important factor in the diagnosis of leukemia?

 **HEMATOPOIETIC NEOPLASM CLASSIFICATION**

Two classification systems of hematopoietic neoplasms are currently recognized: the French-American-British (FAB) and the World Health Organization (WHO). The newer WHO classification system is widely accepted and is replacing the older

FAB classification. The FAB system is discussed for historical information, but the WHO classification is used in this text.

Classifications of hematopoietic neoplasms are considered to be important for three reasons:

1. They allow clinicians and researchers a way to compare various therapeutic regimens.
2. They allow a system for identification and comparison of clinical features and laboratory findings.
3. They permit meaningful associations of cytogenetic abnormalities with disease.

FAB CLASSIFICATION

The French-American-British system classifies neoplastic disorders into three main groups: myeloproliferative disorders (MPD), myelodysplastic syndromes (MDS), and acute leukemia (AL).

In 1976, in an effort to improve and standardize the classification of AL, a group of **French, American, and British** physicians proposed a classification and nomenclature system based on cell lineage as determined by the morphologic characteristics of blast cells on Romanowsky-stained smears and the results of cytochemical stains.²⁰ In the FAB classification, a blast count >30% is diagnostic of AL. In 1984, the FAB group proposed a classification for the MDS using the blast count (<30%) and degree of dysplasia in subgrouping the MDS. The MDS are characterized by peripheral blood cytopenias (except chronic myelomonocytic leukemia). Dameshek recognized the MPDs in 1951. Myeloproliferative disorders are characterized by neoplastic increases in erythrocytes, leukocytes, and/or platelets.

In the FAB system, both MPD and MDS have a blast count <30% and can have a chronic or acute course and the potential to evolve into acute leukemia (Figure 1). Of the three groups of neoplastic bone marrow disorders, acute leukemias represent the frankly malignant hematopoietic neoplasms with a proliferation of blast cells.

Malignant lymphoproliferative disorders can occur in the hematopoietic system (bone marrow and peripheral blood) or in the lymphatic system (lymph nodes and spleen). When the malignant proliferation involves the bone marrow and peripheral blood, the disease is referred to as *acute* or *chronic lymphocytic leukemia*. When the malignant proliferation is in the lymphoid tissue, the disease is referred to as a *lymphoma*. Lymphomas can eventually spread to the bone marrow, and the malignant cells can then be found in the peripheral blood.

Each of the three primary FAB groups of neoplastic disorders can be further divided into subgroups based on blast count and degree of differentiation as well as degree of dysplasia and cell lineage(s) involved. These subgroups are listed in Table 6.

TABLE 6

FAB Classification of Hematologic Neoplasms

Acute Nonlymphocytic Leukemias

M0	Acute myeloblastic leukemia without differentiation
M1	Acute myeloblastic leukemia with minimal differentiation
M2	Acute myeloblastic leukemia with maturation
M3	Promyelocytic leukemia, hypergranular
M3m	Promyelocytic leukemia, microgranular variant
M4	Acute myelomonocytic leukemia
M4eo	Acute myelomonocytic leukemia with abnormal eosinophils
M5a	Acute monoblastic leukemia without differentiation
M5b	Acute monoblastic leukemia with differentiation
M6	Acute erythroleukemia
M7	Megakaryocytic leukemia

Acute Lymphoblastic Leukemias

L1	Lymphoblastic leukemia with homogeneity
L2	Lymphoblastic leukemia with heterogeneity
L3	Burkitt type lymphoblastic leukemia

Myelodysplastic Syndromes

Refractory anemia (RA)
Refractory anemia with ringed sideroblasts (RARS)
Refractory anemia with excess blasts (RAEB)
Refractory anemia with excess blasts in transformation (RAEB-T)
Chronic myelomonocytic leukemia (CMML)

Myeloproliferative Disorders

Chronic myelogenous (or myelocytic, myeloid, granulocytic) leukemia (CML or CGL)
Polycythemia vera (PV)
Essential thrombocythemia (ET)
Agnogenic myeloid metaplasia (AMM), also known as <i>myelofibrosis with myeloid metaplasia</i> (MMM).

THE WHO CLASSIFICATION

Genetic features, prior therapy, and a history of myelodysplasia recently have been recognized to have a significant impact on the clinical behavior of the hematopoietic neoplasms. The Society for Hematopathology and the European Association of Hematopathologists developed the WHO to better define the hematopoietic neoplasms. This classification uses features similar to those in the FAB classification including morphology, cytochemistry, and immunophenotype of the neoplastic cells to determine cell lineage and degree of maturation. However, it also uses genetic and clinical features such as prior therapy and history of MDS to define distinct subgroups²¹ (Table 7).

The classification according to lineage of the neoplastic cells includes four groups: myeloid, lymphoid, mast cell, and histiocytic. Mast cells are derived from hematopoietic progenitor cells and possess myeloid cell characteristics. Thus, mast cell disease can be considered a myeloid disorder. The four major groups of myeloid disease are defined by morphology, genetic abnormalities, immunophenotyping, and clinical features:

- Myeloproliferative disorders (MPD)
- Myelodysplastic/myeloproliferative disorders (MDS/MPD)
- Myelodysplastic syndromes (MDS)
- Acute myeloid leukemia (AML)

Although this classification is similar to the FAB classification of myeloid disorders, the criteria for subgroups within these four major groups differ. WHO also adds the MDS/MPD category that includes diseases that have features of both MDS and MPD such as chronic myelomonocytic leukemia.

A significant change in the WHO classification relates to the bone marrow blast count used to define and differentiate AML from the other myeloid neoplasms. This classification uses the standard of >20% blasts to define AML versus the FAB standard of >30% blasts. This is based on the observation that patients with 20–30% blasts have a prognosis similar to those with >30% blasts. The percentage of blasts is determined as the number of blasts in all nucleated marrow cells (except for acute erythroleukemia).²² If AML exists concurrently with another nonmyeloid hematologic neoplasm, the cells from the nonmyeloid neoplasm are not included when performing the differential.²²

The WHO classification also defines the criteria for blasts differently than previous classifications. When counting blasts for a diagnosis of AML, the following are included in addition to myeloblasts:²²

- Monoblasts and promonocytes in acute monoblastic/ monocytic and acute and chronic myelomonocytic leukemia
- Megakaryoblasts in acute megakaryoblastic leukemia
- Abnormal promyelocytes in acute promyelocytic leukemia
- Erythroblasts only in pure erythroleukemia

★ TABLE 7

2001 WHO Classification of Hematologic Neoplasms*

Myeloproliferative Diseases

Chronic myelogenous leukemia (CML), Philadelphia chromosome, (9;22)(q34;q11), BCR/ABL1 positive
 Chronic neutrophilic leukemia (CNL)†
 Chronic eosinophilic leukemia (CEL)/hypereosinophilic syndrome (HES)†
 Chronic idiopathic myelofibrosis (CIMF)
 Polycythemia vera (PV)
 Essential thrombocythemia (ET)
 Myeloproliferative disease, unclassifiable (MDP-U)†

Myelodysplastic/Myeloproliferative Diseases†

Chronic myelomonocytic leukemia (CMML)
 Atypical myelogenous leukemia (aCML)
 Juvenile myelomonocytic leukemia (JMML)

Myelodysplastic Syndromes

Refractory anemia (RA)
 Refractory anemia with ringed sideroblasts (RARS)
 Refractory cytopenia with multilineage dysplasia (RCMD)†
 Refractory cytopenia with multilineage dysplasia with ringed sideroblasts (RCMD-RS)†
 Refractory anemia with excess blasts-1
 Refractory anemia with excess blasts-2
 MDS associated with isolated del(5q)†
 Myelodysplastic syndrome, unclassifiable (MDS-u)†

Acute Myeloid Leukemia‡

Acute myeloid leukemias with recurrent genetic abnormalities†
 Acute myeloid leukemia with multilineage dysplasia†
 Acute myeloid leukemia and myelodysplastic syndromes, therapy related†
 Acute myeloid leukemia not otherwise categorized§
 Acute leukemia of ambiguous lineage

Acute Lymphoid Leukemias (precursor B- and T-cell neoplasms)

Precursor B cell acute lymphoblastic leukemia† (classified by cytogenetic subgroups)
 Precursor T cell acute lymphoblastic leukemia†

B Cell Neoplasms (mature cell neoplasms)‡**T Cell Neoplasms (mature cell neoplasms)‡****Hodgkin lymphoma‡**

In the lymphoid neoplasms, the proposed WHO classification adopts the revised European-American lymphoid neoplasm (REAL) classification, which uses morphology, immunophenotype, genetic, and clinical features. There are three groups of lymphoid neoplasms: B cell, T/NK cell, and Hodgkin's disease. The T and B cell neoplasms are grouped into precursor (lymphoblastic) and mature neoplasms. The ALLs are in the precursor group and include B cell and T cell ALL and Burkitt cell leukemia (L3 in FAB). The mature neoplasms include B cell chronic lymphocytic leukemia (CLL) and hairy cell leukemia. The REAL classification for lymphoid neoplasms is in general use.

**CASE STUDY** (continued from earlier in this chapter)

The CBC results on Agnes were:

WBC	83.9 × 10 ⁹ /L	
RBC	3.15 × 10 ¹² /L	
Hb	9.5 g/dL (95 g/L)	
Hct	0.29 L/L	
Platelets	130 × 10 ⁹ /L	
Differential	segs	12%
	lymphs	88%

1. Given the patient's laboratory results, would this most likely be considered an acute or chronic leukemia? Explain.
2. What group of leukemia (cell lineage) is suggested by the patient's blood cell differential results?
3. What would you expect the blast count in the bone marrow to be?

▶ LABORATORY PROCEDURES FOR DIAGNOSING AND CLASSIFYING NEOPLASMS

As mentioned, the hematopoietic neoplasms are initially classified into myeloid (nonlymphocytic) and lymphoid groups, depending on the predominant cell types present. In the acute leukemias, identification of the cell lineage (myeloid or lymphoid) of leukemic blasts is often difficult by morphology alone unless Auer rods are present. However, the distinction of cell lineage is important for selecting the appropriate therapy. Distinction of MDS and MPD is not as difficult as in acute leukemias because in MDS and MPD, the maturation of the neoplastic cell is not blocked and the cell matures into recognizable blood cells.

Differentiation of leukemic blasts allows classification of acute leukemia into cell lineage (lymphoid or myeloid) and various subtypes (Table 8★). Differentiation can be determined by morphology, immunologic marker analysis (im-

*The 2008 WHO classification is on the Website.

†Not included in FAB classification.

‡Subgroups not listed.

§Includes subgroups of AML in FAB classification.

TABLE 8

Comparison of Acute Lymphoblastic Leukemia (ALL) and Acute Nonlymphocytic Leukemia (ANLL)

	ALL	ANLL
Age	Common in children	Common in adults
Hematologic presentation	Anemia, neutropenia, thrombocytopenia, lymphoblasts, prolymphocytes	Anemia, neutropenia, thrombocytopenia, myeloblasts, promyelocytes
Prominent cell morphology	Small to medium lymphoblasts, fine chromatin with scanty to abundant cytoplasm, indistinct nucleoli	Medium to large myeloblasts with distinct nucleoli, fine nuclear chromatin and abundant basophilic cytoplasm, Auer rods can be present
Cytochemistry	PAS positive, peroxidase negative, Sudan black B negative, TdT positive	PAS negative, peroxidase positive, Sudan black B positive, TdT negative or positive

munophenotype), cytochemical stains, and/or chromosome analysis. Immunophenotyping and cytochemistry are not usually necessary in classification of MDS and MPD, but genetic studies are helpful in subgrouping.

CYTOCHEMICAL ANALYSIS

Cytochemistry in hematology refers to in vitro staining of cells that allows microscopic examination of the cells' chemical composition. Cell morphology is not significantly altered in the staining process. Most cellular cytochemical markers represent organelle-associated enzymes and other proteins. The cells are incubated with substrates that react with specific cellular constituents. If the specific constituent is present in the cell, its reaction with the substrate is confirmed by the formation of a colored product. The stained cells are examined and evaluated on smears with a light microscope, although electron microscopy occasionally is necessary to identify very weak reactions at the subcellular level. The results of these cellular reactions in normal and disease

states are well established. Cytochemistry is particularly helpful in differentiating the lymphoid or myeloid lineage of the blasts in acute leukemias when morphologic identification on Romanowsky-stained smears is difficult (Table 9). Cytochemistry is also helpful in subgrouping the AML.

It is important to remember that the blast cells seen in leukemias are neoplastic cells and can therefore differ from normal blasts in both morphology and metabolic activity. Leukemic cells often display nuclear/cytoplasmic asynchrony similar to that of megaloblastic cells. As a result, although the nucleus appears very immature, the cytoplasm of leukemic blasts can contain constituents normally present only in more mature cells or can lack one or more constituents expressed by their normal counterparts. In addition, there can be abnormal accumulation and distribution of cellular metabolites.

The cytochemical staining reactions are either enzymatic or nonenzymatic. The enzymatic group includes stains for myeloperoxidase, esterases, alkaline and acid phosphatases. The nonenzymatic stains include Sudan black B for lipids,

TABLE 9

Cytochemical Stains Useful in Differentiating Acute Myeloid Leukemia (AML) from Acute Lymphoblastic Leukemia (ALL)

Stains	Myeloblasts	Lymphoblasts	Cell constituent stained
MPO/SBB	Positive	Negative	MPO: myeloperoxidase SBB: lipids
Chloroacetate esterase (specific)	Positive	Negative	Esterases
PAS	Negative or diffusely positive	Negative or chunky positive	Glycogen
TdT	10–20% positive	Over 90% positive	DNA polymerase

Note: When all cytochemical stains are negative, the differential diagnosis is usually between ALL and AML with minimal differentiation. TdT is not helpful in differentiating the two because it can be positive in 90% of cases of AML with minimal differentiation. Thus, distinction of AML with minimal differentiation from ALL is not possible by cytochemical stains. Flow cytometric analysis is required in this situation. AML with minimal differentiation expresses myeloid antigens (CD13, CD15, and CD33), while ALL expresses lymphoid markers (CD19, CD20, and CD22 or CD3, CD2, CD5, CD7, etc.).

periodic acid-Schiff (PAS) for glycogen, and toluidine blue O for mucopolysaccharides.

Myeloperoxidase (MPO) and Sudan black B (SBB)

The **MPO** and SBB stains are generally performed first to differentiate the myeloid and lymphoid blasts. The myeloblasts are positive, but lymphoblasts are negative. Additional staining can be necessary to assist in subgrouping the AML and ALL.

Esterases

The esterase stains are generally used to differentiate monoblasts and myeloblasts. Myeloblasts are positive for **specific esterases** (chloroacetate esterase), and monoblasts are positive for **nonspecific esterases** (alpha-naphthyl acetate esterase, ANAE).

Periodic Acid Schiff (PAS)

The **PAS** stain is helpful in diagnosing ALL and acute erythroid and megakaryoblastic leukemias. Normal erythroblasts do not stain with PAS. However, PAS activity is strongly positive in erythroid leukemia. Leukemic lymphoblasts can demonstrate blocklike or coarse granular activity. This typical positivity of lymphoblasts in ALL can sometimes be seen in AML (monocytic, erythroleukemia, and megakaryoblastic). The PAS stain reaction is not useful in differentiating other acute leukemias.

Leukocyte Alkaline Phosphatase (LAP)

Leukocyte alkaline phosphatase (LAP) is an enzyme present within the specific (secondary) granules of maturing granulocytes (from the myelocyte stage onward). The enzyme is not present in eosinophils and basophils. Activated neutrophils contain an increased amount of LAP. Therefore, the LAP score is useful in distinguishing leukemoid reactions/reactive neutrophilia (high LAP) from chronic myelogenous leukemia (low LAP).^{23,24}

Acid Phosphatase

A constituent of lysosomes and present in most human cells, acid phosphatase activity is present in most normal leukocytes, but the acid phosphatase activity in T cell ALL is characteristic, exhibiting focal polarized acid phosphatase activity. Hairy cells in hairy cell leukemia are positive, but the activity is not inhibited by **tartrate resistant acid phosphatase (TRAP)**, differentiating them from other leukocytes whose activity is inhibited by tartrate.^{25,26}

Terminal Deoxynucleotidyl Transferase (TdT)

TdT, a DNA polymerase found in cell nuclei, is a primitive cell marker and is of value in distinguishing ALL from malignant lymphoma.^{27,28} It is also helpful in identifying leukemic cells in body fluid specimens. TdT is present in

90–95% of ALL (T cell ALL and precursor B cell ALL, but not in mature B cell ALL). TdT staining might not be beneficial in evaluating acute leukemias because up to 20% of AMLs can show TdT positivity, and more than 90% of minimally differentiated AML can be TdT positive.

Toluidine Blue

Toluidine blue is specifically positive for basophils and mast cells and is useful in diagnosing mast cell disease and rare cases of AML with basophilic differentiation.^{29,30,31} The granules in basophils and mast cells have a strong affinity for toluidine blue. A negative reaction should not rule out neoplasm of these cells because the acid mucopolysaccharides can be scarce or negative in neoplastic disorders.

Reticulin Stain and Masson's Trichrome Stain

These stains are used to evaluate both the presence and extent of fibrosis. However, the presence of fibrosis can be suspected on hematoxylin and eosin (H&E) stained sections. The Gomori methenamine silver-staining method is more suitable for detecting reticulin. Masson's trichrome stain is useful to evaluate the degree of collagenous fibrosis. Increased staining can be seen in myelofibrosis and indicates severe and dense fibrosis.

IMMUNOLOGIC ANALYSIS

Immunologic analysis is based on identifying specific membrane antigens (surface markers) that are characteristically found on a particular cell lineage. Immunologic techniques with monoclonal antibodies are widely used to identify cell membrane antigens on a variety of cells. The development of a large number of monoclonal antibodies that react with surface antigens on normal and neoplastic cells and technical advances in flow cytometry, have greatly enhanced the ability to define leukemic cell lineage, the stage of cell development, and clonality. By utilizing a panel of monoclonal antibodies, a more complete picture of the cells' lineage can be determined.

The routine use of immunologic markers to characterize AML subtypes and myeloid antigenic development has lagged behind the use of these markers in ALL. There are two possible explanations for this lag.³² The first is that AML unlike ALL has two specific cytochemical markers—peroxidase and nonspecific esterase—that help to identify the myeloid origin of the cells. The second is that to subtype AML, markers for myeloblasts, erythroblasts, monoblasts, and megakaryoblasts need to be identified. An increasing repertoire of antibodies to myeloid antigens has been developed. These antibodies have helped not only in subtyping the myeloid leukemias but also in identifying the lineage of those leukemias that lack specific morphologic and cytochemical characteristics. A more thorough discussion of

monoclonal antibodies and their use in the identification of neoplastic hematopoietic disorders can be found.

GENETIC ANALYSIS

Cytogenetics

Advances in cytogenetics have allowed cytogeneticists to identify characteristic nonrandom abnormal karyotypes in the majority of the acute leukemias and in some MPD and MDS.³³ Some specific chromosome changes are consistently associated with a particular neoplastic subgroup and thus are helpful in diagnosis. For example, the t(15;17)(q22;q11) is diagnostic of acute promyelocytic leukemia, and the Philadelphia chromosome characterized by t(9;22)(q34;q11.2) confirms a clinical diagnosis of chronic myelogenous leukemia (CML). In the lymphoid leukemias, nonrandom chromosome changes are often associated with either the B or T lymphocyte lineage and provide important prognostic as well as diagnostic information. Chromosomal rearrangements and their accompanying molecular abnormalities can identify distinct clinical groups with a predictable clinical course and response to specific therapy. In addition to helping physicians evaluate their patients, cytogenetic studies provide new insights into the pathogenesis of neoplastic diseases.

When cytogenetic abnormalities are present before therapy, their presence or absence can be used to identify remission, relapse, and minimal residual disease after therapy. If the cytogenetic abnormality identified before therapy is identified after therapy, it is evidence that the neoplastic cells are still present in the bone marrow. In some cases, additional chromosome aberrations can be identified during the course of the disease or after a period of remission. This is usually a signal of disease progression. Thus, patients can have multiple cytogenetic analyses.

Molecular Analysis

Molecular genetic analysis, the process of using DNA technology to identify genetic defects at the molecular level, is being used increasingly as a diagnostic tool in studying neoplasms. In some cases, the chromosome karyotype is normal, but a genetic mutation can be identified. About 5% of patients with CML do not show the typical Philadelphia chromosome on karyotyping, but the *BCR-ABL* mutation can be identified by molecular techniques. When present, this helps establish or confirm the diagnosis.

Molecular analysis also is helpful in providing clues to the pathogenesis of hematopoietic neoplasms. For example, the specific t(15;17)(q22;q11) mutation found in acute promyelocytic leukemia produces an abnormal form of the nuclear hormone receptor, retinoic acid receptor- α (RAR- α). The receptor in its normal form is important in the transcription of certain target genes. The abnormal receptor is involved in the maturation blockade seen in these cells. When patients

who have this mutation are treated with retinoic acid derivatives, the cells are induced to differentiate into mature granulocytes.

One of the limitations of molecular genetic analysis is that the specific genetic aberration must be identified first so that probes can be made to detect the gene abnormality. Currently, this technology is helpful in diagnosis of M3-AML, CML, PV, and T and B ALL. Another limitation of molecular techniques is that only a single gene mutation usually can be identified using a given probe, so other gene mutations are not detected. Thus, it is important for the clinical laboratory scientist to understand the advantages and limitations of each diagnostic procedure and recommend the appropriate combination as well as sequence of testing.

Quantitative molecular methods are used to monitor treatment of CML. Baseline levels of mRNA transcripts of *BCR/ABL* are obtained before treatment is started and then at intervals (3–6 months) to determine whether patients are responding to treatment.^{34,35}

Checkpoint! 5

A patient has 35% blasts in the bone marrow. They do not show any specific morphologic characteristics that will allow them to be classified according to cell lineage. What are the next steps that the clinical laboratory scientist should take with this specimen?

► PROGNOSIS AND TREATMENT OF NEOPLASTIC DISORDERS

PROGNOSIS

Before the 1960s, a patient diagnosed with acute leukemia could expect to die within a few months. With new treatment modalities, remission rates for both ALL and AML have improved dramatically. Remission was defined originally as a period of time in which there were no clinical or hematologic signs of the disease. More recently with the various diagnostic and monitoring modalities available, several levels of remission can be defined. For treatment purposes, complete remission (response) is defined as the total absence of disease according to the test utilized (e.g., hematologic versus cytogenetic versus molecular). **Hematologic remission** refers to the absence of neoplastic cells in the peripheral blood and bone marrow and the return to normal levels of hematologic parameters. **Cytogenetic remission** refers to the absence of recognized cytogenetic abnormalities associated with a given neoplastic disease.

Molecular remission refers to the absence of detectable molecular abnormalities using PCR or related molecular technologies.

Sensitive molecular testing such as PCR can detect the presence of less than 1 in 10^6 tumor cells (∞ Chapter 39) whereas the sensitivity of detection of malignant cells using cytogenetics is much lower. Thus, a complete molecular response is highly desirable and the most promising evidence that the neoplasm has been eliminated. A combination of negative “traditional” tests (peripheral blood and bone marrow blast count and cytogenetics) and positive molecular tests (PCR/FISH) is sometimes referred to as a state of **minimum residual disease (MRD)**. The designation “partial response” is used when the relevant laboratory values have a significant decrease without achieving a total absence of disease. A “major response” can include either a complete or partial response.

Therapeutic success rates differ by disease and the patient’s condition at time of diagnosis. Often a complete hematologic or cytogenetic remission is achieved initially only to be followed by a return of the disease (relapse) after a period of time. It has been recognized recently that most currently used treatment regimens are targeting the actively proliferating cancer cells and might not, in fact, be effective against the leukemic stem cells (LSC). Thus, the relapse seen in some patients following a complete remission is likely due to the reemergence of the disease from a quiescent LSC, which was not eliminated by the treatment regimen utilized.

Survival in acute leukemias varies with age and group—ALL or AML. Approximately 80% of children treated for ALL can be expected to enter a prolonged remission with an indefinite period of survival. The prognosis for ALL in adults is not so good as for children. Two years is the median survival for adults after remission has been achieved. Only 10–25% of patients typically achieve a 5-year survival. The remission rate for AML is about 55–65%. Approximately 50% of these patients remain in remission for more than 3 years. Patients who receive bone marrow or stem cell transplants, especially younger ones, have a better prognosis. Patients who had a previous myelodysplastic syndrome or chronic myeloproliferative disorder respond poorly to standard chemotherapy.

Survival in the chronic neoplasms is longer. The International Randomized Study of Interferon and STI571 (IRIS) reported that for CML patients receiving imatinib as initial therapy, overall survival at 60 months was 89%.³⁶ After onset of blast crisis, survival is generally only 1–2 months.³⁷ Survival in CLL depends on the severity of the disease at diagnosis and ranges from 30 to more than 120 months. Patients with other MDS and MPD diseases usually survive for a year or more and even longer for some subtypes without treatment. Prognosis for the lymphomas depends on the cell type and can range from 6 months to 10 years or longer.

CASE STUDY (continued from earlier in this chapter)

4. Would you expect Agnes to survive more than 3 years or succumb fairly quickly after treatment?

TREATMENT

Chemotherapeutic drug and radiotherapy protocols have been developed by cancer and leukemia groups (CALG) and are used by cooperative oncology groups (COG) to access statistically valid data in a highly efficient fashion.

Chemotherapy

Chemotherapy remains the treatment of choice for many leukemias. The goal of this therapy type is to eradicate all malignant cells within the bone marrow, allowing repopulation by residual normal hematopoietic precursors. The problem with this type of therapy is that the drugs used in treatment are not specific for leukemic cells. Thus, treatment also kills many normal cells. Complications of traditional therapy include bleeding due to decreased platelet counts, infections due to suppression of granulocyte counts, and anemia due to erythrocyte suppression in the marrow. Supplemental support with recombinant growth factors can be used to mitigate the cytopenias.

Most drugs used to treat leukemia are included in three groups: antimetabolites, alkylating agents, and antibiotics. The antimetabolites are purine or pyrimidine antagonists, which inhibit the synthesis of DNA. These drugs kill cells in cycle, affecting any rapidly dividing cell. In addition to leukemic cells, the antimetabolites also kill cells lining the gut, germinal epithelium of the hair follicles, and normal hematopoietic cells. This leads to complications of gastrointestinal disturbances, loss of hair, and life-threatening cytopenias. The alkylating agents (chemical compounds containing alkyl groups) are not specific for cells in cycle but kill both resting and proliferating cells. The drug attaches to DNA molecules, interfering with DNA synthesis. These drugs as a class are mutagenic and carcinogenic; they fragment and clump chromosomes, inactivate DNA viruses, and inhibit mitosis but not protein function. The side effects of these compounds include myelosuppression, stomatitis, nausea, and vomiting. Antibiotics bind to both DNA and RNA molecules, interfering with cell replication. Toxic effects of this therapy are similar to those of alkylating agents.

Since the 1970s, various drug combinations have been found to be more effective than single drug administration. The drugs commonly used and their modes of action are included in Table 10 .

Therapy for most leukemias is divided into several phases. The **induction therapy** phase is designed to induce the disease into complete remission (i.e., eradicating the leukemic blast population). Once a complete remission has been achieved, it is often followed by a continuation of

TABLE 10

Chemotherapeutic Agents Usually Used in Acute Leukemia (AL) Treatment

Drug	Class	Action
Doxorubicin	Anthracycline antibiotic	Inhibits DNA and RNA synthesis
Daunorubicin	Anthracycline antibiotic	Inhibits DNA and RNA synthesis
Idarubicin	Anthracycline antibiotic	Inhibits DNA and RNA synthesis
5-azacytidine	Pyrimidine antimetabolite	Inhibits DNA and RNA synthesis
6-thioguanine	Purine antimetabolite	Inhibits purine synthesis
Methotrexate	Folic acid antimetabolite	Inhibits pyrimidine synthesis
6-mercaptopurine	Purine antimetabolite	Inhibits pyrimidine synthesis
Cytosine arabinoside	Pyrimidine antimetabolite	Inhibits DNA synthesis
Prednisone	Synthetic glucocorticoid	Lyses lymphoblasts
Vincristine	Plant alkaloid	Inhibits RNA synthesis and assembly of mitotic spindles
Asparaginase	<i>E. coli</i> enzyme	Depletes endogenous asparagines
Cyclophosphamide	Synthetic alkylating agent	Cross-links DNA strands

treatment, referred to as **maintenance chemotherapy**, or **consolidation therapy**. The purpose of maintenance therapy is to eradicate any remaining leukemic cells.

The treatment regimen for AML and ALL is similar, although the combination of antileukemic agents differs. However, the purpose of chemotherapy is the same: to eradicate the leukemic blasts. CNS involvement is a common feature of ALL but not AML. Therefore, CNS prophylactic treatment (cranial irradiation and/or intrathecal chemotherapy) is part of the therapy regimen for ALL.

Permanent remission in CLL is rare. Treatment is conservative and usually reserved for patients with more aggressive forms of the disease. Treatment for the MPD and the MDS is also primarily supportive and designed to improve the quality of the patient's life (Table 11). Drugs designed to reverse epigenetic alterations in MDS recently have been introduced (see below).

Molecular-Targeted Therapy

As the genetic mysteries of hematologic neoplasms are being resolved, novel therapies that target the genetic mutation are being developed to silence the gene's expression or that

TABLE 11

Treatment and Prognosis of Myeloproliferative Disorders (MPD) and Myelodysplastic Syndromes (MDS)

Neoplasm	Treatment	Prognosis
Myeloproliferative disorders		
CML	Imatinib; stem cell transplant	>5 years
PV	Phlebotomy, chemotherapy, or no treatment	8–15 years
ET	Chemotherapy, or no treatment	>10 years
CIMF	Chemotherapy, bone marrow transplant	2–10 years
Myelodysplastic syndromes	Not curable except with stem cell transplant, chemotherapy; demethylating agents	5–50 months, depending on classification of MDS

CML = chronic myelogenous leukemia; PV = polycythemia vera; ET = essential thrombocythemia; CIMF = chronic idiopathic myelofibrosis

of the mutated protein or to reactivate silenced genes. The therapies appear to be tolerated better than the traditional chemotherapy regimens. Two targeted therapies are in current use as first-line therapy: imatinib for CML and all trans retinoic acid (ATRA) for acute promyelocytic leukemia.³⁶ Although hematopoietic stem cell transplantation had been recommended as first-line therapy for CML because it was the only treatment that had the potential for cure, recent studies reveal that survival is superior in patients receiving drug treatment (interferon and/or imatinib).³⁸

Epigenetic Therapies

With the recognition of the contribution of epigenetic alterations to the neoplastic process, a number of drugs have been developed and are in various stages of clinical trials. Both demethylating agents (e.g., azacitidine) and histone deacetylase inhibitors (HDAC-I) (e.g., valproic acid, phenylbutyrate) are being evaluated with promising early results.^{15,39,40}

Bone Marrow Transplant

Bone marrow transplants have provided hope as a possible cure for hematopoietic disorders; the highest rate of success in transplant patients has occurred with those younger than 40 years of age in a first remission with a closely matched donor. In this procedure, drugs and irradiation are used to induce remission and eradicate any evidence of leukemic cells. Bone marrow from a suitable donor is then transplanted into the patient to supply a source of normal stem cells.

Autologous transplants have been used when a compatible donor cannot be found. This procedure involves removing some of the patient's marrow while the patient is in complete remission. The marrow specimen is then treated in vitro with monoclonal antibodies or 4-hydroperoxycyclophosphamide to remove any residual leukemic cells (purged) and cryopreserved. Chemotherapy and/or radiotherapy is administered to the patient to remove all traces of leukemia, and the treated marrow is given back to the patient.

Autologous bone marrow transplantation has been applied to patients in remission and to those in early relapse. Overall survival appears to be better in those transplanted during the first complete remission. Bone marrow transplantation appears to be successful in many cases; the number of patients who are undergoing this type of therapy is increasing.

Stem Cell Transplants

Peripheral blood as well as bone marrow stem cells can be used to reestablish hematopoiesis in the marrow after intensive chemotherapy or radiotherapy in a process called *stem cell transplantation*. In this procedure, apheresis is used to collect stem cells from the peripheral circulation, usually after they have been mobilized (induced to exit the marrow) by cytokines such as G-CSF. These stem cells can come from either the patient (autologous) or from a suitable donor (allogeneic). People who receive allogeneic stem cells are given drugs to prevent rejection. Production of new blood cells becomes established usually in 10–21 days following infusion of the stem cells. Stem cell transplantation is still a fairly new and complex treatment for leukemia.

CASE STUDY (continued from earlier in this chapter)

5. Is Agnes a suitable candidate for a bone marrow transplant? Why or why not?

Hematopoietic Growth Factors

Recombinant hematopoietic growth factors are used in the supportive care of AL patients. Erythropoietin was introduced in 1989 and has been used in the treatment of chemotherapy-related anemia.⁴¹ Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) have been available since 1991 to aid in decreasing the incidence of severe neutropenia and infection in patients receiving myelosuppressive chemotherapy.⁴¹ Interleukin-11, introduced for use in 1997,⁴² promotes the maturation of megakaryocytes by stimulating stem cells and megakaryocyte progenitor cells. Research in the area of identifying additional hematopoietic growth-stimulating

factors continues in the hope of accelerating hematopoietic recovery in chemotherapy patients.

Complications of Treatment

Treatment for leukemia actually can aggravate the patient's clinical situation. Although uric acid levels are commonly elevated in leukemia from an increase in cell turnover, the concentration of this constituent can increase manyfold during effective therapy because of the release of nucleic acids by lysed cells. Uric acid is a normal end product of nucleic acid degradation and is excreted mainly by the kidney. In excessive amounts, the uric acid precipitates in renal tubules, leading to renal failure (uric acid nephropathy). Lysed cells also can release procoagulants into the vascular system, precipitating disseminated intravascular coagulation. In this case, the resulting decrease in platelets and coagulation factors can lead to hemorrhage. This complication is especially prevalent in acute promyelocytic leukemia. The granules of the promyelocytes contain potent activators of the coagulation factors.

Chemotherapeutics destroy normal as well as leukemic cells. The cytopenias that develop during aggressive chemotherapy can lead to death from infection, bleeding, or complications of anemia. To prevent these life-threatening episodes, the patient may need supportive treatment including transfusions with blood components and/or cytokines as well as antimicrobial therapy.

CASE STUDY (continued)

6. What types of treatment are available for our patient Agnes?

SUMMARY

A neoplasm is an unregulated production of cells that can be either malignant or benign. The WHO classification of neoplastic disorders of the bone marrow hematopoietic cells groups the disorders according to lineage of the neoplastic cells: myeloid, lymphoid, mast cell, histiocytic. The four major groups of myeloid disease are defined by morphology, genetic abnormalities, immunophenotype and clinical features. They include: myeloproliferative disorders, myeloproliferative/myelodysplastic disorders, myelodysplastic syndromes and acute myeloid leukemia.

The myeloproliferative disorders are characterized by an overproduction of erythrocytes, leukocytes, and/or platelets. Myelodysplastic syndromes show peripheral blood cytopenias and dysplasia of cell maturation. Both MPD and MDS can follow a chronic or acute course, and both have the potential to evolve into an acute leukemia. The abnormal proliferation of cells sometimes occurs within the lymphatic tissue or lymph nodes. These solid tumors are referred to as *lymphoma*.

Leukemia is a progressive malignant disease of hematopoietic stem cells characterized by an inability of these cells to mature into functional peripheral blood cells. Leukemias can be classified as

acute or chronic based on the aggressiveness of the disease and degree of differentiation of the cells. Acute leukemias are characterized by accumulation of immature cells and have a rapidly progressive course. Chronic leukemias are characterized by an accumulation of more differentiated cells and have a slowly progressive course. The chronic leukemias are classified with other chronic neoplastic stem cell disorders: MPD, MDS, and chronic lymphoproliferative disorders.

The role of oncogenes in the pathogenesis of hematopoietic disorders remains under intense investigation. Oncogenes are altered cellular proto-oncogenes known to contribute to tumorigenesis. Many proto-oncogene protein products are involved in regulating cell growth and include hematopoietic growth factors as well as their cellular receptors, signaling proteins, and transcription factors. Proto-oncogenes can be mutated to oncogenes by mutagens, viruses, or chromosome breaks and translocations. Oncogenes can cause production of abnormal growth factors, abnormal amounts of growth factors, abnormal growth factor receptors, or other abnormalities in the regulatory mechanisms of cell proliferation and differentiation. Epigenetic alterations also play an important role in silencing tumor-suppressor genes in neoplastic cells.

Differentiation and classification of acute leukemias depend on accurate identification of the blast cell population. Because the lineage of blast cells is sometimes difficult to differentiate using only morphologic characteristics, immunologic phenotyping using monoclonal antibodies and cytochemical analysis are employed routinely to help identify blast phenotypes and stage of cell differentia-

tion. Chromosome and molecular analyses are helpful because specific mutations often are associated with specific types of leukemias.

Hematologic findings of hematopoietic neoplasms include anemia, thrombocytopenia (in acute leukemia and MDS), and often leukocytosis. A leukocytic shift to the left is consistently found with a combination of blasts and mature cells in acute leukemia. In the chronic leukemias and other chronic neoplastic stem cell disorders, cells appear more on a continuum from immature to mature. Morphologic abnormalities of neoplastic cells are not unusual. Auer rods can be found in blasts of AML.

Historically, hematopoietic neoplasms have been treated using a combination of cytotoxic drugs (chemotherapy). The goal is to induce remission by eradicating the leukemic cells. Hematopoietic stem cell transplants are being used increasingly to restore the marrow after intense chemotherapy or radiotherapy. New approaches include drugs to reverse epigenetic modifications characteristic of neoplastic cells and other drugs targeted at the exact molecular abnormality associated with the neoplastic cell. Treatment with hematopoietic growth factors is used in some cases to stimulate leukemic cells to proliferate, making these cells more susceptible to cytotoxic drugs. This therapy also has been used to decrease the neutropenic, anemic, and thrombocytopenic period after chemotherapy or radiotherapy.

The WHO classification of neoplastic hematologic diseases was updated in 2008, but it was too late for inclusion in the printed version of this text. For the updates, refer to the book's Website.

REVIEW QUESTIONS

LEVEL I

- A gap in the normal maturation pyramid of cells with many blasts and some mature forms is known as: (Objectives 2, 5)
 - leukemic hiatus
 - chronic leukemia
 - mixed cell lineage
 - lineage restricted
- Auer rods are inclusions found in: (Objective 5)
 - myeloblasts
 - lymphoblasts
 - erythrocytes
 - polymorphocytes
- Chromosome changes in hematologic neoplasms are: (Objective 8)
 - present in AL but not MPD or MDS
 - nonrandom
 - associated with a poor outcome
 - not usually present
- Genes that can cause tumors if activated are: (Objective 6)
 - cancer genes
 - proto-oncogenes
 - preleukemia genes
 - tumor-suppressor genes

LEVEL II

- This stain is helpful in distinguishing myeloblasts from lymphoblasts: (Objective 8)
 - myeloperoxidase
 - TRAP
 - LAP
 - esterase
- Oncogenes can cause leukemia by: (Objective 1)
 - suppressing proliferation of normal cells
 - activating retroviruses
 - encoding for an aberrant growth protein
 - encoding proteins that cause DNA damage
- The PAS stain is helpful in diagnosis of: (Objectives 3, 8)
 - CLL
 - CML
 - MDS
 - ALL
- Which of the following factors has **not** been proposed as playing a role in the causation of leukemia? (Objective 6)
 - benzene
 - therapeutic radiation for Hodgkin's disease
 - living at high altitudes
 - chromosome translocations

REVIEW QUESTIONS (continued)

LEVEL I

5. A common characteristic of acute lymphoblastic leukemia is: (Objective 2)
 - a. found primarily in the elderly
 - b. bone and joint pain
 - c. many blast cells with Auer rods
 - d. leukocytopenia
6. The FAB classification is used to divide acute leukemias into groups according to: (Objective 3)
 - a. immunology
 - b. clinical presentation
 - c. cytogenetics
 - d. morphology
7. A leukemia that shows a profusion of granulocytes at all stages of development from blasts to segmented neutrophils is: (Objectives 2, 5)
 - a. AML
 - b. CML
 - c. ALL
 - d. CLL
8. Acute lymphoblastic leukemia occurs with greatest frequency in which age group? (Objective 7)
 - a. 2–5 years
 - b. 10–15 years
 - c. 20–30 years
 - d. over 50 years
9. Chronic leukemias primarily affect: (Objectives 2, 7)
 - a. all ages, progress rapidly, and have immature cells in peripheral circulation
 - b. children, progress rapidly, and have mature cells in peripheral circulation
 - c. young adults, progress slowly, and have immature cells in peripheral circulation
 - d. adults, progress slowly, and have mature cells in circulation
10. A 19-year-old patient's bone marrow is classified by the WHO system as a precursor B-cell leukemia. Which of the following best describes this leukemia? (Objectives 2, 3, 5)
 - a. CLL
 - b. ALL
 - c. AML
 - d. CML
11. Immunologic phenotyping of the blast cells is important to: (Objective 8)
 - a. help determine cell lineage
 - b. identify the etiology of the leukemia
 - c. determine whether cytogenetic analysis is necessary
 - d. replace the need to do multiple cytochemical stains

LEVEL II

5. A 3-year-old child with Down syndrome presents with pallor, fatigue, lymphadenopathy, and hepatosplenomegaly. The initial CBC results were: (Objectives 3, 7)

WBC	$18.7 \times 10^9/L$	WBC differential	10 segs
RBC	$2.34 \times 10^{12}/L$		27 lymphs
Hb	5.8 g/dL (58 g/L)		63 blasts
Hct	0.174 L/L		
PLT	$130 \times 10^9/L$		

These findings are suggestive of:

 - a. acute lymphoblastic leukemia
 - b. chronic lymphocytic leukemia
 - c. acute myeloid leukemia
 - d. chronic myelogenous leukemia
 6. A patient with a hypercellular, dysplastic bone marrow, and anemia and neutropenia in peripheral blood most likely has which of the following neoplasms? (Objective 7)
 - a. MPD
 - b. MDS
 - c. AML
 - d. ALL
 7. A 52-year-old female was admitted to the hospital for minor elective surgery. Her preop CBC was:

WBC	$49.4 \times 10^9/L$
RBC	$4.50 \times 10^{12}/L$
Hb	12.7 g/dL (127 g/L)
Hct	0.38 L/L
PLT	$213 \times 10^9/L$
WBC differential	3% segs 97% lymphs

What is the best explanation for this patient's leukocytosis and lymphocytosis? (Objectives 3, 7)

 - a. ALL
 - b. AML
 - c. CLL
 - d. CML
- Use the following information to answer questions 8–10:
- A 43-year-old male had been working with the Peace Corps in Mexico for the past 10 years. His primary responsibilities were taking X-rays and doing laboratory work at the various clinics. He had been complaining of weakness and fatigue for about a month and had several severe nosebleeds. His CBC upon admission to the hospital was:
- | | | | |
|-----|-------------------------|------------------|----------------|
| WBC | $25.6 \times 10^9/L$ | WBC differential | 75% blasts |
| RBC | $3.11 \times 10^{12}/L$ | | with Auer rods |
| Hb | 8.9 g/dL (89 g/L) | | 20% lymphs |
| Hct | 0.267 L/L | | 3% monos |
| PLT | $13 \times 10^9/L$ | | 2% segs |

REVIEW QUESTIONS (continued)

LEVEL I

12. The minimum percentage of blast cells required for a diagnosis of acute leukemia using the WHO classification is: (Objective 3)
- 50%
 - 40%
 - 30%
 - 20%

LEVEL II

8. Which leukemia is this patient most likely to have acquired? (Objectives 3, 7)
- ALL
 - AML
 - CLL
 - CML
9. What would be the most likely causative agent of the leukemia? (Objective 2)
- virus
 - age
 - hepatitis
 - ionizing radiation
10. What treatment would result in the *best* prognosis for this patient if there were no complicating factors? (Objective 5)
- hematopoietic growth factors
 - stem cell transplantation
 - radiation therapy
 - chemotherapy
11. You are doing several cytochemical stains on a bone marrow from a patient who was recently diagnosed with acute leukemia. You are looking at the MPO, and the blasts are negative. However, the reagent is getting close to the expiration date, and you are not sure if the stain worked properly. What cells found in the bone marrow normally express myeloperoxidase and could be used to assess the stain's integrity? (Objectives 8, 9)
- neutrophils
 - red cell precursors
 - megakaryocytes
 - lymphocytes
12. Use this information to answer questions 12 and 13.
- A pathologist is looking at the bone marrow aspirate of a 26-year-old male. The marrow is packed with undifferentiated blasts. After careful searching, she could not find any Auer rods. She thinks that the patient most probably has acute lymphoblastic leukemia but cannot rule out AML by using morphology. She is thinking of ordering a TdT stain on the slides. Is that going to be useful? (Objectives 8, 9)
- Yes, TdT is always positive in acute lymphoid leukemia but never in myeloid leukemia.
 - Yes, TdT is always positive in acute myeloid leukemia but never in lymphoid leukemia.
 - No, TdT is positive in the majority of acute lymphoid leukemias but approximately 20% of acute myeloid leukemias can be positive.
 - No, TdT is positive in the majority of acute myeloid leukemias, but approximately 20% of acute lymphoid leukemias can be positive.

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

13. Which stain would you suggest the pathologist order in question 12? (Objectives 8, 9)
 - a. PAS
 - b. myeloperoxidase
 - c. nonspecific esterase
 - d. trichrome
14. Heritable changes in gene expression not due to changes in DNA are known as: (Objective 10)
 - a. mutations
 - b. molecular genetics
 - c. epigenetics
 - d. cytogenetics

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Agnes has chronic lymphocytic leukemia. The patient is elderly and had been in good health, and the symptoms of the leukemia had progressed slowly. The predominant cell present on the peripheral blood smear is a mature lymphocyte. The patient's prognosis should be good, with a life span of 5 years or more with supportive therapy.

Question:

1. Given the patient's laboratory results, would this most likely be considered an acute or chronic leukemia? Explain.

Explanation:

It is likely chronic leukemia. The peripheral blood shows an accumulation of mature lymphocytic cells with an increased white blood cell count.

Question:

2. What group of leukemia (cell lineage) is suggested by the patient's blood cell differential results?

Explanation:

Lymphocytic leukemia is suggested. The patient exhibits an increased percentage of mature lymphocytes with an increased white blood cell count and a lack of myelocytic cells.

Question:

3. What would you expect the blast count on the bone marrow to be?

Explanation:

It would be <20% under the WHO definition. In acute leukemias, blasts constitute more than 20% of the nonerythroid marrow nucleated cells; in MDS, MPD, and chronic leukemia, blasts compose less than 20% (WHO) of the marrow cells.

Question:

4. Would you expect Agnes to survive more than 3 years or succumb fairly quickly after treatment?

Explanation:

She should survive more than 3 years. Chronic leukemias progress slowly, and the course of the disease is measured in years rather than months as is typical for the acute leukemias.

Question:

5. Is Agnes a suitable candidate for a bone marrow transplant? Why or why not?

Explanation:

She is not. The highest rate of success with bone marrow transplants has occurred in those younger than 40 years of age in a first remission with a closely matched donor. Because this patient is 72 years old and CLL patients usually do well with supportive therapy, it is unlikely that she would be a candidate for a bone marrow transplant.

Question:

6. What types of treatment are available for our patient Agnes?

Explanation:

Chemotherapy, radiation, bone marrow transplant, immunotherapy are available. Permanent remission in CLL is rare. Treatment is conservative

and usually reserved for patients with more aggressive forms of the disease.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

A patient has 50% monoblasts in the bone marrow. Which of the four major types of leukemia does he have, AML, CML, ALL, or CLL?

Answer

A patient with 50% monoblasts in the bone marrow has AML. ALL and CLL can be eliminated due to their lymphoid lineage, and CML <20% blasts in the bone marrow.

Checkpoint! 2

A 62-year-old male presents with an elevated leukocyte count, mild anemia, and a slightly decreased platelet count. His physician suspects leukemia. Explain why the erythrocytes and platelets would be affected.

Answer

Leukemia is a stem cell disorder in which all cell progeny are involved. If the patient has the suspected leukemia, he would experience an unregulated production of neoplastic cells. As the neoplastic cell population increases, the concentration of normal cells, such as the platelets and erythrocytes, decreases.

Checkpoint! 3

Does a 3-year-old child with Down syndrome have an increased risk of developing leukemia? Why or why not?

Answer

Yes, some individuals with congenital abnormalities associated with karyotypic abnormalities have a markedly increased risk of developing acute leukemias.

Checkpoint! 4

Why is the finding of Auer rods an important factor in the diagnosis of leukemia?

Answer

Auer rods can be found in the blast cells and promyelocytes of some acute myeloid leukemias. The finding of Auer rods can help establish the diagnosis because these unique, pink-staining inclusions are not found in ALL. Auer rods are fused lysosomes.

Checkpoint! 5

A patient has 35% blasts in the bone marrow. They do not show any specific morphologic characteristics that will allow them to be classified according to cell lineage. What are the next steps that the CLS should take with this specimen?

Answer

Cytochemistry can help establish cell lineage as myeloid or lymphoid. An immunologic analysis provides information on what specific membrane antigens are on the blast cells. By using a panel of monoclonal antibodies, the cells' lineage can usually be determined because specific surface markers are characteristically found on each particular cell line. Genetic analysis can also be performed because some cytogenetic chromosome karyotypes are commonly found in certain types of leukemia.

Myeloproliferative Disorders

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Classification of myeloproliferative disorders (MPD)
- ▶ Pathophysiology
- ▶ General features
- ▶ Chronic myelogenous leukemia (CML)
- ▶ Chronic neutrophilic leukemia (CNL)
- ▶ Hypereosinophilic syndrome (HES)
- ▶ Chronic basophilic leukemia (CBL)
- ▶ Chronic idiopathic myelofibrosis (CIMF)
- ▶ Polycythemia vera (PV)
- ▶ Essential thrombocythemia (ET)
- ▶ Chronic myeloproliferative disease, unclassifiable (CMPD-U)
- ▶ Mast cell disease (mastocytosis)
- ▶ Summary
- ▶ Review questions

Myeloproliferative Disorders

*Sue S. Beglinger, M.S.
Shirlyn B. McKenzie, Ph.D.*

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Interpret the leukocyte alkaline phosphatase (LAP) activity found in patients with chronic myelogenous leukemia (CML).
2. Identify the major lineages involved with the various myeloproliferative disorders (MPD): chronic myelogenous leukemia, CML; polycythemia vera, PV; essential thrombocythemia, ET; and chronic idiopathic myelofibrosis, CIMF.
3. Recognize abnormal complete blood count (CBC) results that suggest an MPD.
4. Explain the diagnostic chromosome abnormality associated with CML and its significance in acute lymphoblastic leukemia (ALL).
5. Identify the peak incidence of CML according to age and sex distribution.
6. Describe and recognize the peripheral blood findings in CML patients.
7. List and recognize laboratory findings typically associated with CIMF.
8. Define criteria that indicate a transformation of an MPD into a blast crisis.
9. Compare the lab findings in primary PV to secondary polycythemia.
10. Describe and recognize the characteristic peripheral blood picture found in essential thrombocythemia (ET).

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Differentiate the subgroups of myeloproliferative disorders (MPD) from other reactive and neoplastic diseases based on laboratory findings in the peripheral blood, bone marrow, and other diagnostic laboratory tests.
2. Contrast laboratory findings in MPD and myelodysplastic syndromes (MDS) as well as acute leukemia (AL).
3. Describe molecular gene mutations in MPD and hypothesize how these changes in the pluripotential stem cell lead to MPD and blast crisis (Ph-chromosome; *BCR/ABL1* rearrangement; *p53*, *p16* mutations, *FIP1L1/PDGFR α* , and *JAK2* (V617F) mutations and expression of growth factor receptors).
4. Differentiate chronic myelogenous leukemia (CML) from a benign leukemoid reaction using laboratory tests.
5. Assess the role of platelet-derived growth factor (PDGF) in the fibrosis found with CIMF.
6. Assess laboratory results including the evaluation of peripheral blood and bone marrow smears using the diagnostic criteria associated with CIMF.

■ OBJECTIVES—LEVEL II (*continued*)

7. Compare clinical and laboratory findings, and interpret laboratory findings in relative polycythemia and absolute polycythemia.
8. Infer the significance of finding one form of the glucose-6-phosphate dehydrogenase (G6PD) isomer in myeloproliferative disorders.
9. Use laboratory results and clinical findings to differentiate essential thrombocythemia from nonmalignant conditions that result in thrombocytosis.
10. Use the criteria suggested for diagnosing variants of CML, chronic eosinophilic leukemia, CEL; chronic basophilic leukemia, CBL; and chronic neutrophilic leukemia, CNL to evaluate laboratory results of patients.
11. Differentiate unclassifiable myeloproliferative disease from other subgroups of MPD based on laboratory features.
12. Describe systemic mastocytosis by giving the criteria for diagnosis.
13. Using peripheral blood and bone marrow findings and patient medical history, determine the classification of MPD.

KEY TERMS

Chronic basophilic leukemia (CBL)
 Chronic eosinophilic leukemia (CEL)
 Chronic idiopathic myelofibrosis (CIMF)
 Chronic myelogenous leukemia (CML)
 Chronic neutrophilic leukemia (CNL)
 Essential thrombocythemia (ET)
 Hypereosinophilic syndrome (HES)
 Janus kinase 2 (*JAK2*) gene
 Leukemic hiatus
 Mastocytosis
 Myelophthitic anemia
 Panmyelosis
 Plethora
 Polycythemia vera (PV)
 Spent phase

BACKGROUND BASICS

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Outline the cell cycle; describe stem cell differentiation and maturation for the various myeloid lineages. ▶ Describe and recognize morphology for the various stages of myeloid maturation.
- ▶ Calculate red cell indices.
- ▶ Use appropriate morphologic terms to describe size and chromia of red cells in anemic states.
- ▶ Outline and explain the classification of hematopoietic neoplasms.

Level II

- ▶ Describe the influence of growth factors on hematopoietic cell proliferation.
- ▶ Explain the evaluation of red cell mass based on changes in fluid volume.
- ▶ Explain the hemoglobin–oxygen dissociation curve.
- ▶ Describe how cell marker panels can be used to differentiate hematopoietic neoplasms.
- ▶ Discuss the value of cytogenetic studies in suspected hematologic malignancies.
- ▶ Explain how the utilization of molecular tests can assist in diagnosis of hematopoietic neoplasms.

CASE STUDY

We will refer to this case throughout the chapter.

Roger, a 52-year-old man with hyperuricemia, was seen at the clinic for a follow-up evaluation for splenomegaly. His palpable spleen, noted 18 months earlier, had been gradually enlarging. He originally denied fatigue, fever, and discomfort. He was examined, and a CBC was ordered. The results revealed leukocytosis, thrombocytosis, and anemia. Consider reflex laboratory testing that can assist in diagnosing this patient.

OVERVIEW

This chapter is a study of the group of neoplastic but not frankly malignant disorders called *myeloproliferative disorders* (MPD). The MPD must be distinguished from other neoplastic and benign hematologic disorders for the physician to select appropriate therapy for the patient. The chapter begins with the classification, pathophysiology, and general characteristics of the MPD, which provide the groundwork for a more detailed explanation and description of each subgroup. More specific pathophysiology, clinical findings, laboratory findings, and therapy are included for each subgroup. These are followed by an explanation of how to differentiate the MPD from diseases with similar laboratory findings. Systemic mastocytosis (SM) considered to be a type of MPD but included in a separate WHO group is also briefly discussed.

INTRODUCTION

As discussed, hematopoiesis is a highly regulated process whereby a normal steady-state production of hematopoietic cells in the bone marrow and destruction of senescent cells in the tissues maintain a constant peripheral blood cell concentration. Acquired mutations in hematopoietic stem cells that allow them to escape the regulatory controls for proliferation and/or differentiation in the bone marrow result in hematopoietic neoplasms.

In the French-American-British (FAB) classification, neoplastic disorders of hematopoietic cells typically are grouped into three main categories: MPD, myelodysplastic states or syndromes (MDS), and acute leukemias (AL) including both myeloid and lymphoid. This classification uses the blast count, lineage commitment, and level of differentiation of the neoplastic cells to classify the diseases. The classification uses cell morphology, cytochemistry, and immunophenotyping. Recently, the World Health Organization (WHO) proposed a newer classification for hematopoietic neoplasms that integrates cytogenetics and clinical features with cytochemistry and immunophenotyping. The WHO myeloid classification includes the same three categories as the FAB—acute myelogenous leukemia (AML), MPD, and MDS—and

adds a fourth category, the *myelodysplastic/myeloproliferative disorders* (MDS/MPD), which has both myeloproliferative and myelodysplastic features, and a fifth category, mast cell disease (mastocytosis). In the WHO classification, the percentage of blasts, degree of cell maturation, and dysplasia are critical initial assessments used to classify the hematopoietic neoplasms. A blast count $\geq 20\%$ is necessary for a diagnosis of AML. The other groups have $< 20\%$ blasts. Each group has subcategories based on clinical history, genetic and other laboratory findings.

Although not clearly malignant, MPD and MDS, are characterized by an autonomous, neoplastic clonal proliferation of hematopoietic precursors. MPD generally can be distinguished from MDS because in MPD, both the bone marrow and peripheral blood show increases in erythrocytes, leukocytes, and/or platelets. MDS, on the other hand, are most commonly characterized by a hyperproliferative bone marrow, dysplastic maturation, and increased apoptosis that yields peripheral blood cytopenias. Both MPD and MDS have a chronic and acute course with the potential of evolving into AL. Some hematologists believe that MDS are actually acute leukemias diagnosed at an early stage. The WHO proposed MDS/MPD category includes neoplasms that are proliferative like MPD but have dysplastic features like MDS.

CLASSIFICATION OF MYELOPROLIFERATIVE DISORDERS (MPD)

The term *myeloproliferative syndrome*, coined by William Dameshek in 1951, describes a group of disorders that result from an unchecked, autonomous clonal proliferation of cellular elements in the bone marrow.¹ Myeloproliferative disorders are generally characterized by panhypercellularity (**panmyelosis**) of the bone marrow accompanied by erythrocytosis, granulocytosis, and/or thrombocytosis in the peripheral blood. Although trilineage cell involvement (erythrocytic, granulocytic, thrombocytic) is characteristic of MPD, one cell line is usually more prominently affected than the others. Hematologic classification is based on the most affected cell line (Table 1). In the WHO classification, the spectrum of myeloproliferative disorders includes:

- Chronic myelogenous leukemia (CML) Ph positive, t(9;22) (q34;q11)
- Chronic neutrophilic leukemia (CNL)
- Chronic eosinophilic leukemia (CEL)/hypereosinophilic syndrome (HES)
- Chronic idiopathic myelofibrosis (CIMF) also known as *myelofibrosis with myeloid metaplasia* (MMM)
- Polycythemia vera (PV)
- Essential thrombocythemia (ET)
- Myeloproliferative disease, unclassifiable (MPD-u).

TABLE 1

Classification of Myeloproliferative Disorders (MPD) by Predominance of Cell Types

Involved Cell Line	Myeloproliferative Disorder
Erythroid	Polycythemia vera (PV)
Myeloid	Chronic myelogenous leukemia (CML) and chronic neutrophilic leukemia (CNL)
Megakaryocytic	Essential thrombocythemia (ET)
Fibroblast*	Chronic idiopathic myelofibrosis (CIMF) with extramedullary hematopoiesis
Eosinophil	Chronic eosinophilic leukemia (CEL)
Basophil	Chronic basophilic leukemia (CBL)
Mast cell	Mast cell disease (mastocytosis)
Variable	Myeloproliferative disease, unclassifiable (MPD-u)

*The fibroblast in CIMF is not a part of the neoplastic process but is increased due to a reactive process.

The most important change from the FAB to the WHO classification of the MPD is that only cases with the Philadelphia (Ph) chromosome are included as CML in the WHO classification. The Ph chromosome negative cases with myelodysplastic and myeloproliferative features are included in the WHO MDS/MPD group and called *atypical CML (aCML)*. Another rare neoplasm, chronic basophilic leukemia, is also considered an MPD and will be discussed in this chapter.

The classification of these disorders is not always clear because of overlapping clinical and laboratory features between subgroups at different times during the course of the disease (Table 2).

▶ PATHOPHYSIOLOGY

The primary defect in MPD appears to be in the pluripotential hematopoietic stem cell (HSC) (Figure 1). Studies indicate that in myeloproliferative diseases, increased numbers of stem cells and progenitor cells are found in the precursor cell compartment.² A clone of abnormal hematopoietic stem cells and their progeny preferentially expands until normal hematopoietic cell growth is inhibited and the majority of functioning bone marrow is derived from the abnormal clone. Excessive proliferation of hematopoietic cells occurs through various mechanisms that require multiple genetic mutations^{3,4}. Commitment, differentiation, and maturation of the abnormal clone are generally preserved, leading to increased numbers of mature cells in the peripheral blood, usually with one lineage (erythroid, myeloid, or megakaryocytic) predominating.

The finding of uniform biochemical, cytogenetic, or molecular genetic abnormalities in hematopoietic cells from the bone marrow or peripheral blood of patients with MPD suggests a clonal origin for these disorders. The most useful biochemical marker for demonstrating monoclonality of MPD is the glucose-6-phosphate dehydrogenase (G6PD) enzyme. G6PD isoenzymes (A and B) are coded for by a gene on the X chromosome. The inactivation of one X chromosome in a cell containing two or more X chromosomes is random. Hence, each cell has only one active G6PD gene. Females heterozygous for isoenzyme A and isoenzyme B produce both enzymes. Approximately half of the cells contain isoenzyme A; the remaining cells contain isoenzyme B. The blood cells of G6PD heterozygous females with MPD, however, contain either one or the other isoenzyme in their granulocytes, erythrocytes, and platelets, reflecting their origin from a common HSC (i.e., “clonal” hematopoiesis).

TABLE 2

Differential Features of Myeloproliferative Disorders

Parameter	CML	CIMF	PV	ET	CEL	CNL
Peripheral blood:						
Hematocrit	N or ↑	↓	↑↑↑	N or ↓	N	N or ↑

■ **FIGURE 1** This schematic of hematopoietic cell development shows that a mutation in the pluripotential hematopoietic stem cell, HSC (CD34⁺), results in clonal proliferation of the progeny of that cell, all containing the mutation. Thus, all cell lines will be affected. This is thought to be the original neoplastic cell in CML and other MPDs. The common lymphoid progenitor cell is thought to be the original neoplastic cell in ALL. In AML, the cell of origin can be the common myeloid progenitor cells (CMP), the committed myeloid progenitor cells or occasionally the HSC. (ALL = acute lymphocytic leukemia; MPD = myeloproliferative disorder; AL = acute leukemia)

In addition, many individuals with a MPD have identical karyotypic abnormalities in all hematopoietic lineages, also suggesting that these cells were derived from a single mutant stem cell. These abnormalities are not present in other somatic cells, indicating that the mutations are acquired rather than inherited. The most consistent chromosome abnormality, the Ph chromosome, is found in all hematopoietic blood cells in patients with CML. Recently, the **Janus kinase 2 (JAK2) gene**, which codes for a tyrosine kinase involved in cell signaling was found to be mutated in almost all cases of PV and some cases of ET and CIME. These mutations are discussed in more detail later in the chapter. The application of molecular biology in the study of hematopoietic neoplasms has been useful in identifying the specific genetic abnormality at the DNA, mRNA, and protein levels. These studies have supported the clonality hypothesis of MPD.

▶ GENERAL FEATURES

Myeloproliferative disorders usually occur in the middle-aged and older adults (peak frequency in the fifth to seventh decades of life). They are rare in children. The onset of the disease is gradual, evolving over months or even years. The

MPD frequently overlap in clinical, laboratory, and morphologic findings among the specific entities.

Clinical findings can include hemorrhage, thrombosis, infection, pallor, and weakness. Anemia or polycythemia, leukoerythroblastosis, leukocytosis, and thrombocytosis with bizarre platelets are common laboratory findings that can occur in almost any of the subtypes of MPD. Anemia, when present, is caused by ineffective erythropoiesis, marrow fibrosis, and/or a shortened cell survival due to splenomegaly.

Decreased bone marrow iron, not reflective of true iron deficiency, is a consistent finding in MPD.⁵ For this reason, serum ferritin and serum iron are more reliable estimates of iron deficiency in the presence of MPD than is the evaluation of bone marrow iron.

Thrombocytosis can be a common occurrence in MPD. When thrombocytosis is classified as the primary disorder, it is believed to result from an autonomous, unregulated proliferation of megakaryocytes. The level of interleukin-6 (IL-6) and thrombopoietin (TPO), cytokines that promote megakaryopoiesis, is normal in MPD, whereas the level is usually increased in secondary or reactive thrombocytosis.⁶ Platelet membrane proteins—glycoprotein IIb/IIIa, von Willebrand factor (VWF), fibrinogen, fibronectin, and vitronectin—are significantly decreased in many patients with

MPD.^{7,8} Genetic changes altering growth factor receptors, including the thrombopoietin receptor (MPL), and mutations in the Janus kinase (JAK) signaling pathways result in increased megakaryopoiesis and enhanced activation and aggregation of platelets.⁹

The bone marrow is usually hypercellular at onset of the MPD but often becomes fibrotic during the course of the disease. Fibroblasts are a part of the bone marrow stroma, which provides a suitable microenvironment for developing hematopoietic cells. Fibroblasts produce reticular fibers that form a three-dimensional supporting network for vascular sinuses and hematopoietic elements. *Fibrosis* refers to an increase in fibroblasts and reticular fibers. Fibrosis in MPD is thought to be a reactive process that is secondary to the increased production of cytokines from the abnormal hematopoietic cells (primarily megakaryocytes). As evidence of their benign proliferation, fibroblasts exhibit normal karyotypes and G6PD mosaicism in female heterozygotes. Although often considered the hallmark of CIMF, fibrosis can be seen in the other MPD entities as well.

Reactive fibrosis can result from the intramedullary release of cytokines from platelets, megakaryocytes, and malignant cells that are mitogenic for fibroblasts. Human platelet-derived growth factor (PDGF) stimulates growth and cell division of fibroblasts as well as other cells. The platelet concentration of PDGF in patients with MPD is significantly decreased. Although this could be due to either decreased synthesis or excessive release, assays of circulating PDGF in MPD suggest that the mechanism is excessive release. The serum PDGF level is significantly higher in patients with CIMF and ET than in other MPD or in normal controls. Not surprisingly, CIMF and ET are the two MPD with the most significant degree of fibrosis.⁴ Increased fibroblasts lead to an increase in collagen, laminin, and fibronectin in the medullary cavity.

When marrow fibrosis supervenes over the course of the disease, the major sites of hematopoiesis become the extramedullary tissues, particularly the liver and spleen. Hepatosplenomegaly is a common clinical finding. Extramedullary hematopoiesis can also occur in benign diseases such as chronic hemolytic anemias, but the hematopoiesis in these disorders is confined to the erythrocyte lineage. In contrast, all cell lineages are present in the extramedullary masses that accompany the MPD. It has been hypothesized that marrow fibrosis causes distortion of marrow sinusoids, which permit hematopoietic stem cells to escape into the sinusoids and gain entry to the peripheral blood.¹⁰ These stem cells then lodge in extramedullary sites, such as the spleen, to proliferate and differentiate.

MPD carry a significant risk of terminating in acute leukemia. This transition is commonly seen in CML. The question has been raised as to whether acute leukemia is a natural transition of MPD or is the result of leukemogenic chemotherapy and radiotherapy for the original myeloproliferative disorder.

 **Checkpoint! 1**

In essential thrombocythemia, all hematopoietic lines have increased cell proliferation. Which lineage has the greatest increase?

▶ CHRONIC MYELOGENOUS LEUKEMIA (CML)

Chronic myelogenous leukemia (CML), also known as *chronic granulocytic leukemia (CGL)* and *chronic myeloid leukemia*, is the best defined MPD. It is characterized by a neoplastic growth of primarily myeloid cells in the bone marrow with an extreme elevation of these cells in the peripheral blood. Extramedullary granulocytic proliferation in the spleen and liver is progressive. Erythrocytic and megakaryocytic lineages can also expand.

The natural history of the disease has three phases: chronic followed by one or both of two aggressive transformed stages—accelerated transition and blast crisis. The initial chronic phase responds well to therapy. Normal health can usually be restored and maintained for months or years. CML eventually transforms into an accelerated phase and blastic leukemia, either AML or acute lymphoblastic leukemia (ALL). After progression to blast crisis, the prognosis is poor with a survival of less than 6 months. With the newer treatment protocol using Gleevec, survival time has been increased to more than 5 years.

ETIOLOGY AND PATHOPHYSIOLOGY

The Ph chromosome, an acquired chromosome abnormality, is present in all neoplastic hematopoietic cells in CML except T lymphocytes and sometimes B lymphocytes (Figure 2 ■). This was the first chromosome abnormality found consistently associated with a malignant disease. It is not found in somatic cells or fibroblasts.

In some cases, the Ph chromosome was detected months before the diagnosis of CML. Once the chromosome abnormality is present, it rarely disappears, even in patients in remission. Because all hematopoietic cells are involved in the neoplastic process, the original neoplastic cell (cell of origin) is most likely a pluripotential HSC common to all lineages (Figure 1).

Molecular biology has dramatically increased our understanding of the role of the Ph chromosome in this disease. The Ph chromosome results from a balanced reciprocal translocation between the longarms of chromosomes 9 and 22, t(9;22)(q34;q11.2) (Figure 3 ■). On chromosome 9, the break point is spread across 90 kb within the first exon of *ABL*, translocating the 3' end of exon 1 and exons 2–11 (in which the tyrosine kinase domains reside) to chromosome 22. The break point in chromosome 22 occurs within the *BCR* gene, a large 70-kb gene with 20 exons. The break point usually involves a 5.8-kb area known as the *major break point*

FIGURE 2 Karyotype from a patient with CML showing the Philadelphia chromosome translocation, t(9;22)(q34;q11.2). The Philadelphia chromosome is chromosome 22.

cluster region (M-BCR) between either exons b2 and b3 or b3 and b4. Two different fusion genes can be formed, both joining the translocated portion of the *ABL* gene with either exon b2 of *BCR* or exon b3 of *BCR*. The resulting Ph chromosome has a 5' end of *BCR* from chromosome 22 and a 3' end

FIGURE 3 The Philadelphia translocation in CML. Arrows indicate the chromosome breakpoints at 9q34 (*ABL* gene) and 22q11.2 (*BCR* gene) in the genes directly involved in the translocation. The translocation results in a lengthened 9q+ chromosome and a shortened 22q- chromosome (Philadelphia chromosome).

of *ABL* sequences from chromosome 9 (Figure 4■). This hybrid gene is then transcribed into an 8.5-kb mRNA, in contrast to the normal *ABL*, which is transcribed to a 6- or 7-kb mRNA.^{11–13}

Translation of the 8.5-kb mRNA creates a new, abnormal protein, with a molecular mass of 210 kD (p210) with enhanced tyrosine kinase activity, increasing autophosphorylation within the cell. (Tyrosine kinase proteins regulate metabolic pathways and some serve as receptors for growth factors [RTK—receptor tyrosine kinase]). The normal *ABL* protein codes for a 145-kD protein. The oncogenic role of p210 is found in association with increased granulocyte colony-stimulating factor (G-CSF) and PDGF. Studies also suggest that this activation of tyrosine kinase activity suppresses apoptosis in hematopoietic cells.¹³ Over a period of several years, the t(9;22) cell line replaces the normal marrow cells, and CML is expressed. The reciprocal fusion gene, *ABL/BCR1* is transcribed in approximately two-thirds of CML patients, although its significance is not clear. Characteristics of the *ABL* and *BCR* proto-oncogenes, as well as the *ABL/BCR1* fusion oncogene, are described in Table 3★.

Detection of the *BCR* gene rearrangement has several clinical uses in the diagnosis and prognosis of CML (Table 4★).¹⁴ About 5–10% of patients with the CML phenotype lack the Ph chromosome. In these cases, the translocation is not detected at the karyotypic level by cytogenetic studies, but molecular analyses by reverse transcriptase polymerase chain reaction (RT-PCR) or fluorescent in situ hybridization (FISH) show that the molecular *BCR/ABL1* rearrangement

FIGURE 4 Exon maps of the normal *BCR* and *ABL1* genes, and the *BCR/ABL1* fusion gene formed by the Philadelphia-chromosome translocation found in CML resulting in a protein of 210 kilodaltons. Upward arrows show breakpoints in the major *BCR* (M-BCR) region of the *BCR* gene and in exon 1 of the *ABL1* gene that results in the *BCR/ABL1* fusion gene.

TABLE 3

Characteristics of the Proto-Oncogenes and Oncogenes Involved in the *BCR/ABL* Gene Rearrangements in CML

Gene	Size	No. Exons	Break Point	Transcript(s)	Protein	Location	Activity
<i>ABL</i>	>230 kb	11	5' of exon II (100–200 kb)	6 kb; 7 kb	p145	Nucleus	Tyrosine kinase (normal)
<i>BCR</i>	>100 kb	20	bcr (5.8 kb)	4.5 kb; 6.7 kb	p160	Unknown	Unknown
<i>BCR/ABL1</i> fusion	Varies	Varies	Fusion hybrid	8.5 kb	p210	Plasma membrane	Tyrosine kinase (increased)

has occurred. The malignant cells in these cases also express the 8.5-kb chimeric mRNA and the p210 protein (Table 5).

Cases of phenotypic CML that are Ph chromosome and *BCR/ABL1*-negative are aCML or possibly cases of CMML (if absolute monocytosis and leukocytosis are present); both of these disorders are now considered myelodysplastic/myeloproliferative disorders.¹⁵ Other chronic myeloproliferative diseases, similar to CML, include chronic eosinophilic leukemia, chronic basophilic leukemia, and chronic neutrophilic leukemia. All have high proliferative rates, but are Ph-chromosome negative.^{16,17}

Disease Progression and Additional Chromosome/Molecular Mutations

Progression of CML is marked by an accelerated or acute phase (blast crisis). In more than 75% of patients, this progression is preceded or accompanied by the development of additional chromosomal abnormalities (Table 6).¹⁸ Thus, repeated chromosome analysis in patients with CML can be helpful in predicting impending blast crisis.

At the molecular level, mutations in the *p53* gene, a tumor suppressor antioncogene, are found in at least 30% of patients in blast crisis, especially in those with myeloid or

megakaryocytic blast crisis.¹⁹ Mutations/alterations of this gene in the chronic state of CML are rare.

RAS proteins, found on the inner surface of the cell membrane where they associate with cell surface receptors, also are altered in CML. *RAS* genes encode for proteins that bind guanosine diphosphate (GDP) in their neutral (unactivated) state. When the cell surface receptor is activated by a cytokine, the RAS protein is activated by expelling the GDP and binding GTP in its place. By binding G-proteins, RAS proteins transfer cell activation signals from the cytokine/receptor complex into the nucleus in a process that is carefully regulated. Oncogenic forms of RAS have a reduced ability to be deactivated, thus sending unregulated proliferation signals to the cell nucleus. Both normal and oncogenic RAS proteins must have a farnesyl group added in a post-translational modification of the protein to be fully active. One of the new treatment approaches for those malignancies with elevated RAS activity is a “farnesyl transferase inhibitor” drug, which reduces or blocks activation of RAS and decreases the proliferative stimulus.

TABLE 4

Clinical Uses of Molecular Analysis for the *BCR* Gene Rearrangement

- Diagnosis of CML when the Ph chromosome is absent
- Differentiation of CML in blast crisis from de novo ALL when the Ph chromosome is present
- Confirmation of a diagnosis of CML when the patient presents in the blast crisis phase of CML
- Differentiation of CML from other myeloproliferative diseases and myelodysplastic syndromes when overlapping clinical and/or morphological features are present
- Monitoring of CML patients on therapy for minimal residual disease

Adapted from: Mattson J, Crisan D, Wilner F, Decker D, Burdakin J. Clinical problem solving using bcl-2 and BCR gene rearrangement analysis. *Lab Med.* 1994;25:648–53.

TABLE 5

Genetic Rearrangements and Related Proteins Found in Philadelphia Chromosome Positive CML, ALL, and Philadelphia Chromosome Negative MPD, or ALL

Clinical Condition	Involvement of Ph/BCR	PTK
Normal	Ph–, BCR–	145 kD
CML	Ph+, BCR+	210 kD
	Ph–, BCR+	210 kD
Other MPD	Ph–, BCR–	145 kD
ALL	Ph+, BCR+	210 kD (CML blast crisis)
	Ph+, BCR–	190 kD (? de novo ALL)
	Ph–, BCR–	145 kD (? de novo ALL)

PTK = protein tyrosine kinase; CML = chronic myelogenous leukemia; ALL = acute lymphoblastic leukemia; Ph+ = Philadelphia chromosome positive; Ph– = Philadelphia chromosome negative; BCR+ = rearrangement within the M-BCR region; BCR– = no rearrangement within the M-BCR region

★ TABLE 6

Additional Mutations in Blast Crisis of CML

Frequent

- Duplication of Ph chromosome
- Trisomy 8
- Isochromosome 17
- Loss of Y chromosome

Rare

- Translocation (15;17)
- Translocation (3;21)(q26;q22)
- Translocation (3;3)/inversion (3)

Very Rare

- Deletion of chromosome 5 (-5) or the long arm (5q-)
- Deletion of chromosome 7 (-7) or the long arm (7q-)

Philadelphia (Ph) Chromosome in Acute Leukemias

About 2–5% of childhood ALL, 25% of adult ALL, and some cases of AML have the Ph chromosome. Ph-positive AML cases can actually be CML in blast crisis that were not diagnosed in the chronic (CML) stage. In about 50% of the Ph-positive ALLs, the molecular defect is identical to that found in CML and the BCR/ABL protein, p210, is present. These cases probably represent the blast crisis phase of CML. In the remaining 50% of Ph-positive ALL, the break points on chromosome 22 fall 5' to the BCR but are still within the first intron of the BCR gene. These leukemias express a distinct translation product of the mRNA hybrid termed the *p190kd protein* (Figure 5 ■).^{13,20} These Ph-positive ALLs can actually be de novo acute leukemia cases (Table 5). Like p210, the p190 protein also shows an increased tyrosine kinase activity, but its role in the development of the ALL phenotype is unclear.

✓ **Checkpoint! 2**

A patient has the CML phenotype, but the genetic karyotype does not show the Ph chromosome. If this is truly a CML, what should molecular analysis show?

CLINICAL FINDINGS

CML is the most common MPD, accounting for 15–20% of all leukemia cases. It can occur at any age, but the incidence increases dramatically among those 55 years of age and older. It is most prevalent in the seventh, eighth, and ninth decades of life. It is almost equally distributed between sexes and can occur in young adults more so than other MPD. Although rare, CML can occur in childhood. More economically advanced countries report higher incidences of CML.

■ **FIGURE 5** Exon maps of the normal BCR and ABL genes and the BCR/ABL gene rearrangement in the Philadelphia translocation of de novo acute leukemias resulting in a protein of 190 kilodaltons. Upward arrows show breakpoints in intron 1 of the BCR gene, upstream of the common major breakpoint region (M-BCR), and in exon II of ABL that result in the BCR/ABL gene rearrangement.

The question arises, however, as to whether the higher incidences reflect the ability to detect and diagnose the disease because of increased availability of advanced medicine and diagnostic tools in these countries.

The disease has an insidious onset with the most common symptoms being increased weakness, loss of stamina, unexplained fever, night sweats, weight loss, and feelings of fullness in the abdomen (hepatosplenomegaly). Gastrointestinal tract bleeding or retinal hemorrhages are occasionally the first signs of the disease. Physical examination reveals pallor, tenderness over the lower sternum, splenomegaly, and occasionally hepatomegaly. Lymphadenopathy is not typical; when present, it suggests an onset of the acute phase of the disease. Petechiae and ecchymoses reflect the presence of quantitative and/or qualitative platelet abnormalities. Some individuals are asymptomatic, and CML is found incidentally during examination for other medical problems or in a routine physical.

Any organ eventually can be infiltrated with myeloid elements, but extramedullary masses in areas other than the spleen and liver are uncommon findings in the chronic phase. On fresh incision, extramedullary masses appear green, presumably due to the presence of the myeloid enzyme myeloperoxidase. These greenish tumors have been called *chloromas*. The green color fades to a dirty yellow on exposure of the tissue to air.

Without intervention, symptoms worsen over the next 3–5 years, and increased debilitation heralds the onset of the blast phase. When the onset of blast crisis has been reached, response to therapy is poor and survival is less than 6 months.

LABORATORY FINDINGS

Peripheral Blood

The most striking abnormality in the peripheral blood is the extreme leukocytosis. The white count is usually more than $100 \times 10^9/L$ with a median of about $170 \times 10^9/L$. Patients diagnosed earlier may have a leukocyte count of $25\text{--}75 \times 10^9/L$. Thrombocytosis, which can exceed $1000 \times 10^9/L$ and variation in platelet shape are found in more than half of the patients. If thrombocytosis is a new observation, blast crisis is probably imminent. During blast crisis, thrombocytopenia is often a common finding. Platelet function also is frequently abnormal. Megakaryocyte fragments and micromegakaryocytes can be found (Figure 6 ■).

At the time of diagnosis, a moderate normocytic, normochromic anemia is typical with a hemoglobin concentration in the range of 9–13 g/dL. The severity of anemia is proportional to the increase in leukocytes. Erythrocyte morphology is generally normal, but nucleated erythrocytes can be found. Reticulocytes are normal or slightly increased.

Blood smears exhibit a shift to the left with all stages of granulocyte maturation present (Figure 7 ■). The predominant cells are the segmented neutrophils and myelocytes. Promyelocytes and blasts do not usually exceed 20% of the leukocytes. Eosinophils and basophils are often increased in both relative and absolute terms. Increasing blast concentrations or progressive basophilia herald blast crisis. Monocytes are moderately increased. Signs of myeloid dysplasia including pseudo-Pelger-Huët anomaly (hyposgmentation of PMN nucleus) and decreased leukocyte alkaline phosphatase (LAP) are frequent. Low or absent LAP is characteristic but not specific for CML. Monocytosis, myeloid dysplasia, and micromegakaryocytes are overlapping features found in both CML and chronic myelomonocytic leukemia (CMML). The presence of the Ph chromosome helps differentiate the two disorders.

■ **FIGURE 6** Arrow points to the micromegakaryocyte in the peripheral blood of a patient with chronic myelocytic leukemia. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

■ **FIGURE 7** Chronic myelocytic leukemia (CML) with leukocytosis and a shift to the left. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

Bone Marrow

The bone marrow is 90–100% cellular with a striking increase in the myeloid:erythroid ratio (10:1 to 50:1). The active red marrow can extend into the long bones. Thinning of the cortex and erosion of the trabeculae can be present. The hematopoietic marrow cells are primarily immature granulocytes with <20% blasts by WHO classification, an important characteristic that distinguishes CML from AL.²¹ The marrow differential count of leukocyte precursors often is within the normal range. The typical **leukemic hiatus** (gap) between the number of immature cells (blasts) and mature cells (segmented neutrophils) characteristic of AL is not present in CML. Auer rods can be found in the myeloblasts during blast crises, but this is an unusual finding. Erythropoiesis is normoblastic, but normoblasts can be decreased. Megakaryocytes are usually increased with frequent immature and atypical forms. In contrast to the large megakaryocytes found in other subgroups of MPD, CML typically reveals small megakaryocytes.

Gaucher-like cells (histiocytes) have been observed in the bone marrow. However, these cells, with the typical wrinkled tissue paper appearance of the cytoplasm, are not due to the lack of the β -glucocerebrosidase enzyme as in Gaucher's disease but to the overload of cerebroside caused by increased cell turnover. The histiocytes in CML have normal to increased amounts of the β -glucocerebrosidase, but the cell cannot process the cerebroside fast enough to prevent them from accumulating in the cell.

The marrow can become fibrotic late in the course of the disease. If a physician does not see the patient until the fibrosis is prominent, a diagnosis of CIMF may be considered. At this point, only chromosome analysis can establish the correct diagnosis.

Other nonspecific findings related to the increased proliferation of cells can be present. Total serum cobalamin and the unsaturated cobalamin binding capacity are increased. Serum transcobalamin I is often elevated. These findings are

probably related to the increased number of granulocytes that are thought to synthesize the cobalamin-binding proteins. Uric acid and lactic dehydrogenase (LD) are elevated, secondary to increased cell turnover. Muramidase is normal or only slightly increased.

Checkpoint! 3

Describe the peripheral blood differential of a CML patient.

CASE STUDY (continued from earlier in this chapter)

Physical examination revealed a slightly enlarged liver and palpable spleen. Roger had hyperuricemia. Blood counts showed:

Hb 11.6 g/dL Hct 0.35 L/L RBC $3.6 \times 10^{12}/L$
 WBC $26.2 \times 10^9/L$ Platelets $853 \times 10^9/L$

The blood cell differential showed marked anisocytosis, poikilocytosis with many teardrops, and numerous NRBC. Immature myeloid cells were found along with basophilia and large platelets.

1. What are Roger's MCV and MCHC?
2. How would you classify his anemia morphologically?
3. Based on Roger's history and current laboratory data, what other tests should be performed?

TERMINAL PHASE

Historically, about 3–5 years after the diagnosis of CML, the typical course of the disease is transition to the accelerated stage (Figure 8■). This transitional, accelerated stage can occur at any time after the initial diagnosis and often precedes blastic transformation. Transition is heralded by one or more of the changes listed in Table 7♣. Marked granulocytic dysplasia or dysplastic megakaryocytes in clusters/sheets with increased fibrosis in the marrow suggests the accelerated phase. Additional chromosomal abnormalities also

■ **FIGURE 8** Peripheral blood film from a patient with CML in accelerated phase. There is an increase in blasts. Arrows point to blasts (Wright-Giemsa stain; 1000× magnification)

♣ **TABLE 7**

Accelerated Phase of CML

Characterized by the Presence of One or More of the Following

- 10–19% myeloblasts in peripheral blood or bone marrow
- $\geq 20\%$ basophils in peripheral blood
- Platelet count $< 100 \times 10^9/L$ unrelated to therapy
- Persistent thrombocytosis $> 1000 \times 10^9/L$ unresponsive to therapy
- Increasing WBC count and spleen size unresponsive to therapy
- Additional clonal genetic aberrations not present in the chronic phase
- Megakaryocytic proliferation in sheets and clusters associated with marked reticulin or collagen fibrosis and/or severe granulocytic dysplasia*

*Not yet evaluated as a criteria in large clinical studies

Adapted from: Vardiman JW, Harris NL, Brunning RD. The World Health Organization (WHO) classification of the myeloid neoplasms. *Blood*. 2002;100(7):2292–2302

can be found. Clinical features reflect an increase in debilitation including pyrexia, night sweats, weight loss, increased weakness, malaise, bone pain, and lymphadenopathy. About 30% of those patients in the accelerated phase die before developing a blastic crisis.

Although blast crisis typically develops after a short accelerated phase, about one-third of cases abruptly develop a blastic transformation. After onset of blast crisis, survival is about 1–2 months. The clinical features in blast crisis are similar to those of acute leukemia.

The hematologic criteria for identifying a blast crisis is made by finding moderate to marked diffuse bone marrow fibrosis and 20% or more blasts^{21,22} in the peripheral blood or bone marrow of a patient previously diagnosed as having CML (Table 8♣ and Figure 9■). Any type of blast involvement is possible including myeloid, lymphoid, erythroid, or megakaryocytic cells. Because blast morphology alone is often not sufficient to identify the type of blast involved, cytochemical, enzymatic, ultrastructural, and immunophenotyping studies are helpful. About 65–75% of blast crises are myeloblastic, and 25–35% of blast crises are lymphoblastic. The lymphoblasts in blast crisis immunologically type common acute lymphocytic leukemia antigen positive (CALLA+) and demonstrate an elevated terminal deoxynucleotidyl transferase (TdT), findings indicating that these cells belong

♣ **TABLE 8**

Blastic Crisis Phase of CML

Characterized by the Presence of One or More of the Following

- $\geq 20\%$ blasts in the bone marrow or nucleated cells in the peripheral blood
- Extramedullary blast proliferation
- Presence of large clusters of blasts in the bone marrow biopsy specimen

■ **FIGURE 9** Peripheral blood from a patient with CML in blast crisis. Note the cluster of blasts with vacuoles. (Wright stain; 1000× magnification)

to the B lymphocyte lineage. Erythroblastic and megakaryoblastic crises are uncommon.

THErapy

Therapy for CML seeks to reduce the leukocyte mass, restore bone marrow function, reduce splenomegaly, and abolish symptoms. Leukapheresis is sometimes used initially to reduce the leukocyte mass when excessive numbers of cells result in a significant increase in blood viscosity. Supportive measures during therapy regimens include transfusion to treat severe anemia and antibiotics to treat infections.

Before the discovery of molecularly targeted therapy for malignant diseases, interferon- α plus cytarabine were considered standard therapy for patients with CML who were not candidates for an allogeneic HSC transplant. Interferon- α , a glycoprotein produced by a variety of cells in response to viral infection, immune stimulation, or chemical inducers, has a myelosuppressive effect directly inhibiting myeloid progenitor cells.^{13,23} It induces a remission in 55–75% of CML patients and, in some cases, eliminates the Ph chromosome clone. A cytogenetic response is more favorable in patients who are treated early in the chronic phase of the disease.^{13,29}

Now imatinib mesylate (Gleevec), formerly known as STI571, is considered the first treatment option except in pregnant patients. It is a molecular-targeted therapy. Imatinib competitively binds to the ATP binding site of the tyrosine kinases of ABL (BCR/ABL and TEL/ABL), C-KIT, stem cell factor receptor and platelet derived growth factor receptor (PDGFR) thus inhibiting kinase activity and preventing cell signal transduction. Gleevec is well tolerated with mild to moderate side effects, primarily involving the gastrointestinal track and skin. However, it is teratogenic in laboratory animals. Results of a 5-year study using imatinib indicate

that 96% of patients have a complete hematologic response by 12 months and 98% at 60 months.²⁴ The rates of major cytogenetic response (<35% Ph+ metaphases) and complete cytogenetic response (0 Ph+ metaphases) were 92% and 87%, respectively.²⁴ Imatinib also has been shown to be effective in delaying progression of disease in patients in blast crisis.²⁵ Current research is assessing the benefits of combining treatment options (i.e., imatinib and interferon alpha).

Patients initially responsive to imatinib therapy can develop resistance (secondary resistance or loss of response), but other patients might not respond even in the early phase of the disease (primary resistance). Patients in the advanced stages of CML might not respond to imatinib.

Primary resistance is defined as a:

- Complete hematologic response (CHR) is not achieved by 3 months
- Cytogenetic response is not achieved by 6 months (>95% Ph+ metaphases persist)
- Major cytogenetic response is not achieved by 12 months (>35% Ph+ metaphases persist)

Loss of response is defined as:

- Loss of a complete hematologic response
- Loss of a major cytogenetic response
- Increasing levels of *BCR/ABL* as assessed by real-time PCR

Loss of response is related to development of additional mutations in the kinase domain of *BCR/ABL*.²⁶ A first therapeutic option in loss-of-response patients is increasing the dose of imatinib. Other options include switching to another tyrosine kinase inhibitor (TKI) such as dasatinib or nilotinib.

Baseline assessment for CML patients before imatinib therapy should include bone marrow morphology, cytogenetics, and RT-PCR to determine baseline level of *BCR/ABL* transcripts. Measuring *BCR/ABL* mRNA levels in plasma has been found to correspond with patient tumor burden and is suggested as a monitoring standard for patients.²⁷ The RT-PCR assay of blood should be performed at least every 3 months after therapy begins, or a single assay at 6 months can be performed if the patient is responding.²⁸ Bone marrow cytogenetics should be performed every 6 months until a major cytogenetic response (MCyR) is achieved. A complete cytogenetic response and *BCR/ABL*-negative results (complete molecular response) in treated patients predict a favorable outcome. Incomplete response and *BCR/ABL*-positive results indicate the presence of minimal residual disease and the potential for disease relapse.

Mutation screening is suggested for those who do not have an adequate initial response or loss of response to imatinib because the position of the mutation within the kinase domain can be clinically relevant. Some mutations have inferior survival (P-loop mutations) compared to mutations at other sites.²⁷ A particular ABL mutant, T315I, in which threonine is mutated to isoleucine at the gatekeeper position of

the kinase domain is not responsive to any of the TKIs currently used in CML therapy.²⁹

Allogenic HSC transplantation can be an option for patients who meet the bone marrow transplant criteria.¹³ Limitations are based on patient age (<60 years) and availability of a compatible donor.¹³ High-dose chemoradiotherapy is followed by transplantation of HSC from syngeneic or allogeneic donors. Stem cell transplantation is most successful when administered during the first chronic phase of CML. Of patients receiving HLA-matched sibling stem cells, 80% have cure rates that exceed 5 years of leukemic-free survival.²⁴

DIFFERENTIAL DIAGNOSIS

Many infectious, inflammatory, or malignant disorders and severe hemorrhage or hemolysis can cause a leukemoid reaction with subtle distinctions from the picture of CML (Table 9). At times, the clinical findings permit an accurate diagnosis, but in some cases, differential diagnosis requires further investigation. In a leukemoid reaction, leukocytosis is generally accompanied by a predominance of segmented neutrophils and bands on the blood smear. Myelocytes and metamyelocytes can be present, but if so, they are few in number compared to CML. Although blasts and promyelocytes are easily found in CML, these cells are rarely present in a leukemoid reaction. Toxic granulation, cytoplasmic vacuoles, and Döhle bodies in granulocytes often accompany benign toxic leukocytosis due to infection. These findings are not common at the time of diagnosis in CML. Monocytes, eosinophils, and basophils are generally not elevated in a leukemoid reaction, but typically are in CML.

Other diagnostic tests are helpful in differentiating a leukemoid reaction from CML. In a leukemoid reaction, the LAP score is typically elevated and the Ph chromosome is absent. Splenomegaly is uncommon in a leukemoid reaction. A bone marrow examination rarely is necessary to make a differ-

ential diagnosis. The marrow can be hypercellular, but in contrast to CML the maturation of granulocytic cells is orderly.

CML occasionally resembles CIMF. Distinguishing features of CIMF include markedly abnormal erythrocyte morphology with nucleated erythrocytes and immature leukocytes (leukoerythroblastic reaction), an increased LAP score, frank bone marrow fibrosis, and the absence of the Ph chromosome.

✓ Checkpoint! 4
What clinical, peripheral blood, and genetic features differentiate CML from an infectious process?

▶ CHRONIC NEUTROPHILIC LEUKEMIA (CNL)

Chronic neutrophilic leukemia (CNL) is an MPD characterized by a sustained increase in neutrophils in the peripheral blood with a slight shift to the left. Monocytosis and basophilia are absent. The bone marrow is hypercellular due to increased neutrophilic granulocyte proliferation. Dysplasia is not present. The BCR/ABL mutation is also absent. All causes of a reactive neutrophilia and other MPD must be ruled out for a diagnosis of CNL, so it is a diagnosis of exclusion. The diagnostic criteria for CNL are defined in Table 10.³⁰

ETIOLOGY AND PATHOPHYSIOLOGY

The cause of CNL has not been identified. About 20% of cases are associated with an underlying neoplasm, particularly multiple myeloma. However, clonality of the neutrophils when neutrophilia is associated with multiple myeloma has not been demonstrated. Thus, neutrophil proliferation can be related to abnormal cytokine production in

★ TABLE 9

Comparison of Peripheral Blood Features of CML and Leukemoid Reactions

Laboratory Parameter	CML	Leukemoid Reaction
Leukocytes	Blasts and promyelocytes in peripheral blood; toxic changes usually absent; eosinophilia and basophilia; neutrophils with single-lobed nuclei and hypogranular forms may be present	Toxic granulation; Döhle bodies and vacuoles present; blasts and promyelocytes rare; no absolute basophilia or eosinophilia
Platelets	Often increased with abnormal morphological forms present; occasional micromegakaryocytes	Usually normal
Erythrocytes	Anemia usually present; variable anisocytosis; poikilocytosis; NRBC present	Anemia may be present, but NRBC not typical
LAP	Low	Increased
Chromosome karyotype	Ph chromosome or BCR/ABL translocation present	Normal

TABLE 10

Diagnostic Criteria for CNL

- Peripheral blood leukocytosis $\geq 25 \times 10^9/L$
Bands and segmented neutrophils $> 80\%$ white blood count (WBC)
Immature granulocytes $< 10\%$ WBC
Myeloblasts $< 1\%$ WBC
- Hypercellular BM with increased percent of neutrophilic granulocytes;
 $< 5\%$ myeloblasts, normal neutrophil maturation pattern
- Hepatosplenomegaly
- No cause identified for physiologic neutrophilia
Absence of infection/inflammation
No underlying tumor or if present, demonstration of clonality of myeloid cells by cytogenetics/molecular diagnostics
- Absence of Ph chromosome or BCR/ABL mutation
- No evidence of other MPD
- No evidence of a MDS or MDS/MPD disorder; monocytes $< 1 \times 10^9/L$

From: Imbert M et al. Chronic neutrophilic leukemia. In: Jaffe ES, Harris NL, Stein H, Vardiman JW. *World Health Organization Classification of Tumours: Tumours of the Haematopoietic and Lymphoid Tissues*. Lyon, France: IARC Press; 2001:27.

this setting. CNL's cell of origin is probably a bone marrow stem cell with limited myeloid lineage potential colony forming unit granulocyte monocyte (CFU-GM) or colony forming unit-granulocyte (CFU-G).

CLINICAL FINDINGS.

CNL is a rare MPD with less than 150 reported cases. The median age at diagnosis is 67 years. The male:female ratio is about 1:1. Most patients are asymptomatic at the time of diagnosis, but fatigue, weight loss, easy bruising, bone pain, and night sweats can occur. Hepatosplenomegaly is usually present.

LABORATORY FINDINGS

The most notable feature is neutrophilia ($> 25 \times 10^9/L$) (Figure 10). Mature segmented forms and bands predominate, and more immature cells account for $< 10\%$ of the WBC. Neutrophils can appear toxic but not dysplastic. Both red blood count (RBC) and platelet morphology are normal. Platelets are usually present in normal concentration, but thrombocytopenia can develop as the disease progresses and the spleen enlarges. Bone marrow is hypercellular with an M:E ratio that can reach 20:1 or higher. Granulocytic hyperplasia is present, but dysplasia, Auer rods in blasts, and increased number of blasts are absent. Excessive erythroid and megakaryocytic proliferation can be present. The LAP score is usually increased.

GENETICS

Cytogenetics are normal in most patients but up to 25% have mutations including 20q-, 21+, 11q-, and +8, +9.³¹ The Ph chromosome and BCR/ABL fusion gene are absent. If

FIGURE 10 Peripheral blood from a patient with CNL. Note the increased numbers of mature neutrophils. (Wright stain; 1000× magnification)

plasma cell proliferation is present, clonality of the neutrophils should be established by cytogenetic or molecular studies for a diagnosis of CNL.

THERAPY

Hydroxyurea is a first-line therapy for CNL. Response lasts for about 12 months. Second-line therapy is interferon- α . Allogeneic stem cell transplantation is a potentially curative treatment for those patients who are eligible.

Median survival is 2 years. CNL also has an accelerated phase. The accelerated phase is marked by progressive neutrophilia unresponsive to treatment, anemia, thrombocytopenia, and splenomegaly.³¹ Blasts and other immature cells can be present in the peripheral blood.

DIFFERENTIAL DIAGNOSIS

CNL must be differentiated from CML and physiologic causes of neutrophilia such as infection or inflammation. Differential diagnosis from other myeloid neoplasms requires an absence of circulating blasts, absolute monocytosis, eosinophilia, and basophilia.

▶ HYPEREOSINOPHILIC SYNDROME (HES)

Eosinophils are derived from the CFU-GEMM (CMP) through the action of eosinophilic cytokines, GM-CSF, IL-3, and IL-5. IL-5 is relatively lineage specific for eosinophils. The cells are released into the peripheral blood and rapidly migrate to tissues where they have a short survival.

The accumulation of eosinophils can result from a progenitor cell disorder (primary) often defined by clonal genetic mutations or from increased production of eosinophil cytokines secondary to or associated with another diagnosis. Primary eosinophilia is collectively known as **hypereosinophilic syndrome (HES)**. Eosinophilia associated with other diseases is polyclonal, and the CMP is normal. The classification of these disorders is evolving as genetic mutations are identified (Table 11).

HES includes a heterogeneous group of disorders defined by a sustained eosinophil count of $1.5 \times 10^9/L$ or higher, the presence of eosinophil-associated organ/tissue damage such as cardiomyopathy, and absence of conditions known to cause reactive (secondary) eosinophilia. Until recently, most of these disorders had no known pathogenesis and were referred to as “idiopathic” HES (I-HES). As new molecular mutations and immunologic markers as well as clinical subtypes are being defined, these disorders are being reclassified (Figure 11). Two major subtypes include the myeloproliferative (M-HES) and lymphocytic (L-HES) variants. These account for about 50% of HES.³² Some of the remaining cases have clinical features that allow them to be classified into subgroups, but in most, the underlying cause is unknown, so they are considered I-HES. **Chronic eosinophilic**

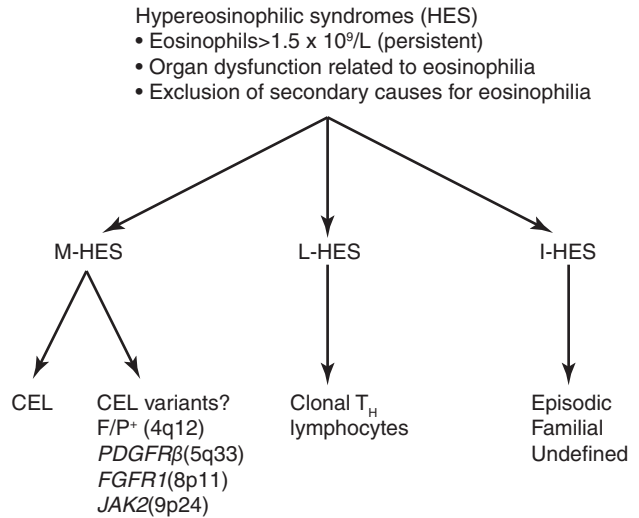

FIGURE 11 Hypereosinophilic syndrome classification. The two major variants are myeloid and lymphoid. The myeloid includes chronic eosinophilic leukemia (CEL) and other variants that have clonal genetic mutations. It is not clear whether these other variants should be classified as CEL. The lymphoid variant is characterized by an abnormal clonal T cell proliferation that produces IL-5, which is a growth factor for eosinophils. The idiopathic HES is a group of disorders in which the pathogenesis is not known and the genetic basis for the disease has not been identified. (M-HES = myeloid-hypereosinophilic syndrome; L-HES = lymphocytic hypereosinophilic syndrome; I-HES = idiopathic hypereosinophilic syndrome; CEL = chronic eosinophilic leukemia; T_H = T-helper; F/P+ = FIP1L1/PDGFRA mutation)

TABLE 11

Classification of Eosinophilia

Hypereosinophilic syndrome (HES, primary)

- Myeloproliferative variant of HES (M-HES)
 - Chronic eosinophilic leukemia (CEL), not defined molecularly
 - Platelet derived growth factor receptor- α (*PDGFRA*) or platelet derived growth factor receptor- β (*PDGFRB*) mutations
 - FGFR1*(8p11)
 - JAK2*(9p24) mutation
 - Eosinophilia associated with other primary neoplasms, including AML, ALL, CML, MDS, MPD
- Lymphocytic variant of HES (L-HES)
- Idiopathic HES (I-HES)
 - Episodic
 - Familial
 - Undefined

Eosinophilia secondary to or associated with another primary diagnosis

- Parasitic infection
- Asthma
- Allergies
- Skin diseases
- Loeffler’s syndrome
- Malignancy
- Immune diseases
- Vasculitis
- Drug hypersensitivity
- Nonhematologic malignancies
- Connective tissue and cutaneous disorders
- Lymphoma

leukemia (CEL) is classified under M-HES whose nomenclature is controversial.

Diseases typically associated with secondary eosinophilia must be ruled out before considering a diagnosis of HES. Associated diseases are included in Table 11. Testing for these disorders are listed in Table 12 . It is especially important to do serology to rule out infection with *Strongyloides* sp. because patients with this infection given corticosteroids (common treatment for HES) can experience dissemination of the disease, which can be fatal.³³

MYELOPROLIFERATIVE VARIANT (M-HES)

The molecular basis of some MPD-type eosinophilias have been determined, forming the basis for a semimolecular classification of these disorders.^{31,35} Most of the clonal molecular abnormalities result in constitutive activation of tyrosine kinases, and the resulting phenotype is an eosinophil-associated MPD. Because the WHO classification specifies that if patients who would have been classified as having I-HES have clonal genetic abnormalities, the diagnosis is CEL, these M-HES variants could fit the criteria for CEL. However, the diagnostic terminology has not been agreed upon.

TABLE 12

Suggested Information and Testing to Exclude Diseases Associated with Secondary Eosinophilia

Clinical

- Patient history
- Physical examination

Laboratory tests

- Complete blood count and differential
- Bone marrow aspiration and biopsy
- Routine chemistries
- Serum IgE
- Vitamin B₁₂
- HIV serology
- Serology testing and stool analysis for parasites

Other tests

- Pulmonary function tests
- Chest and abdominal CT scan

From: Klion AD. Recent advances in the diagnosis and treatment of hyper-eosinophilic syndromes. Hematology 2005. *Amer Soc Hematol Program Book*. 2005;209–14.

FIP1L1/PDGFRα (F/P) Fusion Gene

This variant was discovered when some HES patients who were unresponsive to corticosteroid therapy were found to respond to imatinib therapy. This led to the identification of a fusion between the FIP1-like1 gene and the platelet-derived growth factor receptor α gene (*FIP1L1/PDGFRα* [*F/P*]), which gives rise to an abnormal tyrosine kinase protein that is constitutively activated. Although some of these mutations can be identified by cytogenetics, most require molecular analysis because the mutation is a small interstitial deletion in chromosome 4, del(4)(q12q12). This can be demonstrated by reverse transcriptase-polymerase chain reaction (RT-PCR) or FISH techniques.

Most of the cases involving this mutation are found in males.³² There is evidence of eosinophil-related tissue damage and tissue fibrosis. Splenomegaly is present. Increased serum tryptase, anemia, eosinophilia, thrombocytopenia, and bone marrow hypercellularity are typical. These findings also are present in a significant number of patients who have systemic mastocytosis with increased atypical (spindle-shaped) mast cells in the bone marrow and a codon 816KIT mutation. However in M-HES with atypical mast cells, the codon 816KIT mutation is not present, the *F/P* fusion gene is present, and the bone marrow has no mast cell aggregates.³⁶ It has not yet been established whether this syndrome should be considered a variant of CEL or systemic mastocytosis.^{36,37} The *F/P* mutation is sensitive to imatinib therapy. Other molecular mutations identified in M-HES are listed in Table 13.

TABLE 13

Genetic Abnormalities Found in M-HES*

- *FIP1L1/PDGFRα* at 4q12 (F/P)[†]
- *PDGFRB* at 5q31-33[†]
- *FGFR1* at 8p11 (8p11 Myeloproliferative syndrome)
- Janus Kinase 2 (*JAK2*) at 9p24

*In 2008, the WHO placed genetic abnormalities of *PDGFRA*, *PDGFRB* or *FGFR1* in a new category of “Myeloid and lymphoid neoplasms with eosinophilia” regardless of morphologic classification. See Website for an update on the WHO classification of MPD.

[†]Imatinib therapy is effective.

Chronic Eosinophilic Leukemia

CEL is a Ph-chromosome-negative variant of CML that is difficult to distinguish from other subgroups of HES. CEL is defined as a clonal eosinophilia with an HES phenotype. The diagnostic criteria are listed in Table 14. Note that since these criteria were established, the genetic clonal aberrations noted previously in this section have been identified. Thus, whether the categories with clonal mutations described in M-HES (e.g., F/P⁺) should actually be considered CEL if the other criteria are met is controversial.³⁴

When clonality cannot be established, CEL can be diagnosed based on clinical and hematologic features including splenomegaly, hepatomegaly, increased blast cells in the peripheral blood and/or bone marrow, increased bone marrow cellularity, dysplastic blood cells, increased vitamin B₁₂ and tryptase, and no increase in IL-5.

Etiology and Pathophysiology The cell of origin for this leukemia may be the hematopoietic stem cell (HSC), multipotential progenitor cell (MPP), or a committed

TABLE 14

Diagnostic Criteria for Chronic Eosinophilic Leukemia and Hypereosinophilic Syndrome

- Required: Persistent eosinophilia ($\geq 1.5 \times 10^9/L$ in blood; increased eosinophils in bone marrow), and <20% blasts in blood or bone marrow
- Exclude all secondary causes of eosinophilia
- Exclude neoplastic disorders with secondary eosinophilia
- Exclude neoplastic disorders when eosinophils are a part of the neoplastic clone (e.g., AML)
- Exclude presence of an aberrant phenotypic T-cell population
- With all of the preceding conditions and evidence of clonality or >2% blasts in the peripheral blood and >5% blasts in the bone marrow, diagnosis is CEL
- With no identified causes of eosinophilia, no abnormal T-cell population, and no evidence of eosinophil clonality, diagnosis is HES

From: Bain BJ. Relationship between idiopathic hypereosinophilic syndrome, eosinophilic leukemia, and systemic mastocytosis. *Amer J Hematol*. 2004;77:82–85.

eosinophilic progenitor cell (CFU-Eo). In some cases, cytogenetic abnormalities can be identified.

Clinical Findings CEL is most often diagnosed in middle-aged men (male: female ratio is 9:1). Presenting symptoms include fever and significant weight loss. Clinical features include central nervous system (CNS) irregularities, hepatosplenomegaly, congestive heart failure, pulmonary fibrosis, and occasionally lymphadenopathy. Release of excessive eosinophilic granules in the blood cause fibrosis of the endothelial cells resulting in peripheral vasculitis, gangrene of digits, and organ damage, particularly of the heart and lungs.^{39,40}

Laboratory Findings CEL is characterized by a peripheral blood eosinophilia of $1.5 \times 10^9/L$ or more. There are cytogenetic abnormalities and/or $>2\%$ blasts in the peripheral blood or 5–19% blasts in the bone marrow. The leukocyte count is usually $>30 \times 10^9/L$ with 30–70% eosinophils. Anemia and thrombocytopenia can be present. The LAP score is normal, but the serum cobalamin, uric acid, and muramidase are frequently elevated. The bone marrow shows a left shift with many eosinophilic myelocytes. Marrow fibrosis is a common finding.

Genetics Cytogenetic abnormalities can include del(4q12), +8, t(10;11)(p14;q21), t(7;12)(q11;p11), monosomy 7, and 20q-. The case should be classified as CML if the Ph chromosome or molecular evidence of the BCR/ABL translocation is found.

Therapy When therapy is ineffective, the prognosis is poor. Most patients do not live beyond 1 year of diagnosis. The major cause of death is congestive heart failure due to tissue injury.

Differential Diagnosis Ruling out conditions associated with eosinophilia is important. CEL should also be differentiated from clonal eosinophilia found in other hematologic disorders (Table 15 .

LYMPHOCYTIC-HES (L-HES)

About one-third of patients with HES are estimated to have an underlying T cell disorder.⁴¹ Eosinophilia in this condition

is associated with the expansion of a population of nonmalignant helper T cells with an aberrant phenotype (CD34+) with a type 2 cytokine profile (TH2).⁴² The L-HES is also referred to as *T cell-related eosinophilia*. The activated T cells produce IL-3, IL-5, and IL-13, resulting in eosinophilia. Because the increase in eosinophils is due to increased secretion of IL-5 by aberrant lymphocytes, this variant could be considered secondary. It is currently referred to as *lymphocytic-HES*.

The T cells are often clonal and can have chromosomal abnormalities. The eosinophils are polyclonal. Demonstration of T cell clonality by T cell receptor rearrangement (α/β or δ/γ receptor genes) supports the diagnosis.⁴¹ Evidence of TH2 activation includes elevated serum IgE and **t**hymus and **a**ctivation-**r**egulated **c**hemokine (TARC). Patients have cutaneous manifestations. Therapy is aimed at blocking production of eosinophiliopoietic cytokines by the aberrant T cells and controlling the T cell's proliferation. Glucocorticoids can reduce the production of type 2 cytokines, but their effect on controlling aberrant T cell proliferation is not clear. Progression to a T cell lymphoma is common.

IDIOPATHIC HES (I-HES)

Idiopathic HES is a diagnosis of exclusion. I-HES is characterized by persistent eosinophilia and usually with organ-associated involvement, no evidence of clonality or T cell abnormality. Pathogenesis is unknown. As more molecular mutations are found and more diagnostic techniques become available, this diagnosis has been made less frequently. Subgroups can be identified based on clinical features.

Episodic

This disorder is characterized by monthly episodes of eosinophilia preceded by cyclic increases in eosinophilic cytokines. The primary patient complaint is swelling and weight gain. Also referred to as Gleich's syndrome.

Familial

Multiple family members may have a history of persistent eosinophilia. It appears to be inherited in an autosomal dominant manner: Marked eosinophilia is present from birth. When clinical disease is present, it is similar to *F/P*-HES.

Undefined

A number of disorders with eosinophilia could have organ involvement and not meet the criteria for a L-HES or M-HES.

EOSINOPHILIA SECONDARY TO OR ASSOCIATED WITH ANOTHER PRIMARY DIAGNOSIS

This group of disorders includes conditions in which eosinophilia is thought to be secondary to another primary diagnosis such as parasitic infection in which the body's nat-

 TABLE 15

Hematologic Disorders That Can Be Associated with Clonal Eosinophilia

- Acute myelogenous leukemia (AML)
- Chronic myelogenous leukemia (CML)
- Myelodysplastic syndrome (MDS)
- Myeloproliferative disorders (MPD)
- Atypical MPD
 - Systemic mastocytosis (SM)
 - Chronic myelomonocytic leukemia (CMML)
 - Myeloproliferative disease, unclassified (MPD-u)

ural response is to produce eosinophils to help eliminate the parasites. Other conditions have clinical findings and test results that overlap with HES such as a persistent eosinophilia, but they might not meet all criteria for HES (eosinophil damage may affect only one organ or type of tissue (e.g., eosinophil-associated gastrointestinal disease, EGID).

TREATMENT

First-line therapy for most patients with HES is the use of corticosteroids except in F/P^+ HES.⁴³ In F/P^+ patients, the treatment is imatinib. Patients refractory to corticosteroid therapy can receive cytotoxic therapy, most commonly hydroxyurea. Immunomodulatory therapy (i.e., IFN- α , cyclosporine) is also utilized in patients with corticosteroid-refractory HES. These agents affect type 2 cytokine production (IL-4 and IL-5) and T cell proliferation.³⁴ An anti-IL5 monoclonal antibody results in a prolonged decreased eosinophil count after a single dose. As additional molecular mutations are identified, new therapies (such as imatinib) aimed at the specific defect likely will become available.

▶ CHRONIC BASOPHILIC LEUKEMIA (CBL)

Chronic basophilic leukemia (CBL) is the rarest entity of the MPD and is not included in the WHO classification of MPD. More recently, CBL has been identified as a distinct pathologic entity.⁴⁴ It is considered an atypical myeloproliferative disease (aMPD).³¹ The disease needs to be distinguished from the basophilia in CML that commonly precedes the blast crisis and from the basophilia found in other myeloproliferative disorders and mast cell leukemia.

ETIOLOGY AND PATHOPHYSIOLOGY

The etiology and pathophysiology of CBL are not known. The cell of origin appears to be a bipotential progenitor cell capable of differentiation into either basophil or eosinophil lineages or differentiation into basophil or mast cell lineages.⁴⁴

CLINICAL FINDINGS

CBL occurs in middle-aged individuals with a slight predominance in males. Its onset can be insidious or abrupt, and clinical features are similar to those found in CML. Many patients have symptoms related to hyperhistaminemia such as wheezing, urticaria, diarrhea, pruritis, and peripheral edema. These symptoms are related to the massive increase in histamine-containing granules derived from basophils.³¹ Massive release of basophil granules can occur following effective therapy resulting in shock or severe disseminated intravascu-

lar coagulation (DIC). The disease is aggressive with the potential to transform into acute leukemia.

LABORATORY FINDINGS

The leukocyte count can be normal but is most often increased. The most striking finding on the blood smear is an extreme increase in basophils, usually between 40% and 80% of the WBC with some immature forms present. The basophils are abnormal, resembling tissue mast cells. Fine uniform granules cover most of the nucleus and cytoplasm. Eosinophils are usually increased as well. Abnormal neutrophils, monocytes, and eosinophils also can be found. The LAP score is normal or low. Serum and urine histamine levels are from 10 to 15 times normal. The bone marrow is hypercellular with trilineage hyperplasia. There is a slight shift-to-the-left in granulocyte maturation, and myeloblasts can be increased. Often there is dysmegakaryopoiesis with small mononucleated and binucleated forms.⁴⁴

GENETICS

No clonal genetic mutations have been associated with the disorder. The Ph chromosome and the *BCR/ABL* fusion gene are absent.⁴⁴

THERAPY

Patients do not respond well to conventional therapy modalities. Allogenic bone marrow transplant can result in long-term survival. Table 16  summarizes the similarities and differences of CML, CNL, CEL, and CBL.

Checkpoint! 5

What one feature separates other forms of MPD from CML?

▶ CHRONIC IDIOPATHIC MYELOFIBROSIS (WITH MYELOID METAPLASIA)

Chronic idiopathic myelofibrosis (CIMF), also known as *myelofibrosis with myeloid metaplasia (MMM)*, is a clonal hematopoietic stem cell disorder with splenomegaly, leukoerythroblastosis, extramedullary hematopoiesis (myeloid metaplasia), and progressive bone marrow fibrosis.⁴⁵ The fibroblast, collagen-producing cell, is an important component of normal bone marrow, where the fibroblasts provide a support structure for hematopoietic cells. Fibroblast proliferation in CIMF is reactive and secondary to the underlying disorder. Fibrotic tissue eventually disrupts the normal architecture and replaces hematopoietic tissue marrow. The proliferation of hematopoietic cells is neoplastic. Myeloid metaplasia usually occurs in both the spleen and the liver. These

★ TABLE 16

Comparison of CML Features with CML Variants

Disorder	Predominant Age in Years/Sex	Leukocyte Count ($\times 10^9/L$)	Leukocyte Differential	LAP Score	Ph Chromosome
Chronic myelogenous leukemia	Middle age; 60–80 peak, rarely in adolescence, equal sex distribution	100–500	Left shift; less than 20% blasts	Decreased	Present
Chronic eosinophilic leukemia	Middle age/male predominance	>30	30–70% eosinophils with immature forms; left shift in neutrophils	Normal	Absent
Chronic basophilic leukemia	Middle age/slight male predominance	Normal or increased	40–80% basophils with immature forms present	Normal or slight decrease	Absent
Chronic neutrophilic leukemia	Over 50/equal between sexes	Marked increase	Mature cells	Increased	Absent

organs can become massive in size due to islands of proliferating erythroid, myeloid, and megakaryocytic elements. The extramedullary hematopoiesis is similar to that occurring during embryonic hematopoiesis.

CIMF has been known by many synonyms. Most of the different names were attempts to describe the typical blood, bone marrow, and spleen abnormalities. Some of the terms that have been used include *agnogenic myeloid metaplasia*, *myelofibrosis with myeloid metaplasia*, *primary myelofibrosis*, *aleukemic myelosis*, *myelosclerosis*, *splenomegalic myelophthisis*, and *leukoerythroblastic anemia*.

PATHOPHYSIOLOGY

About 50% of CIMF patients can be found to have a somatic mutation, either a point mutation in the Janus kinase 2 (*JAK2*) tyrosine kinase gene or a mutation of the thrombopoietin membrane receptor (*MPL*) gene. These mutations constitutively activate cell signaling and DNA replication.⁴⁶ G6PD isoenzyme and cytogenetic studies demonstrate clonality of the neoplastic cells. Chromosome aberrations, when present, are restricted to cells derived from the mutated HSC. Some of these cells are highly sensitive to or independent from regulation by their respective stimulatory factors. The disorder has been reported to terminate in ALL as well as AML in some patients.

In most cases, only megakaryocytes and granulocytes are involved, but all three lineages, including erythrocytes, can be involved in the disease process. CIMF is often preceded by a hypercellular phase of variable duration. The disease evolves from this prefibrotic stage with minimal reticulin fibrosis to a fibrotic stage with marked reticulin or collagen fibrosis. Thus, at the time of diagnosis, the bone marrow can exhibit varying degrees of fibrosis. The fibrosis is not considered part of the primary abnormal clonal proliferation but is a secondary reactive event occurring in response to the progeny of the clonal hematopoietic cells. Fibroblasts do not

contain the chromosome abnormalities found in the hematopoietic cells, and they exhibit heterozygosity rather than homozygosity for the G6PD isoenzymes in females.

Our understanding of this disease has increased considerably with a better understanding of normal bone marrow structure and the changes that occur in myelofibrotic marrow associated with megakaryocyte growth factors that mediate fibrogenesis.⁴⁷ The bone marrow extracellular matrix or microenvironment (stroma) supports hematopoietic cell proliferation. Myelofibrotic stroma is characterized by an increase in total collagen, fibroblasts, vitronectin (a cytoadhesion molecule), fibronectin (a cytoadhesion molecule normally limited to megakaryocytes and walls of blood vessels), and laminin (a glycoprotein that supports adhesion and growth of cells).

CIMF is associated with a profound hyperplasia of morphologically abnormal megakaryocytes (dysplastic and necrotic). Evidence indicates that the megakaryocytes play an important role in the pathogenic development of the abnormal CIMF marrow. In areas of megakaryocyte necrosis, fibroblast proliferation and collagen deposition often are prominent. This stromal reaction is a cytokine-mediated process.⁴⁴

PDGF, epidermal growth factor (EGF), and transforming growth factor beta ($TGF-\beta$) are contained in the α -granules of megakaryocytes and platelets, and all stimulate the growth and proliferation of fibroblasts. Reduced platelet concentrations of PDGF and increased levels of serum PDGF are characteristic of CIMF. This condition is thought to represent the abnormal release or leakage of the growth factor from the platelet. PDGF does not stimulate synthesis of collagen, laminin, or fibronectin, but $TGF-\beta$ stimulates increased expression of genes for fibronectin and collagen while decreasing synthesis of collagenase-like enzymes. Thus, the net effect is the accumulation of bone marrow stromal elements.^{45,47}

In 2005, a gain in function mutation in the *JAK2* tyrosine kinase gene, *JAK2(V617F)*, was identified in many patients with CIMF. The normal JAK 2 protein is a cytoplasmic protein kinase closely associated with cytokine receptors and thus is

distributed almost exclusively near the cell membrane. When a receptor binds cytokines, the JAK2 protein is transphosphorylated and activated. In turn, JAK2 phosphorylates signal transducers and activators of transcription (STAT5) proteins. The JAK-receptor complex also activates other signaling pathways. Several inhibitory control mechanisms constrain the normal JAK2/STAT5 activation pathway. The JAK2 protein has 2 homologous domains: JH1, which has functional (kinase) activity, and JH2, which lacks kinase activity. JH2 normally interacts with the JH1 domain to inhibit kinase activity and to modulate or regulate receptor signaling.

In the mutated *JAK2(V617F)* gene, a point mutation replaces valine with phenylalanine at codon 617 in the JH2 domain.^{46,47,48} This mutation results in a conformational change in the tyrosine kinase protein, which allows it to phosphorylate STAT5 molecules independent of cytokine interaction with the receptor (i.e., autonomous signaling). This gain-of-function mutation gives the cells a proliferation advantage. The mutation also results in increased responsiveness to erythropoietin (EPO) and IL-3. *JAK2(V617F)* is found in ~50% of patients with CIMF, ~50% of patients with essential thrombocythemia (ET), and most patients with polycythemia vera.^{46,48}

Research also has identified a mutation in the *MPL*. This mutation, *MPL-W515L*, leads to a myeloproliferative disorder similar to CIMF with thrombocytosis, extramedullary hematopoiesis, and increased reticulin fibrosis in mice that are negative for the *JAK2(V617F)* mutation.⁴⁹

✓ Checkpoint! 6

What growth factors are primarily responsible for stimulating fibrogenesis in the bone marrow?

CLINICAL FINDINGS

CIMF generally affects individuals over 50 years of age. It rarely occurs in childhood. It appears to occur equally between sexes. The onset is gradual and the disease is chronic. Early in the disease process, the patient might have no symptoms, making the time of onset difficult to determine. If symptoms are present, they are usually related to anemia or pressure from an enlarged spleen. Bleeding occasionally is a presenting symptom. Patients complain of weakness, weight loss, loss of appetite, night sweats, pain in the extremities, and discomfort in the upper left quadrant. The major physical findings are splenomegaly, hepatomegaly, pallor, and petechiae. Myeloid metaplasia is found in the spleen and frequently in the liver and can be found in the kidney, adrenal glands, peritoneal and extraperitoneal surfaces, skin, lymph nodes, and spinal cord. Osteosclerosis is a frequent finding and, when found in association with splenomegaly, suggests a diagnosis of myelofibrosis.

An atypical acute form of the disease has been described with a rapid and progressive course of a few months to one

year. Anemia develops rapidly, and the leukocyte count is decreased. The bone marrow in these cases exhibits a proliferation of reticular and collagen fibers.

Patients with systemic lupus erythematosus (SLE) can present with myelofibrosis morphologically indistinguishable from the myelofibrosis of CIMF. These patients also have various peripheral blood cytopenias similar to those found in CIMF, but splenomegaly is not found. The myelofibrosis in SLE has been referred to as *autoimmune myelofibrosis*. It has been suggested that all patients with myelofibrosis and an absence of splenomegaly should have an antinuclear antibody (ANA) test to rule out SLE.⁵⁰

LABORATORY FINDINGS

Peripheral Blood

The typical peripheral blood findings for CIMF reflect both qualitative and quantitative cellular abnormalities. Although peripheral blood findings are variable, a moderate leukoerythroblastic anemia with striking anisocytosis and poikilocytosis is characteristic (Figure 12 ■). The anemia is usually normocytic, normochromic, but hypochromia can be found after a history of hemorrhage or hemolysis. Folic acid deficiency can develop as a result of increased utilization by the neoplastic clone and is associated with a macrocytic anemia. Anemia uncomplicated by iron deficiency or folic acid deficiency correlates directly with the extent of bone marrow fibrosis and the effectiveness of extramedullary hematopoiesis. The anemia becomes more severe with the progression of the disease and is aggravated in some patients by the combination of splenomegaly, which causes sequestration of erythrocytes, and expanded plasma volume, (dilutional anemia).

■ FIGURE 12 Peripheral blood from a patient with CIMF. Leukoerythroblastic picture with nucleated erythroblast at about 1 o'clock and a myeloblast below it. The arrow points to a large platelet at about 11 o'clock. Other abnormal platelets are present. Note the poikilocytosis with dacryocytes. (Wright stain; 1000× magnification)

The presence of abnormal erythrocyte morphology is an important feature of CIMF. The most typical poikilocyte is the dacryocyte, although elliptocytes and ovalocytes are also present (Figure 12). A few nucleated erythrocytes are usually found and sometimes can be numerous. Basophilic stippling is a common finding. Reticulocytosis is typical, ranging from 2% to 15%. The majority of patients have an absolute reticulocyte count $> 60 \times 10^9/L$.

The leukocyte count is usually elevated but can be normal or less often decreased. The count generally ranges from 15 to $30 \times 10^9/L$. A leukocyte count above $60\text{--}70 \times 10^9/L$ prior to splenectomy is rare. The leukocyte concentration is rather constant and does not decrease with the progression of the disease as is typical of erythrocytes and platelets. An orderly progression of immature granulocytes is characteristically found. Blasts generally compose less than 5% of circulating leukocytes. Other common findings include basophilia, eosinophilia, and pseudo-Pelger-Huët anomaly. The LAP is elevated or normal but occasionally is decreased. Low LAP scores correlate with leukopenia. When elevated, the LAP score helps to differentiate this disease from CML. The Ph chromosome is not present.

Platelets can be decreased, normal, or increased. Higher counts are associated with early disease stages; thrombocytopenia is usually found in the later stages. Thrombocytopenia is often attributed to excessive splenic pooling. The platelets can appear dysplastic: typically giant, bizarre, and frequently hypogranular. Circulating megakaryocyte fragments, mononuclear micromegakaryocytes, and naked megakaryocyte nuclei can be found. The micromegakaryocytes can present a problem in identification because they frequently resemble lymphocytes. However, an important differentiating feature is the presence of demarcation membranes with bull's-eye granules in the cytoplasm, characteristic of megakaryocytes. Qualitative platelet abnormalities including abnormal aggregation, adhesiveness, and defective platelet factor-3 (PF3) released on exposure to collagen are consistent findings.

Of patients, 15% have major hemolytic episodes during the course of their disease.⁵¹ Hemosiderinuria and decreased haptoglobin are found in about 10% of patients, suggesting intravascular hemolysis. The cause of hemolysis can be hypersplenism, PNH-like defective erythrocytes, and antierythrocyte antibodies.

A bleeding diathesis ranging from petechiae and ecchymoses to life-threatening hemorrhage can be found in patients. It likely results from a combination of thrombocytopenia and/or abnormal platelet function. Defective platelet aggregation is a common finding. Hemostatic abnormalities suggestive of chronic DIC can be present, including decreased platelet count, decreased concentration of factors V and VIII, and increased fibrin degradation products.⁵¹

Other laboratory tests are frequently abnormal in this disease. Serum uric acid and LD are elevated in most patients. Serum cobalamin can be slightly increased but is usually normal.

✓ Checkpoint! 7
 What erythrocyte morphologic feature is a hallmark for myelofibrosis?

Bone Marrow

The bone marrow is difficult to penetrate and frequently yields a dry tap. If aspiration is successful, smears may show no abnormalities; biopsy specimens are needed to reveal the extent of fibrosis. In most CIMF cases, the marrow is hypercellular with varying degrees of diffuse fibrosis and focal aggregates of megakaryocytes (Figure 13 ■).

Three bone marrow histologic patterns have been described: (1) panhyperplasia with absence of myelofibrosis but a slight increase in connective tissue reticulin, (2) myeloid atrophy with fibrosis, prominent collagen, and reticulin fibers, and cellularity less than 30%, and (3) myelofibrosis and myelosclerosis with bony trabeculae occupying 30% of the biopsy and extensive fibrosis.

🌀 CASE STUDY (continued from earlier in this chapter)

During the office visit, Roger stated that he had symptoms of fatigue, weakness, dyspnea, bone pain, and abdominal discomfort. A bone marrow biopsy was ordered. The aspiration was unsuccessful, but the marrow biopsy showed moderate to marked hyperplasia, clusters of platelets, abnormal megakaryocyte morphology, and fibrotic marrow spaces.

4. What diagnoses are suggested?
5. Give a reason for the unsuccessful, dry-tap bone marrow aspiration.
6. What characteristic peripheral blood morphologies correlate with the bone marrow picture and physical exam?

■ **FIGURE 13** Bone marrow stained with reticulum stain shows increased collagen (black staining fibers) in a patient with CIMF. (BM biopsy; reticulum stain; 100× magnification)

Genetics

Cytogenetic analysis is important to differentiate myelofibrosis from other myeloproliferative disorders, in particular CML, which also can have some degree of fibrosis. The Ph chromosome is not present in CIMF. Although no specific cytogenetic abnormality is diagnostic for CIMF, *JAK2* (V617F) is found in about 50% of patients, and a trisomy or deletion of Group C chromosomes is also associated with myelofibrosis. Complete or partial loss of chromosomes 5, 7, and 20 is associated with CIMF patients treated with chemotherapy.

PROGNOSIS AND THERAPY

The average survival time after diagnosis is 4–5 years. The main causes of death are infection, hemorrhage, thrombosis, and cardiac failure. About 10–15% of patients terminate with an acute myelogenous leukemia and some with acute lymphoid leukemia.

In the past, corticosteroids and androgens were used to stimulate erythropoiesis, but most patients required periodic transfusions. Cytokine therapy (interferon- α with erythropoietin and/or GM-CSF) is now used with variable success.⁵¹ When anemia cannot be controlled, splenectomy can be considered. Irradiation has been suggested to decrease spleen size in an attempt to relieve symptoms or to decrease excessive erythrocyte destruction. Alkylating agents have been used but have the potential to cause severe pancytopenia. Allogeneic stem cell transplantation is the only curative therapy for CIMF, but due to the advanced age of many patients, the mortality rate is high. Thalidomide derivatives, protease inhibitors, and antibodies to growth factors show some promise for patients resistant to conventional treatment.^{48,52} Drugs to control hyperuricemia have been used to prevent or decrease problems with gout and nephropathy.

DIFFERENTIAL DIAGNOSIS

Differentiation of CIMF from other conditions associated with fibrosis is essential to ensure appropriate therapy regimens (Table 17 ). Splenomegaly, anemia, and a leukoerythroblastic blood picture are significant findings in both myelofibrosis and CML. In myelofibrosis, the leukocyte count is generally lower—less than $50 \times 10^9/L$, in CML, the count is expected to be higher. In myelofibrosis, the shift to the left is less pronounced and poikilocytosis is striking. The bone marrow in myelofibrosis is fibrous with large numbers of megakaryocytes. In CML, the bone marrow can also exhibit some fibrosis, but the most abnormal finding is the myeloid hyperplasia. The serum cobalamin level is not as elevated in myelofibrosis as it is in CML. The LAP score in myelofibrosis is variable, but when elevated, it is strong evidence against CML. The most reliable test to differentiate CML and CIMF is cytogenetic analysis for the Ph chromosome.

 TABLE 17

Conditions Associated with Marrow Fibrosis

- Chronic idiopathic myelofibrosis (CIMF)
- Chronic myelogenous leukemia (CML)
- Polycythemia vera (PV)
- Essential thrombocythemia (ET)
- Megakaryocytic leukemia
- Metastatic carcinoma
- Miliary tuberculosis
- Fungus infection
- Hairy cell leukemia
- Lymphoma
- Hodgkin's disease
- Granulomas
- Marrow damage by radiation or chemicals

Differentiation of myelofibrosis from polycythemia vera (PV, see below), especially in the later stages, is more difficult. The later stages of PV can be accompanied by increased marrow fibrosis, or actual transformation to myelofibrosis can occur.

When thrombocytosis is the principal initial hematologic finding, myelofibrosis can be confused with ET. A bone marrow biopsy aids in the differentiation, revealing a frank fibrosis in myelofibrosis.

Myelophthitic anemia or leukoerythroblastosis is found with a fibrotic bone marrow and extramedullary hematopoiesis. *Myelophthitic anemia* refers to the reduction of cells formed in normal bone marrow resulting from a neoplastic disease process. Various disease processes including bone marrow tumors and metastatic disease from solid tumors are associated with myelophthitic anemia. Although myelophthitic anemia can have a morphologic peripheral blood picture very similar to myelofibrosis, the leukocyte count in myelophthitic anemia is usually normal or decreased. Bone marrow examination from more than one site may be necessary to rule out a secondary reaction due to tumor or other cells replacing the marrow.

CASE STUDY (continued from the previous page)

Over the next several months, Roger experienced increasing splenomegaly and abdominal discomfort. Cytogenetic studies revealed a trisomy 8.

7. What is the most likely explanation for the increased splenomegaly?
8. What are possible outcomes of this disorder?

► **POLYCYTHEMIA VERA**

The term *polycythemia* literally means an increase in the cellular elements of the blood; however, it is most commonly used to describe an increase in erythrocytes exclusive of leukocytes and platelets. **Polycythemia vera (PV)** is a myeloproliferative disorder characterized by an unregulated proliferation of the erythroid elements in the bone marrow and an increase in erythrocyte concentration in the peripheral blood. In addition to erythroid cells, other progeny of the HSC can also be simultaneously or sequentially involved in the autonomous proliferation, resulting in a pancytosis (increase in all hematopoietic cells in the blood). Polycythemia vera has several synonyms, including *polycythemia rubra vera*, *primary polycythemia*, *erythremia*, and *Osler's disease*.

CLASSIFICATION

Polycythemia is a general term used to describe erythrocytosis resulting in an increase in both hemoglobin concentration and red cell mass (RCM) or hematocrit. Hemoglobin, hematocrit, and erythrocyte count are parameters measured in relative terms (e.g., the ratio of hemoglobin or erythrocytes to plasma volume), not in absolute concentrations. When evaluating a patient for polycythemia, it is important to determine whether these parameters are elevated because of an absolute increase in total erythrocyte mass (absolute erythrocytosis) or from a decrease in plasma volume (relative erythrocytosis) (Figure 14 ■). Although an absolute erythrocytosis suggests a diagnosis of PV, polycythemia that is secondary to tissue hypoxia, cardiac or pulmonary disease, and abnormal hemoglobins should also be considered.

In an attempt to clarify the pathogenesis of the disorder, polycythemia is classified into three different groups: polycythemia vera, secondary polycythemia, and relative polycythemia (Table 18 🌱). PV and secondary polycythemia

🌱 **TABLE 18**

Classification of Polycythemia	
Classification	Associated Conditions
Polycythemia vera (primary)	Normal or decreased erythropoietin levels; autonomous cell proliferation
Secondary polycythemia (erythropoietin-driven)	High altitude Chronic obstructive pulmonary disease Obesity (Pickwickian syndrome) Inappropriate erythropoietin production Tumors (e.g., hepatoma, uterine fibroma, renal carcinoma) Renal ischemia Familial erythrocytosis Hemoglobins with high oxygen affinity Congenital decrease in erythrocyte 2,3-BPG
Relative polycythemia	Gaisböck's syndrome (stress polycythemia, spurious polycythemia, pseudopolycythemia) Dehydration

both result from an absolute increase in the total body RCM. Secondary polycythemia can be distinguished from PV by a distinct, although not always apparent, physiologic stimulus for erythrocytosis—hence, the name *secondary polycythemia*—and is associated with elevated plasma EPO levels. PV results from a primary, unregulated or dysregulated increase in erythrocyte production with no identifiable inciting cause. Relative polycythemia is characterized by a normal or even decreased RCM and occurs as a result of a decreased plasma volume. It is generally a mild polycythemia due to dehydration, hemoconcentration, or a condition known as *Gaisböck's syndrome*.

PATHOPHYSIOLOGY

The panhyperplasia often associated with PV suggests a clonal stem cell defect. The clonal nature of the disease is confirmed by G6PD isoenzyme and cytogenetic studies. Evidence of clonality persists in cells even during complete remission.

Although all lineages in the peripheral blood can be increased in PV, an increase in erythropoiesis is the outstanding feature. Possible mechanisms for this increase are suggested in Table 19 🌱.^{16,53} In vitro studies using cell culture systems show that PV bone marrow cells from some patients form erythroid colonies without the addition of erythropoietin (endogenous erythroid colonies/EEC), suggesting that increased proliferation is due to an unregulated neoplastic proliferation of stem cells. Other patients' bone marrow cells show increased sensitivity to EPO, insulin like growth factor I, and IL-3, forming in vitro colonies at significantly reduced

■ **FIGURE 14** The hematocrit can be increased due to an absolute increase in erythrocyte mass, a condition known as *absolute polycythemia* (center) or a decrease in plasma volume, a condition known as *relative polycythemia* (right).

TABLE 19

Possible Mechanisms for Increased Erythropoiesis in Polycythemia Vera

- Erythropoietin-independent proliferation of neoplastic progenitor cells
- Hypersensitivity of erythroid progenitor cells to erythropoietin
- Hypersensitivity of erythroid progenitor cells to growth factors other than erythropoietin
- Inhibition of apoptosis in progenitor cells

cytokine concentrations. This increased sensitivity to cytokine stimulation gives PV progenitor cells a growth advantage.^{54–58} The erythroid maturation is morphologically normal and the erythrocytes function normally and have a normal lifespan.

Several mutations have been identified in patients with PV. The *JAK2(V617F)* mutation, which codes for a mutated protein kinase activator of cell signal transduction, is found in almost all patients with PV. The mutated protein binds to the cytoplasmic domain of the EPO receptor and promotes receptor activation independent of EPO binding and signaling. PV patients also have an increased level of Bcl-x_L, an antiapoptotic protein member of the Bcl-2 family, which inhibits apoptosis of progenitor cells.⁵⁵ This defect in programmed cell death creates an accumulation of altered, hypersensitive stem and progenitor cells. Similar thrombopoietin receptor hypersensitivity and resistance to apoptosis are found in the megakaryocytic lineage, resulting in the common finding of thrombocytosis associated with PV.^{9,16,55–57}

CLINICAL FINDINGS

The annual incidence of PV varies geographically from 2 cases per million in Japan to 13 per million in Australia and Europe. The annual incidence in the United States averages 8–10 per million population. It occurs most often between the ages of 40 and 60 years with a peak incidence in the sixth decade of life. The disease is rare in children. It occurs more frequently in males than females and is more common in whites than blacks, particularly in those of Jewish descent.⁵³ PV has been reported to occur in several members of the same family, suggesting a possible genetic predisposition for the disease.

The onset of the disease is usually gradual with a history of mild symptoms for several years. In some cases, PV is found in asymptomatic individuals. When symptoms are present, they are typically related to the increased erythrocyte mass and the associated cardiovascular disease due to hyperviscosity of the blood. Headache, weakness, pruritus, weight loss, and fatigue are the most common symptoms. Pruritus is attributed to hyperhistaminemia that can be spontaneous or induced by hot showers or baths. Itching is generalized with absence of a rash.

About one-third of the patients experience thrombotic or hemorrhagic episodes. Myocardial infarctions, retinal vein

thrombosis, thrombophlebitis, and cerebral ischemia can occur at any stage of the disease and occasionally is the first indication of the disease.

When the hematocrit exceeds 60%, the blood viscosity increases steeply, decreasing blood flow and increasing peripheral vascular resistance. These interactions produce hypertension in about 50% of the patients with PV. **Plethora** (a florid complexion due to an excessive amount of blood), especially on the face but also on the hands, feet, and ears, is a common finding on physical examination.

After a period of 2–10 years, the patient may develop bone marrow failure accompanied by an increase in splenomegaly. At this time, anemia and bleeding may be the primary clinical findings, secondary to a decreased platelet count and decreasing hematocrit. This is known as the **spent phase** and is often a transition to AML. Postpolycythemic myelofibrosis and myeloid metaplasia develop in about 30% of PV cases. Splenomegaly is characteristic at this stage. Acute leukemia develops as an abrupt transition in 5–10% of patients. Leukemia appears to develop at a higher rate in patients treated with myelosuppressive drugs than in those treated with phlebotomy alone.

LABORATORY FINDINGS

Peripheral Blood

The most striking peripheral blood finding in PV is an absolute erythrocytosis in the range of 6–10 × 10¹²/L, with a hemoglobin concentration >18.5 g/dL in males and >16.5 g/dL in females. The hematocrit in females is usually >0.48 L/L (48%) and in males >0.52 L/L (52%). The total RCM is increased >25% of mean normal; the plasma volume can be normal, elevated, or decreased. Early in the disease, the erythrocytes are normocytic, normochromic; however, after repeated therapeutic phlebotomy, iron-deficient erythropoiesis can result in microcytic hypochromic cells. Patients with PV occasionally present with iron deficiency secondary to occult blood loss as a result of abnormal platelet function. This can create a confusing peripheral blood picture because the concentration of erythrocytes is normal to increased with significant microcytosis, simulating a thalassemia. Nucleated erythrocytes can be found. On the blood smear, the erythrocytes typically appear crowded even at the feathered edge. The reticulocyte count is normal or slightly elevated. The erythrocyte sedimentation rate (ESR) does not exceed 2–3 mm/hour.

Leukocytosis in the range of 12–20 × 10⁹/L occurs in about two-thirds of the cases because of an increase in granulocyte production. Early in the disease there can be a relative granulocytosis and a relative lymphopenia with a normal total leukocyte count. A shift to the left can be found with the presence of myelocytes and metamyelocytes, but finding promyelocytes, blasts, or excessive numbers of immature myeloid cells is unusual. Relative and absolute basophilia is common. The LAP score is usually higher than 100.

Megakaryocytic hyperplasia in the bone marrow accompanied by an increase in platelet production is a consistent finding in PV. In some patients, the megakaryocytes proliferate without expressing the receptor for thrombopoietin (those patients with a mutation in the *MPL* gene) and have decreased apoptosis as do the erythroid progenitor cells.^{16,55,57} The platelet count is $>400 \times 10^9/L$ in 20% of PV patients and occasionally exceeds $1,000 \times 10^9/L$. Giant platelets can be found on the blood smear. Qualitative platelet abnormalities are reflected by abnormal aggregation to one or more aggregating agents—epinephrine, collagen, adenosine diphosphate (ADP), or thrombin. Lack of aggregation with epinephrine is the most common abnormality. The prothrombin time (PT) and activated partial thromboplastin time (APTT) are usually normal. Abnormal multimeric forms of VWF are found in about half of PV patients and can lead to a diagnosis of acquired von Willebrand's disease (VWD)⁵⁶.

Advanced disease is accompanied by striking morphologic changes in erythrocytes (Figure 15■). The peripheral blood picture can resemble that seen in myelofibrosis with a leukoerythroblastic anemia, poikilocytosis with dacryocytes, and thrombocytopenia. In cases that advance to acute leukemia, the blood picture exhibits anemia with marked erythrocyte abnormalities, thrombocytopenia, and blast cells.

Bone Marrow

Most patients with PV have a moderate to marked increase in bone marrow cellularity. The hypercellularity is greater than is seen in secondary polycythemia, and hematopoietic marrow can extend into the long bones. Granulopoiesis as well as erythropoiesis is often increased; consequently, the myeloid:erythroid ratio is usually normal. The relative number of myeloblasts is not increased. One of the most signifi-

■ **FIGURE 15** Peripheral blood from a patient with polycythemia vera showing thrombocytosis and large platelets. There is a reactive lymphocyte and segmented neutrophil in the center. (Wright-Giemsa stain; 600× original magnification)

cant findings is an increase in megakaryocytes. Eosinophils are also often increased. Sometimes bone marrow biopsies reveal a slight to marked increase in fibrotic material or reticulin, generally directly proportional to the degree of cellularity (e.g., more cellular marrows demonstrating more reticulin). Iron stores are usually absent, presumably due to a diversion of iron from storage sites to the large numbers of developing erythroblasts.

In the postpolycythemic stage, the bone marrow reveals reticulin and collagen fibrosis. Cellularity varies but is often hypocellular with prominent clusters of megakaryocytes. Erythropoiesis and granulopoiesis decrease. A shift to the left can be present, but blasts are usually $<10\%$ and dysplasia is unusual.

Other Laboratory Findings

EPO levels are normal or low in PV, and arterial oxygen saturation levels are normal. In secondary polycythemia resulting from tissue hypoxia, EPO levels are elevated, and arterial oxygen saturation levels are decreased. When secondary polycythemia occurs due to an inappropriate increase in EPO, oxygen saturation levels are usually normal.

Other laboratory tests also can be abnormal. Serum uric acid is >7 mg/dL in two-thirds of the patients and can cause symptoms of gout. The increase probably reflects an increase in the turnover of nucleic acids from blood cells. Serum cobalamin-binding capacity in most of the untreated PV patients is increased, primarily due to the increase in transcobalamin III derived from granulocytes. Serum cobalamin also is increased but not in proportion to the unsaturated binding capacity.

Genetics

The nonspecific molecular mutation, *JAK2*(V617F), is found in $>90\%$ of patients with PV and in about 50% of CIMF and ET patients.^{16,48,59,60} Due to the frequency of this mutation in PV, peripheral blood screening for *JAK2*(V617F) in the initial evaluation of patients suspected of having PV has been recommended.

Cytogenetic abnormalities including chromosomal aneuploidy and deletions can be found. The most consistent abnormality is an extra Group C chromosome, especially a trisomy 8 or 9, an abnormally long chromosome 1 due to additional chromosomal material on the long arms with a partial deletion of chromosome 13 and 20. The frequency of multiple karyotypic abnormalities increases after years of treatment to more than 80% in patients who develop acute leukemia. Thus, progression from a normal to an abnormal karyotype is an adverse prognostic indicator.⁵⁸

PROGNOSIS AND THERAPY

There is no known cure for PV but treatment usually prolongs survival. Two types of therapy, phlebotomy and myelosuppressive therapy generally have been used. Thera-

peutic phlebotomy is performed to keep the hematocrit below 0.45 L/L (45%) and to reduce iron supplies. It is expected that lack of iron will slow the production of erythrocytes. Myelosuppressive therapy with chemotherapy and/or radiotherapy is utilized to reduce the amount of proliferating hematopoietic cells. Hydroxyurea inhibits ribonucleotide reductase and carries less risk of secondary leukemia than busulphan, an alkylating agent.

Without treatment, 50% of the patients survive about 18 months. With only phlebotomy as the palliative treatment, survival extends to about 14 years. Thrombosis is the most frequent complication, and often patients are given antiplatelet therapy.⁵⁶ Patients receiving myelosuppressive therapy with or without phlebotomy have a mean survival of 9 years with chlorambucil therapy and 12 years with ³²P therapy. However, these patients show a progressive incidence of malignant complications. Research is ongoing to find a molecularly targeted therapy specific for the abnormal JAK2 kinase similar to the use of imatinib in CML.

DIFFERENTIAL DIAGNOSIS

It is essential that PV be differentiated from the more benign causes of secondary erythrocytosis and relative polycythemia so that effective therapy can be initiated.

Secondary Polycythemia

Secondary polycythemia can be classified into the following groups:

1. Polycythemia due to an increase in EPO as a normal physiologic response to tissue hypoxia
2. Polycythemia due to an inappropriate, nonphysiologic increase in erythropoietin
3. Familial polycythemia associated with high oxygen-affinity hemoglobin variants
4. Neonatal polycythemia associated with intrauterine hypoxia or late cord clamping

Tissue Hypoxia A decreased arterial oxygen saturation and subsequent tissue hypoxia are the most common cause of secondary polycythemia. The polycythemia disappears when the underlying cause is identified and effectively treated. Residents of high-altitude areas demonstrate a significant increase in hemoglobin and hematocrit that is progressively elevated at higher altitudes. The decrease in barometric pressure at high altitudes decreases the inspired oxygen tension. As a result, less oxygen enters the erythrocytes in the alveoli, and the arterial blood oxygen saturation decreases. The reduced pO₂ in the lungs is partially compensated for by a chronic hyperventilation. Compensation at the cellular level involves an increase in 2,3-BPG, facilitating the transfer of oxygen to the tissues. Tissue hypoxia secondary to a decrease in arterial blood oxygen saturation can also occur in severe obstructive lung disease and in obesity.

The hematocrit is generally not higher than 0.57 L/L in these cases.

Inappropriate Increase in Erythropoietin A non-physiologic increase in EPO (inappropriate) has been described in association with certain tumors that appear to secrete EPO or an EPO-like substance. About 50% of these patients have renal tumors. Other tumors that have been associated with erythrocytosis include those of the liver, cerebellum, uterus, adrenals, ovaries, lung, and thymus. In almost all cases, EPO levels return to normal and the erythrocytosis disappears after resection of the tumor. Renal cysts are also associated with polycythemia, possibly because of localized pressure and hypoxia to the juxtaglomerular apparatus, resulting in increased EPO secretion. In some patients with hypertension, renal artery disease, and renal transplants, renal ischemia can occur, resulting in erythrocytosis secondary to increased EPO production.

Familial Polycythemia Inherited hemoglobin variants with increased oxygen affinity cause tissue hypoxia and are associated with a secondary erythrocytosis. Because of the increased oxygen affinity, less oxygen is released to the tissues, stimulating erythropoietin production. Inherited deficiency of 2,3-BPG also results in decreased oxygen release to tissues. These inherited conditions are usually found in young children and in other family members as well.

Neonatal Polycythemia Hematocrits >0.48 L/L are common in neonates. The etiology is attributed to placental transfusion that occurs as a result of late cord clamping (7–10 seconds after delivery) and/or increased erythropoiesis stimulated by intrauterine hypoxia.⁶¹

Checkpoint! 8

Renal tumors can produce an inappropriate amount of EPO, resulting in what type of polycythemia?

Relative Polycythemia

Relative polycythemia is a mild polycythemia due to dehydration, hemoconcentration, or a condition known as *Gaisböck's syndrome*. Gaisböck's syndrome is known by several synonyms, including *spurious polycythemia*, *pseudopolycythemia*, and *stress erythrocytosis*. These patients have a relative polycythemia and hypertension with nephropathy or relative polycythemia associated with emotional stress⁵⁶ RCM is essentially normal. High hematocrit and hemoglobin concentrations appear to result from a combination of high-normal erythrocyte concentrations with a low-normal plasma volume. The most common symptoms are light-headedness, headaches, and dizziness. Plethora is common but splenomegaly is rare. These patients have a high incidence of thromboembolic complications and cardiovascular disease. Although the hemoglobin, hematocrit, and erythrocyte counts are increased, leukocytes and platelets are normal.

Bone marrow cellularity is normal with no increase in megakaryocytes or reticulin. Bone marrow iron stores are absent in 50% of the patients, but serum iron studies are normal. Chromosome karyotypes are almost always normal.

Laboratory Differentiation of Polycythemia

The WHO-defined diagnostic criteria for PV includes initial determination of total RCM or hemoglobin to establish the presence of an absolute polycythemia (Table 20).⁶² However, it has been shown that in some cases with hemoglobin levels below the value used for a diagnosis of PV and thrombocytosis, the RCM was higher than that required, thus revealing an occult erythrocytosis.⁶³ Without the RCM, these cases would have been diagnosed as essential thrombocythemia. This suggests that RCM is an important test to perform when PV is suspected. Determination of serum EPO levels is important because it helps to distinguish between primary and secondary polycythemia. If EPO levels are low, screening for the *JAK2(V617F)* mutation and bone marrow histology should be done.^{51,58} An elevated EPO indicates secondary polycythemia.

A diagnostic algorithm for PV using initial peripheral blood screening for the *JAK2(V617F)* mutation and serum EPO has been suggested. Depending on the results of these

tests, bone marrow biopsy might not be indicated.⁶⁴ However, the diagnostic utility of this algorithm must be determined in large studies.

 **Checkpoint! 9**

Which of these conditions—iron deficiency, smoking, emphysema, pregnancy, dehydration—are associated with an absolute increase in RCM?

Erythropoietin Measurement EPO is critical in differentiating PV from secondary polycythemias. With the *JAK2(V617F)* mutation, erythropoiesis occurs without the need for EPO stimulation. Serum EPO levels are usually very low or not detectable in PV. Secondary causes of polycythemia are related to elevated EPO levels either because of hypoxia or an inappropriate release of EPO from the kidneys (tumors and renal carcinomas).

Genetic Studies Studies should include molecular analysis for the *JAK2(V617F)* along with karyotype screening for trisomies of chromosome 8 and 9 as well as deletions of 13 or 20. In addition, molecular markers can show a decreased expression of thrombopoietin receptor, MPL, and an overexpression of polycythemia rubra vera-1(*PRV-1*) in mRNA of granulocytes.⁶⁵

Bone Marrow Changes A bone marrow assessment can be helpful in patients in whom EPO is not low and *JAK2(V617F)* is not detected, but an elevated RCM and clinical symptoms suggest PV. Histologic changes for PV include hypercellularity with increased erythroid precursors, megakaryocytes with megakaryocyte clusters, and reticulin fibrosis.⁵¹

It is always imperative in any classification scheme to recognize the possibility of two coexisting disease states. For instance, a patient can have both PV and a secondary polycythemia as occurs in chronic obstructive pulmonary disease. Differentiating features of polycythemia vera from secondary and relative polycythemia are found in Table 21.

 **ESSENTIAL THROMBOCYTHEMIA (ET)**

Essential thrombocythemia (ET) is a myeloproliferative disorder affecting primarily the megakaryocytic lineage. Sustained proliferation of megakaryocytes in the marrow and extreme thrombocytosis in the peripheral blood with thrombocytopathy (a qualitative disorder of platelets) occurs. In the past, considerable controversy has existed concerning the inclusion of ET as a specific entity in the myeloproliferative disorders because thrombocytosis is often a component of CML, CIMF, and PV. However, ET is now firmly estab-

★ TABLE 20

Diagnostic Criteria for Polycythemia Vera as Defined by WHO

Diagnosis of PV requires 2 of category A criteria and one other A criterion or 2 B criteria⁶²

Category A: Two Diagnostic Criteria Required

1. Increased RBC mass >25% mean normal or Hb >18.5 g/dL in men or >16.5 g/dL in women or >99th percentile of method-specific reference range for sex, age, altitude
2. Causes of secondary polycythemia ruled out:
 - a. Familial erythrocytosis
 - b. No increase of EPO due to:
 - i. Hypoxia
 - ii. High oxygen–affinity Hb
 - iii. Truncated EPO receptor
 - iv. Inappropriate EPO production by tumor
3. Splenomegaly
4. Clonal genetic abnormality other than BCR/ABL in bone marrow
5. Endogenous erythroid colony (EEC) formation in vitro

Category B: Two Diagnostic Criteria Required

1. Platelet count >400 × 10⁹/L
2. Leukocyte count >12 × 10⁹/L in absence of obvious infection or fever
3. Low EPO levels
4. Bone marrow biopsy shows panmyelosis with prominent erythroid and megakaryocytic proliferation

TABLE 21

Differential Features of Polycythemia

Feature	PV	Secondary	Relative
Spleen size	↑	N	N
RCM	≥36 mL/Kg (males) ≥32 mL/Kg (females)	↑	N
Leukocyte count	↑	N	N
Platelet count	↑	N	N
Serum cobalamin	↑	N	N
Arterial O ₂ saturation	N	↓	N
Bone marrow	Panhyperplasia; reticululin deposits	Erythroid hyperplasia	N
LAP	N to ↑	N	N
Iron stores	↓	N	N
EPO	N, ↓	N, ↑	N
Chromosome studies	Abnormal; >90% JAK2(V617F)+	N	N

N = normal; ↑ = increased; ↓ = decreased; LAP = leukocyte alkaline phosphatase; EPO = erythropoietin.

lished as a hematologic malignancy with distinct clinical manifestations and complications.⁶⁶

Synonyms for ET include *primary thrombocythemia*, *hemorrhagic thrombocythemia*, *primary thrombocytosis*, and *idiopathic thrombocytosis*.

PATHOPHYSIOLOGY

ET is a neoplastic disorder of the HSC usually resulting in clonal hematopoiesis affecting all three lineages, but in some cases, only the megakaryocytes are involved.⁶⁶ Normal megakaryocyte colony formation from CFU-Meg depends on the addition of cytokines in in vitro cultures. Although spontaneous megakaryocyte colony formation in serum-containing cultures has been reported, data on spontaneous colony formation in serum-free conditions are conflicting.⁶⁶ Early studies suggested that TPO and/or its receptor (MPL) were not directly associated with the underlying pathology in ET. Expression of MPL and its mRNA are generally decreased in ET, yet proliferation of progenitor cells ensues.⁶⁵ Serum levels of thrombopoietin are normal or slightly elevated in most patients.^{16,67} The clonal population of cells appears hypersensitive to some cytokines, including IL-3 and IL-6, but the clones are not hypersensitive to GM-CSF. However, sensitivity to the inhibitory effects of TGF-β is decreased, thus minimizing inhibition of thrombopoiesis.

Thus, a combination of increased sensitivity to some cytokines that promote platelet production coupled with a decreased sensitivity to negative regulators could account for the increased megakaryocyte proliferation characteristic of ET.

The recently discovered *JAK2(V617F)* mutation has been shown to be present in about 50% of patients with ET.⁶⁸ Because the cytokine receptors for EPO, MPL, and CSF-G have been associated with disease transformation mediated by *JAK2(V617F)*, mutations in these receptors may activate *JAK2* in those cases that are *JAK2(V517F)*-negative. Recent studies have revealed a mutation in *MPL* (*MPLW515L*) in some patients with *JAK2(V617F)*-negative ET and CIME. This mutation results in cytokine-independent growth and constitutive downstream signaling pathways.⁶⁸

CLINICAL FINDINGS

A rare disorder, ET's incidence peaks primarily from 50 to 60 years of age and secondarily from 20 to 30 years of age. The older group of patients has no gender predilection, but the younger age peak predominantly involves women. The overall incidence is ~1.5–2.4/100,000 people annually.⁶⁶

The presenting symptoms of patients with ET are variable. With the inclusion of platelet counts as a part of a routine CBC by most instrumentation now, extreme thrombocytosis is being detected more frequently than previously recognized. Many of these patients are asymptomatic, and their diagnosis is made incidentally.⁶⁹ Symptomatic patients most commonly present with thrombosis (primarily involving the microvasculature) or minor bleeding. Neurologic complications are common (e.g., headache, paresthesias of the extremities) and are associated with platelet-mediated ischemia and thrombosis. Circulatory insufficiency involving the microvasculature of the toes and fingers is frequent and is associated with pain and occasionally gangrene. Hemorrhagic episodes can occur, primarily involving the gastrointestinal tract, skin, urinary tract, and oral mucosal membranes. These problems appear to be more frequent in patients over 59 years of age with thrombosis occurring more frequently than bleeding at the lower values of thrombocytosis.^{9,17,67,70,71}

About half the patients have a palpable spleen, but splenomegaly is usually slight. Occasionally, splenic atrophy resulting from repeated splenic thrombosis and silent infarctions is seen. When this occurs, it is associated with typical morphologic alterations on the peripheral blood smear as discussed in the next section.

LABORATORY FINDINGS

Peripheral Blood

The most striking finding in the peripheral blood is extreme and consistent thrombocytosis (Figure 16■). Platelet counts are more than 600 × 10⁹/L and usually range from

FIGURE 16 Essential thrombocythemia. Platelets are markedly increased, and a giant form is present. (Peripheral blood; 1000× magnification; Wright-Giemsa stain)

1000–5000 × 10⁹/L. The peripheral blood smear can show giant bizarre platelets, and platelets can appear in aggregates. Megakaryocytes and megakaryocyte fragments also can be found. However, in many cases, platelet morphology appears normal. Abnormalities in platelet aggregation and adhesion suggest defects in platelet function (see Tests of Hemostasis).

Anemia, if present, is generally proportional to the severity of bleeding and is usually normocytic; however, longstanding or recurrent hemorrhagic episodes can lead to iron deficiency and a microcytic, hypochromic anemia. In about one-third of the patients, slight erythrocytosis is present, which can cause confusion with polycythemia vera. Aggregated platelets can lead to an erroneous increase in the erythrocyte count on automated cell counters. Therefore, hemoglobin determinations are better to assess the patient's anemic status. Histograms can reveal a high tail on the leukocyte histogram because of platelet clumps. The reticulocyte count can be increased if bleeding is present and mild polychromatophilia is noted. Peripheral blood abnormalities secondary to autosplenectomy may occur if the spleen has been infarcted. These abnormalities include Howell-Jolly bodies, nucleated erythrocytes, and poikilocytosis.

A leukocytosis from 22 to 40 × 10⁹/L is almost always present. Occasional metamyelocytes and myelocytes can be found with ET. Mild eosinophilia and basophilia also are observed. The LAP score can be normal or increased; it rarely is low. Nucleated erythrocytes are found in 25% of patients.

Bone Marrow

The bone marrow exhibits marked hyperplasia with a striking increase in megakaryocytes often with clustering of megakaryocytes along the sinusoidal borders. The background of stained slides shows many platelets. The megakaryocytes are large with abundant mature cytoplasm

and frequently increased nuclear lobulation. Mitotic forms are increased. Erythroid and myeloid hyperplasia also are evident. Stains for iron reveal normal or decreased stores but normal serum ferritin levels. In ~25% of cases, reticulin is increased, but significant fibrosis is generally not seen.⁶⁶

Tests of Hemostasis

Laboratory tests alone are unreliable in predicting bleeding or thrombotic complications in ET. The PT and APTT are usually normal, but evidence of low-grade DIC can be present. Platelet aggregation studies are frequently abnormal with the most common findings including defective platelet aggregation with epinephrine, ADP, and collagen. A loss of platelet α-adrenergic receptors associated with reduced epinephrine-induced aggregation is characteristic of an MPD and is useful in differentiating ET from secondary thrombocytosis. Spontaneous in vitro platelet aggregation or hyperaggregability is a common finding. In vivo platelet aggregation is suggested by finding increased plasma levels of β-thromboglobulin and platelet factor 4 (released from platelet α-granules). Other platelet abnormalities that have been described in association with ET are included in Table 22.⁷² A form of acquired VWD has been described in association with excessively high platelet counts and ET. The increase in number of circulating platelets is associated with adsorption of larger VWF multimers and their removal from the circulation. The laboratory features are characteristic of Type II VWD with a decrease or absence of large VWF multimers and reduced levels of ristocetin cofactor activity.

Genetics

A low incidence of clonal chromosomal cytogenetic abnormalities (about 5%) are found in ET. No diagnostic abnormality has been reported, but trisomies of Group C chromosomes can be seen. However, in 25–50% of cases, molecular screenings yield a *JAK2*(V617F) or *MPL* (W515L or W515K) mutation.¹⁶

★ TABLE 22

Platelet Abnormalities Found in Essential Thrombocythemia
• Decreased MPL receptors for thrombopoietin (TPO)
• Shortened platelet survival
• Increased beta-thromboglobulin (β-TG)
• Increased urinary thromboxane B ₂ (TxB ₂)
• Acquired Von Willebrand disease
• Defective epinephrine, collagen, ADP-induced platelet aggregation
• Decreased ATP secretion
• Acquired storage pool deficiency due to abnormal in vivo platelet activation

Other Laboratory Findings

Other laboratory tests can be abnormal. Serum cobalamin and the unsaturated cobalamin binding capacity are increased. An increase in cell turnover can cause serum uric acid, LD, and acid phosphatase to be elevated. Serum potassium can be elevated as a result of in vitro release of potassium from platelets (pseudohyperkalemia). The spurious nature of this hyperkalemia can be verified by performing a simultaneous potassium assay on plasma, which should be normal. Arterial blood gases can reveal a pseudohypoxia if the sample is not tested promptly due to the in vitro consumption of oxygen by the increased numbers of platelets.

PROGNOSIS AND THERAPY

About 64–80% of the patients with ET survive 10 years. The prognosis appears to be better in younger patients. One large study found no significant difference in survival probability compared to the control population. The most common causes of death are thrombosis and bleeding. Occasionally, the disease transforms to AML, PV, or CIMF (usually <10% of patients for each type of transformation).⁷³

Controversy exists as to which patients with ET require therapy. It is generally agreed that patients with a history of thrombosis or cardiovascular risk factors require therapy to reduce the platelet count. Plateletpheresis is utilized to quickly reduce the platelet count below $1000 \times 10^9/L$ for control of vascular accidents. Anticoagulants and drugs to inhibit platelet function are used to control thrombosis.⁷⁰

The benefit of specific therapy in asymptomatic patients has not been established. Therapeutic trials with β -interferon show improvement of both hematologic parameters and clinical symptoms on nearly all patients.⁷⁰ Withdrawal of interferon, however, leads to recurrence of thrombocytosis. Chronic megakaryocyte suppression can be achieved by radiation or chemotherapy. However, the leukemogenic potential of these therapeutic agents is of concern.

DIFFERENTIAL DIAGNOSIS

Although the other MPDs have certain diagnostic markers, ET is largely a diagnosis of exclusion. Essential thrombocytosis must be differentiated from a secondary, reactive thrombocytosis (Table 23). Secondary thrombocytosis is associated with many acute and chronic infections, inflammatory diseases, carcinomas, and Hodgkin’s disease. The platelet count in ET exceeds $1000 \times 10^9/L$ and is persistent over a period of months or years. Secondary or reactive thrombocytosis rarely reaches $1000 \times 10^9/L$ and is transitory. In addition, in secondary thrombocytosis, platelet function is normal, leukocytes and erythrocytes are normal, and splenomegaly is absent.

Differentiating ET from PV can be difficult. However, marked erythrocytosis with clinical findings suggestive of hypervolemia is more typical of PV.

TABLE 23

Conditions Associated with Thrombocytosis

- Essential thrombocythemia (ET)
- Polycythemia vera (PV)
- Chronic myelogenous leukemia (CML)
- Chronic idiopathic myelofibrosis (CIMF)
- Chronic inflammatory disorders
- Acute hemorrhage
- Hemolytic anemia
- Hodgkin’s disease
- Metastatic carcinoma
- Lymphoma
- Postsplenectomy
- Postoperative
- Iron deficiency

The Polycythemia Vera Study Group (PVSG) proposed a set of diagnostic criteria for ET, which were adopted as diagnostic criteria in the WHO classification (Table 24). The first criterion, a platelet count of more than $600 \times 10^9/L$, excludes many cases of secondary thrombocytosis. The second criterion of increased megakaryocytes in the bone marrow is necessary to confirm the diagnosis of ET and rule out other causes of clonal thrombocythemia.³¹ The third, a hemoglobin of less than 18.5 g/dL in males and less than 16.5 g/dL in females, and the fourth, presence of iron in the bone marrow or failure of response to iron therapy, exclude cases of PV. The fifth criterion, absence of the Ph chromosome, was designed to rule out CML, and the sixth, absence of collagen fibrosis, rules out CIMF. The seventh, absence of dysplasia and related genetic mutations, rules out MDS. The eighth criterion excludes conditions associated with reactive thrombocytosis.

Checkpoint! 10

Is a patient who has a platelet count of $846 \times 10^9/L$, splenomegaly, and abnormal platelet function tests of hyperaggregation likely to have reactive or essential thrombocytosis? Explain.

▶ CHRONIC MYELOPROLIFERATIVE DISEASE, UNCLASSIFIABLE (CMPD-U)

Chronic myeloproliferative disease, unclassified (CMPD-U) is the diagnosis for cases that have the characteristic clinical, laboratory, and morphologic features of an MPD but do not meet the specific criteria for one of the other MPD categories or have features that overlap two or more categories. The Ph

TABLE 24

WHO Diagnostic Criteria for Essential Thrombocythemia (ET)

Diagnostic Criteria for ET	Helps Differentiate ET From:
Sustained platelet count $>600 \times 10^9/L$	Secondary thrombocytosis
Bone marrow biopsy shows megakaryocytic hyperplasia (enlarged, mature megakaryocytes)	
Hemoglobin ≤ 18.5 g/dL in males, <16.5 g/dL in females or normal RCM	PV
Stainable iron in the marrow, normal serum ferritin, or normal MCV or failure of iron therapy to increase the RCM or raise the hemoglobin to the PV level after one month of iron therapy	PV
Absence of the Ph chromosome or BCR/ABL fusion gene	CML
Absent collagen fibrosis of marrow and minimal or absent reticulin fibrosis	CIMF
No evidence of myelodysplastic syndrome (absent del[5q]; t[3;3][q21;q26]; inv[3][q21q26]; absence of granulocytic dysplasia and micromegakaryocytes)	MDS
No known cause for reactive thrombocytosis	Reactive thrombocytosis

RCM = red cell mass

Experience of the Polycythemia Vera Study Group with essential thrombocythemia: A final report on diagnostic criteria, survival, and leukemic transition by treatment. *Semin Hematol.* 1997;34:29–39, and Imbert M, Vardiman JW, Pierre RV et al. Essential thrombocythemia. In Jaffe ES, Harris NL, Stein H, Vardiman JW, eds. *World Health Organization Classification of Tumours: Tumours of the Haematopoietic and Lymphoid Tissues.* Lyon, France: International Agency for Research on Cancer (IARC) Press; 2001:17–44.

chromosome and BCR/ABL are absent. The cell of origin is most likely the pluripotent HSC.

Most cases of CMPD-U are either very early stages of PV, CIMF, or ET or are at a late stage of advanced MPD in which extensive myelofibrosis, osteosclerosis, or transformation to an aggressive stage obscures the true disorder. Follow-up at intervals can permit an accurate diagnosis. A specific diagnosis should be made as soon as possible because of the therapeutic implications for each of the neoplastic disorders.

The incidence of CPMD-U is unknown but can be as high as 20% of MPDs. Clinical features are similar to those found in other MPD including splenomegaly and hepatomegaly.

LABORATORY FINDINGS

WBC and platelets can be increased. Hemoglobin is variable. The bone marrow is hypercellular with megakaryocytic hy-

perplasia and variable granulocytic and erythroid proliferation. In advanced stages, the BM is fibrotic or osteomyelosclerotic. If there are 10–19% blasts in the peripheral blood, the disease is diagnosed as an accelerated stage.

GENETICS

No specific cytogenetic or molecular abnormalities are identified with this disorder.

▶ MAST CELL DISEASE (MASTOCYTOSIS)

Mast cell disorders are heterogeneous. They are characterized by the abnormal proliferation of mast cells in one or more organ systems. Mast cells share a common progenitor cell with myelomonocytic cells. Based on current knowledge about mast cells, it has been suggested that mast cell disorders be classified as myeloproliferative disorders, but classification schemes for them have not been universally accepted. The WHO classification is included in Table 25.

The two major groups of mast cell disorders are cutaneous and systemic. Cutaneous disease is based on the presence of histological skin lesions and typical clinical signs but no systemic involvement. It is typically found in children.

Systemic disease is characterized by multifocal histological lesions in the bone marrow and other organs. There may be anemia and an increase or decrease in leukocytes and platelets. Eosinophilia can be marked.

Genetic studies reveal that systemic mastocytosis (SM) is a clonal disorder. It is characterized by a somatic mutation of the *KIT* (CD117) protooncogene. *KIT* codes for the tyrosine kinase receptor for SCF, which is a major regulator of mast cell development, and hematopoietic stem cells. When mutated, the receptor is constitutively activated giving the cell a proliferative advantage.⁷⁴

TABLE 25

WHO Classification of Mast Cell Disorders (Mastocytosis)

- Cutaneous mastocytosis
- Indolent systemic mastocytosis
- Systemic mastocytosis associated with other clonal, nonmast cell hematologic disorders
- Aggressive systemic mastocytosis
- Mast cell leukemia
- Mast cell sarcoma
- Extracutaneous mastocytoma

Adapted from: Valent P, Harry HP, Escribano L, Longley BJ, Li CY, Schwartz LB et al. Diagnostic criteria and classification of mastocytosis: A consensus proposal. *Leuk Res.* 2001;25(7):603–25.

One subgroup of systemic mast cell disease is mast cell leukemia, (MCL) an aggressive disease with a short survival. The criteria for a diagnosis of MCL include criteria for systemic mastocytosis fulfilled; circulating mast cells in the peripheral blood ($\geq 10\%$) and $>20\%$ of the nucleated cells in bone marrow are mast cells; and multiorgan failure (Table 26). The aleukemic mast cell leukemia variant has $<10\%$ mast cells in the peripheral blood. The bone marrow mast cells can be immature and blastlike. Mast cells with bilobed or polylobed nuclei can be found. Signs of myeloproliferation and dysplasia, can be present but the criteria for another hematologic disorder are not. The mast cells are tryptase positive and express KIT. Serum tryptase levels are elevated. Pancytopenia characterizes later stages of the disease when the bone marrow fails.

Most patients are adults with symptoms related to proteins or mediators released from mast cells and include hypotension, flushing, and diarrhea. Weight loss, bone pain,

and organomegaly occur later in the disease. There is no standard therapy or long-term cure. Antimediator drugs such as aspirin and antihistamines are used to relieve symptoms. Experience with chemotherapy and bone marrow transplant is lacking.⁷⁴

SUMMARY

The myeloproliferative disorders (MPD) are characterized as a group of clonal stem cell disorders differentiated by neoplastic production of one or more of the hematopoietic lineages in bone marrow and peripheral blood. The WHO classification of MPD includes the subgroups chronic myelogenous leukemia (CML), chronic neutrophilic leukemia (CNL), chronic eosinophilic leukemia (CEL), chronic idiopathic myelofibrosis (CIMF) with myeloid metaplasia, polycythemia vera (PV), and essential thrombocythemia (ET).

Although all hematopoietic cell lineages can be involved in the unregulated proliferation in MPD, one lineage is usually involved more than the others. The myeloid cells are primarily affected in CML, CEL, and CNL; the erythrocytes are affected in PV; and the platelets/megakaryocytes are affected in ET. The most characteristic finding of CIMF is a nonmalignant proliferation of fibroblasts in the bone marrow. Splenomegaly, bone marrow fibrosis, and megakaryocytic hyperplasia are findings common to all subgroups. The underlying pathophysiology appears to be chromosomal rearrangements that occur in the regions of proto-oncogenes leading to qualitative or quantitative alterations in gene expression and abnormal control of cell growth. *JAK2(V617F)* and *MPL (W515)* mutations that lead to constitutive phosphorylation, signal transduction, DNA transcription, and decreased apoptosis have been identified.

Abnormal karyotypes in hematopoietic cells can be found in any of the subgroups. The most well-characterized abnormality is the Philadelphia (Ph) chromosome found in up to 95% of individuals with CML. The Ph chromosome is the result of a translocation of genetic material between chromosomes 9 and 22 [t(9;22)(q34;q11.2)]. Molecular testing of CML patients who are Ph chromosome negative by cytogenetics, reveals a *BCR/ABL1* fusion gene encoding for an abnormal tyrosine kinase protein, p210, comparable to that produced by the Ph chromosome. This protein plays a role in the pathogenesis of CML. Trisomies within the Group C chromosomes, trisomy 8 or trisomy 9, are common findings in progressive MPD.

The survival of MPD patients varies according to the subgroup and complications of thrombosis. Patients with PV and ET appear to survive longer than patients with CML or CIMF. Any of the subgroups can evolve into acute leukemia with or without specific therapy. Currently no cure exists for any of the MPDs, although stem cell transplantation, molecular-targeted therapy, and anti-platelet drugs give favorable outlooks for improving prognosis.

TABLE 26

Criteria for Diagnosis of Systemic Mastocytosis (SM) and Mast Cell Leukemia (MCL).

SM requires the major criteria and 1 minor criteria or 3 minor criteria. MCL requires criteria for SM plus those listed for MCL in this table.

Major criteria:

- Bone marrow or other organs that show multifocal, dense infiltrates of tryptase positive mast cells

Minor criteria:

- Biopsy of bone marrow or other organs shows spindle-shaped or atypical morphology in $>25\%$ of mast cells or $>25\%$ of all mast cells in the bone marrow are immature or atypical
- Presence of KIT point mutation (codon 816) in mast cells from bone marrow or other organ
- Mast cells in peripheral blood, bone marrow, or other tissue coexpress CD117 with CD2 +/-or CD25
- In absence of associated clonal myeloid disorder, total serum tryptase is >20 ng/mL

Mast cell leukemia criteria

- Criteria for SM fulfilled
- Diffuse infiltration by atypical immature mast cells shown in bone marrow biopsy
- Bone marrow aspirate with $\geq 20\%$ mast cells
- Peripheral blood with $\geq 10\%$ mast cells

REVIEW QUESTIONS

LEVEL I

1. The most prominent cell line in CML is the: (Objective 2)
 - a. erythroid
 - b. myeloid
 - c. megakaryocyte
 - d. fibroblast
2. The most prominent cell line found in polycythemia vera (PV) is the: (Objective 2)
 - a. erythroid
 - b. myeloid
 - c. megakaryocyte
 - d. fibroblast
3. The Philadelphia chromosome is a gene fusion resulting from a translocation of: (Objective 4)
 - a. chromosomes 8 and 14
 - b. chromosomes 9 and 22
 - c. chromosomes 12 and 17
 - d. chromosomes 15 and 17
4. The peak age for CML is: (Objective 5)
 - a. less than 5 years
 - b. 15–30 years
 - c. 40–59 years
 - d. over 60 years
5. The Philadelphia chromosome can be found in patients with: (Objective 4)
 - a. CML
 - b. ALL
 - c. ET
 - d. polycythemia vera
6. Which of the following represent a characteristic peripheral blood finding in patients with CIMF? (Objective 7)
 - a. elliptocytes
 - b. dacrocytes
 - c. target cells
 - d. schistocytes
7. Polycythemia vera (PV) can be distinguished from secondary polycythemia by measuring: (Objective 9)
 - a. hematocrit
 - b. plasma volume
 - c. hemoglobin concentration
 - d. erythropoietin
8. A 50-year-old man was admitted to the emergency room for chest pain and a blood count was ordered. The results showed erythrocyte count $6.5 \times 10^{12}/L$; hematocrit 0.60 L/L; leukocyte count $15 \times 10^9/L$; platelet count $500 \times 10^9/L$. These results indicate: (Objective 3)
 - a. the need for further investigation of a possible diagnosis of MPD
 - b. normal findings for an adult male
 - c. that the patient has experienced a thrombotic episode
 - d. a malfunction of the cell counting instrument

LEVEL II

Use this case study to answer questions 1–5.

A 45-year-old Caucasian female was admitted to the hospital from the emergency room. She had experienced pain in the upper quadrant and bloating for the past several weeks. She had multiple bruises on her legs and arms. She also stated that her gums bled easily when she brushed her teeth. She had been unusually tired and lost about 10 pounds in the last 2 months. Results of physical examination showed a massive spleen. The following laboratory results were noted on blood count admission.

Hb	7.4 g/dL (74 g/L)
Erythrocyte count	$2.9 \times 10^{12}/L$
Hct	.22 L/L
RDW	18.0
Leukocyte count	$520 \times 10^9/L$
Platelet count	$960 \times 10^9/L$
Differential	31% segmented neutrophils 26% bands 8% metamyelocytes 11% myelocytes 4% promyelocytes 2% blasts 4% lymphocytes 3% monocytes 5% eosinophils 6% basophils 4 nucleated erythrocytes/100 leukocytes Occasional micromegakaryocytes

There was moderate anisocytosis and poikilocytosis.

A bone marrow aspiration was performed. The marrow was 90% cellular with a myeloid:erythroid ratio of 10:1. The majority of the cells were neutrophilic precursors. There was an increase in eosinophils and basophils. Myeloblasts accounted for 10% of the nucleated cells. Megakaryocytes were increased.

1. What findings suggest that this patient has a defect in the pluripotential stem cell rather than a benign proliferation of hematopoietic cells? (Objective 4)
 - a. the presence of a leukoerythroblastic blood picture
 - b. the involvement of several cell lineages in the proliferative process including neutrophilic cells and platelets
 - c. the shift to the left in the neutrophilic cell line
 - d. an increase in the RDW
2. Molecular analysis by (RT-PCR) revealed the presence of a BCR/ABL fusion product. Based on this information, what myeloproliferative disorder is present? (Objectives 1, 3)
 - a. CML
 - b. PV
 - c. ET
 - d. CIMF

REVIEW QUESTIONS (continued)

LEVEL I

9. A patient previously diagnosed with CML now has a platelet count of $540 \times 10^9/L$ and a leukocyte count of $350 \times 10^9/L$ with a peripheral blood differential showing 15% segmented neutrophils, 23% bands, 2% metamyelocytes, 35% blasts, 6% lymphocytes, 4% monocytes, 6% eosinophils, and 8% basophils. These results are most consistent with: (Objective 6)
 - a. chronic CML
 - b. ET
 - c. CML in blast crisis
 - d. CIMF
10. A patient presenting in the ER with a platelet count of more than $1000 \times 10^9/L$ and a leukocyte count of $25 \times 10^9/L$ with a normochromic, normocytic anemia should be evaluated for: (Objective 10)
 - a. Philadelphia chromosome
 - b. essential thrombocythemia
 - c. CIMF
 - d. primary polycythemia

LEVEL II

3. What cytochemical stain is used to help differentiate a leukemoid reaction from CML? (Objectives 1, 4)
 - a. myeloperoxidase
 - b. new methylene blue
 - c. leukocyte alkaline phosphatase
 - d. Perl's Prussian blue
4. Which of the following terms most accurately describes the peripheral blood picture of this patient? (Objectives 10, 13)
 - a. leukemoid reaction
 - b. leukoerythroblastic
 - c. leukopenia
 - d. myelodysplastic
5. What is the best description of the bone marrow? (Objective 1)
 - a. decreased M:E ratio and increased cellularity
 - b. increased M:E ratio and decreased cellularity
 - c. increased M:E ratio and increased cellularity
 - d. decreased M:E ratio and decreased cellularity
6. Extensive bone marrow fibrosis, leukoerythroblastic peripheral blood, and the presence of anisocytosis with dacryocytes are most characteristic of which MPD? (Objective 6)
 - a. CML
 - b. PV
 - c. ET
 - d. CIMF
7. A 68-year-old man was seen in the clinic for lethargy, dyspnea, and light-headedness. Results of his blood counts were erythrocyte count $5.0 \times 10^{12}/L$; hematocrit 0.55 L/L; leukocyte count $60 \times 10^9/L$; platelet count $70 \times 10^9/L$. His differential showed a shift to the left in myeloid elements with 40% eosinophils. The bone marrow revealed 10% blasts. Philadelphia chromosome was negative. He most likely has: (Objective 10)
 - a. polycythemia vera
 - b. CML in blast crisis
 - c. essential thrombocythemia
 - d. chronic eosinophilic leukemia
8. A molecular test should be performed on the patient in question 7 for which mutation? (Objective 3)
 - a. JAK2(V617F)
 - b. BCR/ABL
 - c. FIP1L1/PDGFRA
 - d. MPL(W515)
9. Which of the following does *not* cause secondary polycythemia? (Objective 7)
 - a. chronic obstructive pulmonary disease
 - b. smoking
 - c. emphysema
 - d. dehydration

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

10. Evidence of clonal proliferation in myeloproliferative disorders can be identified by: (Objective 8)
 - a. G6PD isomers
 - b. myeloperoxidase stain
 - c. Perl's Prussian blue
 - d. trisomy 8

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: The clinical findings of abdominal discomfort, increasing splenomegaly, weakness, and bone pain are consistent with chronic myeloproliferative disorders. The laboratory findings of increased uric acid, left shift, increased platelet count, difficult bone marrow aspiration, dacryocytes on peripheral blood smear, and cytogenetic abnormalities are all characteristic of CIMF (chronic idiopathic myelofibrosis). Malignant stem cells give rise to abnormal leukocytes, erythrocytes, and megakaryocytes. The megakaryocytes secrete excessive PDGFs that stimulate fibroblasts to lay down excessive reticulin and collagen in the bone marrow cavity. This fibrosis leads to the extramedullary hematopoiesis causing splenomegaly and hepatomegaly.

In this case, the peripheral blood film with a leukoerythroblastic picture of immature myeloid cells, nucleated red blood cells, and dacryocytes should rule out causes of marrow infiltration by nonhematopoietic tumor cells, granulomas, or fungus.

The diagnosis of this case is CIMF. Myelofibrosis can evolve into any of the chronic myeloproliferative disorders or acute leukemia. A moderate leukocytosis (WBC <30.0 × 10⁹/L), leukoerythroblastosis, dry tap, and lack of the Philadelphia chromosome distinguish CIMF from the other myeloproliferative disorders.

Question:

1. What are Roger's MCV and MCHC?

Explanation:

MCV = 35/3.6 × 10 = 97 fL and MCHC = 11.6/35 × 100 = 33%

Question:

2. How would you classify his anemia morphologically?

Explanation:

The patient has a normochromic, normocytic anemia.

Question:

3. Based on Roger's history and current laboratory data, what other tests should be performed?

Explanation:

Because of the hepatosplenomegaly and laboratory results, a bone marrow and Philadelphia chromosome analysis should be considered. *BCR/ABL1* gene rearrangement is also necessary.

Question:

4. What diagnoses are suggested?

Explanation:

All MPD (CML, essential thrombocytosis, polycythemia vera, or CIMF) can produce a leukocytosis and fibrotic bone marrow.

Question:

5. Give a reason for the unsuccessful, dry-tap, bone marrow aspiration.

Explanation:

Increased fibrosis in the bone marrow makes aspiration difficult. Excess PDGF and TGF-β stimulate collagen proliferation and reticulin fibrosis in the bone marrow. Dry taps may also result from improper placement of the needle into the marrow cavity, a marrow that is hypocellular, or one that is packed tightly with neoplastic cells.

Question:

6. What characteristic peripheral blood morphologies correlate with the bone marrow picture and physical exam?

Explanation:

You would expect to see dacryocytes and should look for micro-megakaryocytes in the peripheral blood.

Question:

7. What is the most likely explanation for the increased splenomegaly?

Explanation:

The progressive bone marrow fibrosis causes anemia, resulting in extramedullary hematopoiesis in the spleen and liver. This increases splenic blood flow, red cell pooling, and enlargement of the spleen.

Question:

8. What are possible outcomes of this disorder?

Explanation:

CIMF can show progressive fibrosis or evolve into polycythemia vera, essential thrombocythemia, CML, or acute leukemia.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

In essential thrombocythemia, all hematopoietic lines have increased cell proliferation. Which lineage has the most increase?

Answer

The megakaryocytic cell line is the one most increased in essential thrombocythemia.

Checkpoint! 2

A patient has the CML phenotype, but the genetic karyotype does not show the Philadelphia chromosome. If this is truly a CML, what should molecular analysis show?

Answer

Molecular analysis would show a BCR/ABL gene rearrangement in a new fused hybrid gene.

Checkpoint! 3

Describe the peripheral blood differential of a CML patient.

Answer

There is a shift to the left in granulocytes with high numbers of myelocytes and promyelocytes. If blasts are present, they compose less than 20% of cells.

Checkpoint! 4

What clinical, peripheral blood, and genetic features differentiate CML from an infectious process?

Answer

An extreme peripheral blood leukocytosis—segmented neutrophils with a left shift showing many myelocytes, some promyelocytes, and blasts are found in CML. Age of the patient and absence of infection, low LAP score, and presence of the Philadelphia chromosome or BCR/ABL translocation all are hallmarks for CML that differentiate it.

Checkpoint! 5

What one feature separates other forms of MPD from CML?

Answer

The Philadelphia chromosome occurs in CML.

Checkpoint! 6

What growth factors are primarily responsible for stimulating fibrogenesis in the bone marrow?

Answer

Platelet-derived growth factor (PDGF), transforming growth factor-beta (TGF- β), and epidermal growth factor (EGF) are increased and associated with marrow fibrosis.

Checkpoint! 7

What erythrocyte morphologic feature is a hallmark for myelofibrosis?

Answer

The finding of dacryocytes (teardrop erythrocytes) is a hallmark for myelofibrosis with myeloid metaplasia.

Checkpoint! 8

Which of the following conditions are associated with an absolute increase in red cell mass? Iron deficiency, smoking, emphysema, pregnancy, or dehydration.

Answer

Smoking, emphysema, and pregnancy are conditions in which additional red cells are needed to prevent a physiologic anemia. Iron deficiency prevents the formation of additional red cells. Dehydration causes a relative red cell mass increase due to decreased plasma volume.

Checkpoint! 9

Renal tumors may produce an inappropriate amount of EPO, resulting in what type of polycythemia?

Answer

Secondary polycythemia, or increase of red cell mass due to an identifiable cause.

Checkpoint! 10

Is a patient who has a platelet count of $846 \times 10^9/L$, splenomegaly, and abnormal platelet function tests of hyperaggregation likely to have reactive or essential thrombocytosis?

Answer

This patient is likely to have essential thrombocytosis. Patients with reactive thrombocytosis rarely have platelet counts higher than $1,000 \times 10^9/L$ nor would they have splenomegaly or thrombotic complications.

Myelodysplastic Syndromes

Louann W. Lawrence, DrP.H.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define *myelodysplastic syndromes* (MDS) and list general characteristics of these diseases.
2. List the six subgroups of MDS recognized by the World Health Organization (WHO) Classification System and identify key morphological and clinical criteria that distinguish each group.
3. Describe laboratory findings and recognize changes in morphology that are characteristic of this group of disorders.
4. Define the WHO category of myelodysplastic/myeloproliferative diseases, and list its general/characteristics.
5. List the four subgroups of myelodysplastic syndromes/myeloproliferative diseases (MDS/MPD), and identify key morphological and clinical criteria as well as laboratory findings that distinguish each group.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Describe the pathophysiology of MDS.
2. Distinguish among Type I, Type II, and Type III blasts and promyelocytes.
3. Summarize the treatment and prognosis of MDS.
4. Explain the relationship between MDS and acute leukemia.
5. Assess the results of cytogenetic and molecular tests and correlate them with a diagnosis of MDS.
6. List and briefly describe the MDS variants not listed in the six WHO subgroups.
7. Differentiate MDS from myeloproliferative disorders, acute leukemia, and other hematologic abnormalities using peripheral blood, bone marrow, and cytogenetic characteristics.
8. Differentiate MDS/MPD from MDS, MPD, acute leukemia, and other hematologic abnormalities using peripheral blood, bone marrow, and cytogenetic characteristics.
9. Select laboratory tests that are helpful in diagnosing and differentiating MDS and MDS/MPD.
10. Evaluate a patient's laboratory and clinical findings, and propose a diagnostic MDS or MDS/MPD subgroup.

KEY TERMS

Atypical chronic myeloid leukemia (aCML)
 Chronic myelomonocytic leukemia (CMML)
 Dysplasia
 Dyspoiesis
 Endomitosis
 Juvenile myelomonocytic leukemia (JMML)
 Micromegakaryocyte
 Myelodysplastic syndromes (MDS)
 Myelodysplastic/myeloproliferative diseases (MDS/MPD)
 Refractory anemia (RA)
 Refractory anemia with excess blasts (RAEB)
 Refractory anemia with ringed sideroblasts (RARS)
 Refractory cytopenia with multilineage dysplasia (RCMD)
 Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)
 Ringed sideroblasts

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Create a schematic depicting derivation of different types of blood cells from the pluripotent hematopoietic stem cell.
- ▶ Describe and recognize the cell morphology described by these terms: ringed sideroblasts, Pelger-Huët anomaly, and megaloblastoid erythropoiesis.)
- ▶ Explain what *ineffective hematopoiesis means*.)
- ▶ Summarize the history and basis of the classification system to classify malignant leukocyte disorders.
- ▶ Review normal leukocyte development, differentiation, and concentrations in the peripheral blood.

Level II

- ▶ Describe the use of cytochemical and immunological features that distinguish the different types of blasts.
- ▶ Explain how oncogenes and hematopoietic growth factors affect cellular maturation and proliferation.)
- ▶ Explain the role of epigenetics in cellular development
- ▶ Explain the use of cytogenetics and flow cytometry in the diagnosis of malignant disorders.)

CASE STUDY

We will refer to this case study throughout the chapter. Hancock, a 65-year-old white male, was seen in triage with complaints of fatigue, malaise, anorexia, and hemoptysis of recent onset. A CBC was ordered and revealed anemia and a shift to the left in granulocytes. Hematopoietic cells showed dysplastic features. Consider diagnostic probabilities and reflex testing that could provide differential diagnostic information.

OVERVIEW

This chapter describes the neoplastic hematopoietic disorders known as the *myelodysplastic syndromes* (MDS). It begins with the classification of the disorders into morphologic subgroups according to the classification of both the French-American-British (FAB) and more recently, the WHO. This is followed by a description of the pathogenesis, incidence, and general clinical and laboratory features including peripheral blood and bone marrow findings. Each subgroup is then described with specific features that allow it to be classified. Variants are also described. Genetic findings common to the MDS are discussed. The chapter concludes with prognosis and therapy.

INTRODUCTION

The **myelodysplastic syndromes (MDS)** are considered primary, neoplastic, pluripotential stem cell disorders. They are characterized by one or more peripheral blood cytopenias with prominent maturation abnormalities (**dyspoiesis** or **dysplasia**) in the bone marrow. The peripheral blood cytopenias are the result of ineffective hematopoiesis and increased apoptosis as evidenced by an accompanying bone marrow hyperplasia. These relatively common entities evolve progressively, leading to the aggravation of the cytopenias and, in some cases, transformation into a condition indistinguishable from acute leukemia. MDS occurs most commonly in the elderly, although it is being diagnosed with increased frequency in children.

Before the 1980s, much confusion and disagreement existed in the literature concerning the criteria for defining, subgrouping, and naming the MDSSs. Because of the predisposition of MDS to terminate in leukemia, the term *preleukemia* commonly has been used to describe these disorders. However, the evolution of MDS to acute leukemia is not obligatory, and in fact, many patients die of intercurrent disease or complications of the cytopenia before evolving to leukemia.¹ Whether or not these patients would have developed leukemia had they survived the cytopenic complications is, of course, unknown. In addition, the diagnosis of preleukemia can be made only in retrospect (i.e., after the patient develops leukemia). Thus, the term *myelodysplasia* is

more appropriate until the patient actually develops overt leukemia. In the past, MDS has also been described under the terms *refractory anemia with excess blasts*, *chronic erythremic myelosis*, *hematopoietic dysplasia*, *refractory anemia with or without sideroblasts*, *subacute or chronic myelomonocytic leukemia*, and *smoldering leukemia*. Most hematologists currently consider the terms *dysmyelopoietic syndrome* and *myelodysplastic syndrome* to be more acceptable than *preleukemia* or other synonyms in describing these hematologic disorders. In this book, the term *myelodysplastic syndrome* is used.

▶ PATHOGENESIS

The spectrum of clinical and hematological features in MDS is a result of the gradual expansion of abnormal hematopoietic cells and an accompanying increase in premature destruction (apoptosis) of these abnormal cells, resulting in ineffective hematopoiesis. Cytogenetic, G6PD isoenzyme studies and molecular diagnostic tests support the theory that the abnormal cells in MDS are clones derived from an abnormal pluripotent stem cell.^{2–10} Chromosome abnormalities are present in more than 50% of patients at diagnosis. These abnormalities detected by standard karyotyping are present in granulocytic, monocytic, erythrocytic, and/or megakaryocytic lineages.^{9–11} Recent studies have suggested that lymphocytes could be part of the leukemic clone, but other evidence has been contradictory.^{2,12} Normal clones are found to coexist in the marrow with the abnormal clones. As the disease progresses, additional alterations can affect the abnormal cells, providing them a growth advantage and allowing the abnormal clone to predominate.² In MDS cases that progress to acute leukemia, additional abnormalities in cell culture and karyotypes can be demonstrated. Therefore, it appears that after the abnormal clone is established, additional genetic events can be required for the transformation into acute myeloid leukemia (AML).⁹

THE ROLE OF ONCOGENES

Control of cellular differentiation, maturation, and proliferation occurs through the interaction of hematopoietic growth factors with specific cellular receptors. This interaction causes a complex series of protein and tyrosine kinase phosphorylations, eventually resulting in DNA synthesis. Cellular proto-oncogenes control the entire process. When these genes are mutated to oncogenes, they can disrupt the process, causing disordered control and neoplasia.¹³

The abnormal MDS clone is characterized by altered gene functions resulting from either single gene mutations, chromosomal abnormalities, or gene silencing (epigenetic changes). Many of these chromosomal alterations involve gene deletions suggesting that tumor suppressor genes or DNA repair genes are altered. Changes involving tumor suppressor or DNA repair genes usually require two events: mu-

tation of the target gene and loss of the second allele through deletion or recombination.¹⁰

“Unbalanced” genetic abnormalities (which result in a larger or smaller amount of DNA in the cell, such as trisomies or whole or partial chromosomal deletions) that are characteristically seen in the MDS are thought to be responsible for the ineffective hematopoiesis and cytopenias.¹⁴ These chromosomal abnormalities are in contrast to the balanced abnormalities (which maintain the normal quantity of DNA, e.g., reciprocal translocations) seen primarily in AML.

The most frequent chromosome abnormalities in MDS involve chromosomes 5, 7, and 8, all of which carry proto-oncogenes. Chromosome 5 carries the *FOS*, *RAS*, and *FMS* proto-oncogenes; chromosome 7 carries the *ERB-B* proto-oncogene; and chromosome 8 carries the *MYC* proto-oncogene. The *RAS* gene family has been studied most often in MDS. Of patients with MDS, 10–40% have *RAS* mutations. The most common mutation is a single base change at codon 12 of the *N-RAS* (neuroblastoma-ras) family. The *N-RAS* mutation is associated with a higher risk of AML transformation and a worse prognosis. New drugs aimed to target this specific mutation are being studied.² The *RAS*, *MYC*, and *FOS* proto-oncogenes have been implicated in growth factor-mediated signaling pathways. If these proto-oncogenes are activated, the abnormal clone in MDS can become immortalized by losing the normal control mechanisms that regulate growth. Other gene mutations described in MDS involve the *P53* tumor suppressor gene (seen in 5–10% of cases) and *FLT3* oncogene receptor kinase (seen in 5% of cases).²

MATURATION AND PROLIFERATION ABNORMALITIES

Impaired cellular maturation and function due to intrinsic defects in cells of the neoplastic clone are fundamental pathophysiologic abnormalities in MDS as well as in AML. Erythrocyte precursors in MDS patients have been shown to have decreased sensitivity to erythropoietin. Neutrophils can have decreased myeloperoxidase activity leading to increased risk of infection even when cells are quantitatively normal. Platelets can also have functional defects.¹¹ Progression of MDS to acute leukemia is characterized by a gradual or sudden increase in the blast population with a block in maturation. This progression often is accompanied by the finding of additional chromosome karyotype abnormalities or epigenetic changes.¹⁵

Recent in vitro studies suggest that excessive premature intramedullary cell death of hematologic precursors via apoptosis contributes to ineffective hematopoiesis and peripheral blood cytopenias seen in early MDS. The various gene alterations of the MDS clone result in an intrinsic increase in susceptibility of the clone to apoptosis.² Increased levels of tumor necrosis factor alpha (TNF- α) and other cytokines such as IL-1, IL-6, and IL-8 in the serum and bone marrow of MDS patients have been linked to increased apoptosis of the MDS clone and normal hematopoietic cells.^{2,16} Progression to

leukemia is associated with a reduction in apoptosis, thereby allowing the expansion of the neoplastic clone.¹⁷

SECONDARY MDS

Originally, all MDS cases were classified as idiopathic (primary myelodysplasia). Evidence now indicates that a portion of MDS cases, especially those occurring in patients under 50 years of age, are probably secondary to chemotherapy, radiation therapy (therapy-related myelodysplasia, t-MDS), or exposure to toxic substances, such as benzene.^{18–20} In children, MDS can be associated with predisposing conditions such as constitutional chromosome disorders (e.g., Down syndrome) and immunodeficiency disorders.²¹ Complex karyotypes (presence of three or more different cytogenetic abnormalities) are present in 90% of therapy-related MDS as compared to 10–20% of primary MDS.²

INCIDENCE

MDS occurs primarily in individuals of more than 50 years of age and has a slight male predominance (approximately 60%).¹¹ The risk increases sharply with age. Due to the lack of definition and classification of MDS before 1982, the actual incidence of these disorders has not been accurately assessed by large-scale epidemiological studies. Morbidity and mortality statistics are also lacking, partly because MDS was not included as a separate code in the International Classification of Diseases (ICD) until recently. The difficulty in making correct diagnoses in the early stages of the disease also contributes to unreliable incidence figures. One source estimated the overall incidence as 6–10 cases per 100,000 per year with increasing incidence beyond age 60.² The incidence in persons of more than 70 years has been estimated as 15–50 cases per 100,000 per year.⁹ MDS is more common than AML in patients between 50 and 70 years of age, and the incidence appears to be rising. This rise could be due to an increase in the awareness of MDS on the part of physicians and clinical laboratory professionals, an increased ap-

plication of diagnostic procedures in elderly individuals, and in the number of elderly in the population.⁹

Myelodysplasia is rare in children. Problems in diagnosis can contribute to an underestimation of incidence. The approximate incidence has been reported as 1.0–1.8 cases per million per year.^{12,22} The median age of children at presentation of MDS is about six years, and the male/female ratio is about 1.6:1.

CLINICAL FINDINGS

The most frequent presenting symptoms, fatigue and weakness, are related to an anemia that is nonresponsive to treatment. Less commonly, hemorrhagic symptoms and infection precede diagnosis. These symptoms are related to thrombocytopenia and neutropenia. Many individuals can be asymptomatic, and their disease is discovered on routine laboratory screening.⁴ Infection is a common and life-threatening complication in patients with diagnosed MDS. Neutropenia (<1 × 10⁹/L) and the more aggressive subgroups are associated risk factors for infectious complications.²³ Infection is the most common cause of death. Splenomegaly and/or hepatomegaly are uncommon.

LABORATORY FINDINGS

The MDS present with a range of abnormal morphologic features that can be demonstrated on stained peripheral blood and bone marrow smears. Criteria for classification of MDS into subtypes is presented in a later section of this chapter. Included here are the general hematologic features used to initially define the presence of an MDS (Table 1).²⁴

PERIPHERAL BLOOD

The peripheral blood characteristics of MDS are cytopenias and dysplasia. Findings include anemia, neutropenia, and thrombocytopenia. Anemia is the most consistent finding, which occurs as an isolated cytopenia in 35% of the cases.

★ TABLE 1

Hematologic Abnormalities in Myelodysplastic Syndromes

Findings	Erythroid Series	Myeloid Series	Thrombocyte Series
Peripheral blood	Anemia; macrocytes; oval macrocytes; dimorphism; basophilic stippling; nucleated RBC; Howell-Jolly bodies; sideroblasts; anisocytosis; poikilocytosis; reticulocytopenia	Neutropenia; hypogranulation; abnormal granulation; shift to the left; nuclear abnormalities including pseudo-Pelger-Huët and ring nuclei, monocytosis	Thrombocytopenia, or thrombocytosis; giant forms; hypogranulation; micromegakaryocytes; functional abnormalities
Bone marrow	Megaloblastoid erythropoiesis; nuclear fragmentation and budding; karyorrhexis; multiple nuclei; defective hemoglobinization; vacuolization; ringed sideroblasts	Abnormal granules in promyelocytes; increase in Type I and Type II blasts; absence of secondary granules; nuclear abnormalities; decreased myeloperoxidase; Auer rods in blasts	Micromegakaryocytes; megakaryocytes with multiple, separated nuclei; large mononuclear megakaryocytes; hypogranulation or large abnormal granules in megakaryocytes

Bicytopenia occurs in 30% of the cases and pancytopenia in 19%.²⁴ Less commonly, an isolated neutropenia or thrombocytopenia is found. Dysplastic features of one or more cell lines are typical. Because of the critical importance of recognizing dysplasia in the diagnosis of MDS, smears should be made from samples that have been anticoagulated two hours or less.²⁵ Morphologic changes due to prolonged exposure to anticoagulant can easily be confused with dysplastic changes in cells. Functional abnormalities of hematologic cells are also common.²⁶ Studies show that the higher the degree and number of cytopenias, the worse is the prognosis.²⁷

Erythrocytes

The degree of anemia is variable, but the hemoglobin is generally <10 g/dL. The erythrocytes are usually macrocytic (Figure 1 ■) and less often normocytic. Oval macrocytes similar to those in megaloblastic anemia are frequently present, but patients have normal vitamin B₁₂ and folate levels. A dimorphic anemia with both oval macrocytes or normocytes and microcytic hypochromic cells is also a common initial finding in the refractory anemia with ringed sideroblasts (RARS) subgroup. Reticulocytes show an absolute decrease in number but can appear normal if only the uncorrected or relative number (percent) is reported. In addition to anemia, qualitative abnormalities indicative of dyserythropoiesis are present. These include anisocytosis, poikilocytosis, basophilic stippling, Howell-Jolly bodies, and nucleated erythrocytes. Often hemoglobin F is increased (5–6%) and distributed in a heterogeneous pattern. Acquired hemoglobin H has also been found in MDS.¹² Other erythrocyte changes include altered A, B, and I antigens, enzyme changes, and an acquired erythrocyte membrane change similar but not identical to that found in paroxysmal nocturnal hemoglobinuria (PNH)^{4,12}.

Leukocytes

Neutropenia is the second most common cytopenia observed in MDS. Neutropenia can be accompanied by a shift to the left with the finding of metamyelocytes and myelo-

■ **FIGURE 1** A peripheral blood film of a patient with MDS. Note macrocytic cells, and anisocytosis. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

cytes on the peripheral blood smear. Blasts and promyelocytes can also be present.

Morphologic abnormalities in granulocytes indicative of dysgranulopoiesis are considered a hallmark finding in MDS. Dysgranulopoiesis is characterized by agranular or hypogranular neutrophils, persistent basophilia of the cytoplasm, abnormal appearing granules, hyposegmentation (pseudo-Pelger-Huët) (Figure 2 ■) or hypersegmentation of the nucleus and donut- or ring-shaped nuclei. Care should be taken to distinguish neutrophils with the pseudo-Pelger-Huët anomaly and hypogranulation from lymphocytes and to distinguish neutrophilic-band forms with hypogranulation from monocytes. Neutrophils also can demonstrate enzyme defects, such as decreased myeloperoxidase (MPO) and decreased leukocyte alkaline phosphatase (LAP). In some cases, neutrophils exhibit severe functional impairment, including defective bactericidal, phagocytic, or chemotactic properties. Absolute monocytosis is a common finding even in leukopenic conditions.

Platelets

Qualitative and quantitative platelet abnormalities are often present. The platelet count can be normal, increased, or decreased. Approximately 25% of patients have mild to moderate thrombocytopenia when diagnosed.¹² Giant platelets, hypogranular platelets, and platelets with large fused granules can be seen in the peripheral blood (Figures 3 ■ and 4 ■). Functional platelet abnormalities include abnormal adhesion and aggregation. As a result, platelet function tests can be abnormal.

Micromegakaryocytes

Sometimes circulating **micromegakaryocytes** (small abnormal megakaryocytes), also called *dwarf megakaryocytes*,

■ **FIGURE 2** Peripheral blood film from a patient with MDS showing neutrophils with the pseudo-Pelger-Huët nucleus. One cell's nucleus is peanut shaped and the other is single lobed. The nuclear chromatin is condensed, and the cells contain granules, making identification possible. In many cases, these types of neutrophils are agranular, making differentiation of them from lymphocytes difficult. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

■ **FIGURE 3** A peripheral blood film from a patient with MDS showing large platelets. (Wright-Giemsa stain; 1000× magnification)

can be found in the MDS and myeloproliferative syndromes. Micromegakaryocytes can be difficult to identify and are frequently overlooked unless cytoplasmic tags or blebs are present (Figure 5 ■). Micromegakaryocytes are believed to represent abnormal megakaryocytes that have reduced ability to undergo **endomitosis**. (Megakaryocytes undergo a unique maturation process whereby the DNA content duplicates without cell division, resulting in a polyploid nucleus [endomitosis]). Most micromegakaryocytes have a single-lobed nucleus and are the size of a lymphocyte. Morphologically, they can be confused with lymphocytes but can be distinguished by cytoplasmic tags of one or more platelets attached to a nucleus. Some can have pale blue, foamy, or vacuolated cytoplasm that resembles a nongranular platelet. The nuclear structure is variable, but many cells have very densely clumped chromatin and stain dark blue-black with Wright-Giemsa stain. Others can have a finer, looser chromatin. These cells are also found in the bone marrow.

■ **FIGURE 4** Peripheral blood from a patient with MDS showing large agranular platelet. (Wright-Giemsa stain; 1000× magnification)

■ **FIGURE 5** Micromegakaryocyte in peripheral blood film from a patient with MDS. Note the dense chromatin structure and the irregular rim of cytoplasm with cytoplasmic tags. An agranular platelet in the field matches the appearance of the micromegakaryocyte cytoplasm. (Wright-Giemsa stain; 1000× magnification)

✓ **Checkpoint! 1**

How does the typical peripheral blood picture in MDS differ from that in aplastic anemia?

CASE STUDY (continued from earlier in this chapter)

The results of the CBC on Hancock were:

RBC	$1.60 \times 10^{12}/L$	Differential
Hb	5.8 g/dL (58 g/L)	44% segmented
Hct	0.17 L/L	neutrophils
WBC	$10.5 \times 10^9/L$	7% band
Platelets	$39 \times 10^9/L$	neutrophils
Reticulocyte count	0.8%	6% lymphocytes
		28% eosinophils
		1% metamyelocytes
		1% myelocytes
		9% promyelocytes
		4% blasts

The neutrophilic cells show marked hyposegmentation and hypogranulation. RBC morphology includes anisocytosis and poikilocytosis, teardrop cells, ovalocytes, and schistocytes.

1. In what cell lines is cytopenia present?
2. What abnormalities are present in the differential?
3. What evidence of dyspoiesis is seen in the leukocyte morphology?
4. Calculate the MCV. What peripheral blood findings are helpful to rule out megaloblastic anemia?
5. What features of the differential resemble CML? What helps to distinguish this case from CML?

BONE MARROW

Bone marrow examination is necessary to identify the dyshematopoietic element, to determine cellularity, and to establish a diagnosis. In most cases, the bone marrow is hypercellular with erythroid hyperplasia, although normocellular and hypocellular marrows can occur. The hypercellular bone marrow with a peripheral blood picture of cytopenia is the result of premature cell loss in the marrow (increased apoptosis and ineffective hematopoiesis).¹² The cellularity of the marrow should be interpreted in relation to the patient's age because MDS is commonly found in the elderly. The number of myeloblasts can range from normal to 19% (promonocytes, erythroblasts, promyelocytes, and megakaryoblasts are not included in the blast count). Generally, all cell lines exhibit evidence of dyshematopoiesis.

Bone marrow trephine biopsy can be helpful in establishing the diagnosis of MDS in difficult cases.²⁸ (Trephine biopsy is the removal of a disc of bone using a cylindrical saw.) Abnormal localization of immature myeloid precursors (ALIP) clustering centrally can be seen in biopsy before an increase in myeloblasts is detected in bone marrow smears.²⁹ ALIP has been shown to indicate increased risk for transformation to leukemia and is associated with poor survival. In patients with less than 5% blasts, ALIP can indicate evolution to a more aggressive disease. However, these claims have not been validated in large studies.⁴ A biopsy also gives a better assessment of cellularity and an indication of the amount of reticulin fibers present. On the other hand, ringed sideroblasts, nuclear fragmentation and budding, Auer rods, irregular cytoplasmic basophilia, and abnormal staining of primary granules in promyelocytes are more easily identified in bone marrow aspirate smears. Thus, both aspirate smears and biopsy preparations are necessary for accurate diagnosis.

Dyserythropoiesis

The most common bone marrow finding in MDS is nuclear-cytoplasmic asynchrony similar to that seen in megaloblastic anemia. However, the chromatin is usually hypercondensed. This nuclear chromatin pattern is often described as megaloblastoid (Figure 6 ■). The abnormal erythrocytic maturation is not responsive to vitamin B₁₂ or folic acid therapy. Giant, multinucleated erythroid precursors can be found (Figure 7 ■). Other nuclear abnormalities include fragmentation, abnormal shape, budding, karyohexis, and irregular staining properties. The cytoplasm of erythroid precursors can show defective hemoglobinization, vacuoles, and basophilic stippling. The presence of ringed sideroblasts, reflecting the abnormal erythrocyte metabolism, is a common finding. **Ringed sideroblasts** are defined as erythroblasts in which mitochondrial iron deposits encircle at least one-third or more of the nucleus.

Dysgranulopoiesis

Granulopoiesis is usually normal to increased unless the overall marrow is hypocellular. Abnormal granulocyte matu-

■ **FIGURE 6** Megaloblastoid erythroblasts in the bone marrow of a patient with MDS. Note the condensed chromatin and Howell-Jolly bodies. (Wright-Giemsa stain; 1000× magnification)

ration (dysgranulopoiesis), however, is almost always present (Figure 8 ■). One of the major findings of dysgranulopoiesis in the bone marrow is abnormal staining of the primary granules in promyelocytes and myelocytes. Sometimes the granules are larger than normal and at other times are absent. Secondary granules can be absent in myelocytes and other more mature neutrophils, giving rise to the hypogranular peripheral blood neutrophils. Irregular cytoplasmic basophilia with a dense rim of peripheral basophilia is also characteristic. Nuclear abnormalities similar to those found in the peripheral blood granulocytes can be present in bone marrow granulocytes.

Dysmegakaryopoiesis

Megakaryocytes can be decreased, normal, or increased. The presence of micromegakaryocytes, large mononuclear megakaryocytes, and megakaryocytes with other abnormal

■ **FIGURE 7** Multinucleated polychromatophilic erythroblast in the bone marrow of a patient with MDS. It is also megaloblastoid. (Wright-Giemsa stain; 1000× magnification)

FIGURE 8 Bone marrow from a patient with MDS. Note the metamyelocytes and bands with a lack of secondary granules. The bands have light bluish-pink cytoplasm, and the metamyelocytes have a darker bluish cytoplasm. (Wright-Giemsa stain; 1000× magnification)

nuclear configurations (Figure 9) reflect abnormalities in maturation. The lack of granules or presence of giant abnormal granules is also characteristic.

OTHER LABORATORY FINDINGS

Serum iron is normal or increased, and the TIBC is normal or decreased, distinguishing MDS from IDA (iron-deficiency anemia). Cobalamin (vitamin B₁₂) and folic acid levels are normal to increased, a feature that helps to differentiate MDS with megaloblastoid features from megaloblastic anemias with the typical megaloblastic features.

Immunologic analysis has revealed that MDS is associated with a significant decrease in the total number of T lymphocytes and a decrease in both CD4 and CD8 lymphocyte sub-

sets.³⁰ The responses of T lymphocytes to mitogens, Phytohemagglutinin A, and Concanavalin A can be significantly decreased. Although B lymphocytes are quantitatively normal, serum immunoglobulins are often increased, and circulating immune complexes are frequently present. In addition, granulocytic oxidative metabolism as measured by the nitroblue tetrazolium reduction test can be abnormal and chemotaxis impaired.

Checkpoint! 2

Why is serum vitamin B₁₂, serum folate level, or bone marrow iron stain important in the diagnosis of MDS?

CASE STUDY (continued from earlier in this chapter)

A bone marrow was performed on Hancock. The marrow showed a cellularity of about 75%. There was myeloid hyperplasia with 9% blasts, 26% promyelocytes, 18% myelocytes, 6% metamyelocytes, 4% bands, and 37% eosinophils. The M:E ratio was 12:1. The myelocytes were hypogranular, and some had two nuclei. The erythroid precursors showed megaloblastoid changes. Megakaryocytes were adequate in number but showed abnormal forms with nuclear separation and single nucleated forms.

6. Which of the hematopoietic cell lines exhibit dys-hematopoiesis in the bone marrow?
7. How would you classify the bone marrow cellularity?
8. What does the M:E ratio indicate?
9. Identify at least two features of the bone marrow that are compatible with a diagnosis of MDS.
10. What chemistry tests would be helpful to rule out megaloblastic anemia?

a

b

FIGURE 9 **a.** Abnormal megakaryocyte from a patient with MDS. **b.** Micromegakaryocyte in the bone marrow of a patient with MDS. Note the megaloblastoid features of the surrounding cells. (Both: Bone marrow; Wright-Giemsa stain; 1000× magnification)

▶ BLAST CELL CLASSIFICATION

The blast count appears to be the most important prognostic indicator of survival and progression to acute leukemia in MDS. The maximum number of blasts compatible with a diagnosis of MDS is 19% (<30% in the FAB classification; see below). The minimum criterion for a diagnosis of acute leukemia is at least 20% blasts (>30% in the FAB classification). In MDS, correctly identifying blasts and type and degree of dysplasia is important because these characteristics are the basis of classifying subtypes and differentiating them from AML. Experts recommend performing a 200-cell differential on peripheral blood and identifying at least 500 cells in the bone marrow.²⁵

MORPHOLOGIC IDENTIFICATION OF BLASTS

The dysgranulopoiesis that affects primary azurophilic granules in neoplastic blasts changes the standard criteria for identification and classification of blast cells and promyelocytes. The standard criteria for a blast cell include a cell with a central nucleus with fine nuclear chromatin, prominent nucleoli, a high nuclear:cytoplasmic ratio, and deeply basophilic and agranular cytoplasm. It is now recognized that in MDS and acute leukemia, there are some blast-like cells that contain primary azurophilic granules. These early azurophilic granules do not indicate differentiation but abnormal neoplastic cells.³¹ Consequently, two types of blasts that could be found in the bone marrow and peripheral blood in MDS and AML were recognized: Type I and Type II. More recently, it has been suggested to recognize a third type of blast cell (Type III) in MDS to improve predictions of progression to acute leukemia and survival.³¹ Typical agranular blasts are included in the Type I category. Type II and Type III blasts have typical blast features except that they contain primary azurophilic granules. The following morphologic criteria have been established for identifying Type I blasts, Type II blasts, Type III blasts, and promyelocytes in MDS and acute leukemia.³¹

Type I Blasts

The Type I blast cells (Figure 10a ■) include typical myeloblasts and unclassifiable cells. The nuclear chromatin is finely dispersed with prominent nucleoli. The nuclear cytoplasmic ratio is variable but is higher in the smaller blasts than the larger ones. The cytoplasm contains no granules.

Type II Blasts

Type II blast cells (Figure 10b ■) resemble Type I blasts except that the cytoplasm contains primary granules (fewer than 20) and the nucleus is in a more central position. The nuclear cytoplasmic ratio tends to be lower than that of Type I blasts.

Type III Blasts

These cells are similar to Type II blasts except that they contain more than 20 granules in the cytoplasm (Figure 10c ■).

Promyelocytes

The nucleus is eccentrically placed, and the chromatin pattern is more condensed. The Golgi apparatus is obvious as a clear area adjacent to the nucleus. The nuclear cytoplasmic ratio is lower due to the increase in cytoplasm. Many primary granules are present. In some MDS cases the promyelocyte appears hypogranular or even agranular. In these cases, the abnormal cell can be identified as a promyelocyte by the other nuclear and cytoplasmic criteria. If the azurophilic granules are clumped and heterogeneous in size, the promyelocyte is classified as abnormal.

Using these criteria for distinguishing blasts and promyelocytes, the minimum criteria for a diagnosis of acute leukemia is 20% blasts including any combination of Type I, Type II, and Type III blasts (exclusive of promyelocytes) in the bone marrow. The maximum proportion of blasts compatible with a diagnosis of MDS is 19% including any combination of Type I, Type II, and Type III blasts. Often the blast count in the blood is higher than that in the marrow. It has been suggested that when the blast count exceeds 19% in the blood but the bone marrow concentration is less than 19%, the case should be regarded as acute leukemia. With the exception of subgroup RAEB-2 (refractory anemia with excess blasts, subgroup 2), the blasts in MDS usually do not have Auer rods present.

✓ Checkpoint! 3

Why is it important to correctly identify the number of blasts when evaluating the peripheral blood or bone marrow smear of a patient suspected of having MDS?

CYTOCHEMICAL AND IMMUNOLOGICAL IDENTIFICATION OF BLASTS

Although the blast cells in MDS are derived primarily from myeloid or monocytic precursors, a panel of cytochemical and immunocytochemical reactions should be performed and interpreted to enhance the accuracy of diagnosis.³² Cytochemical stains help to identify the origin of atypical and bizarre dyspoietic cells that are often seen in MDS.⁴ Peroxidase and Sudan black B identify blasts with a myeloid origin; however, in MDS, the blasts can have lower peroxidase activity than normal blasts. Combined esterase stains can be performed on both peripheral blood and bone marrow for a more accurate assessment of monocytic cells. Iron stain can reveal abnormal iron metabolism in erythroblasts with the presence of increased iron stores and ringed sideroblasts. The presence of blocks of PAS-positive material in erythrocyte precursors indicates abnormal carbohydrate metabolism. Abnormal small megakaryoblasts can be difficult to distinguish from lymph-

■ **FIGURE 10** a. Type I myeloblast. b. Type II myeloblast with <20 granules in the cytoplasm. c. Type III myeloblasts with >20 granules. (Both: Peripheral blood; Wright-Giemsa stain; 1000× magnification)

phoblasts or Type I myeloblasts. They can be readily identified, however, by immunochemistry with antibodies against platelet-specific glycoproteins IIb/IIIa (CD41), GPIIIa (CD61) or by antibody against factor VIII in histiologic sections. Diaminobenzidine can be utilized to identify platelet peroxidase in electron micrographs.³²

Immunophenotyping is being used increasingly to aid in diagnosis and prognosis of MDS patients.³³ Immunophenotyping is most useful when marrow morphology and cytogenetics are inconclusive and to distinguish MDS cases with a hypoplastic bone marrow from other bone marrow failure disorders, such as aplastic anemia.³⁴ It has been suggested that increased expression of markers found on immature myeloid cells such as CD13, CD33, CD34, and HLA-DR and decreased expression of NAT-9 (found on mature myeloid cells) can be associated with a worse prognosis and with progression to AML.³⁴⁻³⁶ MDS patients with a low percentage of bone marrow cells expressing CD11b had a higher risk of evolution to AML and shorter survival compared to patients

with more than 53% of marrow cells expressing CD11b.³⁶ CD7-positivity also has been associated with short survival in MDS patients.³⁷ Standardization of methods so that comparable results are obtained by different laboratories must be achieved before surface marker studies can be more fully utilized as diagnostic tools in MDS.^{36,37}

Immunological phenotyping using monoclonal antibodies can be useful in identifying the lineage of blasts in those cases of acute leukemia derived from therapy-related MDS. Many of these cases show trilineage dysplasia and are difficult to define by morphology and cytogenetics.³⁸

► CLASSIFICATION

In 1982, the French-American-British (FAB) group proposed a classification scheme for the myelodysplastic syndromes.³⁹ This classification defined five subgroups based on morphological characteristics, such as the blast count and degree of

dyspoiesis in the peripheral blood and bone marrow. The five subgroups included:

- Refractory anemia (RA)
- Refractory anemia with ringed sideroblasts (RARS)
- Refractory anemia with excess blasts (RAEB)
- Chronic myelomonocytic leukemia (CMML)
- Refractory anemia with excess blasts in transformation (RAEB-t)

Specific criteria for each FAB subgroup are shown in Table 2.

Although the FAB classification system has been the benchmark for diagnosing the MDS for the past two decades, it does not incorporate the newer diagnostic technologies such as cytogenetics and immunophenotyping.^{2,3} In 2001, the World Health Organization (WHO) published a new classification system developed by a group of American and European pathologists, hematologists, and oncologists. This new system incorporates morphology, immunophenotype, and genetics with clinical and prognostic features into a classification of all neoplastic diseases of the hematopoietic and lymphoid tissues. This resulted in significant changes in the classification of the MDS.³

The WHO Classification System criteria for each subgroup of MDS are shown in Table 3. Chronic myelomonocytic leukemia (CMML) was removed from the MDS group of diseases and placed in a newly created category, **myelodysplastic/myeloproliferative diseases (MDS/MPD)** because it has features of both MDS and MPD. RAEB-t was eliminated due to lowering the blast count necessary for a diagnosis of AML from 30% to 20%. It was believed that patients with 20–29% blasts have a prognosis similar to that of patients with ≥30% blasts. Three new categories were added to the WHO classification of MDS: refractory cytopenia with multilineage dysplasia (RCMD), 5q–syndrome, and MDS unclassified (MDS-U). RCMD was created for cases of MDS with less than 5% blasts that have significant dysplasia involving granulocytic and/or megakaryocytic lineages as well as eryth-

rocytic. Recent studies have shown that these cases are more likely to result in death due to bone marrow failure or to progress to acute leukemia than other cases that do not have these distinct features. This category also helps to distinguish these cases from RA and RARS, which typically involve dysplasia in only the erythroid lineage.

Recent studies to evaluate the clinical usefulness of the WHO classification conclude that it clearly identifies more homogenous subgroups and enables clinicians to select the best treatments and better predict prognosis and clinical responses.^{2,4,5} Although at this time both classification systems can be found in clinical practice, most clinicians are adopting the WHO classification system, and it will be followed in this chapter.

▶ DESCRIPTION OF SUBGROUPS OF MDS

The WHO Classification System identifies six MDS subgroups:

- Refractory anemia (RA)
- Refractory anemia with ringed sideroblasts (RARS)
- Refractory cytopenia with multilineage dysplasia (RCMD)
- Refractory anemia with excess blasts (RAEB)
- MDS associated with isolated del(5q–)
- Myelodysplastic syndrome, unclassified (MDS-U)

REFRACTORY ANEMIA

Refractory anemia (RA) occurs with anemia as the primary clinical finding. The anemia is refractory (nonresponsive) to all conventional forms of therapy. Erythrocytes usually appear macrocytic but occasionally are microcytic or normocytic. The peripheral blood shows reticulocytopenia and signs of dyserythropoiesis, but leukocytes and platelets are usually quantitatively and qualitatively normal. Blast cells are usually absent in the peripheral blood, but, if present, they constitute less than 1% of the nucleated cells.

TABLE 2

Differentiating Characteristics of FAB Subtypes of Myelodysplastic Syndromes

Characteristic	RA	RARS	CMML	RAEB	RAEB-t
Blasts in PB (%)	<1	<1	<5	<5	≥5
Blasts in BM (%)	<5	<5	≤20	5–20	21–30 and/or Auer rods
Ringed sideroblasts (%)	<15	≥15	Variable	Variable	Variable
Monos in PB	–	–	>1 × 10 ⁹ /L	–	–
Monos in BM	–	–	≥20%	–	–

RA = refractory anemia; RARS = refractory anemia with ringed sideroblasts; CMML = chronic myelomonocytic leukemia; RAEB = refractory anemia with excess blasts; RAEB-t = refractory anemia with excess blasts in transformation; PB = peripheral blood; BM = bone marrow; monos = monocytes or immature cells of monocytic origin

(Adapted, with permission, from Greer JP, et al. *Wintrobe's Clinical Hematology*, 11th ed., Philadelphia: Lippincott, Williams and Wilkins, 2004; p. 2208.)

★ TABLE 3

World Health Organization Classification Criteria for Myelodysplastic Syndromes

Classification	Peripheral Blood	Bone Marrow
Refractory anemia (RA)	Anemia Rare or no blasts (<1%)	Erythroid dysplasia only <5% blasts <15% ringed sideroblasts
Refractory anemia with ringed sideroblasts (RARS)	Anemia Rare or no blasts (<1%)	>15% ringed sideroblasts Erythroid dysplasia only <5% blasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenias (bicytopenia or pancytopenia) Rare or no blasts No Auer rods <1 × 10 ⁹ /L monocytes	Dysplasia in >10% of the cells of two or more myeloid lineages <5% blasts in marrow No Auer rods <15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)	Cytopenias (bicytopenia or pancytopenia) Rare or no blasts No Auer rods <1 × 10 ⁹ /L monocytes	Dysplasia in >10% of the cells of two or more myeloid lineages <5% blasts in marrow >15% ringed sideroblasts No Auer rods
Refractory anemia with excess blasts 1	Cytopenias <5% blasts No Auer rods <1 × 10 ⁹ /L monocytes	Unilineage or multilineage dysplasia 5–9% blasts No Auer rods
Refractory anemia with excess blasts 2	Cytopenias 5–19% blasts Auer rods present <1 × 10 ⁹ /L monocytes	Unilineage or multilineage dysplasia 10–19% blasts Auer rods present
5q–syndrome	Anemia Usually normal or increased platelet count <5% blasts	Normal to increased mega karyocytes with hypolobulated nuclei <5% blasts Isolated del(5q–) cytogenetic abnormality No Auer rods
Myelodysplastic syndrome, unclassified	Cytopenias Rare or no blasts No Auer rods	Unilineage dysplasia: one myeloid cell line <5% blasts No Auer rods

(Adapted, with permission, from Greer JP, et al. *Wintrube's Clinical Hematology*, 11th ed., Philadelphia: Lippincott, Williams and Wilkins, 2004; p. 2208.)

The bone marrow is hypercellular with erythroid hyperplasia and signs of dyserythropoiesis. Megaloblastoid erythropoiesis is present but unresponsive to folic acid or cobalamin. Ringed sideroblasts are absent or present in low numbers (<15% of erythroblasts). Maturation of neutrophils and megakaryocytes is generally normal. Blast cells compose less than 5% of marrow cells.

Cytogenetic abnormalities are useful in diagnosis and can be observed in up to 25% of cases. However, no specific ab-

normality is associated with this subgroup. Approximately 6% of cases progress to acute leukemia.²⁵

REFRACTORY ANEMIA WITH RINGED SIDEROBLASTS

Refractory anemia with ringed sideroblasts (RARS), or acquired idiopathic sideroblastic anemia (AISA), is similar to RA except that ringed sideroblasts account for more than

15% of the erythroid precursor cells in the bone marrow. The anemia is usually macrocytic but is less often normocytic. Sometimes evidence of a dual population of normochromic and hypochromic cells exists. The peripheral blood shows reticulocytopenia and often leukopenia. The occurrence of leukopenia in one study was 33% with neutropenia occurring in 7%.²⁴ The platelet count occasionally is increased. A few cases exhibit granulocyte and platelet morphologic abnormalities.

The bone marrow is hypercellular with megaloblastoid dyserythropoiesis. If dysgranulopoiesis and dysmegakaryopoiesis are present, it is mild. Fewer than 5% blast cells are in the marrow. Chromosomal abnormalities are seen in less than 10% of cases. Approximately 1–2 % of cases evolve into AML. Secondary causes of ringed sideroblasts, such as exposure to toxic substances, certain drugs, and alcoholism should be ruled out.²⁵

REFRACTORY CYTOPENIA WITH MULTILINEAGE DYSPLASIA

Refractory cytopenia with multilineage dysplasia (RCMD) is a new category established in the WHO classification system for patients with dysplastic features in at least 10% of the cells in two or more cell lines, less than 5% blasts in the bone marrow, and less than 1% blasts in the peripheral blood. Studies have shown that these individuals have a worse prognosis than those with dysplasia in only one cell line and thus a new subgroup was needed.³ They usually display cytopenias in two or more cell lines and have less than $1 \times 10^9/L$ monocytes present in the peripheral blood. Ringed sideroblasts must compose less than 15% of the nucleated red blood cells in the marrow. If more than 15% ringed sideroblasts are present, the case is categorized as **refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)**.²⁵ Chromosomal abnormalities can be present in up to 50% of cases in this category, some being complex. The frequency of evolution to AML is approximately 11%.²⁵

REFRACTORY ANEMIA WITH EXCESS BLASTS

In **refractory anemia with excess blasts (RAEB)**, cytopenia occurs in at least two lineages and conspicuous qualitative abnormalities in all three lineages. The anemia is normocytic or slightly macrocytic with reticulocytopenia. Evidence of dysgranulopoiesis is prominent. The peripheral blood has 0–19% blasts. Monocytosis without leukocytosis can be present, but the absolute monocyte count does not exceed $1 \times 10^9/L$, and serum and urinary lysozyme levels are normal. Platelet abnormalities include giant forms, abnormal granularity, and functional aberrations. Sometimes, circulating micromegakaryocytes can be found.

The bone marrow is hypercellular but less often is normocellular with varying degrees of granulocytic and erythrocytic hyperplasia. All three lineages show signs of dyshe-matopoiesis. The proportion of blasts varies from 5% to 19%. Abnormal promyelocytes can be present. These abnormal cells have blastlike nuclei with nucleoli and no chromatin condensation, and the cytoplasm contains large bizarre granules. Ringed sideroblasts may be increased, but the elevated blast count differentiates RAEB from RARS. In some cases, differentiating RAEB from acute leukemia is difficult. Serial examinations are sometimes necessary to make an accurate diagnosis.

A difference in survival for patients having 5–9% blasts and those having 10–19% blasts has been shown. Those with more than 9% blasts have a worse outcome. The separation of these two groups into RAEB-1 (5–9% blasts in bone marrow, <5% blasts in the peripheral blood) and RAEB-2 (10–19% blasts in the bone marrow, 5–19% blasts in the peripheral blood) provides a more accurate prognostic classification.^{25,31} Cases with 5–19% blasts in the peripheral blood and <10% blasts in the bone marrow are also placed in RAEB-2.²⁵

Between 30–50% of cases show cytogenetic abnormalities, some complex. Immunophenotyping reveals that blasts express one or more myeloid antigens (CD13, CD33, CD117). Approximately 25% of RAEB-1 and 33% of RAEB-2 progress to AML.²⁵

THE 5q-SYNDROME

MDS patients with an isolated deletion of the long arm of chromosome 5 (del 5q or 5q-) and no other chromosomal abnormalities appear to have a unique disease course characterized by a favorable prognosis and low risk of transformation into AML. Women have a marked predominance of cases (70%), and the mean age at presentation is 66 years. The main features are macrocytic anemia, moderate leukopenia, normal to increased platelet count, hypolobulated megakaryocytes, and less than 5% blasts in the peripheral blood and bone marrow.²⁵ The bone marrow is usually hypercellular or normocellular with normal to increased megakaryocytes, some with hyperlobulated nuclei.²⁵ A number of genes coding for hematopoietic growth factors and their receptors are localized on the long arm of chromosome 5. It has been suggested that loss of these genes and/or tumor suppressor genes may be involved in the pathogenesis of this disease.^{11,40}

MDS, UNCLASSIFIABLE (MDS-U)

When the MDS does not fit any of the defined WHO subgroups, it is placed in this category. Blasts in the blood and bone marrow are not increased, and there are no specific morphological findings. Usually neutropenia or

thrombocytopenia is seen. Dysplastic cells can be found in either the neutrophilic or megakaryocytic lineages and can be severe. The bone marrow is usually hypercellular but can be normocellular or rarely hypocellular. No specific cytogenetic findings are present. Cases demonstrating unilineage dysplasia in the granulocytic or megakaryocytic lineages are rare but would be placed in this category.²⁵

CASE STUDY (continued from earlier in this chapter)

Review Hancock's peripheral blood and bone marrow features previously identified.

11. What is the most likely MDS subgroup? Based on what criteria?

▶ VARIANTS OF MDS

A number of patients have blood and/or marrow findings that cause problems in diagnosis and/or classification. Some of these findings occur often enough to consider them as variants of MDS.

HYPOPLASTIC MDS

Although most cases of MDS are associated with hypercellular or normocellular bone marrows, about 10% have hypocellular marrows. In these cases, trephine biopsy is necessary to exclude a diagnosis of aplastic anemia or hypoplastic acute myeloid leukemia (AML). This distinction is important because the diagnosis has an influence on treatment and prognosis.

Hypocellular MDS should be considered when the bone marrow cellularity is less than 30% or less than 20% in patients over 60 years of age.⁴¹ The criteria for MDS must be met in hypoplastic cases as well as the hypercellular or normocellular cases. Dysplasia can be difficult to identify, and dyserythropoiesis has been described in aplastic anemia. Dysmegakaryopoiesis and dysgranulopoiesis, however, are most characteristic of MDS and can be helpful findings. In addition, ALIP, indicating an abnormal bone marrow architecture, is typical of MDS. If present, chromosomal abnormalities help distinguish MDS from aplastic anemia. The distinction of MDS from AML can be made based on the blast count. A count over 19% indicates AML. Although the pathophysiology of hypoplastic MDS is unknown, secretion of inhibitory cytokines by autoreactive or clonal-involved T-cells is believed to suppress normal hematopoiesis.²⁰

MDS WITH FIBROSIS

Mild to moderate fibrosis has been described in up to 50% of patients with MDS; marked fibrosis can be seen in 10–15% of cases.⁴² The incidence of fibrosis appears to be even

higher in therapy-related MDS. If fibrosis is present, other diagnoses including chronic idiopathic myelofibrosis (CIMF), chronic myelogenous leukemia, and acute megakaryoblastic leukemia should be considered and excluded. MDS patients with fibrosis typically have pancytopenia, hypocellular bone marrow with fibrosis, trilineage dysplasia, small megakaryocytes with hypolobulated nuclei, and the absence of hepatomegaly and prominent splenomegaly.^{11,43} The increased fibrosis is thought to be produced by liberation of cytokines such as transforming growth factor- β (TGF- β) and platelet-derived growth factor (PDGF) from dysplastic megakaryocytes.¹²

THErapy-RELATED MYELODYSPLASIA

Myelodysplasia secondary to alkylating chemotherapy and/or radiotherapy for other malignant or nonmalignant diseases is frequently referred to as *therapy-related* or *treatment-related MDS (t-MDS)*. It should be kept in mind, however, that MDS can develop as a second primary disorder unrelated to therapy, especially if MDS develops a very short or a very long time after therapy.

A study of 65 patients with t-MDS or acute leukemia suggests that panmyelosis related to therapy develops in three stages: (1) pancytopenia with myelodysplastic changes and less than 5% blasts, (2) frank MDS, which resembles RAEB, and (3) overt AML.³⁸ Not all stages are found in all patients; some present with overt AML, but others expire from infection, hemorrhage, or other disease before developing MDS or AML. Development of MDS or acute leukemia appears to be related to the duration, amount, and repetition of the therapy as well as the patient's age.

The highest incidence of t-MDS occurs 3–8 years after treatment, and long-term use of DNA alkylating agents appears to present the highest risk.^{4,20} Currently, there is no way to predict which patients will develop MDS after treatment; therefore, posttherapy monitoring is not recommended.⁴

t-MDS tends to have a younger age of onset, an increased frequency and severity of thrombocytopenia, and a higher percentage of patients presenting with RAEB than does primary MDS.⁹ In most cases, the qualitative changes are marked with trilineage involvement, typical of RAEB. The number of blasts, however, is usually less than 5%, typical of RA. Despite the low percentage of blasts, the clinical course of the disease reflects profound marrow failure, and the outcome is very unfavorable (a median survival of 4–6 months).³⁸ About 25% of patients have blast counts of 5–19%, which with the marked qualitative changes in all cell lines, qualify for the RAEB classification. The bone marrow is most often hypercellular or normocellular. The finding of increased megakaryocytes is associated with increased fibrosis. Complex karyotypes are present in the majority of t-MDS cases. Similar to primary MDS, about 30% of t-MDS evolve to acute leukemia.³⁸

CHILDHOOD MDS

Few cases of MDS in children have been reported. This may be due to the lack of a widely accepted classification system and clear diagnostic criteria. Both the FAB and WHO classification systems are based on review of adult cases. A new classification system that allows for the special problems of diagnosis in children and based on WHO criteria has been recently proposed.²² Dysplasia in children with MDS is less pronounced, and the more aggressive subtype (RAEB) predominates; progression to acute leukemia is faster than in adults.²¹ Age of 2 years or less and a hemoglobin F level of 10% or higher are associated with a poor prognosis.¹¹ Cytogenetic abnormalities are seen in approximately 70% of cases, and monosomy 7 is the most common cytogenetic change. Unlike adults, abnormalities of chromosome 7 do not seem to be associated with a poor prognosis in children. One-third of children with MDS suffer from genetic predisposition syndromes, such as trisomy 21 or trisomy 8.⁴⁴ Thus, childhood MDS is believed to have a different etiology and pathogenesis than the adult form and genetic predisposition is a factor.⁴⁴

▶ CYTOGENETICS AND MOLECULAR TESTING

Abnormal karyotypes can be demonstrated in up to 50% of individuals with MDS (Table 4). These are acquired clonal aberrations as are those seen in patients with AML.³⁵ However, the types of chromosomal abnormalities seen in MDS are usually unbalanced (deletions or extra chromosomes) in contrast to the inversions or translocations seen in AML. None of the chromosomal abnormalities seen in MDS are unique to the disease.²⁰ The more frequent cytogenetic

abnormalities involve structural or numeric abnormalities of chromosomes 5 and 7 and trisomy 8.

The most well described and common chromosome defect in MDS is the deletion of the long arm of chromosome 5, known as the 5q-syndrome, discussed previously. Another common abnormality is deletion of the long arm of chromosome 7 (7q-) or deletion of the whole chromosome (-7). The long arm contains the proto-oncogene *ERB-B*, which codes for the epidermal growth factor (EGF) receptor. This abnormality is most common in pediatric MDS.⁴⁵ Trisomy 8 (+8) is found in about 10–15% of the MDS abnormal karyotypes. Chromosome 8 contains the *MYC* proto-oncogene that codes for a nuclear transcription factor.

Adult MDS patients with chromosome aberrations have a worse prognosis than do patients with a normal karyotype and show increased incidence of progression to acute leukemia and complications of marrow failure. The emergence of new abnormal clones is associated with transformation to a more aggressive subgroup of AML.

The t-MDS have more frequent and complex abnormalities than those found in primary MDS. Chromosome changes are almost always present in t-MDS and are usually multiple at diagnosis. The majority of the karyotypic abnormalities include abnormalities of chromosomes 5 and/or 7 either singly or in combination with other abnormalities.⁴⁶ In contrast to primary MDS, the karyotypic aberrations can be extremely variable with no two cells exhibiting the same abnormality.

Examination of the bone marrow for cytogenetic abnormalities is a critical part of the diagnosis and evaluation of the MDS. New techniques such as fluorescence in situ hybridization (FISH) have improved the identification of chromosome abnormalities using specific DNA probes. Certain abnormal karyotypes have been associated with characteristic morphological dysplastic changes. The 5q-syndrome frequently demonstrates hyperlobulated megakaryocytes. Deletion of chromosome 17p has been associated with pseudo-Pelger-Huët cells and small vacuolated neutrophils. Cytogenetic-morphological correlations can become more and more useful to help distinguish subgroups of MDS in the future.²⁵

Molecular diagnostic techniques are also becoming important tools for identifying genetic abnormalities that can aid in more reliable classification and treatment of these diseases. Gene profiles are being studied using microarray analysis. Thousands of genes can be analyzed simultaneously to eventually identify gene profiles that can help identify the subgroups of MDS and lead to more effective treatment. For example, researchers in one study were able to differentiate between AML blasts and MDS blasts by their gene profiles. Deltalike gene (*DLK*), *TEC* gene, and inositol 1,2,5-triphosphate receptor type 1 gene were among the genes highly specific for MDS.² Presently, the only specific gene mutation known to be common in MDS patients is a point mutation in the oncogene *RUNX/AML1*. It is found in

TABLE 4

Most Frequent Cytogenetic Abnormalities in MDS Patients

Numerical	Translocations	Deletions
+8 (19%)	inv 3 (7%)	del 5q (27%)
-7 (15%)	t(1;7) (2%)	del 11q (7%)
+21 (7%)	t(1;3) (1%)	del 12q (5%)
-5 (7%)	t(3;3) (1%)	del 20q (5%)
	t(6;9) (<1%)	del 7q (4%)
	t(5;12) (<1%)	del 13q (2%)

+ = additional chromosome; - = loss of chromosome; inv = inversion; t = translocation; del = deletion; % = frequency of chromosomal aberration

up to 50% of patients depending on the karyotype, prior radiation exposure, and subtype of MDS.⁴ Gene patterns associated with alterations of specific cellular pathways or signal cascades are also being studied in an effort to develop drugs to intervene with these alterations.² In the future, the MDS as well as acute leukemias will be classified according to specific molecular genetic abnormalities along with the corresponding clinical symptoms.

► **PROGNOSIS**

The median survival for all types of MDS is less than 2 years; however, some patients can survive many years with continuous transfusion therapy. The mortality rate varies from 58% to 72%. Leukemic transformation ranges in incidence from 10% to 40%.⁴⁷ The likelihood of transformation to AML increases with the presence of severe cytopenias, more overt dysplastic features of cells, and complex chromosome abnormalities.¹²

The International Prognostic Scoring System (IPSS)^{48,49} (Table 5) was developed in 1997 to assist physicians in predicting prognosis and selection of optimal therapy for this heterogeneous group of disorders.⁵⁰ This system was developed using data from seven large studies that had previously generated prognostic systems and is accepted worldwide. The major variables having an impact on disease outcome and risk of evolution to acute leukemia were:

- Cytogenetic abnormalities
- Percentage of blasts in the bone marrow
- Number of cytopenias.

With these three variables, patients can be divided into four risk groups with distinct risks of death and leukemic

transformation. Low scores indicate prolonged survival. The IPSS complements the WHO classification system, and both can be useful when counseling patients. One criticism of the IPSS is that it does not include secondary MDS cases, such as t-MDS.⁴ Even though it has some disadvantages, the IPSS has been extensively validated in independent patient populations and has become a benchmark for clinical trials and clinical decision making.⁵¹

CASE STUDY (continued from earlier in this chapter)

The patient's karyotype showed multiple complex abnormalities.
12. Using the IPSS, what is the prognosis for this patient?

► **THERAPY**

In patients with pancytopenia, morbidity is associated with infection, bleeding, and anemia. The most common causes of death are hemorrhage and infection. Supportive care includes transfusions with leukocyte-depleted erythrocytes and platelets and prophylactic or curative antibiotic therapy. Hematopoietic cytokines and growth factors are sometimes effective supportive treatment for MDS. Studies with GM-CSF, G-CSF, and IL-3 show that the growth factors improve the neutrophil count in most cases.⁵² Erythropoietin is effective in some patients, leading to decreased requirement for red cell transfusions. A combination of erythropoietin and either G-CSF or GM-CSF appears to have a synergistic effect in MDS patients, resulting in an increased response rate when given in combination.^{11,20} Stimulation of megakaryopoiesis is least successful.⁵³ Use of cytokines that stimulate

★ **TABLE 5**

International Prognostic Scoring System (IPSS) for the Myelodysplastic Syndromes						
Score Value	Cytopenias	BM Blasts (%)	Karyotype	Total Score	Risk Group	Median Survival (Years)

platelet production (IL-11) has had variable results. More studies are needed using combinations of growth factors.

Patients with poor prognosis can be treated more aggressively with AML-type chemotherapeutic regimens. Only about one-third of patients in this risk category can endure high-intensity therapy because of their increased age. Almost all patients who respond to this type of therapy and achieve remission relapse in a short period of time. Only about 5% are alive at 3 years, but there are a few long-term responders.⁴

Bone marrow transplant is the only curative treatment available and is the treatment of choice for those 55–60 years of age or younger. Allogeneic stem-cell transplantation has been the most successful procedure for medically appropriate patients with HLA-matched donors.¹¹ The overall long-term disease-free survival is 60% in low risk patients, 40% for those in the intermediate risk category, and 20% for high-risk individuals.²⁰

A better understanding of the pathophysiology of MDS has led to the development of unique drugs that target both the MDS cell and its interactions with the abnormal marrow microenvironment. Hypomethylating agents (to reactivate silenced genes), immunomodulatory drugs, and farnesyl-transferase inhibitors (which inhibit RAS activation and function) have produced promising results in terms of response and survival in MDS patients.⁵⁴ A more thorough review of these new agents can be found on the website.

► **MYELOYDYSPLASTIC/
MYELOPROLIFERATIVE
DISEASES (MDS/MPD)**

The category of MDS/MPD diseases is new in the WHO classification and is not found in the FAB classification system. It includes clonal hematopoietic neoplasms that, at the time

of initial presentation, have some clinical, laboratory, or morphologic findings of both a MDS and a MPD.²⁵ Typically, patients with MDS/MPD have a hypercellular bone marrow associated with proliferation in one or more of the myeloid lineages. Frequently, the proliferation is effective and results in increased numbers of circulating cells. However, these cells commonly are morphologically and functionally dysplastic. While one or more lineages can show hyperproliferation, one or more other lineages can exhibit ineffective proliferation and resulting cytopenia(s). The percentage of blasts in the bone marrow and peripheral blood is always <20%. Splenomegaly and hepatomegaly are commonly found, but the clinical presentation is highly variable. The disorders included in MDS/MPD are listed in Table 6.

The major clinical and laboratory findings in MDS/MPD disorders are due to abnormalities in the regulation of myeloid proliferation, maturation, and cell survival. Clinical symptoms can be due to cytopenia(s) when present, dysplastic cells that do not function properly, and leukemic infiltration of various organs. At present, there are no identified genetic defects specific for any of the entities included in this category. However, recurring chromosomal and molecular abnormalities have been described (see table below). The incidence varies widely depending on the specific disease as do the prognosis and tendency for clonal evolution and disease progression (see following sections on subgroups).

**CHRONIC MYELOMONOCYTIC
LEUKEMIA (CMML)**

Chronic myelomonocytic leukemia (CMML) is a clonal hematopoietic neoplasm associated with a persistent monocytosis (> 1 × 10⁹/L in the peripheral blood) (Figure 11). The blood or bone marrow has <20% blasts. Determination of the percentage of blasts includes myeloblasts,

★ TABLE 6

The Myelodysplastic/Myeloproliferative Diseases (MDS/MPD)

Classification	Peripheral Blood	Bone Marrow	Genetics	Immunophenotype
Chronic myelomonocytic leukemia (CMML-1)	Monocytosis >1 × 10 ⁹ /L; <5% blasts	<10% blasts; dysplasia of ≥1 myeloid lineages	Absence of Ph chromosome, <i>BCR/ABL1</i>	CD33, CD13 +; CD14, CD68, CD64 +; lysozyme +
CMML-2	5–19% blasts	10–19% blasts	(same as CMML-1)	(same as CMML-1)
Atypical chronic myeloid leukemia (aCML)	Leukocytosis (<10% monocytes); <5% blasts; promyelocytes, myelocytes, metamyelocytes 10–20%	Hypercellular; <20% blasts; dysgranulopoiesis; occasionally dyserythropoiesis	Absence of Ph chromosome, <i>BCR/ABL1</i> neg	CD33, CD13 +; MPO +
Juvenile myelomonocytic leukemia (JMML)	Monocytosis >1 × 10 ⁹ /L; <20% blasts	Hypercellular; <20% blasts; dysgranulopoiesis; occasionally dyserythropoiesis	Absence of Ph chromosome, <i>BCR/ABL1</i> neg	CD33, CD13 +; CD14, CD68, CD64 +; lysozyme +
Myelodysplastic/ myeloproliferative disease, unclassifiable (MDS/MPD-u)	Anemia, leukocytosis and/or thrombocytosis; <20% blasts	Hypercellular; proliferation is any or all myeloid lineages	Absence of Ph chromosome, <i>BCR/ABL1</i> neg	Nondiagnostic

■ **FIGURE 11** Increased monocytes in the peripheral blood from a patient with CMML. (Wright stain; 1000 \times magnification)

monoblasts, and promonocytes. Usually dysplasia involving one or more myeloid lineages is present. Most patients with CMML are older than 50 years (median age at diagnosis ~70 years) with an annual incidence of ~3/100,000. Median survival time is 20–40 months, and progression to acute leukemia is seen in 15–30% of cases. The cell of origin is believed to be the HSC.

In approximately 50% of patients, the WBC count is normal or slightly decreased with monocytosis and neutropenia (more myelodysplastic in presentation). In the remaining patients, the WBC count is increased at the time of diagnosis (more myeloproliferative in presentation). Splenomegaly and hepatomegaly are more common in patients with an elevated WBC count. The liver, spleen, skin, and lymph nodes are common sites of extramedullary leukemic infiltration.

Peripheral blood monocytosis is always present and can range from 2 to 80 $\times 10^9/L$. The monocytes are generally morphologically normal mature cells. They occasionally exhibit abnormal granulation, unusual nuclear lobulation, or dispersed chromatin. If blasts and promonocytes account for $\geq 20\%$ of the WBC, the diagnosis is AML rather than CMML. If the WBC count is increased, accompanying neutrophilia with $< 10\%$ neutrophil precursors (promyelocytes, myelocytes) are often present. Mild basophilia and occasionally mild eosinophilia are sometimes present. Dysgranulopoiesis (hypolobulated, abnormal granulation) is present in most cases but usually is less prominent in patients with leukocytosis. Mild normocytic (occasionally macrocytic) anemia is usually present. Although platelet counts vary, moderate thrombocytopenia is usually present with occasional atypical, giant forms.

The bone marrow is usually hypercellular ($> 75\%$ of patients) but occasionally is normocellular or hypocellular. Cytochemistry (both specific and nonspecific esterase stains) could be necessary to identify both the myelocytic and mono-

cytic cells. Dysgranulopoiesis similar to that found in the peripheral blood and dyserythropoiesis (megaloblastoid changes, ringed sideroblasts) are found in more than 50% of the patients. Micromegakaryocytes are common. Variable fibrosis is seen in the marrow of ~30% of patients.

The WHO classification recommends that CMML be further divided into two subcategories depending on the number of blasts in the peripheral blood and bone marrow. CMML-1 is defined as $< 5\%$ blasts in the blood and $< 10\%$ in the marrow. CMML-2 is defined as 5–19% blasts in the blood or 10–19% in the marrow. An additional subset, CMML with eosinophilia, has been described; in addition to the criteria for CMML, it includes a peripheral blood eosinophil count of $> 1.5 \times 10^9/L$.

Clonal cytogenetic abnormalities are found in 20–40% of patients, but none is specific. The most frequently reported abnormalities include +8, -7/del(7q), structural abnormalities of 12p, and isochromosome 17q [i(17q)]. Point mutations of the RAS protooncogenes are found in ~40% of patients. The Philadelphia chromosome and BCR/ABL fusion gene are absent.

ATYPICAL CHRONIC MYELOID LEUKEMIA (ACML)

Atypical chronic myeloid leukemia (aCML) is a variant of MDS/MPD characterized by primary involvement of the neutrophil series with leukocytosis involving immature and mature neutrophils that are dysplastic. Multilineage dysplasia is common. The peripheral blood and bone marrow are always involved. While splenic and hepatic involvement are also common, skin infiltration is not. Most patients with aCML are older with the median age at diagnosis in the 7th to 8th decade and an annual incidence of ~3/100,000. Median survival time is < 20 months, and progression to acute leukemia is seen in 25–40% of cases. The cell of origin is believed to be the common myeloid progenitor cell (CMP).

The peripheral blood WBC is variable, generally ranging from 35–96 $\times 10^9/L$, although counts in excess of 300 $\times 10^9/L$ have been reported. Blasts are usually $< 5\%$, and always $< 20\%$ of the peripheral blood white cells. Immature neutrophils (promyelocytes, myelocytes, and metamyelocytes) are usually 10–20% of the white cell differential. A mild monocytosis and basophilia occasionally are present. Dysgranulopoiesis can be pronounced, including acquired Pelger-Huët and other nuclear abnormalities as well as abnormal cytoplasmic granularity. Moderate anemia is frequent and can show dyserythropoietic changes including macro-ovalocytosis. The platelet count is variable but is often thrombocytopenic.

The bone marrow is usually hypercellular due to the granulocytic proliferation. Blasts account for $< 20\%$ of the marrow cells. Dysgranulopoiesis is a constant finding while dyserythropoiesis is variable. The M:E ratio usually is $> 10:1$. Megakaryocytes can be increased, decreased, or normal in

number and occasionally are dysplastic. Increased fibrosis is seen occasionally. Immunophenotype and cytochemistry results are typical for the neutrophil lineage although leukocyte alkaline phosphatase (LAP) scores can be elevated, normal, or low.

Up to 80% of patients with aCML have been reported to have cytogenetic abnormalities, but none is specific. Reported cytogenetic abnormalities include +8, +13, del(20q), i(17q), and del(12p). The Philadelphia chromosome and *BCR/ABL* fusion gene are absent.

JUVENILE MYELOMONOCYTIC LEUKEMIA (JMML)

Juvenile myelomonocytic leukemia (JMML) is a clonal hematopoietic neoplasm of childhood characterized by proliferation of the granulocytic and monocytic lineages. Erythroid and megakaryocytic abnormalities are also frequently present. Myelomonocytic proliferation is evident in the blood and bone marrow. The liver, spleen, skin, lymph node, and respiratory tract can have leukemia infiltration. The annual incidence of JMML is 0.13/100,000 children (age 0–14 years of age). JMML accounts for <2–3% of all leukemia in children. The age at diagnosis is variable (from 1 month to early adolescence), but 75% of cases are diagnosed in children <3 years of age. A significant association of JMML with neurofibromatosis type 1 (NF-1) exists with ~10% of cases of JMML occurring in children with this diagnosis. The cell of origin is believed to be the HSC. The overall prognosis is poor with median survival times of 5 months to >4 years; the prognosis varies inversely with patient age at diagnosis. Most children die from organ failure due to leukemic infiltration; only 10–20% progress to acute leukemia.

JMML is characterized by a peripheral blood monocytosis ($>1 \times 10^9/L$) with <20% blasts (including promonocytes). Leukocytosis ($25\text{--}100 \times 10^9/L$), anemia, and often thrombocytopenia usually occur. Both immature neutrophils and monocytes can be present. Eosinophilia and basophilia rarely are observed.

The bone marrow is usually hypercellular with granulocytic and monocytic proliferation. Rare patients have a significant increase in erythroid precursors. Monocytes can account for 5–30% of the marrow cells. Blasts (myeloblasts, monoblasts, and promonocytes) account for <20% of the marrow cells (Auer rods are never seen). Evidence of dyspoiesis includes pseudo-Pelger-Huët, hypogranularity of the neutrophils, and megaloblastoid erythroblasts but rarely megakaryocytic dysplasia.

Cytochemistry and immunophenotype results are as expected for the mixed granulocytic and monocytic cell population. Cytogenetic abnormalities occur in 30–40% of patients, but none are specific for JMML. The Ph chromosome and *BCR/ABL* fusion gene are absent. Point mutations of *RAS* are reported in the neoplastic cells of 20% of patients.

MYELOYDYSPLASTIC/ MYELOPROLIFERATIVE DISEASE, UNCLASSIFIABLE (MDS/MPD-u)

This subcategory, MDS/MPD-u is used for cases that have clinical, laboratory, and morphologic features that support a diagnosis of both MPD and MDS but do not meet the criteria of the other entities included in the MDS/MPD category. Typically, the patient has the clinical, laboratory, and morphologic features of one of the categories of MDS (RA, RARS, RCMD, RAEB) with <20% blasts in the blood and bone marrow and prominent myeloproliferative features associated with either thrombocytosis or leukocytosis. The bone marrow and peripheral blood are always involved; extramedullary tissues (liver, spleen) are sometimes also involved. Blasts account for <20% of the nucleated cells of the marrow and peripheral blood.

The disorders categorized as MDS/MPD-u are characterized by the proliferation of one or more of the myeloid lineages that are ineffective and/or dysplastic. Proliferation of the other myeloid lineages is generally effective with or without dysplasia. Anemia (with or without macrocytosis) usually occurs, occasionally with a dimorphic population of RBC. The bone marrow is hypercellular and can show proliferation in any or all of the myeloid lineages. Dysplastic features are present in at least one lineage.

No cytogenetic or molecular genetic findings are specific for this group. The presence of the Ph chromosome and *BCR/ABL* fusion gene must always be excluded.

SUMMARY

The myelodysplastic syndromes are pluripotential hematopoietic stem cell disorders characterized by one or more peripheral blood cytopenias and prominent cellular maturation abnormalities. The bone marrow is usually normocellular or hypercellular, indicating a high degree of ineffective hematopoiesis. Proto-oncogene mutations are commonly found in patients with MDS indicating that oncogenes most likely play a role in the pathogenesis of MDS.

Although anemia is the most common cytopenia, neutropenia and thrombocytopenia also occur. Erythrocytes are macrocytic or less frequently normocytic. Erythropoiesis in the bone marrow is abnormal with megaloblastoid features commonly present. Neutrophils can show hypolobulation of the nucleus and hypogranulation. Megakaryocytes also show megaloblastoid features and hypolobulation of the nucleus. Platelets can be large and agranular.

The WHO group has classified the MDS into six subgroups depending on the blast count, degree of dyspoiesis and cytopenias, and presence of abnormal cytogenetic findings. These include RA, RARS, RCMD, RAEB, 5q-syndrome and MDS-unclassified. Subgroups with higher blast counts and involvement of multiple lineages in dyspoiesis and complex cytogenetic abnormalities are more aggressive disorders. MDS frequently terminate in acute leukemia. Treatment is primarily supportive unless the patient is a candidate for a bone marrow transplant.

The myelodysplastic/myeloproliferative category (MDS/MPD) includes disorders that have features of both a myeloproliferative and a myelodysplastic disorder simultaneously. This category includes

CMML, JMML, aCML, and MDS/MPD-unclassifiable. An important diagnostic consideration is absence of the Ph chromosome or *BCR/ABL1* fusion gene in these patients.

REVIEW QUESTIONS

LEVEL I

1. In addition to the number of blasts, what other criterion is essential for a diagnosis of RARS? (Objective 2)
 - a. $\geq 15\%$ ringed sideroblasts
 - b. $\geq 30\%$ ringed sideroblasts
 - c. dyshematopoiesis in all three cell lineages
 - d. pancytopenia
2. A patient with suspected MDS exhibits anemia, neutropenia, anisocytosis, poikilocytosis, oval macrocytes, Howell-Jolly bodies, hypogranular neutrophils, and a few pseudo-Pelger-Huët cells. The differential shows a few immature granulocytes but no blasts. Which MDS subgroup would be most likely? (Objective 2)
 - a. RA
 - b. RARS
 - c. RCMD
 - d. RAEB
3. The WHO classification system incorporates: (Objective 2)
 - a. the presence of cellular dysplasia
 - b. cytogenetics
 - c. morphology
 - d. all of the above
4. The type of anemia usually seen in MDS is: (Objective 1)
 - a. macrocytic, normochromic
 - b. normocytic, normochromic
 - c. microcytic, hypochromic
 - d. normocytic, hypochromic
5. The most common cytopenia(s) seen in MDS is(are): (Objective 3)
 - a. leukopenia
 - b. thrombocytopenia
 - c. anemia
 - d. a combination of two of the above
6. The typical bone marrow cellularity in MDS is: (Objective 3)
 - a. hypocellular
 - b. normocellular
 - c. hypercellular
 - d. fibrotic
7. Atypical CML is classified as: (Objective 5)
 - a. MDS
 - b. AML
 - c. MPD
 - d. MDS/MPD

LEVEL II

1. According to the WHO classification system, what is the minimum percentage of bone marrow blasts needed for a diagnosis of acute leukemia? (Objective 4)
 - a. 19%
 - b. 30%
 - c. 5%
 - d. 20%
2. The t-MDS differ from primary MDS in that t-MDS: (Objective 6)
 - a. are usually the less aggressive subgroup
 - b. have more peripheral blood blasts
 - c. have fewer and less complex abnormal karyotypes
 - d. usually have a younger age of onset
3. Progression of MDS to acute leukemia is characterized by: (Objective 4)
 - a. an increase in blast population
 - b. decreased bone marrow cellularity
 - c. a decreased M:E ratio
 - d. splenomegaly
4. A cell resembling a blast that contains 18 primary granules and a centrally located nucleus would be classified as a: (Objective 2)
 - a. Type I blast
 - b. Type II blast
 - c. Type III blast
 - d. promyelocyte
5. The contrast between a hypercellular bone marrow and a cytopenic peripheral blood film seen in MDS is attributed to: (Objective 1)
 - a. premature destruction of abnormal cells in the bone marrow (ineffective hematopoiesis)
 - b. production of blood cells outside the bone marrow (extramedullary hematopoiesis)
 - c. immune destruction of cells in the peripheral blood
 - d. splenic sequestration
6. Which of the following would be most helpful to differentiate RA from 5q-syndrome? (Objective 10)
 - a. percentage of bone marrow blasts
 - b. elevated leukocyte count
 - c. presence of nucleated RBCs
 - d. karyotype

REVIEW QUESTIONS *(continued)*

LEVEL I

8. The most common dyserythropoietic finding in the bone marrow in MDS is: (Objective 3)
 - a. megaloblastoid development
 - b. impaired hemoglobinization
 - c. pseudo–Pelger-Huët cells
 - d. agranular cytoplasm
9. Which abnormality demonstrates myelocytic dysplasia? (Objective 3)
 - a. dimorphism
 - b. pseudo–Pelger-Huët cells
 - c. sideroblasts
 - d. all of the above
10. This group of neoplasms is characterized by a hypercellular bone marrow, effective proliferation of one or more myeloid lineages but morphologically and functionally dysplastic cells. (Objective 4)
 - a. MDS
 - b. MPD
 - c. MDS/MPD
 - d. AML

LEVEL II

7. The most effective treatment for MDS is currently considered to be: (Objective 3)
 - a. chemotherapy
 - b. immunotherapy
 - c. hematopoietic growth factors
 - d. bone marrow transplant

Use the following case history to answer questions 8–10.

A patient presents with the following laboratory data:

RBC	$2.30 \times 10^{12}/L$
Hgb	7.8 g/dL (78 g/L)
Hct	0.24 L/L
MCV	104 fL
RDW	20
WBC	$8.5 \times 10^9/L$
PLT	$140 \times 10^9/L$

The differential was normal except for 2% metamyelocytes. Oval macrocytes, a few abnormal NRBC, and a few siderocytes were seen. The bone marrow contained 3% blasts and exhibited hypercellularity with megaloblastoid development in erythroid cells.

8. What is the most probable MDS subgroup? (Objective 10)
 - a. RA
 - b. RARS
 - c. RCMD
 - d. RAEB
9. What other hematologic disorder does this peripheral blood picture resemble? (Objective 7)
 - a. aplastic anemia
 - b. megaloblastic anemia
 - c. iron-deficiency anemia
 - d. anemia of chronic disease
10. What laboratory test(s) would be helpful to distinguish MDS from megaloblastic anemia? (Objective 7)
 - a. serum lysozyme
 - b. serum ferritin
 - c. serum folate and vitamin B₁₂
 - d. combined esterase stain

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Hancock had bicytopenia (anemia and thrombocytopenia) with a shift to the left and dysplastic erythrocyte and granulocyte features. The bone marrow was hypercellular with an increased M:E ratio. There was trilineage dysplasia. Based on the WHO criteria for subgrouping the MDS, he most probably has RAEB.

The results of the CBC on Hancock were:

RBC: $1.60 \times 10^{12}/L$

Hb: 5.8 g/dL

Hct: 0.17 L/L

WBC: $10.5 \times 10^9/L$

Platelets: $39 \times 10^9/L$

Reticulocyte count: 0.8%

Differential: 44% segmented neutrophils
7% band neutrophils
6% lymphocytes
28% eosinophils
1% metamyelocytes
1% myelocytes
9% promyelocytes
4% blasts

The neutrophilic cells show marked hyposegmentation and hypogranulation. RBC morphology included anisocytosis and poikilocytosis, teardrop cells, ovalocytes, and schistocytes.

Question:

1. Cytopenia is present in what cell lines?

Explanation:

Cytopenia is present in the erythrocytic and megakaryocytic cell lines (RBCs and platelets are decreased).

Question:

2. What abnormalities are present in the differential?

Explanation:

The abnormalities present in the differential are a shift to the left including metamyelocytes, myelocytes, promyelocytes, and a few blasts as well as a marked increase in eosinophils.

Question:

3. What evidence of dyspoiesis is seen in the leukocyte morphology?

Explanation:

Hyposegmentation and hypogranulation in the leukocyte morphology are evidence of dyspoiesis.

Question:

4. Calculate the MCV. What peripheral blood findings are helpful to rule out megaloblastic anemia?

Explanation:

The MCV is calculated as 106 fL ($170/1.6$). The following peripheral blood findings help to rule out megaloblastic anemia: hyposegmentation of neutrophils rather than hypersegmentation, WBC count slightly elevated rather than decreased as is typical in megaloblastic anemia, and shift to the left with blasts that is not characteristic of megaloblastic anemia.

Question:

5. What features of the differential resemble CML? What helps to distinguish this case from CML?

Explanation:

Increased eosinophils and all stages of granulocytes in the peripheral blood are found in both MDS and CML. However, the WBC count is too low for typical CML; the RBC and platelet counts are not usually decreased to this extent in CML.

Question:

6. Which of the hematopoietic cell lines exhibit dyshematopoiesis in the bone marrow?

Explanation:

All three cell lines (myeloid, erythroid, and megakaryocytic) exhibit dyshematopoiesis in the bone marrow.

Question:

7. How would you classify the bone marrow cellularity?

Explanation:

The bone marrow shows increased cellularity for a 65 year old; normal cellularity for a 65 year old would be approximately 35%.

Question:

8. What does the M:E ratio indicate?

Explanation:

The M:E ratio indicates myeloid hyperplasia; a normal M:E ratio is 3:1 or 4:1.

Question:

9. Identify at least two features of the bone marrow that are compatible with a diagnosis of MDS.

Explanation:

Features in the bone marrow compatible with a diagnosis of MDS are increased blasts in the bone marrow (<20%), dyserythropoiesis, dysleukopoiesis, dysmegakaryopoiesis, and hypercellularity.

Question:

10. What chemistry tests would be helpful to rule out megaloblastic anemia?

Explanation:

Testing for vitamin B₁₂ and folate levels would be helpful to rule out megaloblastic anemia; values should be normal to increased, not decreased as would be seen in megaloblastic anemia. Early megaloblastic changes may be detected by testing for methylmalonic acid (MMA) and homocysteine levels. These components are intermediaries in folate and vitamin B₁₂ metabolism and are elevated early in functional vitamin deficiencies.

Question:

11. What is the most likely MDS subgroup based upon what criteria?

Explanation:

The most likely MDS subgroup is RAEB1 based upon the following criteria: <5% blasts in the peripheral blood, 5–19% blasts in the bone marrow, cytopenia in at least two cell lines, and qualitative abnormalities in all cell lines.

Question:

12. Using the International Prognostic Scoring System (IPSS), what is the prognosis for this patient?

Explanation:

Use of the International Prognostic Scoring System (IPSS) on this patient is 2 cytopenias = 0.5; 12% blasts in bone marrow = 1.5; complex karyotype with multiple abnormalities = 1.0. Total = 3.0 (high risk—median survival 0.4 year).

ANSWERS TO CHECKPOINTS

Checkpoint! 1

How does the typical peripheral blood picture in MDS differ from aplastic anemia?

Answer

The typical blood picture in aplastic anemia is pancytopenia, a significant decrease in all three cell populations (∞ Chapter 13). In MDS, cytopenia is present in the peripheral blood in one cell line or more. Pancytopenia has been estimated to occur in only 19% of cases of MDS. Both MDS and aplastic anemia can be macrocytic. MDS exhibits more frequent qualitative abnormalities indicating dyspoiesis, such as anisocytosis, poikilocytosis, basophilic stippling, Howell-Jolly bodies, and nucleated RBCs. The neutrophils often show abnormal granulation and pseudo-Pelger-Huët cells. Giant and hypogranular platelets may be seen. The bone marrow is the best way to differentiate the two syndromes. A hypoplastic bone marrow is typical in aplastic anemia. MDS usually shows a hypercellular marrow, but if it is hypocellular, it may be difficult to differentiate from aplastic anemia.

Checkpoint! 2

Why is serum vitamin B₁₂, serum folate level, or bone marrow iron stain important in the diagnosis of MDS?

Answer

Some features of the blood picture in MDS resemble the megaloblastic anemias (macrocytosis, megaloblastoid changes in erythrocytic precursor cells). A normal serum vitamin B₁₂ and/or folate level rule out megaloblastic anemia. An iron stain on the bone marrow allows assessment of the presence of ringed sideroblasts, which may be seen in RA and are necessary for a diagnosis of RARS.

Checkpoint! 3

Why is it important to correctly identify the number of blasts when evaluating the peripheral blood or bone marrow smear of a patient suspected of having MDS?

Answer

The number of blasts is used to classify the MDS into different subtypes and to predict prognosis and treatment. It is also used to differentiate MDS from acute leukemia.

Acute Myeloid Leukemias

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Basic Biology of AML
- ▶ Laboratory findings
- ▶ Classification
- ▶ Therapy
- ▶ Summary
- ▶ Review questions
- ▶ References

Acute Myeloid Leukemias

Susan J. Leclair, Ph.D.
J. Lynne Williams, Ph.D.

■ OBJECTIVES—LEVEL I

By the end of this unit of study, the student should be able to:

1. Define *acute leukemia*, and explain the difference between acute myeloid leukemia (AML) acute lymphoblastic leukemia (ALL) and myelodysplastic syndrome (MDS).
2. List and define the common variants of AML as defined by the WHO classification.
3. Describe and recognize the typical peripheral blood picture (erythrocytes, leukocytes, and thrombocytes) seen in AML.
4. Describe the M:E ratio in bone marrow in acute leukemia (AL).
5. Give the typical results of cytochemical stains in AML.
6. Identify Auer rods and describe their significance.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Compare and contrast the various presentations of AML.
2. Predict the most likely leukemia type based on patient history, physical assessment, and laboratory findings.
3. Correlate cellular presentation of AML with prognosis and common complications.
4. Correlate Wright-stain morphology of the AML subgroups with cytochemical stains, flow cytometry, and genetic testing.
5. Evaluate peripheral blood results in relation to oncological therapy (i.e., complete or partial remission, relapse, engraftment).
6. Evaluate patient data from the medical history and laboratory results to determine whether a disorder can be classified, and, if not, specify the additional testing to be performed.
7. Compare the WHO and FAB classifications of AML.

KEY TERMS

Acute leukemias (AL)
 Auer rods
 Biphenotypic leukemia
 FAB classification
 Faggot cells
 CD33, CD13, CD34
 CD10, CD19, CD20, CD22
 CD2, CD3, CD5, CD7
 Mixed lineage leukemia
 Pseudo-Pelger-Huët cell
 WHO classification

BACKGROUND BASICS

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review and have an understanding of these concepts before starting this unit of study.

Level I

- ▶ Describe the origin and differentiation of hematopoietic cells.
- ▶ Summarize the leukocyte's maturation, differentiation, and function.
- ▶ Outline the classification and general laboratory findings of the acute leukemias.
- ▶ List and describe the criteria used to differentiate acute leukemias.

Level II

- ▶ Summarize the role of oncogenes and growth factors in cell proliferation, differentiation, and maturation.
- ▶ Describe the role of molecular analysis in diagnosis and treatment of acute leukemia.
- ▶ Describe the use of immunophenotyping in acute leukemia.
- ▶ Describe the role of cytogenetics in diagnosis and treatment of acute leukemia.

CASE STUDY

We will refer to this case study throughout the chapter.

Guillermo, a 34-year-old Latin-American male, had been in excellent health until two weeks prior to admission when he had a mild sore throat. He was seen at a neighborhood clinic and was prescribed penicillin. He was able to return to work and felt better until four days prior to admission when he developed a fever and experienced easy bruising. He noticed other bleeding symptoms including gingival bleeding and petechiae. He reported to the emergency room. A CBC revealed a WBC count of $26.2 \times 10^9/L$ and 6% blasts. He was admitted for further evaluation. Consider what additional laboratory testing could assist in the diagnosis of this patient.

▶ OVERVIEW

This chapter describes the acute myeloid (also referred to as *myelocytic* or *myelogenous*) leukemias (AML), also known as acute nonlymphocytic leukemias (ANLL). It begins with an account of the general laboratory findings in AML followed by a specific description of each subgroup in the WHO (World Health Organization) classification (with some reference to the older French-American-British [FAB] classification). Clinical and laboratory findings are described with an emphasis on defining characteristics. The chapter concludes with a look at the current types of therapy used to treat AML.

▶ INTRODUCTION

All **acute leukemias (AL)** are stem cell disorders characterized by malignant neoplastic proliferation and accumulation of immature and nonfunctional hematopoietic cells in the bone marrow. The neoplastic cells show increased proliferation and/or decreased programmed cell death (apoptosis). The net effect is expansion of the leukemic clone and a decrease in normal cells.¹

Because leukemia is a clonal expansion of a single transformed cell, all ALs begin long before any clinical signs and symptoms appear. A tumor burden of 10^{12} cells is believed to be sufficient for recognizable signs and symptoms. Lethal levels of tumor burden occur at neoplastic cell numbers of 10^{13-14} or higher. As the tumor burden expands, the normal functional marrow cells decrease. The classic triad of anemia, infection, and bleeding seen in acute leukemia occur as a result of “normal” hematopoietic cell cytopenias. Death often occurs from either infection or hemorrhage in weeks to months unless therapeutic intervention occurs.²

The two major categories of acute leukemias are classified according to the cellular presentation of the primary stem cell defect: AML and ALL. If the defect primarily affects the maturation and differentiation of the common myeloid progenitor (CMP) cell, the leukemia is classified as AML or ANLL. If the defect primarily affects the common lymphoid progenitor (CLP) cell, the leukemia is classified as ALL.

The most reliable parameters for defining and classifying neoplastic cells in AML into subtypes are immunologic probes to define cell markers (cell surface or internal antigens) and cytogenetic and molecular studies to identify genetic abnormalities. In the late 1970s, the first internationally accepted classification for the acute leukemias, the FAB classification, was based on a combination of neoplastic cell morphology and cytochemical cellular reactions.³ This classification remained essentially unchanged until 1999 when the WHO and the International Society of Hematology proposed a new classification.⁴ Many health care practitioners have dropped the use of the old FAB system in favor of the **WHO classification**, but because some individuals con-

continue to use the older system, the FAB nomenclature is reviewed here.

► BASIC BIOLOGY OF AML

AML is a disease characterized by two fundamental features: the ability to proliferate continuously and aberrant or arrested development.⁵ Excessive overproliferation can be the result of mutations affecting growth factors, growth factor receptors, signaling pathway components, and transcription factors that regulate genes involved in cell survival and proliferation. The majority of the genetic mutations that have been identified in AML involve transcription factors and other signaling pathway molecules. More than half of the cases of AML display cytogenetic abnormalities. Most are balanced, reciprocal chromosomal translocations with many of the translocation break points located at the loci for genes encoding transcription factors. The most common consequence of the translocation is the generation of a fusion gene that encodes for a novel fusion protein. The fusion proteins that are formed usually alter the normal function of one or both of the rearranged genes and modify the normal programs of cell proliferation, differentiation, and survival. In addition, other types of genetic abnormalities (e.g., epigenetic alterations) likely interact with the cytogenetic mutations (called the *multistep origin* of malignancy) resulting in the full leukemic transformation.^{5,6}

► LABORATORY FINDINGS

PERIPHERAL BLOOD

The peripheral blood picture is quite variable in AML. Although it is traditional to describe leukemias as having elevated leukocyte counts, 50% of the cases can have decreased counts or counts within the reference range at the time of diagnosis. The leukocyte count ranges from less than $1 \times 10^9/L$ to more than $100 \times 10^9/L$. Regardless of the leukocyte concentration, the presence of blasts on the blood smear suggests the AL diagnosis. The current WHO definition of AL requires $\geq 20\%$ blasts in the peripheral blood or bone marrow in contrast to the older FAB requirement of more than 30%. Experienced clinical laboratory professionals are often able to determine the lineage of the leukemic cells by bright-field microscopy on Romanowsky-stained preparations. The remaining cases must be identified through cytochemical, immunologic, and/or genetic methods. Typically, the myeloblast seen in AML is approximately 20μ in diameter with variably prominent nucleoli in a nucleus composed primarily of dispersed chromatin (euchromatin or transcriptionally active DNA). A Golgi apparatus is present but is not easily visualized. Although blasts normally do not have granules visible by bright-field microscopy, neoplastic blasts do not always develop normally and can have a

few granules in the RNA-rich cytoplasm. The FAB group defined neoplastic blasts as Type I, Type II, and Type III; Type I has typical blast features without granules, Type II has <20 granules, and Type III has numerous granules. Although the common presentation includes a variety of immature granulocyte forms, occasionally only myeloblasts are found on the peripheral blood smear. Abnormalities in cell granules, nuclear structure, and function are frequent.

Erythrocytes are typically decreased, and a hemoglobin value less than 10g/dL is common. Erythrocytes can be slightly macrocytic because of the inability to successfully compete with neoplastic cells for folate or vitamin B₁₂ and/or early release of marrow reticulocytes. The RDW often is elevated. Erythrocyte inclusions such as Howell-Jolly bodies, Pappenheimer bodies, and basophilic stippling reflective of erythrocyte maturation defects can be present. Nucleated erythrocytes can be present in proportion to the anemia or marrow damage.

Platelets are typically decreased. Hypogranular platelets and occasional enlarged forms (giant platelets) can be present. As the disease progresses, more immature platelet forms such as megakaryocytic fragments can be seen. The platelet count might not correlate with the potential complication of bleeding because qualitative platelet defects also can be present.

If the physician suspects AL but no blast cells are detected on the peripheral blood smear or if the leukocyte count is low ($<2 \times 10^9/L$), a buffy-coat smear should be prepared. This often reveals the presence of blast cells when they are present in very low concentrations. Finding blasts with azurophilic granules is helpful in identifying the myeloid nature of the leukemia. The presence of granules or **Auer rods** (fused or coalesced primary granules) in blasts excludes a diagnosis of ALL. Auer rods are primarily found in myeloblasts; on rare occasions, they are found in monoblasts or more differentiated monocytic or myelocytic cells.

Other abnormal findings on the blood smear often include monocytosis and neutropenia. Monocytosis frequently precedes overt leukemia. Neutrophils can demonstrate signs of myelodysplasia including **pseudo-Pelger-Huët cells**, hypogranulation, and small nuclei with hypercondensed chromatin. Signs of myelodysplasia are especially common in promyelocytic leukemia.⁷ Eosinophils and basophils can be mildly to markedly increased. When present, basophilia can help to differentiate leukemia from a leukemoid reaction. Absolute basophilia is not present in a leukemoid reaction.

BONE MARROW

Bone marrow testing should include both aspirate and biopsy specimens. The quality of marrow specimen is critical for all subsequent analyses. Typically, the bone marrow presentation is hypercellular with decreased fat content (relative to age-related normals), a predominance of blasts, and sometimes an increase in fibrosis. According to the WHO criteria

for AL, blasts must compose $\geq 20\%$ of the nonerythroid nucleated cells to distinguish AL from myelodysplastic syndromes. Frequently, the blast count is close to 100%. Auer rods are present in bone marrow blasts in about half the cases of AML.

Cells can be clumped together, occasionally forming sheets of infiltrate that disturb the usual marrow architecture. In addition to light microscopy morphologic evaluation, bone marrow samples should be tested for immunologic markers and genetic mutations.

Checkpoint! 1

What results would you expect to find on the CBC and differential in a suspected case of AL?

OTHER LABORATORY FINDINGS

Other laboratory findings can reflect the increased proliferation and turnover of cells. Hyperuricemia and increased lactate dehydrogenase (LD) are common findings resulting from the increased cell turnover. Hypercalcemia, when present, is thought to be caused by increased bone resorption associated with leukemic proliferation in the bone marrow. Increased serum and urine muramidase are typical findings in leukemias with a monocytic component.

CASE STUDY (continued from earlier in this chapter)

Admission laboratory data on Guillermo are as follows:

RBC	$3.2 \times 10^{12}/L$
Hb	9.7 g/dL
Hct	30.5 L/L
PLT	$31 \times 10^9/L$
WBC	$26.2 \times 10^9/L$
Differential	
Blasts	6%
Promyelocytes	79%
Myelocytes	5%
Lymphocytes	11%

Erythrocyte morphology: Erythrocytes are normochromic and normocytic with rare schistocytes seen.

1. What clues do you have that this patient could have an acute leukemia?
2. Based on the presenting data, what additional testing might be of value?

CLASSIFICATION

As mentioned, investigations have shown that the mutant neoplastic “stem” cell can occur at multiple points in the differentiation scheme of the myeloid lineages⁸ (Figure 1 ■).

The original classification of leukemias was based solely on bright-field microscopy and the patient’s signs and symptoms at the time of diagnosis. With the inability to categorize all leukemias by bright-field microscopy, the **FAB classification** developed in 1976 combined morphology and cytochemistry to help identify the neoplastic blast lineage. This classification (Table 1) required $\geq 30\%$ blasts to establish a diagnosis of AML. The FAB classification groups the

++ = strongly present; - = usually not present; +/- = can be present

acute leukemias into AML with eight subgroups, M0–M7 (M4 and M5 have subgroups), and ALL with 3 subgroups, L1–L3.

The newer WHO classification is the result of a worldwide consensus on classification of the hematopoietic neoplasms and expands the parameters used to classify the neoplastic disorders.^{10,11,12,13} The parameters include not only microscopic morphology and cytochemistry but also immunologic probes of cell markers, cytogenetics, molecular genetic abnormalities, and clinical findings. In this classification, $\geq 20\%$ blasts establishes the diagnosis of AL. The WHO four major AML subgroups, each with variants or subtypes, are:

- **AML with recurrent genetic abnormalities.** AML with specific genetic abnormalities, distinctive clinical findings, and characteristic hematologic morphology are defined as subgroups
- **AML with multilineage dysplasia.** The two variants are those with prior history of myelodysplastic syndrome (MDS) and without prior MDS.
- **AML and MDS therapy-related.** These AMLs are distinctly different from de novo (primary) AML in terms of response to therapy and prognosis.
- **AML not otherwise categorized.** Includes any AML not included in the preceding subgroups.

The subgroups of the WHO AML classification are included in Table 2 🌟.

✓ Checkpoint! 2

What is the major difference between the FAB and WHO classification systems in differentiating acute leukemia from the other neoplastic hematologic disorders?

IDENTIFICATION OF CELL LINEAGE

Because blast cells are immature cells, they are often difficult to identify by morphology alone using light microscopy. Cytochemistry, molecular testing, and immunophenotyping give additional information that can help define cell lineage. When both cytochemistry and immunophenotyping are used, most cases of AL can be classified as being of lymphoid or myeloid origin. Rarely, a population of malignant blasts is cytochemically negative by conventional and ultrastructural methods and nonreactive with both lymphoid and myeloid monoclonal antibodies. Such leukemias are classified as undifferentiated.¹⁴

The “acute leukemias of ambiguous lineage” are characterized by a blast population with both myeloid and lymphoid markers on the same cell (**biphenotypic leukemia**) or with two separate populations of malignant blasts (i.e., one myeloid and the other lymphoid—a **mixed lineage leukemia**). The WHO classification defines mixed lineage leukemia. Some believe that the presence of both myeloid

*The 2008 WHO Classification has some revisions and is on the book’s Website.

and lymphoid markers on the same cell is an example of lineage infidelity of malignant cells.¹⁵

Cytochemistry

The common cytochemical stains originally used in the FAB classification include the myeloperoxidase, Sudan black B, naphthol AS-D chloroacetate esterase (specific esterase), and alpha-naphthyl esterases (nonspecific esterase). These stains are still the foundation of cytochemical analysis. Granulocytic cells stain positive with myeloperoxidase and with Sudan black B; lymphoblasts are negative. Thus, these stains help differentiate the acute myeloid leukemias from the acute lymphoblastic leukemias. The esterase stains help differentiate precursor granulocytic cells from precursor monocytic cells. Granulocytic cells stain positive with naphthol AS-D chloroacetate esterase, and cells of monocytic lineage stain positive with nonspecific esterase (Table 1). Many institutions have begun using immunophenotyping and cytogenetics as first line tests to define cell lineage. However, cytochemistry can be helpful in cases undefined by these methods and in the identification of some subgroups.¹⁶

Immunofluorescence or cytochemistry can be used to demonstrate terminal deoxynucleotidyl transferase (TdT) in individual cells. Although originally thought to be a lymphoid specific marker, TdT is found on more immature hematopoietic cells including those of myeloid lineage.¹⁷ Therefore, TdT should not be the sole determinant of lymphoid lineage.

CASE STUDY (continued from earlier in this chapter)

- Based on the peripheral blood examination, what cytochemical stain results would you expect to find on Guillermo's neoplastic cells?

Immunophenotyping

Immunophenotyping has become a necessary component of AL classification, particularly when the morphological appearance and cytochemical reactions do not clearly define

cell lineage or when the presence of more than one neoplastic cell population is suspected.¹⁸ A specific sequence of testing with monoclonal antibodies is followed.^{9,19} The use of extensive panels is costly and time consuming. In most cases, lineage can be determined using a limited, representative panel of monoclonal antibodies. Common cell markers used in identification include CD2, CD3, CD5, CD7, CD10, CD13, CD14, CD15, CD19, CD22, CD33, MPO (myeloperoxidase), HLA-DR, CD34, CD56, CD45, and CD117.⁹

The first panel of monoclonal antibodies should be those that differentiate AML from ALL and T cell ALL (T-ALL) from B cell ALL (B-ALL). More than 90% of AML can be discriminated from ALL using a panel of antibodies such as that listed in Table 3. Individual facilities have their own preferred panels of antibodies. Immunophenotyping using monoclonal antibodies for differentiating AML from ALL should include typing for the myeloid antigens, the B lymphoid restricted cell antigens (CD10, CD19, CD20, and CD22), and the T lymphoid cell antigens (CD2, CD3, CD5, and CD7). Human leukocyte antigen (HLA)-DR is present on both myeloid and B lymphoid cells. Several aberrant antigens are sometimes found on neoplastic cells (e.g., the CD7 [T-lymphoid] antigen can be found on neoplastic myeloid cells in AML). The CD34 marker is also present on the least differentiated myeloid cells and early lymphoid cells. These blasts are considered myeloid in nature if immunophenotyping reveals at least one lineage-specific myeloid antigen.¹⁴

The monoclonal antibodies that react with most cases of AML include CD13, CD15, CD33, and CD117.²⁰ In addition, the monoclonal antibody that identifies myeloperoxidase is helpful, especially when cytochemistry for myeloperoxidase is negative. Myeloperoxidase occasionally is identified in blasts at the ultrastructural level (i.e., electron microscopy) when negative by light microscopy cytochemistry.

The CMP cell is capable of differentiation into granulocytes, erythrocytes, monocytes, and megakaryocytes. Thus, if the neoplastic clone has "early" myeloid antigens, a second panel of monoclonal antibodies should include antibodies to subtype the AML into granulocytic, monocytic, erythrocytic, and megakaryocytic lineages (Tables 4 and 5).

TABLE 3

Differentiation of ALL from AML Using Immunophenotyping with Selected Monoclonal Antibodies

CASE STUDY (continued from the previous page)

- If the cells from Guillermo’s bone marrow were immunophenotyped, would you expect CD 13, CD33, CD34, CD19, CD10, CD7, or CD2 to be positive?

with these WHO subgroups are discussed in subsequent sections. If the expected abnormal karyotype is not found, molecular analysis is sometimes helpful because the genetic alteration may be detected only at the molecular level (see the following discussion of acute promyelocytic leukemia).

CYTOGENETIC ANALYSES

Two-thirds of patients with AML have detectable cytogenetic abnormalities.²¹ Of these, approximately 60% are found to have specific, consistent aberrations. Additional abnormalities can develop in subclones as the disease progresses. A clone is present if two or more cells show the identical structural chromosomal change or additional chromosomes or if three cells show the same missing chromosome.²² The WHO category of AML with recurrent genetic abnormalities has characteristic cytogenetic abnormalities. Therapy-related AML (secondary to alkylating agent therapy) and AML with a history of a previous myelodysplastic disorder also have characteristic cytogenetic abnormalities (and are classified as separate groups of AML in the WHO classification). The nonrandom chromosome abnormalities most commonly associated

✓ Checkpoint! 3
 Explain why molecular analysis is not performed on all suspected cases of acute leukemia.

ASSESSMENT OF BONE MARROW

When a diagnosis of AML or MDS is suspected, the first step is to estimate the bone marrow cellularity followed by an assessment of the percentage of erythroblasts. Further evaluation of the bone marrow depends on the number of erythroblasts present (>50% or <50% of all nucleated marrow cells). If erythroblasts compose more than 50% of all nucleated bone marrow cells, the percentage of nonerythroid blast cells (i.e., myeloblasts, monoblasts) is determined by

TABLE 5

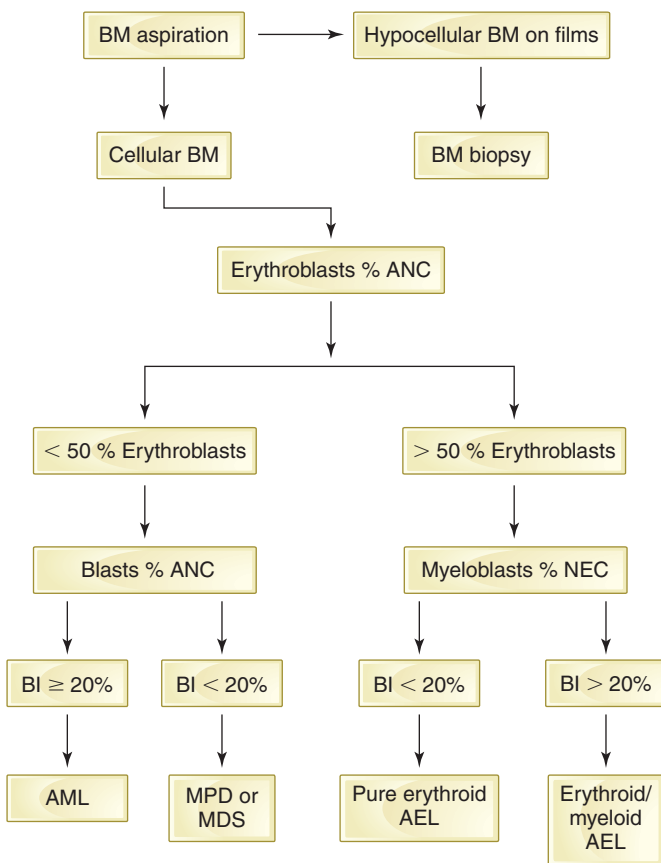

Morphologic, Immunophenotypic, and Cytochemical Results Used to Classify AML (WHO)

	Morphology	Immunophenotype	Cytochemistry
1. AML with recurrent genetic abnormalities			
AML with t(8;21)(q22;q22), AML 1 (CBF α)/ETO	Maturation in the neutrophil lineage Auer rods, pseudo-Pelger Huët nuclei	CD13, CD33, CD34, MPO, CD56 + Occasional CD19 + Occasional TdT +	Myeloperoxidase + Sudan black B +
Acute promyelocytic leukemia, AML with t(15;17)(q22;q12), (PML/RAR α), and variants (old FAB M3)	Hypergranular variant Promyelocytes dominate Abnormal hypergranulation Multiple Auer rods in one cell Microgranular variant Butterfly shaped nuclei No visible granularity	CD33, CD13 + (CD2 and CD9 +/–) CD15, CD34, HLADR–	Myeloperoxidase ++ Sudan black B ++ Nonspecific esterase = weakly +
AML with abnormal bone marrow eosinophils: inv(16)(p13q22) or t(16;16)(p13;q22), (CBF β /MYH11)	Maturation in both the neutrophil and monocytic lineage; abnormal eosinophils (AMML Eo) Eosinophils \geq 5% Abnormal eosinophilic granules present in promyelocyte or myelocyte stage	CD13, CD33, MPO + CD14, CD4, CD11b, CD 11c, CD64, CD36, and lysosyme +	Myeloperoxidase + Sudan black B +
AML with 11q23(MLL) abnormalities	Monoblasts and promonocytes predominate. Pseudopods frequent	CD 13, CD 33 variable CD14, CD4, CD11b, CD11c, CD64, CD36, and lysosyme + for monocytic cells	Myeloperoxidase +/- Sudan black B +/- Nonspecific esterase +
2. AML with multilineage dysplasia			
Following myelodysplastic syndrome or myelodysplastic syndrome/myeloproliferative disorder Without prior MDS	Dysplasia required in \geq 50% of two cell lines Hypogranular neutrophils, pseudo-Pelger-Huët nuclei Dyserythropoiesis with megakblastoid changes, ringed sideroblasts, nuclear fragments or vacuoles Dysmegakaryopoiesis with micromegakaryocytes, hypoblobulated nuclei, and other dysplastic signs	CD34, CD13, CD33 + CD56 and CD7 +/- Multi-drug resistance glycoprotein receptor (MDR-1) +/-	Myeloperoxidase + Sudan black B + Increased iron in ring formation + Periodic Acid Schiff (PAS +)
3. AML and MDS, therapy related			
Alkylating agent related	Pancytopenia or isolated cytopenia Ringed sideroblasts Obvious multiple dysplasias	CD 34+ CD13 and CD33 + CD56 and CD7 +/-	Myeloperoxidase + Sudan black B + Increased iron in ring formation + PAS +
Topoisomerase type II inhibitor-related (some can be lymphoid)	Dominant monocytic component Neutrophil maturation possible		Myeloperoxidase +/- Specific esterase + Nonspecific esterase +

4. AML not otherwise categorized				
AML minimally differentiated (FAB M0)	Minimal evidence of myeloid differentiation No maturation seen Agranular cytoplasm	CD13, CD33, CD117 + CD34, CD38, HLA-DR +	Myeloperoxidase (<3% of blasts) Sudan black B (<3% of blasts) Specific esterase -	
AML without maturation (FAB M1)	Evidence of myeloid differentiation, no maturation seen, Auer rods or some granulation	C13, CD33, CD117, CD34, lysosyme +	Myeloperoxidase + (>3% of blasts) Sudan black B + (>3% of blasts) Specific esterase +	
AML with maturation (FAB M2)	All stages of neutrophil maturation Pseudo-Pelger-Huët Hypogranulation Eosinophilic precursors possible	CD13, CD33, CD 15 + CD 117, CD34, HLA-DR +/- CD 11b, CD11c, CD14 - ; CD 3, CD 20, CD79a -	Myeloperoxidase + Sudan black B + Specific esterase +	
Acute myelomonocytic leukemia AMML (FAB M4)	Neutrophil and monocytic precursors present Vacuolization	CD13, CD33 CD14, CD4, CD11b, CD11c, CD64, CD36 lysosyme +	Myeloperoxidase + Nonspecific esterase +/- Specific esterase +	
Acute monoblastic and monocytic leukemia (FAB M5)	Monoblast/monocyte dominance Hemophagocytosis present Nuclear lobulation	CD13, CD33, CD117 + CD14, CD4, CD11b, CD11c, CD64, CD68, CD36, lysosyme +	Myeloperoxidase - Nonspecific esterase + Specific esterase -	
Acute erythroid leukemia (FAB M6)	>50% erythroid precursors and >20% myeloblasts in the nonerythroid cell population Megakaryoblastoid morphology Auer rods +/-	CD13, CD33, CD117 + Glycophorin A +	Myeloperoxidase + Sudan black B + Nonspecific esterase +/- PAS + (erythroblasts)	
Acute megakaryoblastic leukemia (FAB M7)	Cytopenia with or without thrombocytopenia Basophilic agranular blasts with pseudopods Micromegakaryocytes	CD41 and/or CD61 + CD13, CD 33, and CD 42 +/-	Myeloperoxidase - Sudan black B - Nonspecific esterase +/- Specific esterase - PAS + Platelet peroxidase +	
Acute basophilic leukemia	Basophilic precursors Vacuolization	C13, CD33, CD 34, and class II HLA-DR +	Metachromatic positivity with toluidine blue	
Acute panmyelosis with myelofibrosis	Pancytopenia Dysplastic changes in neutrophils and platelets	CD13, CD33, CD117 + Lysosyme, CD41, CD61 and glycophorin A +/-	Myeloperoxidase +	
Myeloid sarcoma	Biospy of specific lesion	CD13, CD33, CD117 +	Myeloperoxidase + Specific esterase +	

Specific esterase = Naphthol AS-D chloroacetate esterase; nonspecific esterase = Alpha-naphthyl esterase

performing a differential count on the nonerythroid cells. This differential count is used in determining the percentage of myeloblasts in the AML category of erythroleukemia. If fewer than 50% erythroblasts are in the bone marrow, it is not necessary to exclude the erythroid cells from the differential count in determining the percentage of myeloblasts or monoblasts for a diagnosis of AL or MDS (Figure 2 ■). The diagnosis of the myeloblastic/monoblastic AL is made when $\geq 20\%$ of all nucleated bone marrow cells are leukocytic blasts. The WHO classification does not include the RAEB-t subgroup of MDS, which is in the FAB classification (20–29% blasts) but reclassifies it as AL. Additional assessment of the subtypes of AML evaluates only the myeloid cells, not lymphocytes, plasma cells, mast cells, macrophages, or nucleated erythrocytes.

■ **FIGURE 2** Suggested steps in the analysis of a bone marrow aspirate to reach a diagnosis. (ANC = all nucleated cells; NEC = nonerythroid cells; AML = acute myelocytic leukemia; MDS = myelodysplastic syndrome; MPD = myeloproliferative disorders; AEL = acute erythrocytic leukemia; M1–M5 = FAB subtypes of AML; BI = leukocytic blasts.) (Adapted from: Bennett JM, et al. Proposed revised criteria for the classification of acute myeloid leukemia. *Ann Intern Med.* 1985;103:620.)

WHO CLASSIFICATION OF AML

AML with Recurrent Cytogenetic Abnormalities

This classification consists of presentations with recurrent chromosome abnormalities, usually balanced (reciprocal) translocations (see below). In most cases, the chromosomal rearrangements create a fusion gene, encoding a novel fusion (chimeric) protein. Molecular techniques (RT-PCR) have a higher sensitivity than cytogenetics for diagnosing and following the progression of the disease. The AMLs in this category generally have a high rate of complete remission and a more favorable prognosis.

AML with $t(8;21)(q22;q22)$; (AML1/ETO) This subcategory generally presents morphologically as AML with maturation. Myeloblasts are usually large with abundant basophilic cytoplasm containing numerous azurophilic granules and Auer rods. Promyelocytes, myelocytes, and mature neutrophils with variable dysplasia are usually present in the bone marrow. Eosinophilia can be present. Cytochemical and immunophenotypic results are typical for myeloblasts (Table 5). The leukemic “cell of origin” is believed to be the hematopoietic stem cell (HSC). This cytogenetic category accounts for 5–12% of cases of AML.¹³

Core binding factor (CBF), a transcription factor critical for hematopoietic development, is composed of two subunits: CBF α (also known as AML1 or RUNX1) and CBF β . The $t(8;21)$ translocation results in a chimeric protein containing the N-terminal portion of AML1 (chromosome 21) and most of the ETO protein from chromosome 8 (a nuclear protein involved in the regulation of transcription). The fusion protein blocks the normal function of AML-1 and induces abnormal gene activation and gene repression. This presumably contributes to the leukemic phenotype of increased proliferation with blocked differentiation.⁵

AML with abnormal bone marrow eosinophils $inv(16)(p13;q22)$ or $t(16;16)(p13;q22)$ (CBF β /MYH11)

This subcategory generally presents morphologically as AML with monocytic and granulocytic maturation and the presence of abnormal eosinophils in the bone marrow. The combination of acute myelomonocytic leukemia (AMML) with abnormal eosinophils is morphologically *AMML Eo*. The most striking abnormality of the eosinophils is the presence of immature (basophilic) granules, predominantly evident at the promyelocyte and myelocyte stages. The immunophenotypic and cytochemical results reflect the presence of both neutrophilic and monocytic lineages (Table 5). The leukemic cell of origin is believed to be an HSC. This type accounts for 10–12% of all cases of AML.¹³

The $inv(16)(p13;q22)$ and $t(16;16)(p13;q22)$ both result in the fusion of the CBF β gene (16q22) to the smooth muscle myosin heavy chain gene SMMHC (MYH11) at 16p13. Because of difficulties in correctly identifying these mutations with traditional cytogenetics, fluorescent in situ hybridization (FISH) or RT-PCR may be necessary to document the muta-

tion. The CBF β /SMMHC fusion protein binds to AML1/CBF α and represses its function as a transcription factor.⁵

AML with 11q23 (*MLL*) abnormalities. These leukemias are usually associated with monocytic features (monoblasts and promonocytes). They can occur at any age but are more common in children. Identical cytogenetic abnormalities can also be found in therapy-related AML (see below). Patients can have extramedullary monocytic sarcomas (malignant tumors that originate in connective tissue) and tissue infiltration (gingiva, skin) and may present with disseminated intravascular coagulation. Monoblasts and promonocytes can have scattered azurophilic granules and vacuoles and give cytochemical and phenotypic results typical for the monocytic lineage (Table 5). The leukemic cell of origin is believed to be the HSC. AML with 11q23 (*MLL*) abnormalities is found in 5–6% of cases of AML.¹³

The *MLL* gene (11q23) is involved in a number of leukemia-associated translocations with different partner chromosomes. The *MLL* protein is a DNA-binding protein that interacts with other nuclear proteins and permits the association of transcription factors which help regulate transcription. The most common translocations involving 11q23 seen in childhood AML are t(9;11)(p21;q23), t(11;19)(q23;p13.1), and t(11;19)(q23;p13.3). Other translocations involving ~20 different partner chromosomes have also been observed. In addition, some *MLL* gene rearrangements can be identified only by molecular studies, not by conventional cytogenetics.⁵

AML with t(15;17)(q22;q12) (*PML/RAR α*) and Variants One of the most well-studied leukemias is acute

promyelocytic leukemia (APL) with t(15;17)(q22;q12), an AML in which abnormal promyelocytes predominate. Both hypergranular (“typical” APL) and hypogranular or microgranular presentations are seen. APL can occur at any age, but most patients are adults in middle life. APL constitutes 5–8% of AML¹³

The presenting signs for both hypergranular and hypogranular APL often include acute disseminated intravascular coagulation (DIC).²³ The most common clinical finding at initial diagnosis is bleeding. It is believed that the release of procoagulant material from promyelocytic granules initiates DIC, a serious complicating factor of the disease.²⁴ Therapy for the leukemia can potentiate or aggravate this complication because lysed promyelocytes release large amounts of this material. In addition, a significant release of tissue factor-containing particles from dying cells can occur during cytotoxic therapy. Evidence of secondary fibrinolysis as a component of the DIC syndrome is also present. Heparin therapy can be administered with initiation of chemotherapy to prevent or modulate the DIC. Other abnormalities of coagulation can be present.

Hypergranular APL Most patients with the hypergranular subtype are leukopenic or exhibit only slightly increased leukocyte counts. Most cells in the bone marrow are abnormal promyelocytes with heavy azurophilic granulation. The granules can be so densely packed that they obscure the nucleus (Figure 3a ■). Some cells filled with fine dustlike granules also can be present. Cells with multiple Auer rods, sometimes occurring in bundles (**faggot cells**), are characteristic with cytoplasm that is frequently clear and pale blue, but cells can contain only a few azurophilic granules or lakes of clear pink material²⁵ (Figure 4 ■). In some cases, the typi-

a

b

■ **FIGURE 3** **a.** Peripheral blood film from a patient with acute promyelocytic leukemia (APL), hypergranular variant. These promyelocytes have an irregularly shaped nucleus and numerous azurophilic granules. **b.** Peripheral blood film from a patient with APL, microgranular variant. Note the bilobed nuclei and absent or fine granules in these abnormal promyelocytes. (Wright-Giemsa stain; 1000 \times magnification)

■ **FIGURE 4** A faggot cell from promyelocytic leukemia. Notice the bundle of Auer rods. (Wright-Giemsa stain; 1000 \times magnification)

cal hypergranularity of promyelocytes is less evident in the peripheral blood than in the bone marrow.²⁶ The nucleus varies in shape but is often folded or indented or sometimes bilobed. Often a large number of promyelocytes appear to be disrupted on the blood smear with free azurophilic granules and Auer rods intermingled with intact cells. Anemia and thrombocytopenia are typical findings.

Microgranular APL Variant In contrast to typical APL, the leukocyte count in microgranular APL is usually markedly increased.²⁷ The predominant cell in the peripheral blood is a promyelocyte with a bilobular, reniform, or multilobed nucleus (resembling that of a monocyte) and cytoplasm with an apparent paucity of granules on Romanowsky-stained smears (Figure 3b ■). The apparent absence of granules is due to their submicroscopic size, but they are readily visible by electron microscopy and cytochemistry (myeloperoxidase, MPO positive). The nuclear chromatin is fine with nucleoli often visible. A small abnormal promyelocyte with a bilobed nucleus, deeply basophilic cytoplasm, and sometimes cytoplasmic projections is present as a minor population in most cases but occasionally is the predominant cell. When cytoplasmic projections are present, the cells can resemble megakaryoblasts. Faggot cells are scarce or absent, but single Auer rods can be found. In contrast to the hypogranular appearance of peripheral blood promyelocytes, the bone marrow promyelocytes can be more typical of the cells found in the hypergranular form of APL. Cytochemical and immunophenotypic results for APL are given in Table 5.

A form of APL in which some promyelocytes contain metachromatic granules (when stained with toluidine blue) has been described.²⁷ Distinctive features include folded nuclei, hypergranular cytoplasm, and coarse metachromatic granules.

Diagnostic Gene Rearrangement The t(15;17) rearrangement is consistently associated with APL. The break point in-

volves the retinoic acid receptor alpha (*RAR α*) gene on chromosome 17 and the *PML* gene on chromosome 15 and is limited to the neoplastic cells. Some APL patients have a cytogenetically normal karyotype, but molecular analysis has shown submicroscopic insertion of *RAR α* into *PML*, leading to the expression of the *PML/RAR α* transcript. No major differences exist between t(15;17) positive patients and *PML/RAR α* positive patients without t(15;17).¹³ These findings suggest that the t(15;17) translocation/fusion protein is involved in the pathogenesis of the disease. However, other variant translocations have been reported in *PML*, all involving the *RAR α* gene translocated with different target genes, including *PLZF* on chromosome 11 (t[11;17][9q23;q21]), *NuMA* on chromosome 15 (t[11;17][q13;q21]), *NPM* on chromosome 5 (t[5;17][q23;q12]), and *STAT5b* on chromosome 17 (t[17;17]).¹³

The typical t(15;17) gene rearrangement results in a fusion *PML/RAR α* gene and a reciprocal *RAR α /PML* gene. The *PML/RAR α* mRNA has been identified in all APL patients while the *RAR α /PML* mRNA is found in about two-thirds of APL patients.²⁸ Molecular analysis of the *PML/RAR α* gene is important in monitoring therapy and relapse because the gene disappears with successful treatment but returns as an early marker of relapse. Also, some patients have molecular evidence of the fusion protein product (fusion gene) in the absence of a detectable cytogenetic abnormality.

The *RAR α* protein is a nuclear hormone receptor that binds to specific DNA sequences (RA responsive elements) and controls transcription of specific target genes under the control of the retinoid hormones. *RAR α* forms a complex with a second protein, retinoid-X receptor (*RXR α*). In the absence of RA, the *RAR α /RXR α* complex represses transcription by recruiting corepressor proteins and inducing histone deacetylation.²⁹ Physiologic concentrations of RA normally induce a conformational change in the RARs, causing release of the corepressor molecules and recruitment of coactivator molecules, resulting in gene transcription and granulocytic differentiation.³⁰

PML is a growth suppressor nuclear protein normally found in complex macromolecular structures containing numerous other nuclear proteins. The *PML/RAR α* fusion protein binds to the RA responsive elements of the target genes. Like the native protein, the fusion protein recruits corepressor molecules and in the absence of RA inhibits transcription of RA-responsive genes. Although the fusion protein can bind RA, physiologic concentrations of RA are not sufficient to induce the release of the corepressor proteins from *PML/RAR α* , and repression of gene transcription is maintained.³⁰ Thus, the cells do not differentiate into granulocytes.

Pharmacological concentrations of RA (all-transretinoic acid—ATRA) have proven to be an effective treatment for inducing complete hematologic remission in APL (but the remission is generally short lived). ATRA induces the neoplastic promyelocytes to differentiate to mature granulocytes, thus overcoming the maturation arrest.³¹ It is thought that a high

concentration of RA, as is given in induction therapy for APL, overcomes the interference with receptor activation (it promotes release of the corepressor molecules and assembly of the coactivator molecules on the target genes, allowing gene transcription and cellular differentiation). Cells previously unable to mature and initiate apoptosis are then able to do so, causing a transitory situation known as *hyperleukocytosis*.

Unfortunately, the stem cells bearing the t(15;17) translocation are unaffected by ATRA and continue to proliferate, resulting in relapse of the disease. The current approach to therapy is to induce hematologic remission with ATRA and then administer traditional chemotherapy (to try to eradicate the leukemic stem cells). When the promyelocytes are first induced to differentiate and are no longer present in large numbers, the subsequent chemotherapy does not result in the massive death of promyelocytes (and the release of procoagulants), thus avoiding or minimizing the life-threatening effects of DIC. Instead, the chemotherapy destroys the dividing stem cells that bear the t(15;17) translocation and induces a durable remission.

About 25% of patients given RA therapy become acutely ill associated with the death and lysis of the large number of cells. The mortality rate in these individuals can be high. The illness is similar to capillary leak syndrome with fever, respiratory disease, renal impairment, and hemorrhage.³²

Checkpoint! 4

Why is it important to do molecular studies on patients with acute promyelocytic leukemia?

AML with Multilineage Dysplasia (With or Without Prior Myelodysplastic Syndrome)

AML with multilineage dysplasia is an acute leukemia ($\geq 20\%$ blasts) with dysplasia in two or more myeloid cell lines. It occurs de novo (anew) or following a myelodysplastic/myeloproliferative disorder (MDS/MPD). Diagnosis requires dysplasia in $\geq 50\%$ of the cells of at least two lineages.¹³ Examples of dysplasia include hypogranular PMNs, pseudo-Pelger-Huët anomaly, megaloblastic erythrocytes, erythrocytes with multinuclearity or nuclear fragmentation, ringed sideroblasts, micromegakaryocytes, and/or megakaryocytes with monolobed nuclei or multiple separated nuclei. No significant difference in the disease progression and prognosis between AMLs arising from myelodysplasia or from de novo AMLs with multilineage dysplasia has been identified.¹¹

Immunophenotypic and cytochemical results for this category of AML are included in Table 5. The cytogenetic abnormalities are variable and are similar to those seen in MDS including: $-7/\text{del}(7q)$; $-5/\text{del}(5q)$; $+8$, $+9$, $+11$, $\text{del}(11q)$, $\text{del}(12p)$, -18 , $+19$, $\text{del}(20q)$ and $+21$.¹³ The cell of origin is believed to be the HSC. This type of AML (with multilineage dysplasia) generally has a poor prognosis.¹³

AML and Myelodysplastic Syndrome, Therapy-Related

These disorders arise as a result of cytotoxic chemotherapy and/or radiation therapy. Two major subtypes are described, those following alkylating agent/radiation treatment and those following topoisomerase II inhibitor treatment.¹³

AML can develop 5–6 years following alkylating agent therapy (range 1–10 years). The disease often presents initially with a myelodysplastic syndrome, eventually evolving to AML. Cytogenetic abnormalities are similar to those seen in AML with multilineage dysplasia and de novo MDS (unbalanced translocations or deletions involving chromosomes 5 and 7). Other chromosomes involved include 1, 4, 12, 14, and 18.

AML develops an average of ~ 3 years following therapy with a topoisomerase II inhibitor (range 1–15 years). In this instance, AML usually presents without a preceding MDS phase. Cytogenetic abnormalities are most commonly associated with a balanced translocation involving 11q23 (the *MLL* gene).

The cell of origin is thought to be the HSC. Therapy-related AML is generally refractory to treatment and is associated with shortened survival.³³

Acute Myeloid Leukemias not Otherwise Categorized

This AML category includes cases of AML that do not fulfill criteria for any of the other described groups.¹³ The subcategories in this group are primarily differentiated on morphology and cytochemical features. The defining criteria for all is $\geq 20\%$ blasts (the blast percentage includes promyelocytes in APL and promonocytes in AML with monocytic differentiation). For pure erythroid leukemias, the blast percentage is based on the percentage of abnormal erythroblasts. Immunophenotypic and cytochemical results for this category of AML are included in Table 5.

AML—Minimally Differentiated This rather rare leukemia is characterized by lack of evidence of myeloid differentiation by morphology (absence of granules) or cytochemistry ($< 3\%$ of the blasts are positive for SBB or MPO).¹³ This subtype accounts for less than 5% of all AMLs and is generally associated with a poor prognosis. The blasts, however, demonstrate myeloid differentiation by immunologic markers for the myeloid lineage (CD13 and CD33) and/or ultrastructural cytochemistry studies.³⁴ Most cases are also CD34, CD38, and HLA-DR +. No unique chromosomal abnormalities are associated with this subtype, but trisomy 13, 8, and 4 as well as monosomy 7 have been reported. Cells that fulfill these criteria but also have evidence for ultrastructural platelet peroxidase and/or show the glycoprotein IIb/IIIa (CD41) immunophenotype should be classified as acute megakaryoblastic leukemia.³⁵ Because the blasts in the minimally differentiated AML group have no morphologic differentiating features, immunophenotyping should also be used to exclude the lymphoid lineage. The cell of origin is thought to be a hematopoietic precursor cell at the earliest stage of myeloid differentiation.¹³

AML Without Maturation Characterized by a high percentage of bone marrow blasts without significant evidence of maturation to more mature neutrophils, the variant AML without maturation may occur at any age but most commonly in adulthood. It accounts for ~10% of the cases of AML.¹³ Leukocytosis is present in about 50% of patients at the time of initial diagnosis. The defining feature is its lack of cellular maturation (<10% of all granulocytic cells show evidence of maturation beyond the myeloblast stage) (Figure 5 ■).

The predominant cell in the peripheral blood is usually a poorly differentiated myeloblast with fine lacy chromatin and nucleoli. Myeloblasts are usually $\geq 90\%$ of nonerythroid cells in the bone marrow with $>3\%$ of blasts positive for MPO and/or SBB. The blasts may have azurophilic granules, Auer rods, and vacuoles. If no evidence of granules or Auer rods is present, the blasts can resemble lymphoblasts and must be differentiated by immunophenotype. Patients frequently present with anemia, thrombocytopenia, and neutropenia. Cytochemical staining reactions for Auer rods are similar to reactions for myeloblasts (Table 6 ■). About 50% of patients demonstrate clonal chromosome aberrations in the leukemic cells, which are of variable origin. If the karyotype is abnormal, the prognosis is significantly worse for this subtype of AML. The cell of origin is thought to be a hematopoietic precursor cell at the earliest stage of myeloid differentiation.¹³

✓ Checkpoint! 5

What hematologic features help differentiate AML minimally differentiated from AML without maturation?

■ **FIGURE 5** Peripheral blood film from a patient with AML without maturation. The large mononuclear cells are myeloblasts. The cell in the center (arrow) is a myeloblast with an Auer rod. AML With Maturation. AML with maturation is characterized by $\geq 20\%$ blasts with evidence of maturation to more mature neutrophils ($>10\%$ of cells at differentiated stages of maturation: promyelocytes, myelocytes, metamyelocytes). Monocytes and their precursors constitute $<20\%$ of the marrow cells. This type of AML occurs in all age groups (20% of patients are <25 years of age, and 45% are >60 years of age) and accounts for about 30% of AML cases.¹³ Patients often present with anemia, thrombocytopenia, and neutropenia.

Blasts with and without azurophilic granulation can be present, and blasts frequently contain Auer rods. Variable dysplasia can be seen, including myeloid hypogranulation, granulocytic hypo- and hyper-segmentation, and occasionally binucleated myeloid cells (Figure 6 ■). The bone marrow is hypercellular, and myeloblasts make up from 20 to 89% of the non-erythroid nucleated cells. Eosinophils and sometimes basophils can be increased. The cell of origin is thought to be a hematopoietic precursor cell at the earliest stage of myeloid differentiation.¹³

■ **FIGURE 6** Peripheral blood film from a patient with AML-with maturation. Myeloblasts are at the bottom and hypogranulated segmented neutrophils are at the top. (Wright-Giemsa stain; 1000 \times magnification)

✓ Checkpoint! 6

A patient with AML has a peripheral blood differential that includes 91% myeloblasts, 4% promyelocytes, 3% granulocytes, and 2% monocytes. Which category of AML is the most likely diagnosis? Explain.

Acute Myelomonocytic Leukemia (AMML)

Characterized by proliferation of both myelocytic and monocytic precursors, the bone marrow in AMML is hypercellular with $\geq 20\%$ blasts; neutrophils and their precursors as well as monocytes and their precursors compose $\geq 20\%$ of marrow cells. AMML is one of the most common AML variants, accounting for 15–25% of AML cases. Some patients have a history of chronic myelomonocytic leukemia. Infiltrations of leukemic cells in extramedullary sites are more frequent than in the pure granulocytic variants. Serum and urinary levels of muramidase (lysozyme) are usually elevated because of the monocytic proliferation.

The peripheral blood leukocyte count in AMML is usually increased. Monocytic cells (monoblasts, promonocytes, monocytes) are increased to $\geq 5 \times 10^9/L$ (Figure 7). Anemia and thrombocytopenia are present in almost all cases. The myeloblasts appear similar to blasts in AML with differentiation. Monoblasts are usually large with abundant bluish-gray cytoplasm and can show pseudopods. Scattered fine azurophilic granules and vacuoles can be present. The nucleus is round or convoluted with delicate chromatin and one or more prominent nucleoli. The monoblasts and myeloblasts demonstrate the expected cytochemical and immunophenotypic results for their respective lineages (Table 5). The bone marrow can reveal erythrophagocytosis by monocytes. The cell of origin is thought to be a hematopoi-

■ **FIGURE 7** Peripheral blood film from a case of acute myelomonocytic leukemia (AMML). Monoblasts and promonocytes are present. (Wright-Giemsa stain; 1000 \times magnification)

etic precursor cell with the potential to differentiate into neutrophil and monocytic lineages (CFU-GM).¹³

Additional laboratory testing is required when (1) the bone marrow findings are as previously described but the peripheral blood monocyte count is $< 5 \times 10^9/L$ and (2) the peripheral blood monocyte count is $\geq 5 \times 10^9/L$ but the bone marrow has $< 20\%$ monocytic cells. In these cases, ancillary laboratory tests such as lysozyme levels or cytochemical methods can be utilized to confirm the presence of a significant monocytic component and establish a diagnosis of AMML (Table 7).

Acute Monoblastic Leukemia and Acute Monocytic Leukemia

These subtypes are myeloid leukemias in which $\geq 80\%$ of the leukemic cells are monocytic (including monoblasts, promonocytes, and monocytes). The neutrophilic component, if present, is $< 20\%$ of the cells. The majority of the monocytic cells (usually $> 80\%$) found in acute monoblastic leukemia are monoblasts (Figure 8a and b). The majority of the monocytic cells in acute monocytic leukemia are promonocytes (Figure 9a and b). Acute monoblastic leukemia accounts for 5–8% of AML cases, and acute monocytic leukemia accounts for 3–6% of the cases.¹³ This disease is usually seen in children or young adults.

The most common clinical findings are weakness, bleeding, and a diffuse erythematous skin rash. One notable aspect of this disease is the degree of extramedullary leukemic proliferation (gingival and cutaneous infiltration, central nervous system involvement). As with AMML, serum and

★ TABLE 7

Nonimmunophenotypic Criteria for Diagnosis of AMML

II. Peripheral blood	$\geq 5 \times 10^9/L$ monocytic cells
and Bone marrow	Blasts $\geq 20\%$ of nonerythroid cells Monocytic cells $< 20\%$ of nonerythroid cells
Requires ancillary tests	Serum or urinary lysozyme $3 \times$ normal; or naphthol AS-D chloroacetate esterase and alpha-naphthyl acetate esterase (+) in blasts; or naphthol AS-D acetate esterase with and without NaFl reveal $> 20\%$ monocytic cells in bone marrow

FIGURE 8 **a.** A smear from a bone marrow aspirate of a patient with acute monoblastic leukemia. The cells are predominately monoblasts and promonocytes. **b.** Monoblasts in peripheral blood from a case of acute monoblastic leukemia. (Wright-Giemsa stain; 1000× magnification)

urine muramidase are moderately elevated. Monocytic cells account for 80% or more of cells in the bone marrow. Monocytes in the peripheral blood are increased, and monoblasts are often present. The monoblasts are large (up to 40 μ) with abundant, variably basophilic cytoplasm. Pseudopods with translucent cytoplasm are common and fine azurophilic granules can be present. The nucleus is round or oval with delicate chromatin and one or more prominent nucleoli, but Auer rods are usually not found. Dyshematopoiesis is not conspicuous. Promonocytes have a more irregular and convoluted nucleus, and nucleoli can be present. The cytoplasm is less basophilic than that of the

monoblast with a ground glass appearance. Fine azurophilic granules are often present.

Abnormalities of the long arm of chromosome 11 with translocations or deletions are often found in monocytic leukemias. The t(8;16) abnormality is also found and is associated with hemophagocytosis. The expression of *c-FOS* proto-oncogene on chromosome 14 appears to be enhanced in acute leukemias with monocytic lineage involvement.³⁶ This gene has been linked to normal monocyte-macrophage differentiation. The cell of origin for this AML subtype is believed to be a hematopoietic precursor cell committed to monocytic differentiation (CFU-M).¹³

FIGURE 9 **a.** A smear from a bone marrow aspirate of a patient with acute monocytic leukemia. There is a predominance of promonocytes and monoblasts. (Wright-Giemsa stain; 400× magnification) **b.** Monocytic cells in peripheral blood, including promonocytes and monoblasts, from acute monocytic leukemia. (Wright-Giemsa stain; 1000× magnification)

Acute Erythroid Leukemia (AEL) Acute erythroid leukemias have a predominant erythroid population. The two subtypes described are differentiated by the presence or absence of a significant myeloid component. The erythroid/myeloid variant of erythroid leukemia is defined by $\geq 50\%$ erythroid precursors in the bone marrow (percent of all nucleated cells) with $\geq 20\%$ myeloblasts in the nonerythroid cell population. Pure erythroid leukemias show neoplastic proliferation exclusively in the erythroid lineage ($>80\%$ of total marrow cells).³⁷ Erythroid/myeloid leukemia is predominantly a disease of adults and accounts for 5–6% of cases of AML. Pure erythroid leukemia is extremely rare and can occur at any age.¹³

The most dominant changes in the peripheral blood are anemia with striking poikilocytosis and anisocytosis with a large number of nucleated red blood cells (RBC). Nucleated erythrocytes are dysplastic with megaloblastoid nuclei and/or bi- or multinucleated cells in the more immature stages. The cytoplasm frequently contains vacuoles. Myeloblasts can be seen in the peripheral blood in the mixed lineage form of AEL (Figure 10 ■).

The bone marrow erythroblasts are distinctly abnormal with bizarre morphological features. Giant multilobular or multinucleated forms are common (Figures 11 ■ and 12 ■). Other features include nuclear budding and fragmentation, cytoplasmic vacuoles, Howell-Jolly bodies, ringed sideroblasts, and megaloblastoid changes. Erythrophagocytosis of the abnormal erythroblasts is a common finding. Auer rods can be found in the myeloblasts in the mixed lineage variant. Dysmegakaryopoiesis is common with mononuclear forms or micromegakaryoblasts present. Neutrophils can exhibit hypogranularity and pseudo-Pelger-Huët anomaly. The leuko-

■ **FIGURE 11** Smear of a bone marrow aspirate from a patient with erythroid/myeloid AEL. Most cells are myeloblasts. (Wright-Giemsa stain 400 \times magnification)

cyte alkaline phosphatase score is normal or increased. Leukocytes and platelets are usually decreased.

Normoblasts are typically PAS negative; however, in erythroleukemia, erythroblasts can demonstrate coarse positivity in either a diffuse or granular pattern. PAS-positive erythroblasts are occasionally also found in MDS, other subgroups of AML, iron-deficiency anemia, thalassemia, severe hemolytic anemia, and sometimes in megaloblastic anemia. The myeloblastic component shows reactions similar to those found in other subtypes of AML in both morphology and chromosomal aberrations. Erythroblasts usually react positively with antibodies to glycophorin A or hemoglobin A.

■ **FIGURE 10** Myeloblasts in the peripheral blood from a patient with the erythroid-myeloid variant of acute erythroid leukemia (AEL). The blast morphology is typical of AML-without differentiation. (Wright-Giemsa stain; 1000 \times magnification)

■ **FIGURE 12** Erythroblasts with megaloblastoid features in the bone marrow from a case of AEL. (Wright-Giemsa stain; 1000 \times magnification)

The mixed lineage variant occasionally can evolve to a predominantly myeloblastic leukemia. The cell of origin for the mixed lineage variant is thought to be a multipotential progenitor cell with wide myeloid differentiation potential. The cell of origin for pure erythroid leukemia is thought to be a primitive progenitor cell committed to the erythroid lineage (BFU-E or CFU-E).¹³

✓ Checkpoint! 7

What differentiating hematologic feature of acute erythroid leukemia causes it to be classified into two subgroups?

Acute Megakaryoblastic Leukemia The megakaryoblastic subgroup of AML is an acute leukemia in which $\geq 50\%$ of the leukemic blasts are of the megakaryocytic lineage. It occurs in both adults and children and constitutes $\sim 3\text{--}5\%$ of all AML cases.¹³ It can occur de novo or as an acute leukemic transformation of chronic myeloid leukemia (CML) and myelodysplastic syndromes.³⁸

Patients usually present with cytopenias; although most have thrombocytopenia, some can have thrombocytosis. Dysplastic features in the neutrophils and platelets can be present. There is no significant organomegaly. The bone marrow megakaryoblasts are usually medium to large (12–18 μ) with basophilic, often agranular, cytoplasm. The cells frequently show distinct pseudopod formation. Small blasts resembling lymphoblasts can also be present. On careful examination of the peripheral blood smear, circulating micromegakaryocytes and undifferentiated blasts can be found. However, the finding of cytoplasmic blebs suggests that these cells are megakaryocytic. Megakaryocytic fragments also can be present.

Bone marrow aspiration often results in a dry tap due to extensive marrow fibrosis associated with an expanded megakaryocyte lineage. In these cases, marrow biopsy may be required and usually reveals increased fibroblasts and/or increased reticulin as well as more than 20% blasts. It has been suggested that megakaryocytes secrete a number of mitogenic factors that stimulate fibroblast proliferation.

Blasts can be identified as megakaryocytic by immunophenotyping (CD41, CD61, and occasionally CD42), cytochemistry, and electron microscopy (ultrastructural demonstration of platelet peroxidase [PPO]). The blasts are highly variable, ranging from small round cells with scant cytoplasm and dense heavy chromatin to cells with moderately abundant cytoplasm with or without granules and nuclei with lacy chromatin and prominent nucleoli. Some blasts can have cytoplasmic blebs. Megakaryocytes with shedding platelets occasionally are present. Dysplasia of all cell lines is a common finding.

No unique chromosomal abnormality is associated with acute megakaryoblastic leukemia in adults. Abnormalities of chromosome 21 have been described, but similar abnormali-

ties are also found in other types of acute myeloid leukemias. Children with acute megakaryoblastic leukemia often have a t(1;21)(p13;q13) translocation and a particularly poor prognosis. Individuals with Down syndrome have an increased predisposition to develop acute leukemia, particularly AML. Most often, the subtype of AML is acute megakaryoblastic. The disorder usually manifests in the neonatal period, frequently with significant leukocytosis and $>30\%$ blasts in the peripheral blood. In addition to trisomy 21 (Down syndrome), these patients often have additional clonal abnormalities including trisomy 8 or a chromosome 21 translocation.³⁹

The cell of origin is believed to be a hematopoietic precursor cell committed to the megakaryocytic lineage (CFU-Mk) or a bipotential precursor able to differentiate into both erythroid and megakaryocytic lineages (CFU-EMk).

Acute Basophilic Leukemia The primary differentiation of this acute leukemia is along the basophil lineage. Some cases develop as a blast transformation phase of chronic myelocytic leukemia (CML). This is a very rare form of AML with few reported cases ($<1\%$ of all AML cases). The most characteristic feature by cytochemistry is metachromatic positivity with toluidine blue.¹³ The blasts can show diffuse staining with acid phosphatase and occasionally PAS positivity. They are usually negative for typical cytochemical stains for myeloid cells but express myeloid markers (e.g., CD13, CD33). No consistent chromosomal abnormality has been identified with this subtype of AML. The cell of origin is believed to be a myeloid precursor committed to the basophil lineage.

Acute Panmyelosis with Myelofibrosis This disorder is associated with an acute panmyeloid proliferation and fibrosis of the bone marrow. A rare form of AML, it occurs primarily in adults. It can occur de novo or following alkylating-agent chemotherapy and/or radiation. The major differential diagnosis is with acute megakaryoblastic leukemia (with fibrosis) or other types of AML with associated marrow fibrosis and/or with chronic idiopathic myelofibrosis. This diagnosis is indicated when the proliferative process involves all major myeloid lineages (granulocytes, erythroid cells, and megakaryocytes [i.e., panmyelosis]). Immunohistochemistry is necessary to identify the multilineage involvement. The cell of origin is believed to be the CMP.

Myeloid Sarcoma This designation refers to a disease process in which a tumor mass of myeloblasts or immature myeloid cells occurs in an extramedullary site or in bone. It can occur concurrently with acute or chronic myeloid leukemias or other myeloproliferative or myelodysplastic disorders. The immunophenotype and cytochemistry reflect the specific myeloid cell(s) involved in the malignant process (i.e., myeloblasts, promyelocytes, occasionally monocytes). The cell of origin is believed to be the CMP.

**CASE STUDY** (continued from earlier in this chapter)

A bone marrow aspirate and biopsy were performed on Guillermo to aid in diagnosis. The bone marrow biopsy revealed a hypercellular marrow. The bone marrow aspirate revealed an M:E ratio of 7.8:1. The predominant cell was an abnormal immature cell with an indented or lobulated nuclear configuration. Heavy cytoplasmic granulation was present, and multiple Auer rods were in several cells. The cells were strongly positive with myeloperoxidase.

- Based on the morphology and cytochemical staining of these cells, what is the most likely AML classification?
- What is the major complication associated with this leukemia?
- What chromosome abnormality is associated with this leukemia?

▶ THERAPY

Traditional chemotherapy for AML is designed to reduce tumor load as rapidly as possible. Newer treatment modalities include molecularly targeted therapies (e.g., ATRA), epigenetic-targeted therapies (demethylating agents, histone deacetylase inhibitors), and autologous or allogeneic bone marrow transplants and infusions of donor lymphocyte cells together with total body irradiation to increase leukemic cell destruction. Current research is focusing on novel therapies including the use of monoclonal antibodies and gene therapy and the destruction of the cellular matrix that supports the neoplastic tissue.

Evaluation of peripheral blood counts is essential to support patients during chemotherapy. Development of at-risk stages such as pancytopenia, severe granulocytopenia, and/or thrombocytopenia must be monitored so that early intervention can occur (growth factors to stimulate hematopoietic cell recovery and/or transfusions).

Bone marrow transplantation, whether allogeneic or autologous, remains the only therapeutic choice that currently provides the potential for a prolonged (10+ years) disease-free survival for most patients with AML.

**CASE STUDY** (continued)

- If this patient were treated with all transretinoic acid, what would you expect to find two weeks later when the blood count was repeated?

**Checkpoint! 9**

Predict the peripheral blood picture of a patient on antifolate chemotherapy.

SUMMARY

The acute leukemias (AL) compose a heterogeneous group of neoplastic stem cell disorders characterized by unregulated proliferation and blocked maturation. The two major groups of AL are AML and ALL. These two major groups are further classified into subtypes based on morphologic criteria, cytochemical stains, immunologic analysis, and cytogenetic and molecular abnormalities. The WHO classification system, which separates those AML types with recurrent chromosomal abnormalities, those with multilineage dysplasia, and those following cytotoxic therapy from the classic FAB categories has replaced the FAB classification system. It also recognizes new subcategories of acute basophilic leukemia, acute panmyelosis with myelofibrosis, and myeloid sarcoma.

Peroxidase and/or Sudan black B cytochemical staining help differentiate AML (peroxidase positive) from ALL (peroxidase negative). Subgrouping the AMLs further requires additional cytochemical stains, immunophenotyping, and cytogenetic analysis. The most common cytogenetic abnormality is the t(15;17) found in acute promyelocytic leukemia. This abnormality has been shown at the molecular level to involve the retinoic acid receptor (*RAR*) gene and the *PML* gene.

AL's onset is usually abrupt; without treatment, it progresses rapidly. Symptoms are related to anemia, thrombocytopenia, and/or neutropenia. Splenomegaly, hepatomegaly, and lymphadenopathy are common findings. Hematologic findings include a macrocytic or normocytic, normochromic anemia, thrombocytopenia, and a decreased, normal, or increased leukocyte count. Blasts are almost always found in the peripheral blood. A bone marrow examination is always indicated if leukemia is suspected. The bone marrow reveals $\geq 20\%$ blasts. An update of the WHO classification for AML is on the Website, Chapter 24.

REVIEW QUESTIONS

LEVEL I

- A differential report notes the presence of more than 20% blasts. This number supports the diagnosis of: (Objective 1)
 - CML
 - AML
 - CLL
 - MDS
- The presence of blasts with no evidence of myeloid differentiation by morphology and <3% positive for SBB or MPO is commonly seen in: (Objective 2)
 - AML—minimally differentiated
 - AML—without maturation
 - Acute basophilic leukemia
 - Myeloid sarcoma
- Which M:E ratio is most characteristic of acute leukemia? (Objective 4)
 - 1:1
 - 10:1
 - 1:5
 - 4:1
- A large cell with an immature nucleus containing multiple prominent nucleoli and few azurophilic granules is a: (Objective 3)
 - type 1 myeloblast
 - type 2 myeloblast
 - promyelocyte
 - promyelocyte with hypogranulation
- The leukemia that belongs to the WHO classification of AML with recurrent genetic abnormalities is: (Objective 2)
 - APL
 - megakaryoblastic leukemia
 - erythroleukemia
 - AML minimally differentiated
- PAS stain differs from the traditional stains used in cytochemistry in that PAS: (Objective 5)
 - requires a fresh, nonanticoagulated specimen
 - is reported as positive or negative in different cell lines
 - produces characteristic patterns of positivity in different cell lines
 - is better used in conjunction with monoclonal antibody testing
- Auer rods have been determined to be: (Objective 6)
 - diagnostic for AML
 - composed of histamine
 - positive for proteolytic esterases
 - present in high numbers in adolescent AML

LEVEL II

- In attempting to subtype a case of acute leukemia, the clinical laboratory scientist noted that the blasts were negative with myeloperoxidase, Sudan black B, naphthol AS-D chloroacetate esterase, and alpha-naphthyl butyrate esterase but positive when stained with alpha-naphthyl esterase and PAS. Peroxidase was positive at the ultrastructural level. These blasts should show positivity with the following monoclonal antibodies: (Objectives 2, 4)
 - CD41, CD42, CD61
 - CD24
 - CD7
 - glycophorin A
- The WHO classification of AML is based on: (Objectives 2, 7)
 - genetic abnormalities
 - morphology and cytochemistry of blasts
 - immunophenotyping of blasts
 - A, B, and C
- Which of the following leukemias is associated with faggot cells? (Objective 2)
 - APL
 - AML with multilineage dysplasia
 - AML t(8;21)
 - AML therapy related
- These leukemic blasts demonstrate CD71 positivity and have coarse positivity with PAS: (Objective 4)
 - erythroblasts
 - myeloblasts
 - megakaryoblasts
 - monoblasts
- A bone marrow from a 20-year-old male revealed 40% agranular blasts. Cytochemical stains were negative for myeloperoxidase, SBB, specific and nonspecific esterases. What immunophenotype panel should be used to help identify the blast cell lineage? (Objective 6)
 - CD13, CD33, CD34, CD10, CD19, CD2, CD3, CD5
 - CD11a, CD14, CD10, CD2, CD3, CD71, CD61
 - CD13, CD33, CD34, CD11b, CD71, CD41
 - CD41, CD61, CD13, CD15, CD38, CD117

REVIEW QUESTIONS (continued)

LEVEL I

8. A bone marrow contains many blast cells that stain positively for alpha-naphthyl acetate esterase. This reaction indicates that these cells are more likely of what lineage? (Objective 5)
 - a. erythroblastic
 - b. lymphoblastic
 - c. monoblastic
 - d. myeloblastic
9. When Auer rods are found in blasts of a case of acute leukemia, the leukemia is most probably: (Objective 6)
 - a. undifferentiated
 - b. B lymphocytic
 - c. T lymphocytic
 - d. myelocytic
10. Circulating micromegakaryocytes typically can be found in which of the following acute leukemias? (Objectives 2, 3)
 - a. AML with t(8;21)
 - b. APL
 - c. AML therapy related
 - d. acute megakaryoblastic

LEVEL II

6. A patient has a leukocyte count of $75 \times 10^9/L$. A large number of blast cells are present in the peripheral blood smear. Cytochemical stains reveal the following:

• Periodic acid Schiff	negative
• Sudan black B	positive
• Naphthol AS-D chloroacetate esterase	positive
• Alpha-naphthyl acetate esterase	negative

 Based on the staining reaction, these cells would be considered: (Objective 4)
 - a. myeloblasts
 - b. stem cells
 - c. monoblasts
 - d. promyelocytes
7. A patient with leukemia is receiving chemotherapy that includes a drug that is an antagonist to folic acid metabolism. Which of the following types of erythrocytes will be produced? (Objective 5)
 - a. spherocytes
 - b. microcytes
 - c. macrocytes
 - d. codocytes
8. In neutrophils, the myeloperoxidase activity is located in the: (Objective 4)
 - a. primary granules
 - b. secondary granules
 - c. mitochondria
 - d. nucleoli
9. The presence of CD34, CD13, and CD14 is typically associated with a positive: (Objective 4)
 - a. periodic acid Schiff stain
 - b. TdT
 - c. CD71
 - d. myeloperoxidase
10. All transretinoic acid therapy is used in leukemia patients with this genetic abnormality: (Objectives 3, 5)
 - a. t(9;22)
 - b. t(8;21)
 - c. t(15;17)
 - d. trisomy 8

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Guillermo had bleeding symptoms when he was seen in the emergency room. A CBC was performed and revealed leukocytosis, anemia, and thrombocytopenia. The differential was abnormal with blasts and promyelocytes present. A bone marrow was performed. The M:E ratio was elevated at 7.8:1. The predominant cell was an abnormal promyelocyte. These cells had very heavy granulation and multiple Auer rods. The diagnosis is AML-M3 of the hypergranular type.

Question:

1. What clues do you have that this patient may have an acute leukemia?

Explanation:

There are anemia, increased WBC, decreased platelets, and, most significantly, blasts and promyelocytes on the peripheral blood smear.

Question:

2. Based on the presenting data, what additional testing might be of value?

Explanation:

A bone marrow should be performed. Other tests could include cytogenetics, molecular testing for the RAR- α /PML translocation, and FISH for translocation (15:17).

Question:

3. Based on the peripheral blood examination, what cytochemical stain results would you expect to find on Guillermo's neoplastic cells?

Explanation:

Myeloperoxidase, Sudan black B, and specific esterase should be positive because these cells are myeloid in origin.

Question:

4. If the cells from Guillermo's bone marrow were immunophenotyped, which of the following would be positive? CD13, CD33, CD34, CD2, CD7, CD10, CD19.

Explanation:

Because these are promyelocytes, the cells should be positive for CD13 and CD33. The CD34 is generally negative in APL. CD2, CD7, CD10, CD19 are lymphocyte markers and should be negative.

Question:

5. Based on the morphology and cytochemical staining of these cells, what is the most likely AML classification?

Explanation:

It most likely belongs to the group acute myeloid leukemias with recurrent genetic abnormalities and the subgroup acute promyelocytic leukemia.

Question:

6. What is the major complication associated with this leukemia?

Explanation:

Disseminated intravascular coagulation (DIC) is common due to the release of large numbers of granules from the promyelocytes, which have procoagulant activity.

Question:

7. What chromosome abnormality is associated with this leukemia?

Explanation:

The t(15;17) karyotype is diagnostic of acute promyelocytic leukemia. At the molecular level, the RAR- α /PML is found.

Question:

8. If this patient were treated with all transretinoic acid and 2 weeks later the blood count was repeated, what would you expect to find?

Explanation:

The peripheral blood count would be increased because the promyelocytes mature into granulocytes with this therapy.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

What results would you expect to find on the CBC and differential in a suspected case of acute leukemia?

Answer

You would expect a normocytic, normochromic anemia; decrease in platelets with some large forms present; neutropenia; monocytosis;

and on the differential blast cells, an increase in eosinophils and basophils.

Checkpoint! 2

What is the major difference between the FAB and WHO classification systems in differentiating acute leukemia from the other neoplastic hematologic disorders?

Answer

In the WHO classification, the minimum blast count compatible with AL is 20%; in the FAB classification, the minimum was 30%.

Checkpoint! 3

Explain why molecular analysis is not performed on all suspected cases of AL.

Answer

The molecular aberrations are not known for all AL and, thus, probes are not available. Those in which an aberration is commonly present and can be probed for are APL and the ALL.

Checkpoint! 4

Why is it important to do molecular studies on patients with acute promyelocytic leukemia?

Answer

The RAR- α /PML abnormality is diagnostic of APL. Those with this translocation respond to therapy with all transretinoic acid. If the translocation disappears after therapy and then reappears, relapse can be predicted.

Checkpoint! 5

What hematologic feature helps differentiate AML minimally differentiated from AML without maturation?

Answer

Cytochemical stains in AML without maturation are negative, but some of the blasts in AML minimally differentiated have a positive re-

action with myeloperoxidase and/or Sudan black B. Both have myeloid antigens, CD13 and CD33.

Checkpoint! 6

A patient with AML has a peripheral blood differential that includes 91% myeloblasts, 3% promyelocytes, 3% granulocytes, and 3% monocytes. Which category of AML is the most likely diagnosis? Explain.

Answer

This is an AML minimally differentiated. There are >90% myeloblasts. AML with differentiation has <90% myeloblasts.

Checkpoint! 7

What is the differentiating hematologic feature of acute erythroid leukemia that allows it to be subgrouped?

Answer

More than 50% of the bone marrow cells are erythroid and 20% or more of the remaining cells are blasts.

Checkpoint! 8

Predict the peripheral blood picture of a patient on antifolate chemotherapy.

Answer

There would be a megaloblastic blood picture including pancytopenia with a macrocytic anemia.

Acute Lymphoblastic Leukemias

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Basic biology of ALL
- ▶ Clinical findings
- ▶ Laboratory findings
- ▶ Classification
- ▶ Therapy
- ▶ Summary
- ▶ Review questions
- ▶ References

Acute Lymphoblastic Leukemias

Susan J. Leclair, Ph.D.
J. Lynne Williams, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study the student should be able to:

1. Define *acute lymphoblastic leukemia* (ALL) and differentiate it from acute myeloid leukemia (AML).
2. List and define the common variants seen in ALL as defined by the FAB and WHO classifications.
3. Describe and recognize the typical peripheral blood picture (erythrocytes, leukocytes, blasts and thrombocytes) seen in ALL.
4. Give the typical results of cytochemical stains in ALL.
5. Summarize the clinical signs and symptoms and the most frequent age groups associated with ALL.
6. Define the rare acute leukemias that are not included in AML and ALL groups.

■ OBJECTIVES—LEVEL II

At the end of this unit of study the student should be able to:

1. Compare and contrast the various presentations of ALL.
2. Predict the most likely WHO or immunophenotype subgroup based on patient history, physical assessment, and laboratory findings.
3. Correlate cellular presentation with prognosis and common complications in ALL.
4. Correlate Wright stain blast morphology in the ALL subgroups with cytochemical stains, flow cytometry, and genetic testing results.
5. Evaluate peripheral blood results in relation to oncological therapy (i.e., complete or partial remission, relapse).
6. Identify AL from a peripheral blood smear and recommend laboratory tests that may be useful in differentiation of AML and ALL and in classification of subtypes.

KEY TERMS

Acute undifferentiated leukemia (AUL)
 B cell ALL
 Bilineage acute leukemia
 Biphenotypic acute leukemia
 Burkitt cell
 Consolidation therapy
 Induction therapy
 Maintenance chemotherapy
 Natural killer (NK) cell acute leukemia
 T cell ALL

BACKGROUND BASICS

The information in this chapter will build upon concepts learned in previous chapters. To maximize your learning experience you should review and have an understanding of these concepts before starting this unit of study.

Level I

- ▶ Summarize the origin and differentiation of hematopoietic cells.
- ▶ Describe the maturation, differentiation, and function of the lymphocyte.
- ▶ Outline the classification and general laboratory findings of the acute leukemias.
- ▶ Summarize the typical laboratory findings that define acute myeloid leukemia.

Level II

- ▶ Summarize the role of oncogenes and growth factors in cell proliferation, differentiation, and maturation.
- ▶ Diagram the maturation pathway for T and B lymphocytes.
- ▶ Describe the role of molecular analysis in diagnosis and treatment of acute leukemia.)
- ▶ Describe the use of immunophenotyping in acute leukemia.
- ▶ Describe the role of cytogenetics in diagnosis and treatment of acute leukemia.

CASE STUDY

We will refer to this case study throughout this chapter.

Dan, a 4-year-old white male, is seen by his physician for symptoms of easy fatigue and bruising. His mother states that until one month ago he was a "typical kid." Since then she has noticed increased lassitude, a regression to more baby-like behavior, and loss of appetite. For the past two days, his temperature has been 100°F. Upon physical examination, the child presented as a pale, quiet child of appropriate size for his age. Most systems were unremarkable with the exception of several small firm lymph nodes felt in the cervical and auxiliary regions. His CBC revealed a WBC count of $40.2 \times 10^9/L$ with 90% blasts. Consider the laboratory testing that may help in the diagnosis of Dan's illness.

OVERVIEW

This chapter is a study of the acute lymphoblastic leukemias (ALL). A summary of clinical signs and symptoms as well as hematologic findings associated with ALL are discussed. A description of the classification systems including the morphologic FAB system and the World Health Organization (WHO) system follows. Lastly, the rare acute leukemias that are not grouped into either AML or ALL are briefly reviewed.

INTRODUCTION

Lymphocyte malignancies include a wide spectrum of syndromes, from disorders that primarily involve the bone marrow and peripheral blood (leukemias) to those that initially present as tumorous masses (lymphomas) primarily involving the lymphoid organs (lymph nodes, tonsils, spleen, thymus, and lymphoid tissue of the gastrointestinal tract). The neoplastic transformation (cell of origin) may involve the common lymphoid progenitor cell (CLP), or more differentiated progenitors of the T, B or NK (natural killer) cell lineage.

Generally, T cell and NK cell malignancies tend to have more aggressive clinical behavior than B cell malignancies. T cell malignancies often involve extranodal and extramedullary sites including the skin, central nervous system, or the mediastinum. Neoplastic B cells can secrete monoclonal proteins (immunoglobulins; i.e. IgM, IgA, IgG) inappropriately, which may increase the viscosity of the blood and impair blood flow through the microcirculation (the hyperviscosity syndrome). The monoclonal immunoglobulins can interact with cell surfaces and impair granulocyte or platelet function, or induce the formation of erythrocyte rouleaux in vivo and in vitro. They can also interact with the coagulation proteins, resulting in impaired

TABLE 1

Initial Laboratory Findings Characteristic of ALL

Peripheral Blood	Leukocyte count usually increased but may be normal or decreased
	Neutropenia
	Lymphoblasts
	Normocytic, normochromic anemia
	Thrombocytopenia
Bone Marrow	Hypercellular
	≥20% lymphoblasts (WHO)

associated with increased risk of infection. The platelet count is usually decreased (median $48\text{--}52 \times 10^9/\text{L}$).¹ Normocytic, normochromic anemia is almost always present and can be severe. Anisocytosis, poikilocytosis, and nucleated erythrocytes, however, are not usually present.⁷ (Table 1).

Morphologic evaluation of peripheral blood smears usually reveals the presence of blasts. The most common presentation in children is one in which there is homogeneity in the morphology of the lymphoblasts. The blasts are typically small, up to twice the size of a small lymphocyte, with scant to moderate amounts of light basophilic or blue-grey cytoplasm. The nucleus is round or slightly indented, with finely granular to slightly clumped chromatin, and inconspicuous or absent nucleoli (Figure 1). The chromatin pattern can vary from case to case, but is homogeneous within cases. In adults, the more common presentation is one in which the lymphoblast morphology is heterogeneous. Larger lymphoblasts with moderate amounts of basophilic cytoplasm, irregularly shaped nuclei and prominent nucleoli can be intermixed with smaller blasts, producing a heterogeneous population of leukemic cells

(Figure 2). The cytoplasm can contain amphophilic granules that stain fuchsia, which may make it difficult to distinguish these lymphoblasts from the myeloblasts seen in AML. Cytochemical staining should help clarify the cellular origin of the leukemic blasts (see below). There is significant variability in cell size, nuclear chromatin condensation, and cytoplasmic basophilia. This marked heterogeneity of morphology is seen both within a given case and between cases. The FAB classification distinguished between those diseases with a homogeneous blast population (L1) and those with a heterogeneous blast population (L2). The WHO classification does not. The distribution of ALL into L1 and L2 subtypes has little relevance in predicting outcome and thus, the FAB classification is being replaced by the WHO classification.

 CASE STUDY (continued from earlier in this chapter)

The physician ordered a CBC on Dan. The results are as follows:

WBC	$40.2 \times 10^9/\text{L}$
RBC	$3.45 \times 10^{12}/\text{L}$
Hb	9.7 g/dL
Hct	0.32 L/L
MCV	92.7 fL
MCH	28.1 pg
MCHC	30.3
RDW	17.3
PLT	$63 \times 10^9/\text{L}$

The differential showed 90% lymphoblasts, 8% neutrophils, 1% monocytes, and 1% eosinophils. Rare nucleated erythrocytes are seen on scan. The platelets appear decreased in number.

- Based upon this data, what would be the initial interpretation of John's presentation?

hemostasis. Production of autoantibodies spontaneously or by the B-cell neoplasia may lead to autoimmune hemolytic anemia, autoimmune thrombocytopenia, or autoimmune neutropenia.

This chapter discusses a group of lymphoid malignancies known as acute lymphoblastic leukemia. There are two major categories of acute leukemias, classified according to the cellular origin of the primary defects: acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL). If the defect affects primarily the common lymphoid progenitor cell (CLP) or its progeny, it is classified as ALL. If the defect affects primarily the common myeloid progenitor cell (CMP) or its progeny, it is classified as AML. ALL falls within the WHO classification category of “Precursor B- and T-cell neoplasms” (see below).

▶ BASIC BIOLOGY OF ALL

Similar to AML, the ALLs are hematologic disorders characterized by malignant neoplastic proliferation and accumulation of immature and dysfunctional hematopoietic cells in the bone marrow. The basic abnormality appears to be multiple somatically acquired genetic mutations within a lymphoid precursor cell at one of several possible stages of development, giving rise to a clone of malignant lymphocytes. These lymphoid cells proliferate in an unregulated manner (i.e. they have altered responses to growth and antigrowth signals) and have a block in differentiation at various stages in their maturation sequence. They do not develop into mature cells, have an enhanced ability of self-renewal, and have increased resistance to apoptosis. Thus the leukemic clone expands.¹ The trigger for the original leukemic genetic mutations is unknown but may be a combination of leukemogenic factors. As in AML, impairment of normal hematopoiesis is the primary cause of concern.

The types of genetic alterations include chromosomal rearrangements and abnormalities of leukemic cell ploidy, both of which result in abnormal karyotypes detected by cytogenetic analysis, as well as point mutations affecting a variety of oncogenes or tumor suppressor genes, detectable by molecular techniques (RT-PCR, FISH).²

Initially diagnosis of ALL required the presence of $\geq 30\%$ lymphoblasts and the parameters for classifying the neoplastic cells in ALL were defined by the morphologically-based FAB classification.³ The World Health Organization’s classification utilizes cellular cytochemical reactions, immunophenotyping, and genetic abnormalities as well as cell morphology to discriminate among the various lymphoproliferative disorders. WHO recommends that a diagnosis of ALL should not be made if the blast count is less than 20%.⁴

▶ CLINICAL FINDINGS

Acute lymphoblastic leukemia (ALL) is primarily a disease of young children, with a peak incidence between the ages of 2 and 5 years, and gradually decreasing rates during later childhood and adolescence. The incidence rises again in the sixth decade, reaching a second, smaller peak in the elderly. In the younger population, the onset of signs and symptoms can be insidious or abrupt, and often nonspecific in nature. Without treatment survival is short, but with current treatment regimens, most children enter a period of prolonged remission and many appear to be “cured.”⁵ For an adult with ALL, the onset of signs and symptoms is generally more rapid, with more significant complaints of fatigue, infections, and bruising. Adult onset ALL does not respond to treatment as well as childhood ALL, and morbidity and mortality statistics are significantly worse.⁶

The clinical presentation generally reflects the degree of marrow failure and the extent of extramedullary disease. Symptoms are related to anemia, thrombocytopenia, and neutropenia, due to replacement of normal marrow elements by leukemic lymphoblasts. Common complaints include fatigue, pallor, fever, weight loss, irritability, and anorexia. Fever is often related to a concomitant infection. Petechiae and ecchymoses are present in over half the patients; actual hemorrhage is less common. Bone pain is noted in about 80% of patients, especially tenderness of the long bones, and is associated with expansion of the marrow cavity by leukemic cells. Often this complaint is dismissed as “growing pains.” When severe, the child may refuse to walk or stand. Occasionally children have symptoms related to CNS involvement, including headaches and vomiting. Splenomegaly, hepatomegaly, and lymphadenopathy are common findings, associated with leukemic infiltrations.

Checkpoint! 1

Compare the typical age groups in which AML and ALL are found.

▶ LABORATORY FINDINGS

Evaluation of the peripheral blood and bone marrow is critical to making a diagnosis of ALL.

PERIPHERAL BLOOD

The leukocyte count may be increased, decreased, or normal (from 0.1 to $>50 \times 10^9/L$). The median leukocyte count at presentation is $10\text{--}12 \times 10^9/L$.¹ About 50% of the patients have leukocytosis due to an abundance of circulating leukemic lymphoblasts. Even though the total leukocyte count is usually elevated, neutropenia is often marked, and is

a

b

FIGURE 2 a. Lymphoblasts in peripheral blood from acute lymphoblastic leukemia, heterogeneous morphology. b. Lymphoblasts in the bone marrow of a patient with heterogeneous lymphoblasts. (a. Wright-Giemsa stain; 1000× magnification; b. Wright-Giemsa stain; 500× magnification)

BONE MARROW

The hypercellular bone marrow reveals replacement of normal hematopoietic cells by neoplastic lymphoid cells. Although the WHO criteria requires $\geq 20\%$ lymphoblasts, most patients present with $>65\%$ blasts. The morphology of the blasts can be variable as described for peripheral blood blasts. The more homogenous presentation is frequently seen in pediatric patients, while the heterogeneous population of blasts is more frequently seen in adult patients. Auer rods are not present in lymphoblasts. Intracytoplasmic inclusions have been described in the lymphoblasts of patients with ALL, and cytochemistry suggests they are probably lysosomal in origin.⁸

OTHER LABORATORY FINDINGS

As with AML, other laboratory findings are consistent with increased cellular metabolism, and in general the extent of abnormality of the various laboratory parameters is proportional to tumor burden. Hyperuricemia and an increased lactate dehydrogenase are common findings resulting from the increase in cell turnover. Hypercalcemia, when present, is thought to be caused by increased bone resorption associated with leukemic proliferation in the bone marrow. Impairment of renal function is often seen, due to leukemic infiltration of the kidneys, as well as a uric-acid induced nephropathy. These patients will have serum chemistries consistent with impaired renal function (elevated creatinine, urea nitrogen, uric acid, and phosphorus).

Because the central nervous system (CNS) is a frequent site for extramedullary spread of ALL, cerebrospinal fluid (CSF) is usually analyzed for the presence of circulating lymphoblasts. Although CNS involvement is relatively uncommon at diagnosis, most patients will eventually develop

overt CNS disease unless adequate preventive therapy is administered.

CLASSIFICATION

The first step in classifying acute leukemia (AL) is to differentiate ALL from AML. This can usually be done by evaluating cell morphology and interpreting cytochemical results. Further classification into subgroups relies on analysis of the leukemic cells. Immunophenotyping of ALL helps to differentiate the lineage of the neoplastic cells into T, B, or NK cells. It can also determine the cells' maturation stage. Cytogenetics and molecular analysis can provide evidence of clonality, reveal distinct genetic abnormalities associated with subgroups of ALL and provide important prognostic information. Molecular analysis also can help determine neoplastic cell lineage. Similar to the FAB classification of AML, the FAB classification of ALL is based on morphology and cytochemistry of the malignant cell. The WHO classification relies on identification of the malignant cells as T or B cells and on their degree of maturation.

IDENTIFICATION OF CELL LINEAGE

Cytochemistry

Differentiation of ALL from AML (AML minimally differentiated or AML without maturation) is usually not possible by Romanowsky stained smears alone. Cytochemistry helps identify the lymphoid nature of these abnormal cells. In lymphoblasts, the myeloperoxidase, Sudan black B and non-specific esterase stains are negative. The PAS reaction usually demonstrates a coarse granular or block-like positivity. Some myeloid leukemias can also demonstrate PAS reactivity, but

in AML the granular pattern (if present) is superimposed on a diffusely positive background, whereas in lymphoblasts there is no background positivity. Lymphoblasts often demonstrate acid phosphatase positivity, especially those with a T cell immunophenotype. However, neither PAS nor acid phosphatase reacts exclusively with leukemic lymphoid cells.

Immunophenotyping

As described above, leukemic lymphoblasts lack specific morphologic and cytochemical features. Thus immunophenotyping is essential to not only differentiate ALL from AML minimally differentiated, but also to identify the immunologic subtype (T, B, or NK cell) of the neoplastic lymphoblast. This information has important prognostic implications.¹ Immunophenotyping is also useful in recognizing leukemias of mixed cell lineages, and in identifying minimal residual disease.

In normal lymphoid cells, the appearance of specific cellular markers or antigens is developmentally regulated. Some antigenic determinants appear at a very early developmental stage and disappear with maturity, whereas others appear on more mature cells. Malignant lymphoblasts share many of the features of their normal lymphoid counterparts.⁹ Studies of surface markers and intracellular markers reveal that lymphoblasts in ALL can be subclassified according to recognized stages of normal maturation. However, immunophenotyping has also demonstrated that while some leukemic cells have phenotypes of normal cells, others can show asynchronous gene expression, resulting in an inappropriate combination of antigens¹⁰ (Figure 3 ■). Occasionally, B lineage lymphoblasts will express low levels of the myeloid-associated antigens CD13 and CD33.

Terminal Deoxynucleotidyl Transferase (TdT)

In addition to identification of lymphocytes by immunophenotyping, certain intracellular enzymes are helpful in identifying cellular subtypes. The most important of these

is terminal deoxynucleotidyl transferase (TdT), a DNA polymerase found in cell nuclei. Its presence can be determined by direct enzyme assay, by indirect immunofluorescence, or with monoclonal antibodies. This enzyme is not present in normal mature lymphocytes but can be found in 65% of the total thymic population of lymphocytes, with the TdT cells localized in the cortex.¹¹ It can also be found in very early B cells and occasionally very early myeloblasts (myeloblasts minimally differentiated, or without differentiation). About 1–3% of normal bone marrow cells are TdT positive. Its value in ALL is to identify early precursor lymphoblasts from more mature cells.

Cytogenetic Analysis

Karyotyping of the ALLs is important for providing prognostic information. Specific abnormalities are associated with certain subgroups. Chromosomal translocations are found in 75% of ALL cases, and in many instances the breakpoints involve transcription factor genes such as *MYC*, *TAL1*, *HOX11*, *HOX11L2*, *E2A*, *MLL*, *TEL*, and *AML1*.² Abnormalities appear to be more common in B-cell ALL than in T-cell ALL. In addition to translocations, hyperdiploidy (>46 chromosomes) and hypodiploidy (<46 chromosomes) have been described. Generally, hyperdiploidy is a better prognostic finding than hypodiploidy. Patients who have hyperdiploid chromosome counts >50 have a better prognosis with long-term remission. Patients with hyperdiploid chromosome counts <50 have a worse prognosis.²

Molecular Analysis

Point mutations of major cell cycle regulator proteins are seen in ALL, such as p53; various cyclin-dependent kinase inhibitors (CDKi), including p16, p15, p14; and activating mutations of proto-oncogenes involved in signaling pathways that govern cell proliferation, such as RAS. These are often detectable by standard molecular techniques such as quantitative real-time PCR (RT-PCR) or fluorescent in-situ hybridization (FISH).

■ **FIGURE 3** B lymphocyte maturation pathway with leukemic and other lymphoproliferative counterparts. (ALL = acute lymphoblastic leukemia; CLL = chronic lymphocytic leukemia; PLL = prolymphocytic leukemia; HCL = hairy cell leukemia; Clg = cytoplasmic immunoglobulin; Slg = surface immunoglobulin)

Another application of molecular analysis in acute lymphoid malignancies is to detect DNA rearrangements of the immunoglobulin (Ig) heavy and/or light chain genes, or the proteins which constitute the T-cell receptor (TCR), the α , β , δ , and γ chain. Rearrangement of Ig heavy chain genes occurs before cellular protein expression, and is an early genetic marker of B-lymphocyte ontogeny.¹² Likewise, rearrangement of the TCR polypeptide genes is an early marker of T-lymphocyte ontogeny. Molecular analysis to establish rearrangements of Ig or TCR genes can be used to establish clonality of the T or B cell populations, as well as to determine lineage derivation.¹³ However, Ig gene rearrangement is seen in some instances of T-cell ALL, and TCR gene rearrangement occurs in some cases of B-cell precursor ALL. Thus molecular phenotyping to determine B- or T-cell lineage is not 100% reliable.¹⁴

CASE STUDY (continued from earlier in this chapter)

2. What is the correct choice of tests that should be used in the initial follow up in this case?

Checkpoint! 2
 Contrast the malignant neoplastic cells in ALL with those found in AML.

FAB CLASSIFICATION

The FAB classification divides ALL into three types (Table 2). L1 is characterized by a population of small, homogeneous blasts with scant cytoplasm and inconspicuous nucleoli. It is seen primarily in children. L2 is characterized by a heterogeneous population of cells with more abundant cytoplasm, less condensed nuclei, and more conspicuous nucleoli. L2 is more frequently seen in adults. L3, also known as Burkitt's type leukemia, is characterized by large basophilic lymphoblasts with abundant cytoplasm and vacuoles.

WHO CLASSIFICATION

The WHO classification defines two subgroups of ALL: 1) Precursor B- and T-cell neoplasms (leukemia/lymphoma) (which includes the FAB categories of L1 and L2) and

2) Burkitt type ALL (FAB category L3). The WHO classification considers acute lymphoblastic leukemias and lymphoblastic lymphomas to be a single disease with different clinical presentations. Thus, precursor T-cell and precursor B-cell neoplasms with bone marrow and peripheral blood involvement are acute lymphoblastic leukemias, while precursor T-cell and precursor B-cell neoplasms presenting as solid tumors are lymphoblastic lymphomas. The morphology and heterogeneity of bone marrow lymphoblasts help to define these categories (Table 3).

The cell features evaluated include:

- cell size
- nuclear chromatin
- nuclear shape
- nucleoli
- amount of cytoplasm
- cytoplasmic basophilia
- cytoplasmic vacuolation

Precursor B-Cell Leukemia

Precursor B-cell leukemia (B-cell ALL) is a neoplasm of lymphoblasts committed to the B-cell lineage, involving the bone marrow and peripheral blood. Occasionally, the disease may present with primary involvement of the lymph nodes or extranodal sites, in which case it is called B lymphoblastic lymphoma (B-LBL). Although arbitrary and with exceptions, if a patient has a mass lesion and 25% or fewer lymphoblasts in the bone marrow, the term *lymphoma* is preferred.

B-ALL accounts for 80–85% of the cases of ALL in children, and ~70% of the cases of ALL in adults. In general children diagnosed with precursor B-cell ALL have a good prognosis (long term event-free survival of >80%). Adult event-free survival is lower, between 30 and 50 percent, depending on the disease subtype, and patient age at diagnosis (there is an inverse relationship between age and prognosis). Although the morphologic appearance of the blasts is usually homogeneous, a heterogeneous morphology can be seen in some cases, particularly in adult patients.

Molecular testing may be helpful in establishing the B-cell lineage for B-ALL. B cell lineage is detected by rearrangement of immunoglobulin genes (Ig).^{12,13} The assembly of the D-J light chain segments is the first genetic event that identifies a B cell progenitor. Clonal gene rearrangement helps to differentiate neoplastic B cells from normal B cells. Ig gene

TABLE 2

FAB Classification of ALL			
	Morphology	TdT	CALLA (CD 10)
ALL – L1	Small lymphoblasts scanty cytoplasm; Moderately clumped chromatin; Inconspicuous nucleoli	+	+
ALL – L2	Small and medium size lymphoblasts; Mixed chromatin patterns; Inconspicuous nucleoli	+	+
ALL – L3 Burkitt-type	Large lymphoblasts; Large nucleus with nucleoli; Cytoplasmic vacuolization; Intense cytoplasmic basophilia	–	+/-

★ TABLE 3

WHO Criteria for the Subtypes of ALL

Morphologic Feature	ALL	Burkitt Type ALL
Cell size	Small or large, heterogeneous	Large
Nuclear chromatin	Ranges from fine or clumped to variable-among cells within a single case	Fine and homogeneous
Nuclear shape	Occasional clefting or indentation common	Regular, oval to round
Nucleoli	Range from not visible or small and inconspicuous to large and prominent	Prominent, one or more
Cytoplasm Amount	Variable from scant to abundant	Moderately abundant
Basophilia	Variable	Very deep
Vacuolation	Variable	Often prominent

(WHO Criteria for the Subtypes of ALL Harris NL, Jaffe ES, Diebold J, Flandrin G, Muller-Hermelink HK, Vardiman J, Lister TA, Bloomfield CD. World Health Organization classification of neoplastic diseases of the hematopoietic and lymphoid tissues: report of the Clinical Advisory Committee meeting-Airlie House, Virginia, November 1997. *J Clin Oncol*. 1999 Dec;17(12):3835-49.)

rearrangement is seen in some instances of T-cell ALL, and thus additional markers of B lineage commitment are required for diagnosis.

Immunophenotyping of precursor B-cell ALL reveals that the lymphoblasts may have variable degrees of differentiation, which has clinical and prognostic implications (Table 4 ★, see Figure 3).^{1,10} The precursor B-lymphoblasts are TdT+, HLA-DR+, and almost always CD19+ and CD79a+. The earliest B-cell differentiation stage, the “pro-B,” is identified by this immunophenotype. In the next differentiation stage, the “intermediate pre-B” stage or common ALL, the blasts also express CD10 (the common ALL antigen, or CALLA).¹⁵ B-ALL cases expressing the CD10/CALLA antigen appear to have the best prognosis of the immunologic subtypes.¹⁶ In the most mature precursor B differentiation stage, (“pre-B” stage), the blasts may be CD10 negative, but express CD 20, surface CD22 (sCD22) and cytoplasmic mu chains (cytμ). Surface immunoglobulin is usually absent. Malignancies of later stages of B lymphocyte differentiation are included in the classification of chronic neoplastic lymphoproliferative disorders.

The CD19, CD22, CD10, and TdT phenotype is the same as the phenotype of most normal immature B cells in the bone marrow. Therefore, the distinction of normal and neoplastic B cells may be difficult unless the neoplastic cell also has an abnormal phenotypic marker.¹⁷ This distinction is important for the detection of minimal residual disease after treatment. In some cases, the neoplastic cells lose antigens that usually show synchronous expression, or express two antigens that are usually not found on the same differentiation stage. Up to 50% of cases of B ALL co-express a myeloid-associated antigen, CD13 or CD33. This abnormal finding makes it easier to differentiate the neoplastic cells from normal cells and thus detect MRD.

Cytogenetic abnormalities associated with B-ALL include translocations, hypodiploidy, and hyperdiploidy.^{1,2} However, there appears to be no recurrent abnormality in terms of the specific genes or chromosomes involved. The most common translocation in childhood B-ALL, present in ~25% of the cases, is t(12;21)(p13;q22), producing the *TEL-AML1* fusion gene.² Both the *TEL* and *AML1* genes are translocated in other types of leukemia, including t(5;12), t(8;21), and t(3;21)

★ TABLE 4

Cellular Markers Useful in Diagnosis and Classification of B-ALL

Pre-B ALL	+	+	-	+	+(s)	+/-	+	-	+	-	+	-

(c) cytoplasmic; (s) surface; - = absent; +/- = can be present; + = present

found in various subtypes of AML. *TEL-AML-1* expression in B-ALL is associated with an excellent prognosis, with event-free survival approaching 90%. Hyperdiploid B-ALL is also a common cytogenetic abnormality, found in ~30% of patients at diagnosis. In addition, ~20% of hyperdiploid B-ALL also have mutations in the receptor tyrosine kinase *FLT-3*, resulting in constitutive activation of the receptor. Hyperdiploid B-ALL is also associated with an extremely good prognosis, with event-free survival rates near 90%.

Other cytogenetic abnormalities include: t(4;11)(q21;q23) (*AF4/MLL*)(9%), t(1;19)(q23;p13.3) (*PBX/E2A*)(5%), t(9;22)(q34;q11.2) (*BCR/ABL*)(4%) and hypodiploidy (5%). All are considered poor prognostic factors in B-ALL. The t(9;22) (*BCR/ABL*) translocation is more common in adults than children (10–15%) with B-ALL, and is generally associated with a poor prognosis.¹⁸ In most childhood cases, the *BCR/ABL* translocation results in a p190 kD fusion protein, while in adults, about half of the translocations produce the p210 kD protein that is present in CML. The remainder produce the p190 protein.

Precursor B-ALL generally has a good prognosis. In the pediatric population, the complete remission rate approaches 95%, and in adults, it is 60–85%.³ Long term, event-free survival is lower for both patient groups (~80% and 30–50%, respectively). Positive predictive factors in children include age 4–10, hyperdiploid chromosomes or t(12;21), and a low or normal WBC count at diagnosis. Adverse factors include very young age (<1 year), high WBC counts at diagnosis, and the other cytogenetic abnormalities listed above.

Precursor T-Cell Leukemia

Precursor T-cell leukemia (T-ALL) is a neoplasm of lymphoblasts committed to the T-cell lineage, involving the bone marrow and peripheral blood. Occasionally, the disease will present with primary involvement of the lymph nodes or extranodal sites, in which case it is called T lymphoblastic lymphoma (T-LBL). T-ALL accounts for about 15% of the

cases of childhood ALL. It is more common in adolescents than younger children, and more common in males than females. It accounts for ~25% of the cases of adult ALL.

T cell lineage can be detected by rearrangement of the T-cell receptor (TCR) genes using molecular methods. There are four TCR genes capable of rearranging, coding for the α , β , γ , and δ chains of the TCR. A neoplastic T-cell may exhibit rearrangement of one or more of these genes. Detection of a monoclonal TCR gene rearrangement suggests a neoplasm of the T cell lineage, but a small number of B-cell ALL will also demonstrate TCR gene rearrangement.

Precursor T-ALL usually presents with a high WBC count, and often a mediastinal mass (leukemic infiltration of the thymus) or other tissue masses. The lymphoblasts are similar to those seen in B-ALL, although there is more likely to be variability in size, and cytoplasmic vacuoles may be present. The cytochemistry is also similar to that seen in B-ALL, but acid phosphatase can show focal intense positivity in T-ALL.

The lymphoblasts in T-ALL are TdT+, and usually CD7+ and CD3+. They can have variable expression of CD1, CD2, CD4, Cd5, CD8, and CD10.¹⁰ Lymphoblasts frequently co-express CD4 and CD8, indicative of the cortical stage of thymocyte differentiation (“double-positive cells”).¹⁹ At the medullary stage of differentiation, the cells are either CD4+ or CD8+. CD79a, generally considered to be a B-lineage marker, has been observed in some cases. One or more of the myeloid-associated markers CD13 and CD33 can be seen. As in B-ALL, T-ALL also can be stratified into differentiation stages, with cytoplasmic CD3, CD2, and CD7 appearing in the earliest stage, followed by CD5, CD1a, and subsequently, the appearance of membrane CD3 (Table 5 🌟).

✓ Checkpoint! 3

Why is it necessary to immunophenotype the lymphoblasts in ALL if they have been identified as lymphoblasts morphologically?

🌟 TABLE 5

Cellular Markers Useful in Diagnosis and Classification of T-ALL

Subgroup	HLA-DR	TdT	CD34	CD2	CD1a	CD3	CD7	CD8	CD4	CD10	CD19	Rearrangement of	
												CD20	CD22
Pro T	+/-	+/-	+/-	-	-	+(c)	+	-	-	+/-	-	-	+/-
Pre T	+/-	+/-	+/-	+	-	+(c)	+	-	-	+/-	-	-	+/-
Cortical T	+/-	+/-	-	+	+	+(c)	+	+	+	+/-	-	-	+/-
Medullary T	+/-	+/-	-	+	-	+(c)	+	+* or -	+* or -	+/-	-	-	+/-

* Either CD4 or CD8 positive; (c) = cytoplasmic; - = absent; + = present; +/- may be present; Ig = immunoglobulin; TCR = T cell receptor

Cytogenetic studies reveal translocations in T-ALL as well as B-ALL. About one-third of the cases of T-ALL have translocations involving the alpha and delta T-cell receptor loci (14q11.2), the beta locus (7q35) or the gamma locus (7p14–15). The translocations involve a variety of partner genes including the transcription factors *MYC* (8q24.1), *TAL1* (1p32), *RBTN1* (11p15), *RBTN2* (11p13), *HOX11* (10q24) and *HOX11L2* (5q35).^{4,9} The result is usually a dysregulation of the partner gene, resulting in growth enhancement. In addition, molecular mutations of the *NOTCH1* gene are found in >50% of cases of T-ALL.⁹ *NOTCH1* encodes a transmembrane receptor that is involved in the regulation of normal T-cell development.

Historically, T-ALL was considered a high risk disease with a poorer prognosis than B-ALL. However, with current therapeutic protocols, survival is comparable for the two types of ALL.

✓ Checkpoint! 4

A patient has 50% blasts in his bone marrow. Cytochemical stains are negative with peroxidase and Sudan black B. Immunophenotyping is CD19 positive, but CD20, CD2, CD10, and CD7 negative. What additional testing may be helpful to distinguish the immunologic subgroup of this leukemia?

Acute Lymphoblastic Leukemia—Burkitt Type

This rare form of ALL occurs in both adults and children, and is considered to be the leukemic phase of Burkitt lymphoma. The lymphoblasts are homogeneous or monomorphic in appearance. The cells are large with abundant, intensely basophilic cytoplasm, with prominent cytoplasmic vacuolization (Figure 4 ■). The cytoplasmic vacuoles correspond to lipid vacuoles. The nucleus is oval to round with stippled chromatin and relatively clear parachromatin. They contain multiple basophilic nucleoli. Classically, this tumor

has a high proliferation rate, and many mitotic figures may be seen in the bone marrow smear. A “starry sky” pattern has been described, consisting of fields of basophilic leukemic blasts interrupted by benign macrophages that have ingested apoptotic tumor cells.

Burkitt cells show clonal rearrangement of the immunoglobulin heavy and light chain genes, as appropriate for B cells at this stage of differentiation. In addition, all cases have a translocation of the *MYC* gene (8q24) to the heavy chain region on chromosome 14 [t(8;14)] or to light chain loci on chromosome 2p12 [t(2;8)] or chromosome 22q11 [t(8;22)].^{20,2} As a result of the translocation, the *MYC* gene is under the control of the Ig promoters on chromosomes 14, 2, or 22, and is constitutively expressed. Overexpression of *MYC* drives cells through the cell cycle, and also activates genes involved in apoptosis.² A summary of the cytogenetic findings associated with subgroups of ALL can be found in Table 6 ■.

Treatment for Burkitt leukemia is substantially different from treatment for precursor B-ALL or T-ALL. Treatment consists of very intense chemotherapy of relatively short duration. Most patients have a good prognosis, with 80–90% survival.

✓ Checkpoint! 5

Contrast the morphology of blasts found in the two subtypes of ALL.

🌀 CASE STUDY (continued from earlier in this chapter)

- If the flow cytometry pattern showed a positive CD10, what would be the classification of this acute leukemia?
- In this situation, would the therapeutic outcome be considered as favorable or bleak? Why?

✓ Checkpoint! 6

A 3-year-old patient has 45% lymphoblasts in the bone marrow. The blasts are slightly larger than lymphocytes and appear to be a homogeneous population. The nuclear membrane is regular and nucleoli are not prominent. There is a small amount of moderately basophilic cytoplasm. What is the most likely WHO group of this leukemia? If the cells tested positive for CD19, CD10, and CD34, what is the most likely immunologic subgroup? Why should cytogenetics be done on this patient?

ACUTE LEUKEMIAS OF AMBIGUOUS LINEAGE

This WHO group of leukemias include malignant neoplasms in which the morphology, cytochemistry, and immunophenotype lack sufficient information to classify them within a given lineage, or neoplasms in which the blasts have morphologic and/or immunophenotypic characteristics of more than one lineage.

Acute Undifferentiated Leukemia

The **acute undifferentiated leukemia (AUL)** category includes acute leukemias in which the morphology, cytochemistry, and immunophenotype of the proliferating blasts lack sufficient information to classify them as myeloid or lymphoid origin. In this case, the leukemia is classified as “acute undifferentiated leukemia.”⁴ Electron microscopic studies can sometimes detect ultrastructural evidence of primary granules and/or peroxidase, a finding which would indicate acute non-lymphocytic leukemia. Determination of the myeloid or lymphoblastic origin of the cell is important for treatment decisions. Absence of primary granules and/or peroxidase with electron microscopy together with the other negative or ambiguous findings indicates a diagnosis of AUL. AUL is predominantly found in adults, and only about 1/3 of patients respond to the chemotherapy regimens of AML and ALL.

Acute Leukemias with Lineage Heterogeneity

This category includes those leukemias in which the blasts have morphologic and/or immunophenotypic characteristics of both myeloid and lymphoid cells (or of both T and B lymphocytes). If two distinct populations of blasts are identifiable, each expressing markers of a distinct lineage (i.e., one population myeloid and one population lymphoid, or one population T-lymphoid and one population B-lymphoid) the disease is considered a “**bilineage acute leukemia.**” If the blasts coexpress myeloid and T or B lineage specific markers, or concurrent T and B lineage markers, the disease is considered a “**biphenotypic acute leukemia.**”⁴ A more recently recognized leukemia with lineage heterogeneity is the “myeloid/**natural killer (NK)** cell acute leukemia,” which has markers of both NK cells (CD56+), and myeloid lineage cells (CD13 +/- CD33 +/- MPO).²¹

The biphenotypic designation is reserved for those cases in which there is ambiguity of lineage assignment. It should not be used in situations in which an ALL aberrantly expresses one or two myeloid antigenic markers, or an AML aberrantly expresses one or two lymphoid antigenic markers. These are considered “myeloid antigen positive ALL” and “lymphoid antigen positive AML” respectively. Because many markers are only lineage-associated and not lineage-specific, co-expression of only one or two cross-lineage antigens is insufficient for a diagnosis of biphenotypic leukemia.^{4,22}

Lack of lineage specificity (lineage infidelity) could be the result of genetic misprogramming, or the leukemic clone could represent a bipotential cell that has retained both lymphoid and myeloid markers during development.⁴ Although mixed-lineage leukemias are uncommon, it is important to identify them in order to determine their actual occurrence, to identify appropriate therapy, and to correlate karyotypic abnormalities.²³ A high percentage of the acute leukemias of ambiguous lineage have associated cytogenetic abnormalities. The cell of origin is thought to be the MPP.

Immunological phenotyping is necessary to define mixed lineage leukemias because there are no definitive morphological or cytochemical features for lymphoid cells. Biphenotypic leukemia is suspected if the percentage of cells having myeloid markers overlaps with the percentage having lymphoid markers. More specific diagnosis is possible if a double labeling technique utilizing two immunologic markers or a combination of cytochemistry and immunologic markers is used. This procedure distinguishes between mixed lineage (bilineage) and biphenotypic acute leukemias because it can be determined if the same cell has two separate markers.

✓ Checkpoint! 7

A patient with acute leukemia has two morphologically different types of blasts. One population is positive for CD7 and CD2. The other is positive for CD33 and CD13. What is the most appropriate classification of this leukemia?

► **THERAPY**

A significant number of acute leukemias express inappropriate combinations of antigens making diagnosis challenging. Treatment protocols and prognosis are proving to be more effective and accurate when the leukemic cell lineage is immunologically classified correctly. In addition, therapy response and detection of residual leukemic cells (minimal residual disease/MRD) is possible using immunophenotyping and genetic testing.

Before the 1960s, a patient diagnosed with acute leukemia could expect to die within a few months. With new treatment modalities, remission rates for ALL (T- and/or B-ALL) have improved dramatically. Approximately 80% of children treated for ALL can be expected to enter a prolonged remission with an indefinite period of survival. The prognosis of ALL in adults is not as good as in children. Only 10–25% have achieved a 5-year survival. Poor prognostic factors are listed in Table 7.

Chemotherapy for ALL is divided into several phases. The **induction therapy** phase is designed to reduce the disease into complete remission (i.e., eradicating the leukemic blast population). This is followed by the CNS prophylactic phase. CNS leukemia is the most common form of relapse in young children who have not undergone specific treatment to the brain and spinal column early in remission. The two potential modes of treatment in the CNS prophylactic phase are cranium irradiation and/or intrathecal chemotherapy. Cranial irradiation is seldom a component of most current treat-

★ **TABLE 7**

Poor Prognostic Indicators in Acute Lymphoblastic Leukemia (ALL)

Clinical findings
Infants (<1 year old)
Patients past puberty
CNS or mediastinal involvement
Laboratory findings
High blast counts
Presence of Philadelphia chromosome

ment protocols, due to the risk of neurocognitive deficits, endocrinopathy, and the risk of inducing a second cancer. The third phase is **maintenance chemotherapy**, also called cytoreductive therapy or remission **consolidation therapy**. The need for this type of therapy is controversial. Some studies have shown a slight increase in survival with its use, whereas others reveal no improvement. Before the institution of CNS prophylactic treatment, there was a high incidence of relapse. The maintenance therapy was designed to prevent this relapse and prolong remission. The purpose of maintenance therapy is to eradicate any remaining leukemic cells. Drug treatment usually continues for 2–3 years. The relapse rate after cessation of all therapy is about 25% in the pediatric patient population.

★ **TABLE 8**

Summary of Laboratory Features Helpful in Classification of ALL

Characteristic	Pro-B	Common ALL (Intermediate Pre-B)	Pre-B	Precursor T
Gene rearrangement				
Immunoglobulin (Ig)	+/-	+	+	-
T cell receptor (TCR)	-	-	-	+
Immunologic features				
Cytoplasmic μ	-	+	+	-
Surface Ig	-	-	+/-	-
Immunophenotype				
CD34	+	+/-	-	+
CD19	+	+	+	-
CD22	+(c)	+(c)	+(s)	-
CD10	-	+	+/-	-
CD20	-	+/-	+	-
CD2, CD3, CD5, CD7	-	-	-	+
Cytochemistry				
TdT	+	+	+	+
PAS	-	-	-	+

+ = positive; - = negative; (c) = cytoplasmic; (s) = surface

Allogeneic stem cell transplantation (HSCT) remains controversial. There is an incremental improvement in long term event-free survival in adults treated with HSCT in first remission (40–60%) versus treatment with chemotherapy alone (30–40%).¹ Currently, most clinicians consider HSCT to be of benefit to some high-risk adult patients. Patients who relapse while on therapy, or after only a short remission, are often considered candidates for HSCT. The use of umbilical cord blood as a source of HSC is being considered more frequently, especially in the pediatric patient population, as it does not require the same degree of histocompatibility as do transplants using peripheral blood or marrow stem cells.

Relapse is defined as the reappearance of leukemic cells anywhere in the body, although the bone marrow is the most common site. Leukemic relapse occasionally occurs at extramedullary sites. Most relapses occur during treatment, or within the first two years after completion. Rarely, relapses have been observed up to ten years post remission induction. Relapse indicates a poor outcome for most patients, especially if it occurs while on therapy, or after only a brief initial remission.

SUMMARY

The acute leukemias (AL) are a heterogeneous group of neoplastic hematopoietic cell disorders characterized by unregulated proliferation, blocked maturation, and/or blocked apoptosis. The two

major groups of AL are acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL). These two major groups are further classified into subtypes using the World Health Organization (WHO) Classification based on patient presentation, morphological criteria, cytochemical stains, immunologic analysis, and cytogenetic and molecular abnormalities (Table 8). This classification describes two subtypes for ALL, precursor B and precursor T leukemia. Immunophenotyping in ALL helps subtype the blasts into B- or T-ALL. The B cell lineage ALL includes Burkitt type leukemia. The peroxidase and/or Sudan black B may help differentiate AML (peroxidase positive) from ALL (peroxidase negative).

Acute leukemia with lineage heterogeneity is used to describe ALs in which blasts have characteristics of both myeloid and lymphoid cells or T and B lymphoid cells. *Biphenotypic leukemia* is used to describe ALs with blasts that possess markers of multiple lineages on the same leukemic cells while bilineage is used to describe leukemia with two different populations of blasts.

Regardless of subtype, the onset of AL is usually abrupt and, without treatment, progresses. Symptoms are related to anemia, thrombocytopenia, and/or neutropenia. Splenomegaly, hepatomegaly, and lymphadenopathy are common findings.

Hematologic findings of AL include a normocytic, normochromic anemia, thrombocytopenia, and a decreased, normal, or increased leukocyte count. Blasts are almost always found in the peripheral blood. A bone marrow examination is always indicated if leukemia is suspected. Using the WHO criteria, the bone marrow and/or peripheral blood must have more than 20% blasts.

REVIEW QUESTIONS

LEVEL I

- Which of the following descriptions is more closely associated with the lymphoblasts seen in ALL of childhood? (Objective 3)
 - heterogeneous with a deeply basophilic cytoplasm
 - homogeneous and small with moderate basophilia in the cytoplasm
 - heterogeneous with granules
 - homogeneous with granules
- Acute lymphoblastic leukemia is most often seen in patients: (Objective 5)
 - over the age of 60
 - age 35–60 years
 - age 10–35 years
 - below 5 years
- The WHO classification of ALL is primarily based on: (Objective 2)
 - cytogenetic and morphology abnormalities
 - morphology and cytochemistry of blasts
 - immunophenotyping of blasts and genetic analysis
 - molecular genetic abnormalities and cytochemistry of blasts

LEVEL II

- Cells that are positive for the 8;14 translocation are characteristic of which of the following? (Objective 4)
 - T cell ALL
 - reactive lymphocytosis
 - B cell ALL
 - Burkitt type ALL
- Monoclonal rearrangement of the TCR genes is associated with blasts that have the following immunophenotype: (Objective 2)
 - CD10+, CD22+, CD2–
 - CD2–, CD3–, CD10+
 - CD19+, CD22+, CD3–
 - CD2+, CD3+, CD7+
- In a case of ALL, the lymphoblasts showed strong localized positivity with acid phosphatase and were positive for CD7 and CD2, negative for CD19, CD24, and CD20. These blasts are most likely: (Objective 4)
 - T lymphoblasts
 - B lymphoblasts
 - lymphoid stem cells
 - biphenotypic blasts

REVIEW QUESTIONS (continued)

LEVEL I

4. An acute leukemia has morphologically undifferentiated blasts that are negative with cytochemical stains and lineage-marker associated immunophenotyping. This should be classified as: (Objective 6)
 - a. acute undifferentiated leukemia
 - b. mixed lineage acute leukemia
 - c. myeloid/NK cell acute leukemia
 - d. bilineal acute leukemia
5. Acute leukemia blasts that have myeloid and lymphoid markers on the same cells most likely define what subgroup of leukemia? (Objective 6)
 - a. bilineage
 - b. myeloid/NK
 - c. biphenotypic
 - d. undifferentiated
6. The following are included in the WHO classification of ALL: (Objective 2)
 - a. T and B cell lymphoma
 - b. ALL and Burkitt type ALL
 - c. L1, L2, and L3
 - d. bilineal and biphenotypic ALL
7. This finding in ALL can help differentiate it from AML: (Objective 1)
 - a. presence of Auer rods
 - b. positivity for myeloperoxidase
 - c. >20% blasts
 - d. positivity for CD19 and CD22
8. Blasts that are positive for block like PAS positivity are most likely: (Objectives 1, 4)
 - a. myeloblasts
 - b. monoblasts
 - c. megakaryoblasts
 - d. lymphoblasts
9. Which of the following laboratory results are most commonly found in ALL? (Objective 3)
 - a. Eosinophilia and basophilia
 - b. Neutropenia and thrombocytopenia
 - c. Neutrophilia and thrombocytopenia
 - d. Lymphocytosis and thrombocytosis
10. Which of the following signs is common in the presentation of childhood ALL? (Objective 5)
 - a. gum infiltration
 - b. bone and joint pain
 - c. large, painful nodes
 - d. eosinophilia

LEVEL II

4. While performing a differential count on a 2-year-old child, the clinical laboratory scientist identifies 78% blasts and notes the following other data: (Objectives 4, 6)

Hb	9.5 gm/dL
WBC	$50.3 \times 10^9/L$
PLT	$43 \times 10^9/L$

Which of the following tests most likely is positive?

 - a. Sudan black B
 - b. CD19
 - c. myeloperoxidase
 - d. CD5
5. An adult patient with splenomegaly has an increase in mononuclear cells in the peripheral blood. The bone marrow was filled with a heterogeneous collection of blasts with no granulation. The cells in the marrow were negative for myeloperoxidase and Sudan black B. Flow cytometry shows a positive CD20 and CD10 and negative surface immunoglobulin. Which of the following conditions is most likely? (Objective 4)
 - a. pro-B ALL
 - b. common ALL (CALLA)
 - c. pre-T cell ALL
 - d. cortical T cell ALL
6. BCR/ABL can be seen in: (Objective 2)
 - a. AUL
 - b. Burkitt type ALL
 - c. precursor B cell ALL
 - d. precursor T cell ALL
7. The CD10 antigen found in ALL is also known as the: (Objective 4)
 - a. BALL antigen
 - b. TALL antigen
 - c. Burkitt cell antigen
 - d. CALLA antigen
8. What condition is suggested by the following laboratory findings? (Objectives 2, 4)

WBC	$50.4 \times 10^9/L$
Diff	75% blasts
	20% segmented cells
	2% lymphs
	3% monos
Peroxidase	Negative
Alpha-naphthyl esterase	Negative
CD 19, CD22, CD34	Positive

 - a. acute lymphoblastic leukemia
 - b. acute myeloid leukemia
 - c. chronic myelogenous leukemia
 - d. chronic lymphocytic leukemia

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

9. A 4-year-old male is admitted with the following findings:

WBC	$60 \times 10^9/L$
Segs	15%
Bands	5%
Blasts	80%

The blasts are positive for TdT, CD2, cytoplasmic CD3, and CD7. What type of cell is involved? (Objectives 2, 4)

- null cells
 - T cells
 - B cells
 - NK cells
10. A patient with ALL underwent chemotherapy. Results from hematologic, cytogenetic, and molecular analyses indicated that he entered complete remission. Four years later on his routine followup, the peripheral blood results were in the normal range and cytogenetic analysis revealed no abnormalities, but molecular analysis showed BCR/ABL transcripts that were found in the blasts at diagnosis 4 years ago. This patient can be said to: (Objective 5)
- be in complete remission
 - be in molecular and cytogenetic remission
 - have minimal residual disease
 - have partial cytogenetic remission

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Dan had nonspecific but typical symptoms and clinical findings of an acute lymphocytic leukemia. His CBC revealed anemia, thrombocytopenia, and leukocytosis. The differential showed that the majority of peripheral blood leukocytes were lymphoblasts. A bone marrow, immunophenotyping, and cytogenetics should be done for treatment and prognostic information.

Question:

1. Based on this data, what would be the initial interpretation of Dan’s presentation?

Explanation:

These results are characteristic of acute lymphoblastic leukemia.

Question:

2. What is the correct choice of tests that should be used as the initial follow up in this case?

Explanation:

A bone marrow should be done, and the peripheral blood specimen should be sent for immunophenotyping to determine the T or B cell lin-

eage of the blasts.

Question:

3. If the flow cytometry pattern showed a positive CD10, what would be the classification of this acute leukemia?

Explanation:

The CD10 antigen is found on a pre-B acute leukemia and is called *common acute lymphocytic leukemia antigen*, or *CALLA*. This identifies a subgroup of ALL known as common ALL or CALLA positive ALL.

Question:

4. In this situation, would the therapeutic outcome be considered favorable or bleak? Why?

Explanation:

CALLA positive ALL is the most common ALL found in children in the Western world, and it has the most favorable outcome of the immunologic subtypes.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Compare the typical age groups in which AML and ALL are found.

Answer

The AMLs are characteristically found in adults in contrast to the ALLs, which are typically found in children. The AML minimally differentiated is most common in adults and in infants less than 1 year of age.

Checkpoint! 2

Contrast the malignant neoplastic cells in ALL with those found in AML.

Answer

Myeloblasts are generally larger than lymphoblasts. They have more abundant grayish cytoplasm. The nucleus has fine chromatin and prominent nucleoli. Lymphoblasts have scant, blue cytoplasm. The nucleus has coarser chromatin, and the nucleoli are inconspicuous.

The ALL and AML blasts cannot be definitively identified by morphology alone because considerable heterogeneity occurs from that just described. Cytochemistry is helpful in determining cell lineage. The myeloperoxidase and Sudan black B are positive in myeloblasts and negative in lymphoblasts. Immunophenotyping is helpful also. The myeloblasts are positive for CD13 and CD33; lymphoblasts are negative for these antigens.

Checkpoint! 3

Why is it necessary to immunophenotype the lymphoblasts in ALL if they have been identified as lymphoblasts morphologically?

Answer

The lymphoblasts should be immunophenotyped to determine whether they are of T or B cell origin. This information has treatment and prognostic implications.

Checkpoint! 4

A patient has 50% blasts in his bone marrow. Cytochemical stains are negative with peroxidase, and Sudan black B. Immunophenotyping is CD19-positive, but CD20-, CD2-, CD10-, and CD7-negative. What additional testing may be helpful in distinguishing the immunologic subgroup of this leukemia?

Answer

These appear to be lymphoblasts by cytochemistry results. The cells have the B cell antigen CD19 but are negative for other B cell markers, CD10 and CD20. Cells are negative for the T cell markers CD2 and CD7. This may be a very early progenitor B ALL. Testing for the CD34 marker and the presence of TdT would be helpful. These are markers of very early cells. Molecular testing for the rearrangement of the immunoglobulin genes may also help determine whether these are B cells.

Checkpoint! 5

Contact the morphology of blasts found in the two subtypes of ALL.

Answer

Lymphoblasts are typically small, up to twice the size of a small lymphocyte, with scant to moderate amounts of light basophilic or blue-

grey cytoplasm. The nucleus is round or slightly indented with finely granular to slightly clumped chromatin and inconspicuous or absent nucleoli. The two subtypes of ALL in the WHO classification are precursor B cell leukemia and precursor T cell leukemia. Morphologically, the T and B lymphoblasts cannot be differentiated. T lymphoblasts are similar to B lymphoblasts, although there is more likely to be variability in size, and cytoplasmic vacuoles may be present. The chromatin pattern may vary from case to case but is homogeneous within cases. The cytochemistry is also similar to that seen in B ALL, but acid phosphatase may show focal intense positivity in T ALL.

Checkpoint! 6

A 3-year-old patient has 45% lymphoblasts in the bone marrow. The blasts are slightly larger than lymphocytes and appear to be a homogeneous population. The nuclear membrane is regular, and nucleoli are not prominent. There is a small amount of moderately basophilic cytoplasm. What is the most likely WHO group of this leukemia? If the cells tested positive for CD19, CD10, and CD34, what is the most likely immunologic subgroup? Why should cytogenetics be done on this patient?

Answer

The description of the blasts best fits the precursor B cell leukemia subgroup. These markers suggest the early pre-B immunologic subgroup. Cytogenetics is important in ALL to provide prognostic information.

Checkpoint! 7

A patient with acute leukemia has two morphologically different types of blasts. One population is positive for CD7 and CD2. The other is positive for CD33 and CD13. What is the most appropriate classification of this leukemia?

Answer

This is most likely an acute leukemia with lineage heterogeneity. Because the lineage-associated markers are found on two different sets of blasts, it is most likely a bilineage acute leukemia. The blasts appear by immunophenotype to be myeloblasts and T lymphoblasts.

Lymphoid Malignancies: Chronic Lymphoid Leukemias, Lymphomas, and Plasma Cell Neoplasms

Fiona Craig, M.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Describe the clinical presentation of patients with lymphoid malignancies.
2. Describe how the diagnosis of lymphoid malignancy is made.
3. Differentiate among chronic lymphocytic leukemia (CLL), lymphoma, and multiple myeloma based on peripheral blood findings and ancillary studies.
4. Describe the histology of a normal lymph node.
5. Summarize the causes of lymphadenopathy.
6. Describe the morphologic differences between Hodgkin and non-Hodgkin lymphoma.
7. List and describe the chronic leukemic lymphoproliferative disorders.
8. Recognize and differentiate abnormal and normal lymphocytes on a stained peripheral blood smear and associate their presence with a clinical diagnosis.
9. Describe and apply a multidisciplinary approach to the classification and staging of lymphoid and plasma cell neoplasms.
10. Compare the laboratory and clinical findings of multiple myeloma and Waldenström macroglobulinemia.
11. Define *monoclonal gammopathy*.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Describe the use of immunophenotyping and genotyping in detecting clonality and list the results characteristic of the more common lymphoid malignancies.
2. Contrast the features of low-grade and high-grade lymphoma.

■ OBJECTIVES—LEVEL II (continued)

3. Compare and contrast the laboratory features characteristic of the following non-Hodgkin lymphomas:
 - a. Small lymphocytic lymphoma
 - b. Follicular lymphoma
 - c. Mantle cell lymphoma
 - d. MALT lymphoma
 - e. Waldenström macroglobulinemia
 - f. Diffuse large B cell lymphoma
 - g. Burkitt lymphoma
 - h. Lymphoblastic lymphoma
 - i. Peripheral T cell lymphoma
 - j. Anaplastic large cell lymphoma
4. Compare and contrast the laboratory features characteristic of Hodgkin lymphoma (HL) subtypes.
5. Compare and contrast the clinical and laboratory features characteristic of the following chronic leukemic lymphoproliferative disorders:
 - a. Chronic lymphocytic leukemia (CLL)
 - b. Prolymphocytic leukemia (PLL)
 - c. Hairy cell leukemia (HCL)
 - d. Circulating lymphoma
 - e. Large granular lymphocyte leukemia (LGLL)
 - f. Sézary syndrome
6. Compare and contrast the laboratory features characteristic of the following plasma cell disorders:
 - a. Plasmacytoma
 - b. Multiple myeloma
 - c. Monoclonal gammopathy of undetermined significance
7. Recognize and identify the peripheral blood abnormalities associated with CLL, PLL, HCL, LGLL, Sézary syndrome, multiple myeloma, and non-Hodgkin lymphoma.
8. Describe the etiology and pathogenesis of lymphoid neoplasms.
9. Differentiate reactive from malignant proliferations of lymphoid cells using clinical and laboratory data.

KEY TERMS

- | | |
|---------------------------------------|--|
| Anaplastic large cell lymphoma (ALCL) | Prolymphocyte |
| <i>BCL-2</i> gene | Reed-Sternberg (R-S) cell |
| Bence-Jones proteinuria | Richter's transformation |
| Butt cell | Rouleaux |
| Clonality | Sézary cell |
| Dutcher body | Small lymphocytic lymphoma (SLL) |
| Hairy cell | Smudge cell |
| Lacunar cell | Stage |
| Lymphoepithelial lesion | Starry-sky appearance |
| Lymphoma | Tingible body macrophages |
| Plasma cell neoplasm | Tartrate resistant acid phosphatase (TRAP) |
| Popcorn cell (L&H cell) | |

BACKGROUND BASICS

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- ▶ Describe the structure and function of lymph nodes.
- ▶ Outline the classification and summarize the general characteristics of acute leukemia.

Level II

- ▶ Explain the pathogenesis of neoplasia.
- ▶ Identify the etiology of acute leukemia.

**CASE STUDY**

We will address this case study throughout the chapter.

Julia, a 56-year-old female, presented with a 4-month history of generalized painless lymphadenopathy and fatigue. A CBC revealed leukocytosis due to lymphocytosis. Consider laboratory features that can help differentiate a reactive lymphocytosis from a neoplastic lymphocytosis.

▶ **OVERVIEW**

This chapter discusses the classification of lymphoid malignancies, the formation of a diagnosis and the unique features of selected subtypes. The etiology and pathogenesis of the disorders are discussed first followed by the classification and diagnosis this broad group of diseases. The remainder of the chapter describes characteristics of the more common types of chronic leukemic lymphoid malignancy, malignant lymphoma, and plasma cell neoplasms.

▶ **INTRODUCTION**

Lymphoid malignancies represent a heterogeneous group of disorders composed of cells that resemble one or more stages of normal lymphocyte development. This broad group can be divided into four categories based on the maturity of the neoplastic cells and the distribution of disease:

- Acute lymphoblastic leukemia
- Chronic leukemic lymphoid malignancies
- Malignant lymphoma
- Plasma cell neoplasms

Leukemia is a malignant neoplasm that primarily involves the bone marrow and peripheral blood. Acute lymphoblastic leukemia is a proliferation of blasts belonging to the lymphoid lineage. The chronic leukemic lymphoid ma-

lignancies are composed of mature lymphocytes and usually have an insidious onset and more indolent course than the acute leukemias.

The **lymphomas** are malignant neoplasms that present as tumorous masses that primarily involve the lymphoid organs including lymph nodes, tonsils, spleen, thymus, and lymphoid tissue of the gastrointestinal tract. Although most lymphomas are composed of mature lymphoid cells, blastic malignancies (lymphoblastic lymphoma) do occur. The distinction between leukemia and lymphoma is not always clear cut. Leukemia primarily involves the bone marrow and peripheral blood, but tissue involvement can occur. Lymphoma primarily involves tissue, but bone marrow and peripheral blood involvement can occur. Lymphoblastic lymphoma and acute lymphoblastic leukemia probably represent different clinical manifestations of a single disease entity. Therefore, the World Health Organization (WHO) classification groups them.¹

The **plasma cell neoplasms** are considered a group of diseases composed of immunoglobulin-secreting cells. The boundary between this group and the malignant lymphomas is not sharp. Lymphoma can contain a subset of cells demonstrating plasma cell differentiation, as occurs in lymphoplasmacytic lymphoma. Despite these difficulties in classification, the lymphoid malignancies can usually be divided into groups that provide information about prognosis and help direct treatment.

▶ **ETIOLOGY AND PATHOGENESIS**

The genesis of lymphoid malignancy is thought to be a multistep process involving acquired genetic, inherited genetic, and environmental factors.

ACQUIRED GENETIC FACTORS

As described for the leukemias, acquired alterations of proto-oncogenes and tumor suppressor genes have been associated with the development of lymphoid malignancy. Additional targets for genetic damage are the genes involved in programmed cell death (apoptosis) (e.g., *BCL-2*). The ***BCL-2* gene** on chromosome 18 is involved in the pathogenesis of follicular lymphoma. Translocation of the *BCL-2* gene to the region of the immunoglobulin heavy chain gene, t(14;18), causes overexpression of the *BCL-2* gene. The resulting increase in *BCL-2* protein leads to an inhibition of apoptosis. Decreased cell death results in an accumulation of lymphocytes within the lymph node. Therefore, low-grade follicular lymphoma appears to arise from cell persistence rather than uncontrolled cell proliferation.

INHERITED GENETIC FACTORS

Some inherited immunodeficiency syndromes such as Wiskott Aldrich and ataxia telangiectasia are associated with a higher incidence of malignant lymphoma.

ENVIRONMENTAL FACTORS

The Epstein-Barr virus (EBV) is associated with the development of several forms of lymphoid malignancy including African Burkitt lymphoma, B cell malignant lymphoma in HIV-infected individuals, and Hodgkin lymphoma (HL). Latent infection with EBV is only one of multiple steps involved in the genesis of these types of lymphoma. EBV infection is acquired orally and is often manifest clinically as infectious mononucleosis. The virus infects B lymphocytes where it remains latent under the immune system's control. The EBV-infected cells can proliferate if the host becomes immunocompromised and/or the B lymphocytes acquire additional genetic abnormalities such as the *C-MYC* translocation.

Another infectious agent associated with the development of non-Hodgkin lymphoma is *Helicobacter pylori*. Patients with *Helicobacter pylori*-induced inflammation of the stomach have a high incidence of gastric lymphoma of *mucosa associated lymphoid tissue* (MALT) lymphoma type. Chronic *Helicobacter* infection leads to antigen-driven T lymphocyte stimulation and subsequent B lymphocyte activation. The B lymphocytes initially are polyclonal and depend entirely on T lymphocyte stimulation. With time, the B cell population can proliferate autonomously. If the B lymphocyte proliferation still depends on T lymphocyte stimulation, the lymphoma can regress following removal of the antigenic stimulus with antimicrobial therapy. Lymphoma that is proliferating independent of antigenic stimulation probably requires more drastic therapy including excision and/or chemotherapy.

Checkpoint! 1

How does the *BCL-2* gene rearrangement differ from most other oncogenes?

▶ DIAGNOSIS OF LYMPHOID MALIGNANCY

Knowledge of the distribution of lymphoid malignancy at presentation and of the morphologic appearance and growth pattern of the neoplastic cells is essential for correctly diagnosing it. The phenotype and genotype of the malignant cells often assist in diagnosis and classification, determination of prognosis, and detection of residual disease following treatment.

MORPHOLOGIC APPEARANCE

The diagnosis of a lymphoid malignancy is established by examination of a specimen of peripheral blood, bone marrow, and/or other tissue in the laboratory. For most cases of leukemia, this examination involves a CBC and bone marrow sample (aspirate and biopsy). A diagnosis of lymphoma

is usually rendered from biopsy or a fine-needle aspirate of a mass. In general, normal or reactive proliferations of lymphocytes contain a mixture of cells varying in size, shape, and staining characteristics. The cells present in lymphoid malignancies are usually more homogeneous than normal or reactive lymphocytes because of the expansion of a single cell type. Less frequently, malignant lymphoid cells can be recognized because of an abnormal or bizarre appearance.

ANCILLARY STUDIES

Sometimes morphology alone is not sufficient to diagnose or subclassify lymphoid malignancies. Several additional studies are available to assist in the diagnosis: immunophenotyping, molecular diagnostics, and cytogenetics. These studies can detect abnormal lymphocytes and/or **clonality** (the presence of identical cells derived from a single progenitor). The cells of malignant lymphoma are thought to derive from a single precursor cell (i.e., the cell of origin). The progeny from this cell belong to a clone that shares morphologic, immunophenotypic, and genotypic features. In most circumstances, clonality is synonymous with malignancy. Clonality can be detected by the identification of only one of the immunoglobulin light chains (kappa or lambda) on B cells or the presence of a population of cells with an abnormal phenotype such as CD5 negative T lymphocytes. Clonal rearrangement of immunoglobulin or T cell receptor genes or the presence of an abnormal translocation can also be used to identify malignant lymphocytes. The presence of characteristic translocations can assist in the diagnosis of a subtype of lymphoid malignancy as in the *BCL-2* gene rearrangement in follicular lymphoma.

CLASSIFICATION

The World Health Organization (WHO) scheme currently classifies lymphoid malignancies into distinct disease entities that have similar morphologic, phenotypic, and genotypic features (Table 1).¹ Most disease entities have an expected clinical course and response to treatment. This predicted clinical behavior is referred to as the lymphoma grade. Low-grade lymphoma (e.g., small lymphocytic lymphoma) usually has a long indolent course; patients often die of disorders other than their lymphoma. High-grade lymphoma (e.g., Burkitt lymphoma) is clinically aggressive and kill the patient rapidly if not treated. Ironically, current therapeutic regimens are more effective against high-grade than low-grade lymphoid malignancies. Therefore, many patients with high-grade lymphoma who are treated are cured of their disease. Often patients with low-grade lymphoma are treated for symptomatic relief rather than the intent to cure. In general, histologic sections from lower grade lymphoma more often demonstrate a nodular growth pattern, smaller cells, lower mitotic activity, and an absence of apoptosis. Higher grade lymphoma usually has a diffuse growth

★ TABLE 1

WHO Classification of Lymphoid Neoplasms

B cell neoplasms	Precursor B cell neoplasms	
	Precursor B lymphoblastic leukemia/lymphoma	
	Mature B cell neoplasms

Lymphocyte depleted Hodgkin lymphoma		

pattern, is often composed of larger cells, and displays more numerous mitoses and apoptotic bodies.

In addition to the prognostic information provided by identifying the disease entities defined in the WHO classification, some diseases can be divided into further prognostic groups. The entity follicular lymphoma, for instance, is divided into three grades defined by the number of large cells (centroblasts). Many prognostic markers including expression of the proteins CD38 and ZAP-70, presence of cytogenetic abnormalities, and degree of mutation of the immunoglobulin heavy chain variable region are used for chronic lymphocytic leukemia. Diffuse large B cell lymphoma is divided into germinal and nongerminal center types.

STAGING

The prognosis of a patient with a lymphoid malignancy is not only related to the lymphoma grade but also to the extent and distribution of disease (**stage**). Patients with widespread lymphoma usually have a worse prognosis. Determining the stage of disease usually involves radiologic studies, peripheral blood examination, and bone marrow aspiration and biopsy. The Ann Arbor scheme is often used to stage malignant lymphoma (Table 2). Bone marrow involvement indicates disseminated disease, stage IV.

The remainder of this chapter describes examples of lymphoid malignancies that illustrate the characteristics of the chronic leukemic lymphoid malignancies, malignant lymphoma, and plasma cell neoplasms.

Checkpoint! 2

How does staging differ from grading in characterizing the lymphoid malignancies?

▶ CHRONIC LEUKEMIC LYMPHOID MALIGNANCIES

The chronic leukemic lymphoid malignancies compose a heterogeneous group of disorders displaying a variety of morphologic appearances and immunophenotypes.² They

★ TABLE 2

Ann Arbor Staging System for Malignant Lymphoma

- I Single lymph node region or single extralymphatic site (I_E)
- II Two or more lymph node regions on same side of diaphragm or with involvement of limited contiguous extralymphatic site (II_E)
- III Lymph node regions on both sides of diaphragm, which can include spleen (III_S) and/or limited contiguous extralymphatic site (III_E)
- IV Multiple or disseminated foci of involvement of one or more extralymphatic organs or tissues with or without lymphatic involvement

FIGURE 1 **a.** Chronic lymphocytic leukemia. Small round lymphocytes with clumped chromatin, a larger polymphocyte with a prominent nucleolus, and numerous smudge cells. **b.** Prolymphocytic leukemia. Numerous large lymphoid cells with prominent nucleoli (prolymphocytes). (Peripheral blood, Wright stain, 1000× magnification)

CLL had been considered a low-grade disease with a uniformly indolent course that could not be cured and was only treated for relief of symptoms. More recently it has been recognized that CLL is actually a rather heterogeneous disorder that includes a subset of patients that requires earlier treatment and has a shorter overall survival. Several prognostic markers have been associated with this difference in clinical behavior and are often evaluated at diagnosis in an attempt to predict outcome. These prognostic markers include the proteins CD38 and ZAP-70 and the mutational status of the immunoglobulin (Ig) heavy chain gene variable region (V_H).³ During normal B cell development, rearranged immunoglobulin variable gene segments undergo somatic hypermutation. CLL cases can be divided into two groups, those with “mutated” V_H genes and those with “unmutated” V_H genes. CLL with a more aggressive behavior is associated with higher levels of expression of CD38 and ZAP-70 as determined by flow cytometry and an “unmutated” Ig V_H gene.

Cytogenetic abnormalities were initially difficult to detect in CLL because the leukemic cells were not easy to induce to proliferate in culture. However, with improved cytogenetic methods such as fluorescence in situ hybridization (FISH), approximately half of all CLL patients are found to have clonal chromosomal abnormalities. The most common chromosomal abnormality, del 13q14-23.1, is associated with a relatively good prognosis. The following chromosomal abnormalities, listed in order of decreasing frequency, are associated with a worse prognosis:

- Trisomy 12
- Del 11q22.3-23.1
- Del 6q21-23
- Deletions at 17p13.1 (*p53* aberrations)
- 14q abnormalities and complex chromosomal abnormalities

Translocations are rarely observed in CLL. Patients with abnormal karyotypes survive for a significantly shorter period than do patients with normal karyotypes.

Less than 10% of patients with CLL develop transformation of their disease into one with a worse prognosis. **Richter’s transformation** is the transition to an aggressive large B cell lymphoma, which occurs in ~3% of patients with CLL. Prolymphocytoid transformation of CLL is associated with an increased number of prolymphocytes (usually prolymphocytes account for <10% of the leukemic cell population).

PROLYMPHOCYTIC LEUKEMIA

Prolymphocytic leukemia (PLL) is an aggressive leukemic disorder that often does not respond to treatment. Its incidence is ~10% that of CLL. It can have either a mature B or T cell phenotype.

B Cell PLL

Approximately 70% of cases of PLL are of a B cell lineage. B cell PLL is a disease of adult patients with a 4:1 male:female predominance. Although most cases arise de novo, PLL can develop from CLL (see above). However, preceding CLL may be asymptomatic and go unrecognized. Unlike CLL, patients with PLL usually have marked splenomegaly but minimal lymphadenopathy.

The CBC in patients with PLL reveals marked absolute lymphocytosis, often $>300 \times 10^9/L$, anemia, and thrombocytopenia. The neoplastic cells have a characteristic appearance: large cells with moderate amounts of pale basophilic cytoplasm, moderately condensed chromatin, and a single prominent nucleolus (Figure 1b). Prolymphocytes represent less than 10% of the lymphocytes seen in CLL and more than 55% of the lymphocytes present in PLL. Cases with 11–55%

are grouped together because they are primarily located in the blood and bone marrow and the malignant cells are mature lymphocytes. Although these malignancies are usually more indolent than the acute leukemias, the prognosis varies with the subtype. The features of the following more common subtypes of chronic leukemic lymphoid malignancies—B cell chronic lymphocytic leukemia, prolymphocytic leukemia, hairy cell leukemia, large granular lymphocyte leukemia (LGLL), Sézary's syndrome, and circulating lymphoma—(Table 3) are discussed further.

B CELL CHRONIC LYMPHOCYTIC LEUKEMIA

Chronic lymphocytic leukemia (CLL) is a disease of adults with a median age of 70 years at diagnosis. The incidence of CLL in men is twice that in women. The disease can be detected in an asymptomatic patient because of lymphocytosis found on a CBC performed for another reason. When present, symptoms are often related to anemia, thrombocytopenia, and neutropenia. These cytopenias can arise from a variety of causes including replacement of the bone marrow hematopoietic cells by neoplastic lymphocytes, hypersplenism, poor nutritional status, and immune mediated cell destruction. Lymphadenopathy is frequently present at diagnosis or can develop during the course of the disease. Indeed, CLL and small lymphocytic lymphoma (see below) are thought to represent different clinical presentations of a single disease entity.

A diagnosis of CLL requires a sustained absolute lymphocytosis $>5 \times 10^9/L$ with characteristic morphologic and phenotypic findings. The lymphocytes are small and mature appearing with scant cytoplasm. The nuclei are usually round, and the chromatin is regularly clumped (block-type chromatin). Nucleoli are inconspicuous (Figure 1a). A few large **prolymphocytes** are usually present but represent less than 10% of all lymphocytes (Figure 1b). Prolymphocytes have abundant pale-staining cytoplasm and a large central prominent nucleolus. The neoplastic cells in CLL appear to be more fragile than normal lymphocytes and often burst open during smear preparation to produce **smudge cells**. However, smudge cells also can be found in reactive lymphocytosis and in other neoplasms; therefore, their presence should not be used to diagnose CLL. In fact, smudge cells can make diagnosing CLL more difficult by preventing visualization of the lymphocytes. The number of smudge cells can be reduced by mixing a drop of albumin with a drop of blood prior to making the smear.

The differential diagnosis of CLL includes reactive lymphocytosis and the other chronic leukemia lymphoproliferative disorders (Table 3). Although a provisional diagnosis usually can be made following smear examination, immunophenotyping is often used to establish a definitive diagnosis. B cell CLL is characterized by aberrant expression of the T lymphocyte antigen CD5. Expression of CD23 and lack

★ TABLE 3

Key Features of Subgroups of Chronic Leukemic Lymphoid Malignancies

B cell chronic lymphocytic leukemia (CLL)	Lymphocytosis Smudge cells Prolymphocytes <10% CD19+, CD5+, CD20+ weak intensity, CD23+, FMC-7– Surface Ig weak intensity
B cell prolymphocytic leukemia (PLL)	Splenomegaly Marked lymphocytosis Prolymphocytes >55% CD19+, CD20+, CD22+, CD5–/+, FMC-7+ Surface Ig strong intensity
T cell PLL	Splenomegaly Skin lesions Marked lymphocytosis Varied morphologic appearance CD3+, CD2+, CD5+, CD4+, CD8–/+ inv(14)q11q32
Hairy cell leukemia	Pancytopenia Circulating hairy cells TRAP+ CD19+, CD5–, CD20+ strong intensity, CD22+, CD103+, CD11c+, CD25+ Surface Ig strong intensity Bone marrow dry tap Bone marrow “fried egg” appearance
T cell large granular lymphocyte (LGL) leukemia	Lymphocytosis Anemia Neutropenia Thrombocytopenia Rheumatoid factor often present CD2+, CD3+, CD4–, CD5+, CD7+, CD8+, CD16+, CD56–/+, CD57+/- T cell receptor (TCR) clonally rearranged Indolent course
Sézary's syndrome	Erythroderma (red skin) Cutaneous T cell lymphoma Circulating malignant cells CD2+, CD3+, CD4+, CD5+, CD7–, CD8–

of FMC-7 positivity distinguishes CLL from leukemic mantle cell lymphoma (MCL). FMC-7 is a monoclonal antibody that binds to an epitope of CD20 formed when this surface antigen is present at high density. The CLL cells usually have weak surface expression of monoclonal immunoglobulin.

prolymphocytes are classified as CLL/PL and have an unpredictable course. The phenotype of prolymphocytes often differs from the cells of CLL in demonstrating stronger intensity expression of surface immunoglobulin and CD20, strong intensity CD22, positivity with FMC-7, and variable expression of CD5 and are often negative for CD23. The karyotype abnormalities in B cell PLL include 14q+, trisomy 12, 6q- and rearrangements affecting chromosomes 1 and 12. Inactivating mutations in the *p53* gene are seen in 75% of cases of PLL.

T Cell PLL

T cell PLL is a rare disorder of adults that, like B cell PLL, usually presents with marked lymphocytosis and splenomegaly. However, patients with T cell PLL have more frequent lymphadenopathy, hepatomegaly, and skin lesions (infiltrations) than do patients with B cell PLL. In addition, the morphologic appearance of T cell PLL is more variable than that of B cell PLL. The cells of T cell PLL usually have a prominent nucleolus but are medium in size and can have convoluted nuclear outlines. T cell PLL has a mature phenotype with expression of CD3, CD2, CD5, and CD7. Most cases are CD4 positive. Like T cell acute lymphocytic leukemia (ALL), some cases of PLL express both CD4 and CD8, but PLL is negative for TdT. The majority of cases of T cell PLL have cytogenetic abnormalities, most frequently *inv(14)q11q32*, *del(11q)*, *i(8q)*, and trisomy 8q. T cell PLL is an aggressive disorder with a median survival time of only 7.5 months, although some response has been seen with anti-CD52 monoclonal antibody therapy (CAMPATH).

HAIRY CELL LEUKEMIA

Hairy cell leukemia (HCL) is an uncommon B cell malignancy presenting in middle age. Males have a higher incidence (male:female = 7:1). At presentation, patients usu-

ally have massive splenomegaly but lack lymphadenopathy. Extensive bone marrow involvement often exists; therefore, patients with HCL usually present with pancytopenia. The white blood cell (WBC) count is low due to both neutropenia and monocytopenia; patients thus have an increased susceptibility to infection, especially with mycobacterial organisms. Although neoplastic cells are usually present on a peripheral smear, they are usually too few to elevate the WBC. The neoplastic cells (**hairy cells**) have a characteristic abnormal appearance with abundant pale-staining cytoplasm, circumferential cytoplasmic projections (“hairs”), usually oval or reniform nuclei, and relatively fine chromatin (Figure 2a ■). Flow cytometric immunophenotyping is used to establish a diagnosis of HCL. HCL cells are mature B lymphocytes that are positive for CD19, CD20 (strong intensity), CD22, CD25, CD103, and CD11c. Although there is usually strong intensity monoclonal surface immunoglobulin, demonstrating it can be difficult because of nonspecific binding of the antibodies used to detect surface antigens. In addition, the cells of HCL show acid phosphatase staining after tartrate (**tartrate resistant acid phosphatase [TRAP]**) incubation.

Bone marrow involvement is often diffuse, and the neoplastic cells are usually surrounded by fibrosis, preventing their aspiration from the bone marrow (resulting in a “dry tap”). Bone marrow biopsy sections reveal a monotonous infiltrate of abnormal lymphocytes with small nuclei and abundant pale-staining cytoplasm (“fried egg” appearance) (Figure 2b ■). Immunohistochemical stains for the B cell antigen CD20 can be used to highlight the infiltrate. Splenectomy specimens reveal marked expansion of the red pulp because of an infiltrate of abnormal cells with the fried egg appearance described in the bone marrow. Lakes of erythrocytes are often formed between the tumor cells (pseudosinususes).

a

b

■ **FIGURE 2** a. Hairy cell leukemia. Two abnormal lymphocytes with abundant pale-staining cytoplasm with hairlike projections and relatively finely distributed chromatin. b. Hairy cell leukemia. Replacement of hematopoietic precursors by abnormal small lymphocytes with abundant clear cytoplasm (“fried-egg” appearance). (a. Peripheral blood, Wright stain, 1000× magnification; b. Bone marrow, H&E stain, 100× magnification)

Hairy cell leukemia is an indolent disease. Long-lasting complete remissions are often obtained with the chemotherapy agents 2-chlorodeoxyadenosine (2-CDA/cladribine) and deoxycoformycin (pentostatin).

LARGE GRANULAR LYMPHOCYTE LEUKEMIA (LGLL)

Only 5% of chronic leukemic lymphoproliferative disorders express T cell antigens. These cases were previously referred to as *T cell CLL*; the vast majority of them are now classified as *large granular lymphocyte (LGL) leukemia (LGLL)*. LGLL is characterized by a modest lymphocytosis composed of cells with abundant pale-staining cytoplasm, azurophilic cytoplasmic granules, and nuclei with mature clumped chromatin (Figure 3 ■). LGLs are normal components of the peripheral blood (10–15% of mononuclear cells) and are usually NK-like T cells (CD3+) or NK cells (CD3–). Therefore, distinction of LGLL from reactive lymphocytosis requires demonstration of an abnormal phenotype or evidence of clonality using molecular diagnostic or cytogenetic studies.

Two categories of LGLL that differ in their phenotype and clinical course are recognized: T lymphocyte and NK cell types.

Approximately 80% of patients with LGLL fall into the T-LGL leukemia category. The neoplastic cells of T-LGL leukemia are T lymphocytes with the following phenotype: CD2+, CD3+, CD4–, CD5+, CD7+, CD8+, CD16+, CD56–/+, CD57+/- (usually CD56–/CD57+). The cells can demonstrate an abnormal phenotype with loss of pan T cell antigens. Molecular diagnostic studies can be used to confirm the diagnosis by demonstration of clonal T cell receptor rearrangement. In addition to lymphocytosis, patients with T-LGL leukemia often have anemia, neutropenia, and thrombocytopenia. Anemia can be related to bone marrow infiltra-

■ **FIGURE 3** Large granular lymphocyte leukemia. Lymphocyte with abundant clear-staining cytoplasm and azurophilic cytoplasmic granules. (Peripheral blood, H&E stain, 1000× magnification)

tion or aplasia of erythroid precursors (pure red cell aplasia). Neutropenia and thrombocytopenia can be the result of immune destruction, splenic sequestration, or marrow infiltration. Although splenomegaly is common, lymphadenopathy and hepatomegaly are uncommon. Approximately 25% of patients with T-LGL leukemia have symptomatic rheumatoid arthritis, and many more are positive for rheumatoid factor. Therefore, many patients with T-cell LGL leukemia have the triad defining Felty's syndrome (rheumatoid arthritis, splenomegaly, and neutropenia). The median age at presentation for patients with T-LGL leukemia is 55 years. Patients with T-LGL leukemia usually have an indolent course with more than 80% actuarial overall survival after 10 years. Death is often due to concurrent infection.

LGLL with a NK phenotype has a morphologic appearance similar to T-LGL leukemia but is usually associated with a more acute presentation and aggressive course with death within 2 months of diagnosis. The median age at presentation is 39 years. Patients often present with fever, hepatomegaly, splenomegaly, involvement of the GI tract, and a bleeding disorder. Although anemia is common, neutropenia is rare. The neoplastic cells of NK-LGL leukemia have an NK phenotype: CD2+, CD3–, CD4–, CD8–, CD7+, CD16+, CD56+/-, CD57–/+ (usually CD56+/CD57–). Conventional molecular diagnostic studies cannot be used to determine clonality because NK cells do not rearrange the T cell receptor gene.

SÉZARY'S SYNDROME

Cutaneous T cell lymphoma (CTCL) composes a group of malignant T-cell lymphomas that are primary to the skin. Mycosis fungoides (MF) is the most common variant of CTCL. A few patients with MF/CTCL present with Sézary's syndrome (erythroderma and circulating **Sézary cells**). Sézary cells are malignant T lymphocytes that have a very irregular, convoluted (cerebriform) nuclear outline and finely distributed chromatin (Figure 4 ■). Abnormal cells can be counted in a blood smear leukocyte differential to determine a Sézary count. The differential diagnosis includes other types of mature and immature malignant lymphoproliferative disorders.

Sézary cells are mature memory helper T cells (CD3+, CD4+) but are usually CD7 negative. Molecular diagnostic studies can be used to confirm the presence of neoplastic cells by demonstrating clonal T cell receptor gene rearrangement. Although the marked nuclear convolutions can be easily identified on electron microscopy, this technique is rarely used for diagnosis.

CIRCULATING LYMPHOMA CELLS

Patients with non-Hodgkin lymphoma can develop peripheral blood involvement. Circulating lymphoma cells must be distinguished from normal lymphocytes and the cells of chronic leukemic lymphoproliferative disorders. Although

■ **FIGURE 4** Sézary syndrome. Abnormal large lymphocyte with relatively finely distributed chromatin and numerous nuclear folds (Sézary cell). (Peripheral blood, H&E stain, 1000× magnification)

the most frequent type of lymphoma to circulate is low-grade follicular lymphoma, others also can have a leukemic phase (mantle cell lymphoma, diffuse large B-cell lymphoma, Burkitt lymphoma). The circulating neoplastic cells of follicular lymphoma often have very irregular nuclear outlines and a deep indentation (cleft) of the nuclear membrane (“buttock” or “**butt**” cells) (see Follicular Lymphoma). Flow cytometric immunophenotyping can assist in the differential diagnosis by demonstrating monoclonal surface immunoglobulin and a phenotype characteristic of the particular subtype of lymphoma.

✓ **Checkpoint! 3**

Chronic leukemic lymphoid malignancies compose a heterogeneous group. What characteristics allow these malignancies to be grouped together?

CASE STUDY (continued from earlier in this chapter)

A CBC revealed a WBC of $20 \times 10^9/L$ with 60% lymphocytes. Examination of the peripheral blood revealed mature lymphocytes with scant cytoplasm, clumped chromatin, and irregular nuclear outlines.

1. What is the differential diagnosis?
2. What studies could be performed to establish the diagnosis?

▶ **MALIGNANT LYMPHOMA**

The two basic types of lymphoma are Hodgkin and non-Hodgkin lymphoma, which differ in clinical presentation, morphologic appearance, phenotype, and treatment (Table 4 and Table 5).

B CELL NON-HODGKIN LYMPHOMA

Within the United States, non-Hodgkin lymphoma of a B cell phenotype has the highest incidence of all lymphoid malignancies. Non-Hodgkin lymphoma of a T cell or NK cell phenotype has a lower incidence. B cell non-Hodgkin lymphoma is a heterogeneous group of neoplasms composed of cells that resemble those found in the normal compartments of the lymph node. The following subtypes of B cell non-Hodgkin lymphoma have been selected for further discussion either because they are more common or illustrate important concepts: small lymphocytic lymphoma, follicular lymphoma, mantle cell lymphoma, MALT lymphoma, Waldenström macroglobulinemia, diffuse large B cell lymphoma, Burkitt lymphoma, and lymphoblastic lymphoma. A more complete description of lymphoma subtypes is available in the cited reference.⁴

★ **TABLE 4**

Differences Between Hodgkin and Non-Hodgkin Lymphomas

Parameter	Hodgkin Lymphoma	Non-Hodgkin Lymphoma
Stage	Usually localized	Usually widespread
Distribution	Usually central nodes	Usually involves peripheral nodes
Mode of spread	Contiguous	Noncontiguous
Extranodal disease	Uncommon	Common
Peripheral blood	Never involved	Can be involved
Cell type	Abnormal bizarre cells	Resembles normal lymphoid cells
Treatment regimen	Often ABVD	Often CHOP

ABVD = doxorubicin (adriamycin), bleomycin, vinblastine, dacarbazine; CHOP = cyclophosphamide, doxorubicin, vincristine, and prednisolone

★ TABLE 5

Key Features of Malignant Lymphomas

Follicular lymphoma	Nodular growth pattern Lack of tingible body macrophages CD19+, CD20+, CD5-, CD10+ Surface Ig strong intensity t(14;18) BCL-2 protein overexpression BCL-2 gene rearrangement
Mantle cell lymphoma (MCL)	Lack of large cells CD19+, CD20+, CD5+, CD23-, FMC-7+ Surface Ig+ strong intensity Cyclin-D1 overexpression t(11;14) BCL-1 rearrangement
MALT lymphoma	Accompanied by infectious or autoimmune disease Often localized Extranodal Lymphoepithelial lesions Benign follicles Heterogeneous neoplastic infiltrate Phenotype and genotype not specific
Waldenström macroglobulinemia	Lymphoid malignancy with plasmacytic differentiation IgM Hyperviscosity syndrome
Burkitt lymphoma	Can be associated with EBV Starry sky growth pattern CD19+, CD20+, CD5-, CD10+ Strong surface Ig t(8;14) C-MYC gene rearrangement
Anaplastic large cell lymphoma (ALCL)	Bizarre, anaplastic cells can resemble HD T cell or null phenotype LCA+/-, CD30+, CD15-, EMA+/-, EBV-, Alk-1+/- t(2;5)
Classic Hodgkin lymphoma (HL)	Reed-Sternberg cells LCA-, CD15+, CD30+, Alk-1- Often EBV positive
Lymphocyte predominant (LP) Hodgkin lymphoma	Growth pattern frequently nodular L&H cells LCA+, CD20+, CD15-, CD30-, EBV-

Ig = immunoglobulin; MALT = mucosa associated lymphoid tissue; LCA = leukocyte common antigen; EMA = epithelial membrane antigen; EBV = Epstein-Barr virus; L&H = lymphocytic and/or histiocytic; Alk-1 = anaplastic large cell kinase

SMALL LYMPHOCYTIC LYMPHOMA

Small lymphocytic lymphoma (SLL) is the tissue equivalent of CLL. The two disorders appear to belong to one disease entity with different clinical manifestations. Patients with CLL present with peripheral blood lymphocytosis but often develop lymph node involvement. Patients with SLL present with lymphadenopathy but often develop peripheral blood and bone marrow disease.

A lymph node biopsy performed in either CLL or SLL reveals an essentially diffuse infiltrate of small mature lymphocytes. The small lymphocytes have dense, regularly clumped chromatin and lack nucleoli (Figure 5). At low power, a vague nodularity is often present due to aggregates of paler large cells (proliferation centers) (Figure 5). Proliferation centers contain larger cells with abundant pale-staining cytoplasm and prominent eosinophilic nucleoli (including prolymphocytes). The immunophenotype, cytogenetic findings, and survival are identical to those of CLL (see previous CLL discussion).

FOLLICULAR LYMPHOMA

Follicular lymphoma is a neoplasm composed of cells originating within the germinal center. It is the most common type of non-Hodgkin lymphoma within the United States. The median age at presentation is 50–60 years. There is no sex predilection. Patients usually present with generalized painless lymphadenopathy, some have peripheral blood involvement (Figure 6a), and most have advanced stage disease with bone marrow involvement (Figure 6b). Involvement of other extranodal sites is unusual.

Lymph node biopsy of follicular lymphoma reveals an infiltrate of lymphoid cells forming poorly circumscribed nod-

■ **FIGURE 5** Small lymphocytic lymphoma. The periphery of the image displays many small lymphocytes with round nuclei and clumped chromatin. The center of the image contains a vague nodule containing paler staining larger cells (proliferation center). (Lymph node biopsy, H&E stain, 50× magnification)

■ **FIGURE 6** Follicular lymphoma, grade 1. **a.** Circulating lymphoma cells with irregular nuclear outlines (Peripheral blood, Wright stain, magnification 1000×). **b.** Bone marrow involvement by low grade follicular lymphoma displaying a characteristic paratrabecular growth pattern (Bone marrow biopsy, H&E stain, magnification 20×). **c.** Loss of the normal lymph node architecture. The abnormal infiltrate forms numerous poorly defined nodules (follicles) (Lymph node biopsy, H&E stain, magnification 20×). **d.** Neoplastic follicle composed of a relatively homogeneous population of small lymphoid cells containing angulated, twisted nuclei. (Lymph node biopsy, H&E stain, magnification 200×)

ules that resemble follicular germinal centers (Figure 6c■). In addition, the lymphoma cells grow in a diffuse pattern in some areas. Neoplastic follicles differ from reactive follicles in lacking apoptosis of lymphocytes. This is manifest on histologic sections as a lack of macrophages engulfing fragments of dead cells (**tingible body macrophages**, which are usually found in areas of extensive apoptosis (reactive germinal centers and high-grade lymphoma). The neoplastic infiltrate always contains a mixed population of small cleaved (centrocytes) and large cells (centroblasts) but is often more homogeneous than a normal germinal center (Figure 6d■). The proportion of large cells varies and is used to separate follicular lymphoma into three grades (1, 2, or 3) (Table 6♣). The presence of more large cells is often associated with a more aggressive clinical course.

Most diagnoses of follicular lymphoma are made using conventional histologic evaluation. Immunophenotyping can be used to confirm the presence of lymphoma (monoclonal lymphocytes) and confirm the subtype of lymphoma (CD10 positive). Most cases of follicular lymphoma arise because of a chromosome translocation $t(14;18)$ involving the *BCL-2* gene that leads to overexpression of BCL-2 protein in lymphocytes. BCL-2 protein inhibits individual cell death (apoptosis), allowing follicle center cells to accumulate and produce lymphadenopathy.

Most patients with follicular lymphoma have an indolent disease with a median survival of 7–9 years. Patients with grade 3 follicular lymphoma are sometimes cured. However, the lower-grade follicular lymphomas (grades 1 and 2) are incurable with current therapies and are therefore treated for

★ TABLE 6

Grading of Follicular Lymphoma

Grade	Definition
1	0–5 centroblasts per defined high power field
2	6–15 centroblasts per defined high power field
3	>15 centroblasts per defined high power field

relief of symptoms. Low-grade follicular lymphoma can progress to a diffuse large cell lymphoma with a median survival of less than 1 year.

CASE STUDY (continued from earlier in this chapter)

A cervical lymph node biopsy reveals effacement of the normal architecture by a lymphoid infiltrate with a nodular growth pattern. The nodules contain a relatively homogeneous population of small lymphocytes and a few admixed large cells. The infiltrating lymphoid cells have irregular nuclear outlines. Tingible body macrophages are lacking, and very few mitotic figures are present.

3. What is the cause of the lymphadenopathy?
4. Is this process low grade or high grade?

MANTLE CELL LYMPHOMA (MCL)

MCL is a neoplasm thought to be derived from the cells of the mantle zone of the lymphoid follicle. The median age at presentation is approximately 60 years, and male predominance exists. Most patients present with disseminated disease involving multiple lymph node groups, bone marrow, peripheral blood, spleen, liver, and gastrointestinal tract. Gastrointestinal tract involvement can present as multiple polyps involving the small bowel (lymphomatous polyposis) (Figure 7a ■).

On histologic sections, MCL can demonstrate either a diffuse or vaguely nodular growth pattern (Figure 7b ■). The neoplastic infiltrate occasionally surrounds a reactive germinal center (mantle zone pattern). The neoplastic cells are usually small to intermediate in size with round to slightly irregular nuclear outlines; in contrast to small lymphocytic lymphoma and follicular lymphoma, MCL usually lacks a large cell component (Figure 7c ■). However, it has a rare morphologic variant referred to as *blastic MCL* composed of either large cells resembling diffuse large B cell lymphoma or cells with finely distributed chromatin resembling lymphoblastic lymphoma.

Diagnosing MCL often requires the use of ancillary studies. The following immunophenotype is characteristic of MCL: CD19+, CD5+, CD23–, FMC-7+, and sIg+ (strong intensity). Immunohistochemistry reveals nuclear staining for cyclin-D1 protein in approximately 90% of cases of MCL

(Figure 7d ■). Cyclin D-1 is involved in regulating progression of cells from the G1 to S phase of the cell cycle. Overexpression of cyclin-D1 in MCL is usually the result of a chromosome translocation, t(11;14), that involves the *BCL-1* gene. The *BCL-1* translocation is thought to lead to neoplastic transformation through loss of cell cycle control. This translocation can be demonstrated by fluorescence in situ hybridization (FISH) studies in the vast majority of cases of MCL. Although molecular diagnostic studies are available, only approximately 60% of MCL cases are routinely identified because of the wide range of break points involved in the t(11;14) translocation.

MCL is a relatively aggressive lymphoma with a poor response to current therapies. The overall median survival is approximately 3–4 years. The blastic variant has a median survival of only 18 months. Therefore, distinction of MCL from the other small lymphoid B cell neoplasms (follicular lymphoma, SLL, and MALT lymphoma [see below]) is important.

MUCOSA ASSOCIATED LYMPHOID TISSUE (MALT) LYMPHOMA

MALT lymphoma is a B cell neoplasm derived from mucosa associated lymphoid tissue. Patients with MALT lymphoma usually present with localized extranodal disease (e.g., involving the stomach, salivary gland, lacrimal gland, thyroid, and lung). A preceding chronic inflammatory disorder such as chronic gastritis due to *Helicobacter pylori* infection or autoimmune disease (Sjögren’s syndrome or Hashimoto’s thyroiditis often occurs).

A biopsy of MALT lymphoma reveals an infiltrate of small to intermediate size lymphocytes intimately associated with epithelial cells (e.g., gastric mucosa, salivary gland ducts). Epithelial structures infiltrated by neoplastic lymphocytes are referred to as **lymphoepithelial lesions** (Figure 8a ■). MALT lymphoma is composed of small lymphocytes with round or slightly cleaved nuclei that often have abundant pale-staining cytoplasm and are referred to as *monocytoid B cells* because of their resemblance to monocytes (Figure 8b ■). MALT lymphoma can demonstrate differentiation to plasma cells. In addition to the neoplastic cells, the infiltrate often contains benign germinal centers. Infiltration of benign germinal centers by neoplastic cells is referred to as *follicular colonization*. The differential diagnosis includes other lymphomas composed of small lymphocytes, including SLL, MCL, and follicular lymphoma. Ancillary studies can assist in obtaining the correct diagnosis. Monoclonality of immunoglobulin light chains can be demonstrated by either flow cytometry immunophenotyping (surface immunoglobulin on lymphocytes) or paraffin section immunohistochemistry (cytoplasmic immunoglobulin in cells demonstrating plasma cell differentiation). In contrast to follicular lymphoma and small lymphocytic lymphoma, MALT lymphoma is usually negative for CD10 and CD5.

■ **FIGURE 7** Mantle cell lymphoma. **a.** Gross photograph of the large intestine in a patient with lymphomatous polyposis of gastrointestinal tract. **b.** Abnormal lymphoid infiltrate in a lymph node displaying a vaguely nodular growth pattern. **c.** Uniform infiltrate of small lymphoid cells with slightly irregular nuclear outlines. **d.** Cyclin D-1 overexpression. (b. Lymph node biopsy, H&E stain, 20× magnification; c. lymph node biopsy, H&E stain, 100× magnification; d. lymph node biopsy, immunohistochemistry stain, 100× magnification)

MALT lymphoma is an indolent disease previously considered to be a reactive condition mimicking lymphoma (pseudolymphoma) but is now considered malignant because like other non-Hodgkin lymphomas, it is composed of monoclonal lymphocytes and has the potential to transform to higher grade, large B cell lymphoma. However, patients with *Helicobacter pylori*-associated gastric MALT lymphoma are often cured with antimicrobial therapy. MALT lymphoma that is unresponsive to antimicrobial therapy or that occurs at other sites is often treated with local excision or radiation therapy.

WALDENSTRÖM MACROGLOBULINEMIA

Waldenström macroglobulinemia is a lymphoid malignancy that produces immunoglobulin IgM. High plasma levels of the large pentamer IgM result in hyperviscosity that can lead

to poor circulation in small blood vessels, visual impairment, headache, dizziness, and deafness. Although several different subtypes of lymphoid malignancy can produce this clinical disorder, including MALT lymphoma, Waldenström macroglobulinemia is often associated with the lymphoplasmacytic subtype of lymphoma. The differential diagnosis includes other types of lymphoid malignancy and neoplasms composed entirely of plasma cells (plasma cell neoplasms).

Patients with lymphoplasmacytic lymphoma usually have peripheral blood and bone marrow involvement and often have lymphadenopathy, hepatomegaly, and splenomegaly at presentation. Unlike the plasma cell neoplasm multiple myeloma, patients with lymphoplasmacytic lymphoma lack lytic bone lesions. Histologic sections demonstrate a diffuse infiltrate composed of lymphocytes, plasma cells, and lymphoid cells that demonstrate some evidence of differentiation toward plasma cells (plasmacytoid lymphocytes).

FIGURE 8 MALT lymphoma. **a.** Parotid salivary gland involved by low-grade lymphoma of MALT type. Two lymphoepithelial lesions are present demonstrating infiltration of ducts by neoplastic lymphocytes. **b.** Heterogeneous lymphoid infiltrate of MALT lymphoma. Many of the infiltrating cells have abundant clear-staining cytoplasm (i.e., monocytoid B cells). (a. Parotid gland biopsy, H&E stain, 50× magnification; b. Parotid gland biopsy, H&E stain, 100× magnification)

Immunohistochemistry can be performed to demonstrate the presence of cytoplasmic monoclonal immunoglobulin light chain (kappa or lambda) and IgM heavy chain.

The median survival for patients with Waldenström macroglobulinemia is 4 years. Plasmapheresis can alleviate many symptoms related to increased plasma viscosity.

DIFFUSE LARGE B CELL LYMPHOMA

Diffuse large B cell lymphoma (DLBCL) is a heterogeneous group of tumors composed of large B-lymphoid cells (Figure 9). Some DLBCL develop as a result of transformation from

FIGURE 9 Diffuse large B cell lymphoma. Abnormal infiltrate composed of large lymphoid cells with pale-staining, vesicular chromatin, irregular nuclear outlines, and basophilic nucleoli. Several mitotic figures are present. (Lymph node biopsy, H&E stain, 200× magnification)

a lower grade lymphoma (e.g., follicular lymphoma or small lymphocytic lymphoma) while others arise de novo. The possibility of blastic mantle cell lymphoma should be excluded using staining for cyclin-D1. The immunophenotype of DLBCL is quite variable and has been associated with the clinical course. Diffuse large B cell lymphoma with a phenotype similar to follicular lymphoma (germinal centerlike phenotype) often has a better prognosis than diffuse large B cell lymphoma with a nongermlinal centerlike phenotype. With multiagent chemotherapy and anti-CD20 monoclonal antibody therapy (Rituxan), some patients can be cured of their lymphoma.

CASE STUDY (continued from earlier in this chapter)

The previous biopsy had established a diagnosis of low-grade non-Hodgkin lymphoma, follicular type. Julia received multiagent chemotherapy for symptomatic relief. Two years following the diagnosis, she returned with rapidly expanding lymph nodes in her neck. Repeat biopsy revealed effacement of the lymph node architecture by a diffuse infiltrate of large B cells.

5. What is the diagnosis?
6. What is the relationship of this disease to the previous diagnosis?

BURKITT LYMPHOMA

Burkitt lymphoma is a high-grade non-Hodgkin lymphoma having a high incidence in Africa (endemic subtype). It represents approximately one-third of all pediatric lymphomas occurring outside Africa (sporadic Burkitt lymphoma). Many adult cases occur in immunocompromised individuals such

as those infected with the HIV virus. Burkitt lymphoma often involves extranodal sites. Endemic Burkitt lymphoma has a predilection for involvement of the facial bones and jaw; sporadic Burkitt lymphoma often presents with disease involving the intestine, ovaries, or kidney. EBV is thought to play a role in the pathogenesis of Burkitt lymphoma. DNA of EBV is present in most cases of endemic Burkitt lymphoma and approximately one-third of the HIV-associated tumors. EBV is found less frequently in the sporadic form.

A biopsy of Burkitt lymphoma usually reveals a diffuse infiltrate of neoplastic cells demonstrating a **“starry sky” appearance** (Figure 10 ■). The “sky” represents the blue nuclei of the neoplastic lymphocytes; the “stars” are formed by scattered pale-staining tingible body macrophages. The infiltrating lymphoid cells are intermediate in size with nuclei approximately the same size as the nuclei of the tingible body macrophages. Multiple small nucleoli are usually present, and mitotic figures and apoptotic bodies are frequent. The latter two features are characteristic of high-grade lymphoma.

The differential diagnosis for Burkitt lymphoma includes lymphoblastic lymphoma and DLBCL. The presence of surface immunoglobulin and absence of TdT allow distinction of Burkitt lymphoma from acute lymphoblastic leukemia (ALL). Distinguishing Burkitt lymphoma from DLBCL is often more difficult because the two can share the same immunophenotype: CD19+, sIg+, CD10+, CD5-. Most cases of Burkitt lymphoma have the t(8;14) or less frequently t(2;8) or t(8;22) chromosome translocations leading to rearrangement of the *C-MYC* gene. *C-MYC* gene rearrangement occurs in only 5% of DLBCL.

■ **FIGURE 10** Burkitt lymphoma. Intermediate size lymphocytes with multiple nucleoli and scant cytoplasm. Numerous mitotic figures are present. The presence of apoptotic bodies indicates individual cell necrosis. There is a “starry-sky” appearance due to pale-staining tingible body macrophages scattered in an infiltrate that appears basophilic due to staining of the tumor cell nuclei. (Lymph node biopsy, H&E stain, 100× magnification).

Burkitt lymphoma is a highly aggressive tumor but is curable with aggressive combination chemotherapy. The therapeutic regimen used for Burkitt lymphoma usually differs from that used for DLBCL.

LYMPHOBLASTIC LYMPHOMA

Lymphoblastic lymphoma is the tissue equivalent of ALL. Children are more often affected than adults. Approximately 80% of lymphoblastic lymphomas are of a T cell lineage, and the remaining cases have an immature B cell phenotype. T cell lymphoblastic lymphoma often affects adolescent males who present with a rapidly enlarging mediastinal mass due to involvement of the thymus. Neoplastic blasts can also be seen in the peripheral blood, bone marrow, pleural fluid, and cerebrospinal fluid. A tissue biopsy of lymphoblastic lymphoma usually reveals intermediate to small cells with scant cytoplasm, finely distributed chromatin, and small nucleoli (Figure 11 ■).

Immunophenotyping is required to distinguish lymphoblastic lymphoma from other types of non-Hodgkin lymphoma, to distinguish lymphoblastic lymphoma from tissue infiltration by AML (extramedullary myeloid sarcoma), and to identify a T or B cell phenotype. TdT is present in the majority of cases of lymphoblastic lymphoma and can be used to help distinguish it from Burkitt lymphoma.

PERIPHERAL T CELL OR NATURAL KILLER (T/NK) CELL LYMPHOMA

Non-Hodgkin lymphoma with a mature T cell or NK (T/NK) cell phenotype represents only 15% of lymphomas in the United States. Several subtypes of peripheral T/NK cell

■ **FIGURE 11** Lymphoblastic lymphoma. Intermediate size lymphocytes with irregular nuclear outlines and finely distributed, speckled, chromatin. A mitotic figure is present. (Lymph node biopsy, H&E stain, 500× magnification)

lymphoma are defined using a combination of parameters including the clinical presentation, distribution of disease (nodal or extranodal), association with Epstein-Barr virus, and immunophenotype (CD4+ or CD8+, and presence of NK-associated or cytotoxic markers). However, a large category of peripheral T-cell lymphoma cannot be put into one of the other subtypes (peripheral T cell lymphoma, unspecified). In general, peripheral T/NK cell lymphoma is an aggressive disease with frequent relapses. However, some patients are cured by combination chemotherapy.

Although the morphologic appearance of peripheral T/NK cell lymphoma is quite variable, a number of morphologic features suggest this diagnosis. Peripheral T/NK cell lymphoma usually has a diffuse growth pattern and is rich in blood vessels. The tumor cells vary in size and can display abundant clear or pale-staining cytoplasm and irregular nuclear outlines. The infiltrate is often heterogeneous with histiocytes, plasma cells, and eosinophils in addition to the neoplastic cells. However, immunophenotyping is essential for distinction from B cell non-Hodgkin lymphoma and, in some cases, Hodgkin lymphoma. Peripheral T/NK cell lymphoma demonstrates expression of pan-T cell antigens with frequent abnormal lack of staining for one or more of the expected antigens (e.g., CD5– and/or CD7–). The presence of an abnormal immunophenotype or clonal rearrangement of the T cell receptor can assist in the distinction of T cell lymphoma from a reactive process.

Anaplastic large cell lymphoma (ALCL) is one of the best characterized subtypes of T/NK cell lymphoma. Most ALCL cases are composed of large bizarre anaplastic cells that can resemble Reed-Sternberg cells and Hodgkin variant cells (Figure 12■). Like Hodgkin lymphoma and some large cell non-Hodgkin lymphomas, ALCL is usually positive for the CD30 antigen (initially referred to as the *Ki-1*

■ **FIGURE 12** Anaplastic large cell lymphoma. Abnormal infiltrate of large cells with abundant eosinophilic cytoplasm. (Lymph node biopsy, H&E stain, 100× magnification)

antigen). However, in contrast to classical Hodgkin lymphoma, ALCL usually lacks CD15 expression and evidence of Epstein-Barr virus infection and is often positive for leukocyte common antigen (LCA) and epithelial membrane antigen (EMA). Although ALCL is derived from T-cells, frequent loss of T-cell antigen expression can result in a null phenotype (lack of expression of either T or B cell antigens).

Most, but not all, ALCL cases involving lymph nodes contain the translocation t(2;5) that joins the nucleophosmin (NPM) and anaplastic large cell kinase (ALK) genes. This leads to abnormal expression of ALK protein that can be detected by immunohistochemistry. The presence of ALK protein expression can assist in the distinction of ALCL from HL and most other subtypes of NHL. However, absence of staining for ALK-1 protein does not exclude a diagnosis of ALCL. Most cases of cutaneous ALCL are ALK negative.

Primary cutaneous ALCL can be treated successfully by local excision or radiation therapy. Approximately 70% of patients with systemic ALCL go into remission with systemic multiagent chemotherapy, but the rate of relapse is high.

HODGKIN LYMPHOMA (HL)

HL differs from non-Hodgkin lymphoma in its clinical presentation and histologic appearance (Table 4). Separation of these two broad categories of lymphoma is important because they are treated with different combinations of chemotherapeutic agents.

HL is composed of large tumor cells that do not resemble a normal cell counterpart and are accompanied by many reactive cells. HL has several histologic subtypes that differ in phenotype, appearance of the large neoplastic cells, and nature of the reactive component. The main histologic types are lymphocyte predominant (LP) HL and classical HL. Classical HL is further classified into nodular sclerosis (NS), mixed cellularity (MC), lymphocyte rich (LR), and lymphocyte depletion (LD) subtypes (Table 7★).

LP HL is composed of numerous reactive small lymphocytes and rare tumor cells that often grow in loose nodular aggregates. The tumor cells in LP HL (L&H cells) characteristically have a large multilobated nucleus with delicate nuclear membranes, finely granular chromatin, and small indistinct nucleoli (**popcorn cells; L&H cells**) (Figure 13■). Unlike the neoplastic cells of classical HL, those of LP HL have a B cell phenotype: LCA+, CD45+, CD20+, CD30–/+, CD15– (Table 5). Therefore, the phenotype of LP HL overlaps that of B cell non-Hodgkin lymphoma. The reactive small lymphocytes that surround the neoplastic cells of LP HL often include an unusual subset of CD57 positive T cells.

The tumor cells in classical HL have large prominent eosinophilic nucleoli and coarse nuclear membranes. One variant of tumor cell is found in all cases of classic Hodgkin lymphoma: the **Reed-Sternberg (R-S) cell**, which has two

★ TABLE 7

Classification of Classic Hodgkin Lymphoma					
Subtype	Sclerosis	Lymphocytes	Tumor Cells	Variants	Cell Type
LP	–	++++	+	L&H	B-cell
NS	Present	++	++	Lacunar	?
MC	–	++	++	–	?
LR	–	++++	+	–	?
LD	–/+	+	++++	–	?

NS = nodular sclerosis classical HL; MC = mixed cellularity classical HL; LD = lymphocyte depletion classical HL; LR = lymphocyte rich classical HL; LP = lymphocyte predominance HL; L&H = malignant cells characteristic of LP HL; ? = uncertain cell of origin; + = few; ++++ = many

or more nuclear lobes containing inclusion-like nucleoli and an area of perinucleolar clearing imparting an owl’s eye appearance (Figure 14a ■). The reactive cells accompanying the neoplastic cells of classical HL include a heterogeneous mixture of small lymphocytes, histiocytes, eosinophils, and plasma cells. The tumor cells of classical HL are negative for LCA and ALK but positive for the CD30 antigen. They can also be positive for CD15 and/or EBV.

Classical HL is further divided into histologic subtypes based on the presence of sclerosis (fibrosis), type of tumor cell variants, and proportion of reactive lymphocytes. The NS subtype of Hodgkin lymphoma is characterized by C-shaped bands of birefringent fibrous tissue (Figure 14b ■), nodular aggregates of cells, and tumor cell variants with cytoplasmic clearing and delicate, multilobated nuclei (**lacunar cells**) (Figure 14c ■). The LR form of classical HL has a background of reactive cells that includes many small lymphocytes, but in contrast to LP HL, the neoplastic cells

have the phenotype of classical HL. LD HL is a rare subtype that has many tumor cells and only rare reactive lymphocytes. A diagnosis of MC HL is made after excluding the other classic subtypes: NS, LR, and LD. However, the histologic subtypes of classical HL do not have independent prognostic significance. The stage of HL is one of the most important prognostic markers. The 5-year survival for patients with stage I or IIA Hodgkin lymphoma currently is approximately 90% and for stage IV 60–70%.

✓ **Checkpoint! 4**
 Name and describe the cell that is characteristic of Hodgkin lymphoma.

▶ **PLASMA CELL DISORDERS**

Plasma cell neoplasms are diverse disorders that rarely involve lymph nodes and usually secrete monoclonal immunoglobulin into the serum and/or urine. They can be divided into disease entities based on the distribution and extent of disease (solitary versus multiple lesions and bone versus extramedullary) and the characteristics of the immunosecretory protein produced (class of heavy chain and the presence of amyloid production, immunoglobulin heavy, or light chain) (Table 8 ★). Primary amyloidosis is a neoplasm of plasma cells producing an abnormal immunoglobulin that becomes deposited in a beta pleated sheet configuration in tissues (amyloid). The heavy chain diseases are characterized by the production of immunoglobulin heavy chain fragments only and vary in their clinical presentation, morphologic features, and class of heavy chain produced. The more common plasma cell neoplasms, multiple myeloma and plasmacytoma, are discussed in more detail along with the precursor lesion monoclonal gammopathy of undetermined significance. Their key features are outlined in Table 9 ★.

- Monoclonal gammopathy of undetermined significance (MGUS)

MULTIPLE MYELOMA

Multiple myeloma is a plasma cell neoplasm that forms multiple tumors throughout the skeletal system (lytic bone lesions) (Figure 15a ■). The median age at diagnosis is 65 years, and there is a male predominance. Patients often present with bone pain and/or pathologic fractures due to tumor infiltration.

Examination of the bone marrow from a lytic lesion or the posterior iliac crest reveals an abnormal infiltrate of plasma cells replacing the normal hematopoietic cells. In multiple myeloma, plasma cells usually represent more than 30% of all bone marrow cells (Figure 15b ■). Although neoplastic plasma cells can appear normal, abnormal forms with

★ TABLE 9

Key Features of Plasma Cell Disorders

Neoplasm	Features
Multiple (plasma cell) myeloma	Lytic bone lesions "M" spike on serum/urine electrophoresis Rouleaux on blood smear >30% plasma cells in bone marrow
Plasmacytoma	Localized mass Monoclonal plasma cells
Monoclonal gammopathy of undetermined significance	Monoclonal serum protein Monoclonal protein <3 gm/dL Lytic bone lesions absent Bone marrow plasma cells <10%

more finely distributed chromatin, nucleoli, or intranuclear inclusions that contain immunoglobulin (**Dutcher bodies**) are often present. Neoplastic plasma cells rarely circulate in the blood, but the peripheral smear is often abnormal due to stacking of the erythrocytes (**rouleaux** formation) (Figure 15c). In addition, the stained blood smear often has a blue background due to increased serum protein.

Serum protein electrophoresis (SPEP) reveals increased protein with a narrow range of electrophoretic mobility (M spike) (Figure 16). The M spike can be further characterized by immunofixation electrophoresis (IFE) to confirm the presence of a monoclonal protein and determine the immunoglobulin class (Figure 16c). The monoclonal protein usually contains one immunoglobulin light chain (kappa or lambda) and one heavy chain with the following incidence: IgG > IgA > IgM > IgD > IgE. Normal immunoglobulin production is usually decreased leading to functional hypogammaglobulinemia. Plasma cell neoplasms can produce an excess of immunoglobulin light chains, light chains only, heavy chains

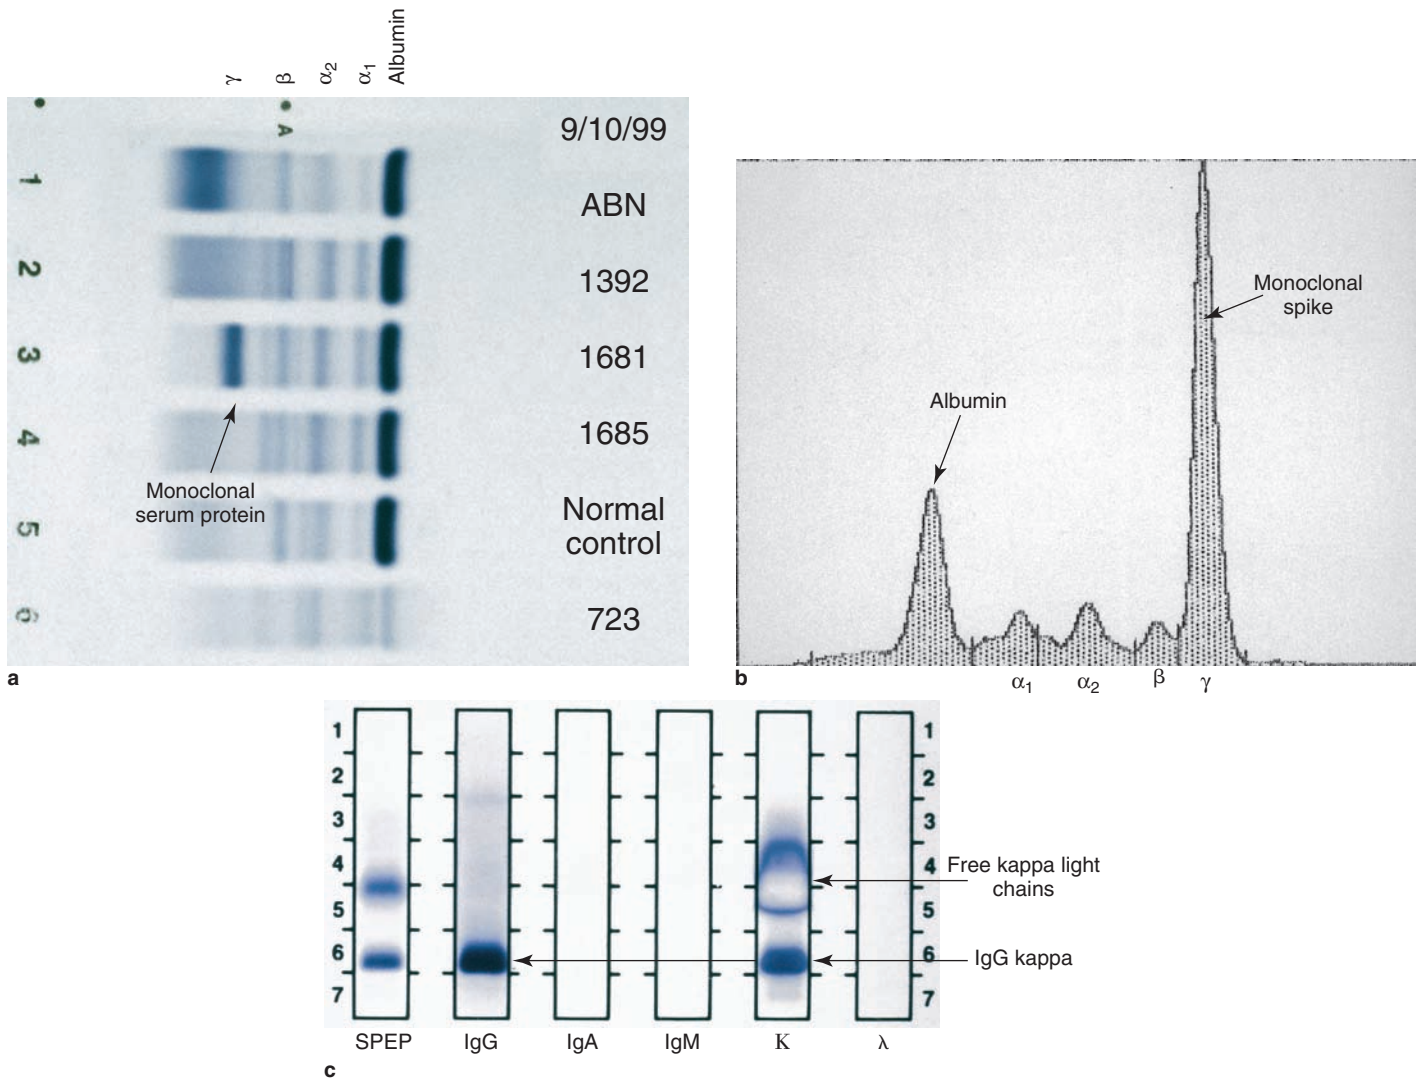

FIGURE 16 Monoclonal gammopathy. **a.** Serum protein electrophoresis. Sample 1681 displays a band in the early gamma region. **b.** Densitometry scan reveals a “spike” in the gamma region. A similar spike was found in the urine. **c.** Immunofixation electrophoresis performed on a urine sample reveals two monoclonal bands composed of IgG kappa and free kappa light chains (Bence-Jones proteins).

only, or no immunoglobulin (non-secretory). Patients with light chain only disease can have a normal SPEP because the protein passes into the urine. Free light chains in the urine are referred to as **Bence-Jones proteins**.

The prognosis of multiple myeloma is poor with a median survival of only 6 months without therapy. The median survival can be increased to 3 years with chemotherapy, and an increased survival has been reported with autologous bone marrow and peripheral blood stem cell transplants. Infection is a major cause of death.

PLASMACYTOMA

A *plasmacytoma* is a localized, tumorous collection of monoclonal plasma cells. The prognosis of a plasmacytoma is related to its location. Many patients with plasmacytoma of

bone go on to develop additional plasmacytomas and ultimately meet the criteria for multiple myeloma. In contrast, plasmacytoma of the upper respiratory tract has a good prognosis with only rare recurrence after excision and a low incidence of dissemination.

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE (MGUS)

Identification of a monoclonal spike is not diagnostic of multiple myeloma. The term *monoclonal protein of undetermined significance (MGUS)* is used to describe a low level of serum monoclonal protein without evidence of an overt neoplasm. Therefore, MGUS is a diagnosis that requires exclusion of other plasma cell and lymphoid malignancies. The prevalence of a monoclonal serum spike increases with

age and is present in 3% of asymptomatic patients over 70 years of age. There is no treatment for MGUS. Although most patients have stable disease and die of other causes, an overt plasma cell dyscrasia such as multiple myeloma develops in approximately 25% of patients.

Checkpoint! 5

What clinical finding differentiates multiple myeloma from other plasma cell neoplasms?

SUMMARY

The lymphoid malignancies compose a diverse group of neoplasms that vary in clinical presentation, morphologic appearance, immunophenotype, and genotype. The malignant cells resemble

one or more of the stages of normal lymphocyte development. The lymphoid malignancies can be classified as acute lymphoblastic leukemia, chronic leukemic lymphoid malignancies, and lymphoma. The leukemic entities are characterized by peripheral blood and bone marrow involvement; lymphomas have tumorous masses involving the lymph nodes and other lymphoid tissue. The diagnosis often requires a combination of conventional morphology and ancillary studies. Ancillary studies include immunophenotyping, molecular diagnostics, and cytogenetics.

Although the classification of lymphoid malignancies is complicated, it is important to separate distinct disease entities that have a predictable outcome and response to specific therapy.

REVIEW QUESTIONS

LEVEL I

1. Which of the following is the most likely distribution of disease in a patient with leukemia? (Objective 3)
 - a. a lytic bone lesion
 - b. a tumorous mass involving lymph nodes
 - c. a tumorous mass involving the tonsil
 - d. widespread involvement of the bone marrow
2. A 60-year-old male being evaluated for insurance purposes was found to have lymphocytosis. Peripheral smear revealed a uniform population of small mature lymphocytes. Which of the following is the most likely diagnosis? (Objectives 3, 7)
 - a. acute lymphoblastic leukemia
 - b. chronic lymphocytic leukemia
 - c. infectious mononucleosis
 - d. malignant lymphoma
3. Which of the following indicate(s) the presence of a lymphoid malignancy? (Objective 2)
 - a. clonal immunoglobulin gene rearrangement
 - b. population of lymphocytes expressing only one immunoglobulin light chain
 - c. population of lymphocytes expressing an abnormal phenotype
 - d. all of the above
4. A patient with non-Hodgkin lymphoma is found to have bone marrow involvement. What stage is the lymphoma? (Objective 9)
 - a. I
 - b. I_E
 - c. III
 - d. IV

LEVEL II

1. Which of the following is involved in the pathogenesis of low-grade follicular lymphoma? (Objective 8)
 - a. genes involved in apoptosis
 - b. inherited immunodeficiency
 - c. proto-oncogenes
 - d. tumor suppressor genes
2. Which type of lymphoma can be cured by antimicrobial therapy? (Objective 8)
 - a. Burkitt lymphoma
 - b. Hodgkin lymphoma
 - c. MALT lymphoma
 - d. HIV-associated non-Hodgkin lymphoma
3. A lymph node biopsy is performed in a patient with lymphadenopathy. Which of the following findings would support the diagnosis of a reactive proliferation rather than malignant lymphoma? (Objective 9)
 - a. a mixed population of cells varying in size, shape, and color
 - b. clonality
 - c. presence of large, bizarre cells
 - d. mitotic activity
4. A CBC performed on a 65-year-old female reveals lymphocytosis. A bone marrow reveals replacement of the hematopoietic precursors by an infiltrate of mature lymphocytes. Which of the following is the most likely course of the disease? (Objective 5)
 - a. cure following therapy
 - b. rapid progression
 - c. slow progression
 - d. spontaneous remission

REVIEW QUESTIONS (continued)

LEVEL I

5. A lymph node biopsy reveals a nodular infiltrate of small, mature lymphoid cells with an absence of mitoses and apoptosis. Which of the following is the correct classification of this lymphoma? (Objective 9)
 - a. high grade
 - b. high stage
 - c. low grade
 - d. low stage
6. Which of the following lymphoid malignancies is most likely to have circulating neoplastic cells? (Objectives 3, 6)
 - a. chronic lymphocytic leukemia
 - b. high-grade lymphoma
 - c. low-grade lymphoma
 - d. Hodgkin lymphoma
7. The WHO classification of lymphoid malignancies recommends which of the following studies? (Objective 9)
 - a. genotype
 - b. morphology
 - c. phenotype
 - d. all of the above
8. A bone marrow sample obtained for staging purposes revealed involvement by non-Hodgkin lymphoma. This finding indicates that the disease is: (Objective 9)
 - a. high grade
 - b. high stage
 - c. low grade
 - d. low stage
9. A peripheral smear performed on a 35-year-old male with lymphocytosis reveals numerous smudge cells. Which of the following does this finding indicate? (Objectives 3, 8)
 - a. chronic lymphocytic leukemia
 - b. infectious mononucleosis
 - c. acute lymphoblastic leukemia
 - d. none because the finding is not diagnostic
10. Peripheral smear examination of a patient with chronic lymphocytic leukemia reveals 8% prolymphocytes. This finding is consistent with which of the following diagnoses? (Objective 8)
 - a. chronic lymphocytic leukemia
 - b. prolymphocytic leukemia
 - c. prolymphocytoid transformation
 - d. Richter's transformation

LEVEL II

5. Which of the following phenotypes is characteristic of chronic lymphocytic leukemia? (Objective 1)
 - a. CD19+, CD5+, CD23+
 - b. CD19+, CD5–, CD23+
 - c. CD19+, CD5+, CD23–
 - d. CD19+, CD5–, CD23–
6. A CBC performed on an 80-year-old female reveals an absolute lymphocyte count of $8 \times 10^9/L$. Examination of the peripheral blood smear reveals a uniform population of small lymphocytes. Which of the following procedures would be most likely to establish a diagnosis? (Objectives 1, 5)
 - a. cytogenetics
 - b. flow cytometry immunophenotyping
 - c. immunoglobulin gene rearrangement
 - d. lymph node biopsy
7. A patient presents with a lymphocyte count of $350 \times 10^9/L$. Peripheral blood examination reveals large cells with moderate amounts of pale basophilic cytoplasm, moderately condensed chromatin, and prominent nucleoli. Which of the following is the most likely clinical finding? (Objective 5)
 - a. massive splenomegaly
 - b. lymphadenopathy
 - c. lytic bone lesions
 - d. lymphomatous polyposis
8. A CBC performed on a 60-year-old male with a history of rheumatoid arthritis revealed neutropenia and an absolute lymphocytosis. Examination of the peripheral smear revealed many lymphocytes with abundant pale-staining cytoplasm and cytoplasmic granules. Which of the following is the most likely phenotype? (Objectives 1, 5)
 - a. CD3+, CD2+, CD57+
 - b. CD19+, CD5+, CD57–
 - c. CD2+, CD3–, CD56+
 - d. CD19+, CD10+, CD34+
9. A patient previously diagnosed with small lymphocytic lymphoma (SLL) is found to have peripheral blood lymphocytosis. The lymphocytes are small and have round nuclei with clumped chromatin. Which of the following is the most appropriate interpretation? (Objective 3)
 - a. This represents the same disease process (SLL).
 - b. The patient has a new lymphoid malignancy: chronic lymphocytic leukemia.
 - c. The lymphoma has transformed.
 - d. The patient has developed a therapy-related malignancy.

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

10. A lymph node biopsy revealed an infiltrate of small lymphoid cells with a vaguely nodular growth pattern. Flow cytometry revealed a monoclonal population of B cells expressing CD5. Immunohistochemistry revealed nuclear staining for cyclin-D1 protein. Which of the following is the most likely diagnosis? (Objective 3)
- mantle cell lymphoma
 - small lymphocytic lymphoma
 - chronic lymphocytic leukemia
 - follicular lymphoma

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Julia, a 56-year-old female, had painless lymphadenopathy. Her laboratory results revealed a leukocytosis with a relative and absolute lymphocytosis. The lymphocytes were mature with clumped chromatin and irregular nuclear outline. The lymphocytes were CD10 positive, characteristic of circulating lymphoma cells. A biopsy of the lymph node showed infiltration with neoplastic lymphocytes. The diagnosis of low-grade, non-Hodgkin lymphoma, follicular type was made. She received chemotherapy. Two years later, she returned with expanding lymph nodes in her neck. A biopsy was performed, and a diagnosis of diffuse large cell lymphoma was made. The second lymphoma was probably a transformation of the previous low-grade lymphoma.

Question:

- What is the differential diagnosis?

Explanation:

The differential diagnosis for a lymphocytosis composed of mature cells includes all chronic leukemia lymphoproliferative disorders discussed: chronic lymphocytic leukemia, prolymphocytic leukemia, hairy cell leukemia, large granular lymphocyte leukemia, Sézary's syndrome, and circulating lymphoma. The nuclear irregularities and history of lymphadenopathy are both suggestive of circulating lymphoma.

Question:

- What studies could be performed to establish the diagnosis?

Explanation:

Flow cytometry immunophenotyping performed on the peripheral blood may help to establish a diagnosis. Chronic lymphocytic leukemia, hairy cell leukemia, large granular lymphocyte leukemia, and Sézary's syndrome all have a characteristic immunophenotype. Circulating lymphoma may either have a generic, monoclonal B cell phenotype or express antigens specific for the subtype of lymphoma such as CD10 expression in follicular lymphoma. The case described was CD10 positive. This information and the appearance of the lymphocytes suggest the presence of non-Hodgkin lymphoma, follicular type. Biopsy of a lymph node would be of value in confirming this interpretation.

Question:

- What is the cause of the lymphadenopathy?

Explanation:

The lymphadenopathy is due to the presence of non-Hodgkin lymphoma. Neoplastic lymphoid cells have replaced the normal cells of the lymph node. The lack of tingible body macrophages and mitotic figures distinguishes the neoplastic nodules from benign germinal centers.

Question:

4. Is this process low grade or high grade?

Explanation:

This non-Hodgkin lymphoma has characteristics of a low-grade lymphoma: nodular growth, small cells, lack of apoptosis (tingible body macrophages), and absence of mitotic figures. The diagnosis of follicular lymphoma, grade 1 was established.

Question:

5. What is the diagnosis?

Explanation:

The diagnosis is diffuse large B-cell lymphoma.

Question:

6. What is the relationship of this disease to the previous diagnosis?

Explanation:

This disease probably represents transformation from the previously diagnosed follicular lymphoma.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

How does the bcl-2 gene rearrangement differ from most other oncogenes?

Answer

The bcl-2 gene rearrangement leads to persistence of cells due to an inhibition of apoptosis rather than uncontrolled cell proliferation.

Checkpoint! 2

How does staging differ from grading in defining and classifying the lymphoid malignancies?

Answer

Staging determines the extent and distribution of disease; *classifying* separates grades of lymphoma and often uses a combination of morphology, phenotype, and genotype.

Checkpoint! 3

The chronic lymphoid leukemic malignancies are a heterogeneous group. What characteristics allow them to be grouped together?

Answer

The chronic lymphoid leukemic malignancies are grouped together because the malignant cell is a mature lymphocyte, a cell found in the blood and bone marrow (leukemic distribution).

Checkpoint! 4

What cell characteristically distinguishes Hodgkin lymphoma from non-Hodgkin lymphoma? Describe this cell.

Answer

The Reed-Sternberg cell characteristically distinguishes Hodgkin lymphoma from non-Hodgkin lymphoma. It has two or more nuclear lobes containing inclusionlike nucleoli and an area of peri-nucleolar clearing (owl's eye appearance).

Checkpoint! 5

What clinical finding differentiates multiple myeloma from other plasma cell neoplasms?

Answer

The presence of multiple lytic bone lesions differentiates multiple myeloma from other plasma cell neoplasms.

Hematopoietic Stem Cell Transplantation

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Origin and differentiation of hematopoietic stem cells
- ▶ Sources of hematopoietic stem cells and types of stem cell transplants
- ▶ Collection and processing of hematopoietic stem cells
- ▶ Quantitation of hematopoietic stem cells
- ▶ Collection target for stem cells
- ▶ Hematopoietic engraftment
- ▶ Role of the clinical laboratory professional in stem cell transplantation
- ▶ Graft-versus-host disease and graft-versus-leukemia effect
- ▶ Complications associated with stem cell transplantation
- ▶ Summary
- ▶ Review questions
- ▶ References

Hematopoietic Stem Cell Transplantation

Aamir Ehsan, M.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Describe the sources of hematopoietic stem cells and characteristics of each source.
2. Identify the diseases that can be treated with different sources of hematopoietic stem cells.
3. List characteristics of stem cells.
4. Describe the significance of ABO and HLA antigens for stem cell transplant.
5. Identify the infections that are serious complications during the peritransplant period.
6. Describe the significance and effects of graft-versus-host disease (GVHD) and compare them to those of the graft-versus-leukemia (GVL) process.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Summarize the collection and processing of hematopoietic stem cells and assess the success of these procedures.
2. Explain the role of the clinical laboratory professional in stem cell transplantation.
3. Select and outline methods to enumerate hematopoietic stem cells.
4. Explain the complications of stem cell transplant, and assess the patient's risk of developing them.
5. Formulate the sequence of events for a patient who will receive a stem cell transplant.
6. Select laboratory tests used to determine engraftment and assess engraftment given results of these tests.

 Syngeneic transplantation
 Variable number tandem repeats (VNTR)

BACKGROUND BASICS

This chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review the following material before starting this unit of study.

Level I

- ▶ Describe the origin and differentiation of hematopoietic cells.
- ▶ Outline the classification and explain the etiology and pathophysiology of neoplastic hematologic disorders.
- ▶ Explain the role of chemotherapy and radiotherapy in treatment of neoplastic hematologic disorders.

Level II

- ▶ Describe the role of cytokines and bone marrow microenvironment in maturation and differentiation of hematopoietic stem cells; explain the role of oncogenes in cancer development.
- ▶ Explain the use of molecular genetic technology and cytogenetics in diagnosis and prognosis of neoplastic hematopoietic disorders.
- ▶ Correlate subgroups of neoplastic hematologic disorders with laboratory findings and prognosis.

**CASE STUDY**

We will refer to this case study throughout the chapter.

Brandon, a 35-year-old male (weight 80 kg), was recently diagnosed with AML with maturation and received induction chemotherapy. Day 21 bone marrow reveals no evidence of residual leukemia. Two weeks later, circulating blasts were seen in the peripheral blood. Brandon is being evaluated for a stem cell transplant. Consider the laboratory's role in evaluating the transplant, collecting and processing the stem cells, and determining engraftment.

OVERVIEW

The use of stem cells in the therapy of neoplastic hematopoietic disorders has become commonplace. The laboratory's role in this therapy is critical and requires that the clinical laboratory professional know not only the associated laboratory tests but also why the tests are necessary and how they relate to the overall process of stem cell transplantation. This chapter reviews the sources of hematopoietic stem cells (HSCs); the use of allogeneic, autologous, and umbilical cord stem cells in treating a variety of malignant and nonmalignant disorders; the mobilization, collection, and enumeration of mononuclear cells (MNCs) and CD34 positive cells; the procedures used to assess transplant success (**engraftment**); and the role of the clinical laboratory professional during this process.

INTRODUCTION

Hematopoietic stem cell transplantation (HSCT) is a recognized therapeutic modality for leukemias, lymphomas, solid organ tumors, and a variety of metabolic and immunologic disorders (Table 1 🌟). The concept of stem cell transplantation (SCT) came from experiments done five decades ago when it was observed that mice given intravenous marrow infusions could overcome lethal doses of radiation.^{1,2} Later, in the 1960s, the first successful bone marrow transplant was performed on a leukemia patient using marrow donated by the leukemic patient's brother.

After the early successful **allogeneic** bone marrow SCTs (transplantation of stem cells between genetically dissimilar but human-leukocyte-antigen-matched [HLA-matched] individuals) using fresh anticoagulated bone marrow from HLA-matched siblings or family members, clinical practice has expanded to include the use of **autologous** bone marrow stem cells (transplantation or infusion of a person's own stem cells), autologous and allogeneic peripheral blood stem cells (PBSCs), and umbilical cord stem cells. HLA genes control the body's ability to mount an immune response. These genes code for histocompatible antigens found on the surface of essentially all nucleated cells.

ORIGIN AND DIFFERENTIATION OF HEMATOPOIETIC STEM CELLS

HSCs are rare cells that can be found in the bone marrow and occasionally in the peripheral blood of healthy individuals. Self-renewal and multilineage differentiation are the two distinct biologic properties that make HSCs remarkable. Pluripotent stem cells differentiate into myeloid and lymphoid stem cells (Figure 2). Myeloid stem cells produce three types of committed/progenitor cells that differentiate into erythroid, granulocyte-macrophage, and megakaryocytic cell pathways. The lymphoid stem cells differentiate into T cells, B cells, and

★ TABLE 1

Diseases That Can Be Treated with Stem Cell Transplantation

Hematologic		
Neoplastic	Non-neoplastic	Nonhematologic
Acute lymphoblastic leukemia	Aplastic anemia	Solid organ malignancies (breast, ovarian, neuroblastoma, Wilms' tumor, germ cell)
Acute myeloid leukemia	Paroxysmal nocturnal hemoglobinuria	
Chronic myelogenous leukemia	Thalassemia	Inborn error of metabolism (e.g., Hurler's syndrome)
Idiopathic myelofibrosis	Sickle cell disease	Severe combined immunodeficiency disease
Chronic lymphocytic leukemia	Fanconi's anemia	Wiskott-Aldrich syndrome
Myelodysplastic syndrome	Congenital pure red cell aplasia	Congenital leukocyte dysfunction syndromes
Non-Hodgkin lymphoma		Malignant osteopetrosis
Hodgkin lymphoma		
Multiple myeloma		

possibly natural killer cells. The committed progenitor cells have been called *colony-forming units (CFUs)* because they give rise to colonies of differentiated progeny in vitro. From these CFUs arise morphologically recognizable precursors of differentiated cells (pronormoblast, myeloblast, monoblast, megakaryoblast) that further differentiate into mature cells. In summary, pluripotent stem cells have the capacity to self-renew and differentiate. With additional divisions, their progeny, the committed progenitor cells, become progressively restricted to proliferation and differentiation into a single cell line. The committed cell lacks the property of self-renewal.

► SOURCES OF HEMATOPOIETIC STEM CELLS AND TYPES OF STEM CELL TRANSPLANTS

HSCs for clinical use³ can be harvested from the bone marrow, peripheral blood, and umbilical cord blood (UCB). Fetal bone marrow and liver are also rich in stem cells, but use is limited

due to ethical issues. Unlike other tissues and organs destined for transplant, HSCs are not routinely taken from cadavers. One reason for this is that in most situations, the stem cell donor receives hematopoietic cytokines for a few days before the stem cells are harvested to maximize stem cell yield.

ALLOGENEIC STEM CELL TRANSPLANTATION

Allogeneic stem cell transplantation is the infusion of HSCs from another individual (donor) into the patient (recipient). In the past, the usual source of stem cells has been the bone marrow, but now allogeneic transplants using PBSCs are more common. Allogeneic transplants are often indicated when the disease process involves the patient's own stem cells, making them potentially unsuitable for transplant (Table 2★). Allogeneic transplant is usually performed for therapy of acute leukemias, chronic myelogenous leukemia (CML), aplastic anemia, hemoglobinopathies, immune deficiencies, and metabolic genetic disorders.^{4,5}

★ TABLE 2

Type of Transplant, Sources of Stem Cells, and Diseases in Which These Stem Cells Are Used

Type of Transplant	Source of Stem Cells	Diseases
Allogeneic	Bone marrow	Acute leukemias, CML, non-neoplastic hematologic conditions (see Table 1), immunologic and inherited diseases
	Peripheral blood	
	Cord blood	
Autologous	Peripheral blood	HL, NHL, solid organ tumors, MM
	Bone marrow	
Syngeneic	Peripheral blood	Any disorder treated by allogeneic/autologous transplant except a genetic disease
	Bone marrow	

CML = chronic myelogenous leukemia; HL = Hodgkin lymphoma; NHL = non-Hodgkin lymphoma; MM = multiple myeloma

Three important factors must be considered in order to achieve successful allogeneic SCT. Adequate numbers of HSCs should be present in the graft so that when infused into the recipient's circulation, engraftment in the marrow microenvironment will occur. The recipient's immune system should tolerate donor stem cells so that graft rejection does not occur, and the donor's immune cells should tolerate host tissue to avoid severe **graft-versus-host disease (GVHD)**. GVHD occurs when immunocompetent donor T lymphocytes recognize nonself HLA antigens on the host cells and initiate cell injury.

Highly incompatible tissues are almost certain to be rejected. Compatibility is based on the immune system's recognition of certain cell markers as "self." The most critical of these cell markers appear to be the HLAs, also known as the *major histocompatibility complex (MHC)*. The HLA system is highly **polymorphic** (occurring in several forms).

Genes present on the short arm of chromosome 6 encode HLA antigens. Class I HLA antigens are encoded by three loci: HLA-A, HLA-B, and HLA-C. Class II HLA antigens are encoded by another three loci: HLA-DR, HLA-DP, and HLA-DQ. Serological and molecular testing methods are available to HLA-type individuals.^{6,7} Although the candidate donors and recipients are tested for HLA-A, -B, -C, -DR, and -DQ antigens, an HLA match requires only that the donor and recipient have compatible HLA-A, HLA-B, and usually HLA-DR antigens. An optimum clinical result occurs when the donor and recipient are matched at the HLA-A, HLA-B, and HLA-DR loci. Even with a complete match, graft rejection and GVHD can occur, indicating the possibility current testing methods may not recognize antigens that are incompatible or not encoded by MHC. On the other hand, successful transplant can occur even with some degree of HLA mismatch.^{8,9}

Approximately 30% of patients requiring allogeneic transplant have a matched sibling donor and another 2 to 5% have a partially matched related donor.¹⁰ If family members do not match or are not available, the search for an unrelated HLA-matched donor is made through the National Marrow Donor Program (NMDP).¹¹ This type of transplant is called a *matched unrelated donor (MUD) transplant*. The NMDP was established in 1987 and currently has more than 3 million registered donors. Even with such a large donor pool in the NMDP, the MUD transplant has certain limitations. First, because of HLA polymorphisms, locating HLA-matched donors is difficult. Second, the length of time to find a compatible allograft is about 4–6 months. Third, the cost of a donor search/procurement is high. Fourth, the racial distribution in the NMDP is unbalanced, limiting its usefulness for patients of minority origins, particularly those of African, Mexican, and Asian heritage. However, considerable efforts are being made to recruit minority donors. Finally, the chance of graft failure, GVHD, and opportunistic infections with MUD transplant increases.

The initial donor selection for an allogeneic transplant is based on HLA compatibility with the recipient. The ABO blood group antigens of the donor and recipient do not need

to be matched to accomplish successful transplantation because these antigens are not expressed on HSCs. Stem cell donors are tested for the same infectious diseases as are required by the Food and Drug Administration (FDA) for volunteer blood donors. Most transplant centers absolutely exclude donors only if they are found to have serologic evidence of HIV infection. Before receiving the allogeneic HSC infusion, the recipient is treated with conditioning chemotherapy and/or total body irradiation.¹² Depending on the underlying disease, this regimen can serve two purposes. First, it provides an antitumor effect, and second, it is immunosuppressive to enable the recipient to better tolerate the donor cells. The goal of giving high-dose chemotherapy/radiotherapy is to destroy all malignant cells but the therapy is also toxic to normal bone marrow cells. The patient's marrow is then rescued with normal cells by infusing the donor stem cells. As in solid organ transplantation, recipients must also be given additional immunosuppressive therapy such as cyclosporine or tacrolimus to minimize graft rejection and GVHD.

Syngeneic transplantation is the use of bone marrow or PBSCs from an identical twin. This type of transplant is rare but could be used for any disorder treated by allogeneic or autologous transplant except genetic diseases that affect both twins. This uncommon situation should have no risk of rejection or GVHD, and no special immunosuppressive drugs need be given.

CASE STUDY (continued from earlier in this chapter)

Brandon had a bone marrow examination, and 6% blasts were present. He has four siblings.

1. Is Brandon a candidate for a stem cell transplant?
2. If yes, what form of transplant is required for him?
3. What testing should be done on Brandon to proceed with the transplant?

AUTOLOGOUS STEM CELL TRANSPLANTATION

Autologous stem cell transplantation infuses the patient's own bone marrow or PBSCs. These stem cells are collected prior to intensive or myeloablative chemotherapy and/or radiotherapy, which are aimed at eliminating the malignant cells. After therapy, the collected stem cells are infused into the patient to re-establish hematopoiesis. Autologous transplantation is usually indicated when the patient's stem cells are not affected by the disease and the underlying disease is potentially responsive to high-dose chemotherapy and/or radiotherapy. This type of transplant is commonly utilized for Hodgkin lymphoma; non-Hodgkin lymphoma; multiple myeloma; solid organ tumors including breast, ovarian, and testicular cancers; and pediatric neoplasms such as neuroblastoma and Wilms' tumor (Table 2).

Autologous PBSC transplant also can be performed if the disease involves the patient's own marrow. However, in this

case, a number of other factors should be evaluated: age, underlying disease, degree of marrow involvement, response to previous chemotherapy, and donor availability. The use of autologous stem cells for transplant in a subset of acute leukemias, myeloproliferative disorders, and myelodysplastic syndrome (MDS) has been attempted but without great success.^{13–15}

Autologous stem cell transplantation has both advantages and disadvantages. One important advantage is that it is not necessary to identify HLA-matched donors. Immunosuppression is not used, so graft rejection and GVHD are not an issue. Peritransplant mortality is low, and older patients tolerate the procedure relatively well. Some disadvantages of autologous transplant include the possibility of neoplastic cells in the stem cell product that could cause disease recurrence; difficulty in obtaining adequate stem cells if the patient has received extensive prior therapy; and the **graft-versus-leukemia (GVL)** effect sometimes seen with allogeneic transplant is not possible. (GVL effect is a favorable effect seen when immunocompetent donor T cells present in the allograft destroy the recipient's leukemic cells. The significance of GVL is described later in the chapter.)

✓ Checkpoint! 1

A physician is evaluating a 28-year-old patient with a history of acute lymphoblastic leukemia for PBSC transplantation. The laboratory professional found circulating leukemic blasts in the peripheral blood. Is this patient a candidate for an autologous PBSC transplant?

UMBILICAL CORD STEM CELL TRANSPLANTATION

Umbilical cord blood contains sufficient numbers of HSCs to provide short-term and long-term engraftment in related and unrelated recipients.^{16–18} The first cord blood transplantation was performed in a 5-year-old boy with Fanconi's anemia in 1988.¹⁹ Clinical data indicate that cord blood from siblings and unrelated donors can be used to reconstitute hematopoiesis in patients with malignant and nonmalignant disorders.^{16–18,20} As a result of the early successes with cord blood transplantation from sibling donors, pilot programs for banking unrelated donor cord blood were initiated in various countries around the world. Cord blood contains sufficient numbers of HSCs for engraftment in most recipients weighing less than 40 kg. However, cord blood transplants have been attempted with some success in patients weighing more than 40 kg. See Table 3 🌟 for the advantages and disadvantages of using cord blood over marrow.

✓ Checkpoint! 2

What would be the best form of transplant for a patient with CML who needs a stem cell transplant, and what antigen type needs to be matched?

🌟 TABLE 3

Advantages and Disadvantages of Using Cord Blood Stem Cells versus Marrow Stem Cell Donors

Advantages	Disadvantages
<ul style="list-style-type: none"> • Cord blood is abundantly available. • Cord blood stem cells can be collected without risk to the mother or infant. • Cord blood can be frozen and readily available on demand. • Ethnic balance of a given population of donors can be maintained. • The risk of latent viral contamination (CMV, EBV) is low. • Cord blood does not contain mature T cells and therefore is likely to be less immunogenic and will reduce the incidence of GVHD. 	<ul style="list-style-type: none"> • Total number of stem cells is generally inadequate for most adult transplant patients. • GVL effect can be reduced. • Only one unit is available for each transplant procedure.

GVL = graft versus leukemia; CMV = cytomegalovirus; EBV = Epstein Barr virus

▶ COLLECTION AND PROCESSING OF HEMATOPOIETIC STEM CELLS

Collecting and processing HSC requires a team of clinical laboratory professionals as well as physicians.

BONE MARROW

Collection of bone marrow stem cells (allogeneic or autologous) is a surgical procedure performed in the operating room using general or local anesthesia. The marrow is taken from the posterior iliac crest with harvest needles and syringes. Approximately 1 liter of marrow is harvested to provide an adequate number of mononuclear cells (MNCs). When the marrow is harvested, it contains a mixture of red blood cells, white blood cells, MNCs, platelets, plasma, and fat particles. If a marrow recipient is ABO compatible with the donor, the marrow can be infused immediately after filtering the fat and small bone particles. Otherwise the marrow can be further processed to remove a mononuclear cell layer that can be frozen and stored. Stem cell collection by this method is rarely used now and is being replaced by peripheral stem cell collection (see below).

PERIPHERAL BLOOD

Because stem cells are rare in the peripheral blood (less than 0.01%), various regimens have been tried to mobilize stem cells in the marrow to enter the peripheral blood and increase the number of circulating MNCs. Transplanting more

stem cells means more rapid hematopoietic recovery.²¹ For autologous PBSC collection, patients can receive cytotoxic chemotherapy (e.g., Cytosan); hematopoietic cytokines (e.g., granulocyte colony-stimulating factor [G-CSF]; granulocyte-macrophage colony-stimulating factor [GM-CSF]); or a combination of chemotherapy and cytokines to mobilize stem cells.

After cytotoxic and cytokine therapy, the stem cells in the marrow rebound and are mobilized to the peripheral blood where they can be collected by **apheresis**, an automated procedure that uses a blood cell separator. Whole blood is withdrawn from the donor and anticoagulated. The components are separated using centrifugation or filtration, and the desired component is collected (in this case, mononuclear cells that contain the hematopoietic stem cells). The remaining components are combined and infused back into the donor.

The optimum timing for collection of PBSCs after cytotoxic and growth factor therapy is sometimes unpredictable, and the time of harvest varies depending on the mobilization protocol. Some centers determine timing of PBSC collection based on a preapheresis peripheral blood CD34 count.²²

For allogeneic PBSC collection, hematopoietic cytokines (G-CSF or GM-CSF) are given to normal, healthy donors to mobilize stem cells, and then the MNCs are collected by apheresis.

CASE STUDY (continued from earlier in this chapter)

An HLA-matched sibling has agreed to be a donor for Brandon.

- Should the source of stem cells be peripheral blood or bone marrow? Why?

UMBILICAL CORD BLOOD

If UCB is collected as a source of stem cells, the mother must sign an informed consent, and a complete medical history of the parents is obtained. Cord blood is usually collected from a delivered placenta or sometimes from an undelivered placenta (after the baby is delivered and the cord is being clamped). A large-bore needle is inserted into the umbilical vein to collect blood in a sterile collection bag containing anticoagulant. Several methods are used to separate MNCs from the whole cord blood: Ficoll-Hypaque, modified Ficoll-Hypaque gradient method, and addition of hydroxyethyl starch (HES).^{23,24} The cord blood is not usually processed if certain conditions are present (Table 4).

PURGING

Purging is a technique to remove undesirable cells present in the product. Purging is performed on the stem cell product that has been collected by apheresis. Depending on the source of stem cells and clinical conditions in which these

TABLE 4

Conditions in Which Stem Cells Are Not Usually Collected and/or Processed from the Cord Blood

- Inadequate volume collected from an individual placenta (less than 40 mL)
- Preterm delivery (less than 36 weeks)
- Fever higher than 100°F (38°C) in mother
- Premature rupture of membranes
- Meconium staining of the fluid
- Family history of inherited diseases
- Congenital anomalies in the infant

cells are used, various purging techniques (mechanical, immunological, and pharmacological) are available.²⁵

When a patient with a history of solid tumor is undergoing an autologous transplant, the bone marrow and PBSCs to a lesser extent can be contaminated with occult tumor cells. Therefore, removal of tumor cells, if present, is theoretically highly desirable.

GVHD is an immunologic response that results from the presence of donor origin CD8-positive T suppressor cells that can interact with the host's CD4-positive T helper cells. In an allogeneic transplantation, GVHD is a potential complication. Purging the donor T lymphocytes from the allograft can prevent GVHD or reduce its severity. However, some of these T cells seem to be necessary for marrow engraftment and for achievement of the GVL effect. A favorable response, GVL is usually seen because the T cells present in the graft can have an active role in destroying the residual leukemic cells of the recipient. In support of this possibility, patients receiving T cell-depleted grafts are known to be at higher risk for disease relapse than patients receiving unmanipulated grafts for the same disease.

CRYOPRESERVATION AND STORAGE OF HSCS

HSCs from bone marrow, PBSCs, or cord blood can be effectively **cryopreserved** (stored at very low temperatures) to maintain cell viability for months or years. When the stem cells are frozen or thawed, cell injury or loss of stem cell viability results from intracellular crystal formation and cellular dehydration.

To achieve the optimum cryopreservation without compromising the cell viability, a cryoprotectant agent is used.²⁵ The most common cryoprotectants are either 10% DMSO (dimethylsulfoxide) or 5% DMSO with 6% HES. The DMSO diffuses rapidly into the cells and increases intracellular solute concentration, thus decreasing intracellular ice crystal formation and preventing cell lysis.

After optimizing the concentration of the stem cells in the presence of cryoprotectant, tissue culture media and autologous plasma are frozen in many small plastic bags. The

freezing rate seems to be an important factor for viable cell recovery. The freezing is usually performed in the chamber of a programmable device into which liquid nitrogen is pumped to maintain the desired rate. When the freezing program has been completed, the bags are removed from the chamber and placed in a liquid nitrogen refrigerator in either liquid or vapor phase at -196°C .

INFUSION OF HSCS

The patient to be infused is premedicated with antihistamine and antiemetic (sometimes diuretics and/or steroids). The frozen bags are immediately thawed in a 37°C water bath just before the infusion. The infusion is carried out as quickly as possible to dilute the cell suspension with the patient's blood volume because DMSO in liquid phase can be toxic to stem cells. The most common adverse reactions associated with cryopreserved stem cells are chills, nausea, vomiting, fever, allergic reactions, transient cough, and shortness of breath. Adverse events from infusion can be related to DMSO-induced histamine release; therefore, some centers thaw and dilute or wash the cell suspension to remove the DMSO, but cell loss and clumping can be a problem.

▶ QUANTITATION OF HEMATOPOIETIC STEM CELLS

The number of stem cells or CD34+ cells that can be obtained varies greatly from donor to donor. For PBSCs, one or more apheresis procedures are needed to acquire the appropriate dose for engraftment and hematopoietic recovery. Because the engraftment outcome depends on the number of stem cells present in the product, the HSCs (from bone marrow, PBSCs, or cord blood) are quantitated by one of the three methods described next.

DETERMINATION OF MONONUCLEAR CELL COUNT

Stem cells are mononuclear cells as are other cells (such as immature myeloid cells, lymphocytes, and monocytes); thus, counting MNCs provides a very indirect estimate of the number of stem cells present in the sample (Figure 1 ■). The volume of cells necessary to achieve a satisfactory dose for successful engraftment can be determined from the MNC count. The dose is usually specified as the number of MNCs per kilogram of the recipient's body weight. Laboratories use automated cell counters or hemacytometers to count the MNCs.

CD34 ENUMERATION BY FLOW CYTOMETRY

Enumerating stem cells that express CD34 antigen and using immunophenotyping has become a routine practice. When bound to fluorescent dyes, anti-CD34 antibodies offer a

■ **FIGURE 1** Wright's stain slide prepared for the manual differential count from the stem cell product showing myeloid precursors and mononuclear cells. (Peripheral blood; Wright's stain, 1000× magnification)

rapid method of enumerating stem cells using a flow cytometer. Flow cytometric enumeration of CD34+ cells has been shown to be the most useful indicator of the hematopoietic reconstitutive capacity of SCT.

The major difficulty with the analysis of CD34+ cells is the low number of cells present in the specimen. The method's sensitivity is 1 in 10,000. Procedures to measure CD34+ cells vary widely. Optimally, 100 CD34+ cells and 75,000 CD45+ (leukocytes) events should be acquired to optimize the accuracy of analysis.^{26,27} The CD34 count is calculated in conjunction with the total leukocyte counts.^{27,28} These results should be reported as soon as possible because the clinical decision to collect more stem cells depends on CD34 yield. CD34 counts can be performed on peripheral blood and stem cell product. Some centers determine the timing of PBSC collection based on a peripheral blood CD34 count.²² If the CD34+ cells are lower than required, the decision can be made to perform more (or postpone) apheresis or "prime" the patient in a different manner.

CELL CULTURE FOR COLONY FORMING UNITS (CFU)

Flow cytometry analysis identifies cells only by their antigenic markers and thus cannot identify cells that are **clonogenic**; only culture techniques can demonstrate clonogenicity. An in vitro clonogenic assay is a culture system containing stem cells and various growth factors. The culture is incubated for 14–15 days on a semisolid medium (agar or methylcellulose). The colonies generated from committed myeloid and erythroid hematopoietic progenitors can be differentiated and counted (Figure 2 ■).

The advantage of the clonogenic assay is that this system tests the capacity of progenitor cells to divide and can pre-

■ **FIGURE 2** Cell culture colonies: **a.** erythroid colonies and **b.** myeloid colonies (on semisolid medium).

dict the engraftment potential of the stem cell product.^{29,30} The 2-week incubation period needed in this method is a distinct disadvantage when data are needed for immediate clinical decisions. The results of clonogenic assay systems from different institutions vary greatly due to variance in reagent lots and the level of staff expertise. Commercial kits are now available to aid in the standardization of clonogenic assays.

✓ Checkpoint! 3

You receive a peripheral blood specimen in the hematology laboratory with a request for a mononuclear cell count and analysis of CD34+ cells. Without any further information, why should you consider this a STAT request?

► COLLECTION TARGET FOR STEM CELLS

The recipient's body weight determines the adequate dose of stem cells, the exact number of which is needed to ensure engraftment is not known, but cell doses of $2.5\text{--}5.0 \times 10^6$ CD34+ cells per kilogram recipient weight are desirable; earlier engraftment are observed with even higher doses.^{31,32} For a transplant using umbilical cord blood, more than 3.0×10^7 of total nucleated cells per kilogram recipient weight is desirable.

🔍 CASE STUDY (continued from earlier in this chapter)

PBSCs were collected by apheresis from the sibling. Enumeration of CD34 count indicates that the total CD34+ cells collected are $6 \times 10^6/\text{kg}$.

5. Is this an adequate dose for SCT?

► HEMATOPOIETIC ENGRAFTMENT

The **conditioning regimen** given to patients for SCT causes severe myelosuppression in recipients and can affect T and B cell immunity (usually in an allogeneic setting). After the conditioning regimen, the HSCs are usually given to restore the marrow function. A period of pancytopenia typically follows during which the patient is prone to develop infections and bleeding complications. To reduce the pancytopenia period, growth factors such as G-CSF or GM-CSF can be given.^{32,33}

EVIDENCE OF SHORT-TERM ENGRAFTMENT

After transplant, the time for engraftment depends on the number of CD34+ cells in the graft. The period of pancytopenia can last from a few days to 2–4 weeks. Myeloid recovery is followed by platelet and red cell recovery. Short-term evidence of hematopoietic engraftment exists when the absolute neutrophil count is more than $500/\mu\text{L}$ and platelet count is more than $20,000/\mu\text{L}$ with no need for platelet transfusion. The pancytopenia period after PBSC transplant, when compared to bone marrow transplant, is somewhat shorter. After cord blood transplants, neutrophil recovery can take 5–6 weeks, and the platelets usually engraft late (median time 80 days).²⁰

EVIDENCE OF LONG-TERM ENGRAFTMENT

When testing reveals that all hematopoietic cells in a SCT recipient are derived from an allogeneic donor, the condition is referred to as full **chimerism** (the presence of donor hematopoietic cells in a recipient). When a recipient's

hematopoietic cells persist together with donor cells after SCT, the condition is referred to as *partial chimerism*.

To evaluate the long-term engraftment of HSCs, various laboratory methods have evolved.³⁴ Detection of red cell antigens was among the first tests used to evaluate donor cell engraftment. For example, if the recipient's blood group is O and the donor's blood group is A, then after hematopoietic engraftment with complete chimerism, the recipient can type as group A. However, because of the long life span of red cells and multiple blood transfusions during transplantation, the red cell antigens are no longer used for chimerism studies.

The most widely used tests for evaluating long-term engraftment currently are in situ hybridization (ISH) with sex chromosomes and the typing of **variable number tandem repeat (VNTR)** polymorphism by DNA amplification. **In situ hybridization** is a technique for detecting specific DNA or RNA sequences in tissue sections or cell preparations using a labeled complementary nucleic acid sequence probe. The ISH is applicable only when the donor and recipient are of the opposite sex. Variable number tandem repeats are DNA sequences that are tandemly repeated in a genome and can vary among different individuals. DNA amplification for chimerism is applicable in allogeneic transplant settings when testing a person's VNTRs can distinguish donor and recipient cells.

In summary, the clinical applications of chimerism tests in marrow transplantation are to document donor cell engraftment, evaluate the persistence of donor cells, and assess the recurrence of disease.

✓ Checkpoint! 4

A physician wants to evaluate the engraftment on a male patient who received SCT from his brother four months ago. What laboratory tests should be performed to make this assessment?

📄 CASE STUDY (continued from the previous page)

Stem cells were collected and frozen for Brandon.

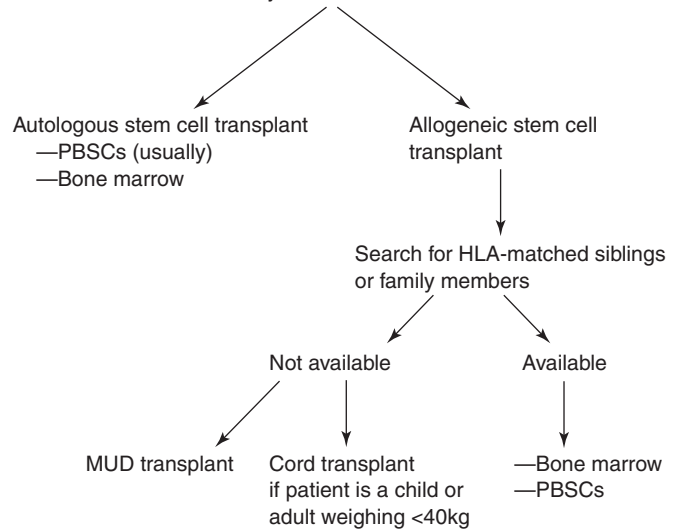

6. Does Brandon need to undergo any form of therapy before the transplant?

▶ ROLE OF THE CLINICAL LABORATORY PROFESSIONAL IN STEM CELL TRANSPLANTATION

When the decision to undertake an SCT has been made, collecting and processing stem cells involves a dedicated clinical laboratory staff that works as a team (Figure 3 ■). The SCT process involves the clinical laboratory professionals working in the department of hematology, apheresis, blood bank, microbiology, flow cytometry, molecular/HLA, cytogenetics, and bone marrow transplant laboratories (Figure 4 ■).

Factors to be considered for the SCT

1. Age of the patient
2. Underlying disease
3. Involvement of patient's own bone marrow or stem cells
4. Degree of marrow involvement
5. Response to previous chemotherapy
6. Donor availability

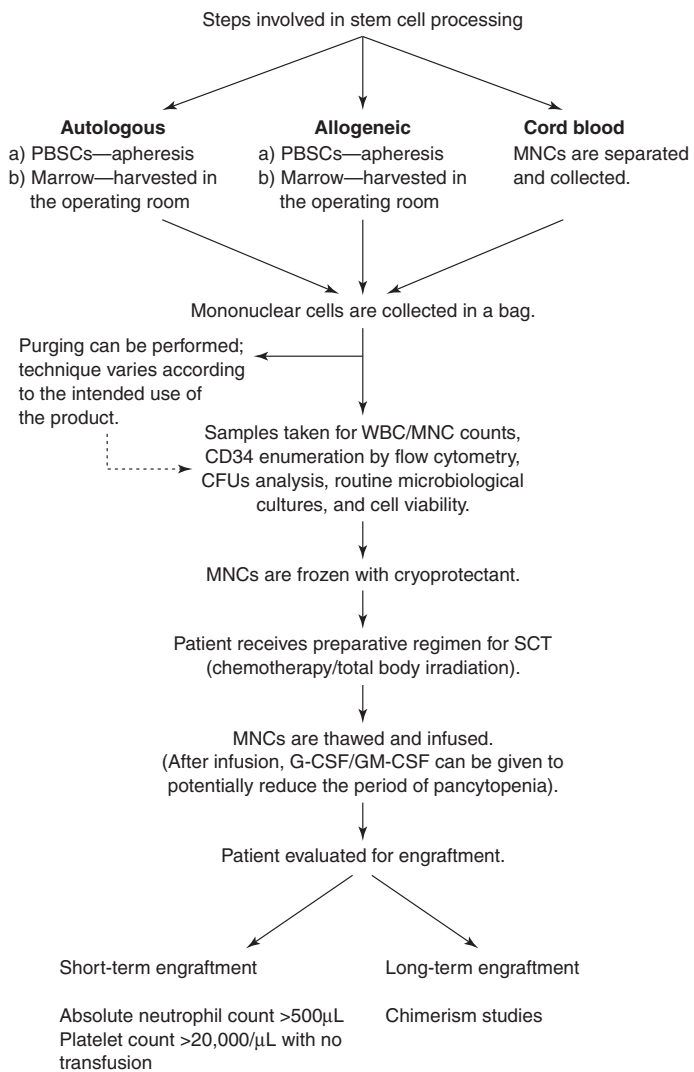

PBSCs: Peripheral blood stem cells
MUD: Matched unrelated donor

■ **FIGURE 3** Decision-making process in stem cell transplantation. The evaluation of the patient for SCT is usually done at the time of primary diagnosis. For allogeneic SCT, a donor is selected based on HLA compatibility. If family members do not match or are not available, the search for an unrelated HLA-matched donor is made through the NMDP. If the patient is a child or small adult (less than 40 kg), the cord blood registry/banks is also an option. In general, if the disease involves the patient's own stem cells, allogeneic transplant is a valid option. Autologous transplant is planned when the disease has not affected the patient's own stem cells. On the other hand, autologous PBSC transplant may be performed even if the disease involves the patient's marrow, but a number of other factors should be evaluated, as shown in this algorithm.

Let's consider a patient for whom the clinical decision for autologous SCT has been made. This patient will receive cytotoxic chemotherapy, or G-CSF, or both. For PBSC collection, the patient will undergo apheresis. (In an allogeneic transplant setting, both the donor and recipient cells are typed for HLA antigens in the molecular/HLA laboratory before collecting stem cells.) The apheresis staff will spend 4–6 hours with the patient to get a good yield of MNCs. After collecting the product, the sample will be sent to the hematology and flow cytometry labs where WBC/MNCs and CD34 counts will be performed on a sample collected by apheresis.

The bone marrow transplant laboratory staff will process and cryopreserve the stem cells for future use. The cells' via-

■ **FIGURE 4** Steps involved from the time the patient is diagnosed with the disease to the final infusion of stem cell product. For autologous transplant, the stem cells are usually collected from peripheral blood or sometimes harvested from the bone marrow. If the stem cells are collected from the peripheral blood, the patient can receive cytotoxic chemotherapy or growth factors, or both to mobilize stem cells into the blood; the stem cells are then collected by apheresis. For an allogeneic transplant, an HLA-matched family member donor or an HLA-matched donor from the NMDP is considered. The stem cells are collected from the iliac crests in a surgical procedure. In an allogeneic setting, stem cells can also be collected by apheresis from peripheral blood after mobilizing the donor with growth factors. Whatever the method of collection, after collecting the required number of stem cells from peripheral blood, bone marrow, or cord blood, samples are taken for appropriate tests and stem cells are cryopreserved for later infusion. Before the transplant, the patient receives a high dose of chemotherapy and/or radiotherapy to destroy the tumor cells. This therapy can be toxic to normal organs including bone marrow. The marrow is rescued by transplanting frozen stem cells that have been reserved for a particular patient.

bility will be checked, samples for bacterial cultures taken, and the cell culture can set up for enumeration of CFUs. On the day of transplant, the clinical laboratory staff (usually of the bone marrow lab) will thaw the units for the infusion.

After the transplant, hematology will evaluate short-term engraftment with a complete blood count. For evaluation of long-term engraftment, the sample will be sent to the cytogenetic and molecular/HLA laboratories to perform chimerism studies. Throughout the course of the transplant, the blood bank personnel will provide special blood components required during the transplantation process.

► GRAFT-VERSUS-HOST DISEASE AND GRAFT-VERSUS-LEUKEMIA EFFECT

The exact mechanism for GVHD is not yet clearly known. However, the suggested pathogenesis of GVHD is that immunocompetent donor T lymphocytes recognize HLA antigens on the host (recipient) cells and initiate secondary inflammatory injury mediated by inflammatory cytokines (interleukin-1, tumor necrosis factor [TNF]). This leads to tissue injury.^{35,36}

Three factors necessary to set the stage for GVHD are the presence of immunocompetent donor T lymphocytes, HLA alloantigens, and an immunosuppressed host. GVHD is more frequent and severe in recipients of partially HLA-matched sibling allografts or in grafts from unrelated donors.⁸ However, GVHD also occurs after HLA-identical sibling donor allografts, indicating the role of other HLA minor antigens or factors that are not usually tested at the time of transplant.

Overall, the risk of acute GVHD for the degree of HLA mismatch is less in recipients of cord SCT than in recipients of marrow transplant perhaps because of the immature nature of cord blood cells. GVHD can be prevented or its severity reduced by decreasing the number of donor T lymphocytes from the graft and/or administration of medications such as cyclosporine A, methotrexate, steroids, cyclophosphamide, antithymocyte globulin, and tacrolimus.^{37,38}

Recipients of T cell-depleted marrow less frequently experience GVHD but have a higher incidence of relapse and higher graft failure than patients with unmanipulated marrow for the same disease. T lymphocytes are known to be essential for marrow engraftment and for achieving desirable GVL effect, which is seen when immunocompetent donor T cells present in the allograft destroy the recipient's leukemic cells.³⁹ For example, in allograft recipients with CML who relapse after allogeneic SCT, donor lymphocyte infusion (DLI) of small numbers of lymphocytes collected by apheresis from the original graft donor⁴⁰ can induce a potent GVL effect and reestablish complete remission in most patients.

The critical issue of how many T lymphocytes need to be removed from the allograft to avoid GVHD yet allow marrow engraftment and GVL effect is controversial. Any number should be interpreted with caution because the T cell

concentration required to achieve long-term engraftment, control of GVHD, and beneficial GVL effect also depends on the disease and the degree of HLA disparity.

► COMPLICATIONS ASSOCIATED WITH STEM CELL TRANSPLANTATION

SCT complications can be categorized as early and late. Complications that usually occur during the first 100 days after transplantation are considered early and those that occur from a few months (>3 months) to several years post-transplantation are late.

EARLY COMPLICATIONS

Early complications include graft rejection, graft-versus-host disease, peritransplant infections, and recurrence of malignant disease.

Graft Rejection

Primary graft failure is the failure to establish hematologic engraftment and can be defined as failure to attain an absolute neutrophil count above 500 μL by 28 days post-transplant. *Secondary graft failure* is the loss of an established graft and is defined as the redevelopment of pancytopenia at any time after primary engraftment. These complications can be seen in the allogeneic transplant setting and rarely in the autologous setting. Causes of graft failure are listed in Table 5 .

Graft-versus-Host Disease

GVHD can be either acute or chronic. Acute GVHD generally occurs in the first three months after allogeneic SCT and usually involves the recipient's skin (maculopapular dermatitis), liver (elevation of bilirubin, abnormal liver function tests), and gastrointestinal tract (nausea, vomiting, diarrhea). Chronic GVHD is defined as symptoms appearing 80–100 days post-transplantation.

Peritransplant Infections

In the peritransplant period, when the patient has been immunosuppressed and has a low neutrophil count, the risk of opportunistic infection is very high. Infections can be bacterial, protozoal, fungal, and/or viral. These infections during

the first 3 months post-transplant can be serious but rarely life threatening. Reactivated cytomegalovirus (CMV), a group of the herpes virus family, and herpes simplex are the most common. In the United States, CMV prevalence in the population ranges from 50 to 85%. SCT patients are particularly vulnerable to CMV infection, which can be primary, but superinfection with a second strain or a reactivation of latent disease also can occur. The complications include pneumonitis, gastroenteritis, and retinitis. Fatal CMV pneumonia occurs in 10–15% of patients.

The relative risk for CMV infection among SCT patients depends on the serostatus of both the donor and the recipient.⁴¹ A seronegative recipient of seropositive transplant is at significant risk of primary transfusion-transmitted CMV infection. Seropositive recipients of seropositive transplants can develop reactivation or superinfection of CMV.

A donor for a CMV negative patient should be an HLA-compatible person who is seronegative for CMV. SCT patients who are at significant risk for acquiring transfusion-transmitted CMV also should receive cellular components that carry a reduced risk of CMV. It has been shown that CMV resides in leukocytes, and studies have indicated that leukocyte-reduced cellular blood components can prevent CMV infection.^{42–44} However, equivalent efficacy of leukocyte-reduced and CMV-seronegative cellular components in preventing transfusion associated (TA)-CMV has not yet been completely resolved. Most transplant physicians believe that if a CMV-seronegative recipient receives stem cells from a CMV-seronegative donor, all subsequent blood components received should be CMV-seronegative. If the CMV-negative blood component is not available, transfusing a leukocyte-reduced filtered component can effectively prevent the transmission of CMV disease.

Recurrence of Malignant Disease

Patients who undergo autologous transplantation are more at risk of dying from disease recurrence than from transplant-related complications. After autologous transplant, recurrence of the original disease can occur because of incomplete eradication of malignant cells or the presence of residual neoplastic cells in the autograft that have not been adequately eliminated by purging techniques. Patients who receive an allogeneic transplant rather than an autologous transplant for hematologic malignancies have a lower relapse rate; however, the risk of leukemic relapse varies from 5 to 70%. This variability depends on the diagnosis and stage of the disease, the degree of immunosuppression, the match or mismatch of the allograft, and the presence or absence of GVHD.

Other Complications

Symptoms and clinical signs of toxicity related to chemotherapy and radiotherapy can occur after SCT including mucositis, myocarditis, pericarditis, pneumonitis, hemorrhagic cystitis, and adverse drug reactions. A serious liver disorder that com-

 TABLE 5

Causes of Graft Failure

- Inadequate number of stem cells
- HLA disparity between donor and recipient
- Significant T cell depletion of the allograft
- Decreased degree of immunosuppression

plicates up to 50% of marrow transplants is called *veno-occlusive disease*; it is characterized by right upper quadrant pain, weight gain, and jaundice and is diagnosed clinically. Other features include ascites, hepatomegaly, hyperbilirubinemia, encephalopathy, and renal failure or multiorgan failure.

LATE COMPLICATIONS

Late complications can be secondary to pretransplantation chemotherapy/radiotherapy, continued effects of acute complications, and/or immunosuppressive states leading to delayed infections. These complications include hypothyroidism, hypogonadism, cataracts, growth retardation in pediatric patients, neuropathies, and sometimes development of post-transplant lymphoproliferative disorders and second malignancies (myelodysplastic syndrome and leukemia).

✓ Checkpoint! 5

A CMV-seronegative patient requires SCT. Two HLA-matched donors are available. Is it important to know the stem cell donor's CMV status? If the stem cell donor is CMV-seronegative and the patient requires red cell transfusion during the peritransplant period, what blood components (in terms of CMV status) would you select for this patient?

🌀 CASE STUDY (continued from earlier in this chapter)

Brandon received stem cells from his HLA-matched sibling that successfully engrafted. Three months later, he developed diarrhea, skin rash, and jaundice.

7. What could be the possible cause for this?

GENE THERAPY

In addition to the HSCT, gene therapy is a technology that offers the possibility for a complete cure for genetic disease.⁴⁵

The discussion of this technology is beyond the scope of this book. Suffice it to say that its goal is to introduce a functional copy of the patient's defective gene into a sufficient number of the appropriate cell types (such as stem cells) and to have sufficient expression of that gene so that its product functions to correct the deficiency. Attempts have been made to use genetically engineered viruses to carry the DNA of interest into host cells. Viral genes required for propagation are replaced with a working copy of the human gene. This form of therapy has been used (with variable success) to treat conditions such as adenosine deaminase deficiency, chronic granulomatous disease, and X-linked combined severe immune deficiency. Before gene therapy using stem cells finds more widespread clinical utility, several important issues such as the isolation of the appropriate cell population for transduction and association of other side effects (such as leukemia-like condition) with gene therapy must be overcome.

SUMMARY

HSCT is a recognized therapeutic modality for leukemias, lymphomas, solid organ tumors, and a variety of metabolic/immunologic disorders. Sources of HSCs can be bone marrow, peripheral blood, and umbilical cord blood. For an autologous transplant, the patient's own stem cells are collected, frozen, and used later for hematopoietic reconstitution. For an allogeneic transplant, the donor is selected based on the best HLA match from either family members or an unrelated donor. In the future, embryonic stem cells could become a source of hematopoietic stem cells.

Determining the number of stem cells can be performed by counting the MNCs, CD34+ cells, and CFUs. Before transplant, the patient undergoes conditioning chemotherapy/radiotherapy, and then the stem cells are infused. Routine blood counts and chimerism studies (in allogeneic SCT only) can be performed to assess the engraftment. Complications of SCT include graft rejection, GVHD, opportunistic infections, and recurrence of malignant disease.

REVIEW QUESTIONS

LEVEL I

1. Which of the following properties is (are) attributable to stem cells? (Objective 3)
 - a. self-renewal
 - b. multilineage differentiation
 - c. mononuclear morphology
 - d. all the above

LEVEL II

1. What does the term *chimerism* mean? (Objective 6)
 - a. recovery of recipient's red cells
 - b. absence of malignant cells
 - c. presence of donor hematopoietic stem cells in a recipient
 - d. recovery of patient's white cells and platelets only

REVIEW QUESTIONS (continued)

LEVEL I

2. What is (are) the source(s) of hematopoietic stem cells? (Objective 1)
 - a. bone marrow
 - b. peripheral blood
 - c. umbilical cord blood
 - d. all of the above
3. What form of transplant can be used for inherited genetic diseases? (Objective 2)
 - a. autologous stem cell transplant
 - b. allogeneic stem cell transplant
 - c. syngeneic stem cell transplant
 - d. stored autologous cord blood
4. What is a syngeneic transplant? (Objective 1)
 - a. infusion of stem cells from any donor into the recipient
 - b. infusion of patient's own stem cells
 - c. infusion of stem cells from an identical twin
 - d. infusion of stem cells from different species
5. What cells are usually CD34-positive? (Objective 3)
 - a. maturing myeloid cells
 - b. stem cells
 - c. B lymphocytes
 - d. T lymphocytes
6. Which of the following is correct regarding allogeneic stem cell transplant and ABO antigens? (Objective 4)
 - a. ABO antigens do not need to be matched.
 - b. ABO antigens are strongly expressed on stem cells.
 - c. The O group patient should not receive stem cells from A or B blood group donors.
 - d. ABO antigens should always be matched.
7. What is the single most important factor considered in donor selection for an allogeneic transplant? (Objective 4)
 - a. HLA compatibility with the recipient
 - b. ABO compatibility with the recipient
 - c. CMV status of the donor
 - d. HLA and ABO compatibility with the recipient
8. Which of the following infections can be serious in the peri-transplant period? (Objective 5)
 - a. bacterial
 - b. fungal
 - c. cytomegalovirus
 - d. all of the above
9. Severe GVHD usually is seen in which group of patients? (Objective 6)
 - a. syngeneic SCT
 - b. autologous SCT
 - c. unmatched allogeneic SCT
 - d. umbilical cord stem transplant

LEVEL II

2. What is the most appropriate form of transplant in an adult patient with CML weighing 80 kg? (Objective 4)
 - a. autologous SCT
 - b. umbilical cord SCT
 - c. allogeneic SCT
 - d. none of the above; transplant is not indicated in patients with CML
3. A risk for GVHD is carried by a patient who has: (Objective 4)
 - a. received allogeneic SCT
 - b. received autologous SCT
 - c. received both allogeneic and autologous SCT
 - d. received autologous SCT for only solid organ tumors
4. What are the three factors necessary to set the stage for GVHD? (Objective 4)
 - a. immunocompetent donor T lymphocytes, ABO antigens, and immunosuppressed host
 - b. immunosuppressed donor T lymphocytes, HLA alloantigens, and immunosuppressed host
 - c. immunocompetent donor B lymphocytes, HLA alloantigens, and immunosuppressed host
 - d. immunocompetent donor T lymphocytes, HLA alloantigens, and immunosuppressed host
5. What procedure usually is used to quantify HSCs? (Objective 3)
 - a. lymphocyte count
 - b. CD4 count by flow cytometry
 - c. monocyte count by automated cell counter
 - d. CD34 count by flow cytometry
6. Which of the following infections can be serious in patients after SCT? (Objective 4)
 - a. pseudomonas
 - b. cytomegalovirus
 - c. fungal
 - d. all of the above
7. This test is appropriate to determine long-term engraftment of HSCs only when donor and recipient are of the opposite sex. (Objective 6)
 - a. detection of RBC antigens
 - b. ISH with sex chromosomes
 - c. typing of VNTR polymorphism by DNA amplification
 - d. platelet and neutrophil counts
8. GVL effect is seen after SCT in patients who: (Objective 4)
 - a. have received autologous transplant
 - b. have received allogeneic transplant
 - c. have received either autologous or allogeneic transplant
 - d. have received umbilical cord transplant

REVIEW QUESTIONS (continued)

LEVEL I

10. What organ(s)/tissue(s) is (are) usually involved in GVHD? (Objective 6)
- skin only
 - skin, liver, and/or the gastrointestinal tract
 - liver only
 - gastrointestinal tract only

LEVEL II

9. For autologous peripheral SCT, the patient usually undergoes therapy in which sequence? (Objective 5)
- myeloablative therapy, apheresis, and then G-CSF
 - G-CSF followed by myeloablative therapy and then apheresis
 - cytotoxic chemotherapy followed by G-CSF and then apheresis to collect CD34+ cells
 - myeloablative therapy and then apheresis to collect CD34+ cells
10. What is the sequence in which successful engraftment occurs after SCT? (Objective 6)
- Neutrophils are increased first followed by an increase in platelets.
 - Platelets are increased first followed by an increase in neutrophils.
 - Red cells are increased first followed by an increase in platelets.
 - Red cells and platelets are increased followed by an increase in neutrophils.

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Brandon, a 35-year-old male (weight 80 kg) was recently diagnosed with AML with maturation and received induction chemotherapy. Day 21 after chemotherapy, the bone marrow reveals no evidence of residual leukemia. Two weeks later circulating blasts were seen in the peripheral blood. He was evaluated for a stem cell transplant. He was given a PBSCT from a sibling and developed what appeared to be GVHD after 3 months.

Question:

1. Is Brandon a candidate for stem cell transplant?

Explanation:

Yes, these findings indicate that he may have a relapse of his leukemia.

Question:

2. If yes, what form of transplant is required for him?

Explanation:

Circulating blasts in the peripheral blood are a poor prognostic sign and indicate that this patient is probably having a relapse of his leukemia. A bone marrow examination is definitely indicated. If this patient has residual leukemic blasts, the patient is a candidate for a stem cell transplant (if the donor is immediately available). The patient has AML, so an allogeneic SCT is an appropriate option.

Question:

3. What testing should be done on Brandon to proceed with the transplant?

Explanation:

HLA typing should be performed on the patient, and the search for HLA-matched siblings should be done.

Question:

4. There is an HLA-matched sibling who has agreed to be a donor for Brandon. Should the source of stem cells be peripheral blood or bone marrow? Why?

Explanation:

To harvest bone marrow stem cells, the donor has to undergo general anesthesia while stem cells from peripheral blood can be collected by apheresis after mobilizing the stem cells from the marrow by administration of G-CSF to the donor. In addition, studies have shown that the PBSCs engraft earlier than the bone marrow stem cells and have less degree of GVHD. Given these facts, peripheral blood should be the source of stem cells.

Question:

5. PBSCs were collected by apheresis. Enumeration of CD34 count indicates that the total CD34+ cells collected are $6 \times 10^6/\text{kg}$. Is this an adequate dose for SCT?

Explanation:

Yes, for allogeneic SCT, the total CD34+ cells should be more than $2 \times 10^6/\text{kg}$.

Question:

6. Stem cells were collected and frozen for Brandon. Does he need to undergo any form of therapy before the transplant?

Explanation:

Yes, the patient should receive myeloablative chemotherapy and/or irradiation, and then the stem cells can be infused later with the hope of complete engraftment.

Question:

7. Brandon received stem cells from his HLA-matched sibling that were successfully engrafted. Three months later, he developed diarrhea, skin rash, and jaundice. What could be the possible cause for this?

Explanation:

Because the patient received allogeneic SCT, the presence of diarrhea, skin rash, and jaundice most likely represents GVHD. However, opportunistic infections and drug reactions should also be considered.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

A physician is evaluating a 28-year-old patient with a history of acute lymphoblastic leukemia for PBSC transplantation. The laboratory professional found circulating leukemic blasts in the peripheral blood. Is this patient a candidate for an autologous PBSC transplant?

Answer

Presence of circulating blasts in a patient who is being evaluated for the autologous PBSC is not a good sign. Because PBSCs are collected from the person's peripheral blood by apheresis technology, the stem cell product in this patient would definitely contain leukemic blasts. It would be almost impossible to separate these leukemic blasts from the normal stem cells even by purging. Therefore, autologous PBSC transplant is not an option for this patient at least at this point. The search for the matched allogeneic stem cell donor should be made.

Checkpoint! 2

A patient with CML needs a stem cell transplant. What would be the best form of transplant for him, and what antigen type needs to be matched?

Answer

CML is a stem cell disorder, which means the patient's own stem cells are affected by the disease. Therefore, the best form of transplant for

this patient is an allogeneic stem cell transplant. For this allogeneic transplant, the patient and donor should be matched for HLA-A, -B and -DR antigens. ABO antigens are tested for both donor and patient; however, the matching is not required for the allogeneic stem cell transplant.

Checkpoint! 3

You receive a peripheral blood specimen in the hematology laboratory with a request for a mononuclear cell count and analysis of CD34+ cells. Without any further information, why should you consider this a STAT request?

Answer

The volume of cells necessary to achieve a successful engraftment may be determined indirectly by the MNC count or the CD34+ count. A clinical decision can be made to collect more cells depending on these counts. The timing of the collection of the stem cells also may be determined based on these counts.

Checkpoint! 4

A physician wants to evaluate the engraftment on a male patient who received SCT from his brother 4 months ago. What laboratory tests should be performed to make this assessment?

Answer

To evaluate the long-term engraftment of HSCs, various laboratory methods have evolved. Currently, the most widely used tests are in situ hybridization (ISH) with sex chromosome and typing of variable number tandem repeat (VNTR) polymorphism by DNA amplification. The ISH is applicable when the donor and recipient are of different sex. In this case, the VNTR polymorphism by DNA amplification to distinguish donor and recipient cells must be performed.

Checkpoint! 5

A CMV-seronegative patient requires SCT. Two HLA-matched donors are available. Is it important to know the CMV status of the stem cell donor? If the stem cell donor is CMV-seronegative and the patient requires red cell transfusion during the peritransplant period, what blood components (in terms of CMV status) would you select for this patient?

Answer

The CMV-seropositive person (i.e., a subject who shows serologic evidence of prior CMV exposure) can be an SCT donor to a CMV-seronegative recipient. However, if two HLA-compatible donors are available for a CMV-seronegative patient, the preference is given to the donor who is seronegative for CMV. The rationale is that CMV infection can be fatal in the peritransplant setting. However, if the CMV-seronegative donor is not available but a matched CMV-seropositive donor is available, transplant can still be performed. Most transplant physicians believe that a CMV-seronegative recipient should receive CMV-seronegative cellular blood components if the stem cells' donor is also CMV-seronegative. If the CMV-negative blood component is not available, transfusing a leukocyte-reduced filtered component may effectively prevent the transmission of CMV disease.

Morphologic Analysis of Body Fluids in the Hematology Laboratory

C. Nanette Clare, M.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. List the types of body fluids studied in the clinical laboratory, and describe the body cavities in which they are found.
2. List and describe the normal tissue cells seen in each body fluid type.
3. Describe various artifact types that can be seen in body fluid preparations including those in cytocentrifuged specimens.
4. Define *transudate*, *exudate*, and *chylous fluid*, and differentiate among these fluid types given laboratory data.
5. Describe the appearance of bacterial and fungal organisms in Wright-stained preparations, and suggest methods to confirm them.
6. List the morphologic features of malignant cells on Wright-stained preparations.
7. List the types of crystals that can be found in joint fluids, and associate them with pathologic conditions.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Identify the procedure used to obtain each type of body fluid.
2. Describe the production of cerebrospinal fluid (CSF).
3. Compare and contrast how each of the following fluids is formed: transudate, exudate, and chylous fluid.
4. Evaluate the significance of microorganisms present in Wright-stained body fluid preparations.
5. Compare and contrast the morphologic distinction between benign tissue cells and malignant cells in cytocentrifuged, Wright-stained preparations of body fluids, and identify these cells when seen.
6. Recognize erythrophagocytosis, and explain its significance in CSF.
7. Define *birefringence*, and explain its use in examining body fluids.
8. Identify and differentiate the various types of crystals that can be found in joint fluids, and associate them with particular disorders.
9. Use peripheral blood and CSF cell counts to differentiate true hemorrhage from a traumatic tap.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Types of body fluids
- ▶ Common cell types seen in body fluids
- ▶ Morphologic findings due to artifact
- ▶ Pleural, pericardial, and peritoneal fluids
- ▶ Cerebrospinal fluid

KEY TERMS

Arachnoid mater
 Ascites
 Ascitic fluid
 Birefringence
 Cardiac tamponade
 Central nervous system (CNS)
 Cerebrospinal fluid (CSF)
 Chylous
 Dura mater
 Effusion
 Exudate
 Meninges
 Pericardial cavity
 Pericardium
 Peritoneal cavity
 Peritoneum
 Pia mater
 Pleura
 Pleural cavity
 Pseudochylous
 Synovium
 Transudate

BACKGROUND BASICS

Although the study of body fluids is not generally included in textbooks of hematology, most clinical hematology laboratories have the responsibility of performing total cell counts and differential cell counts on body fluid samples. Much of this chapter can be read independently of the other chapters. However, the chapter builds on the general knowledge of hematologic morphology and hematologic neoplasms. You should review the following concepts before beginning this chapter.

Level I

- ▶ Recognize the common types of normal cells found in the peripheral blood.
- ▶ List the major types of neoplastic hematopoietic disorders.
- ▶ Describe the major types of lymphoma.

Level II

- ▶ Recognize reactive hematopoietic cells found in the peripheral blood.
- ▶ Describe and recognize the hematopoietic precursors found in the normal bone marrow.
- ▶ Describe and identify the cells associated with the various types of acute leukemia.
- ▶ Compare and contrast the various types of lymphoproliferative disorders.

CASE STUDY

We will address this case study throughout the chapter.

Carolyn, a 51-year-old woman who is otherwise in her usual state of good health, has flulike symptoms. After two weeks, her cough and fever persist. Antibiotics are started, and two days later she has severe right-side chest pain and worsening shortness of breath. Radiologic studies show a large effusion in the right pleural cavity. A thoracentesis is performed, and 1 liter of thick, yellow fluid is aspirated. As you read and study this chapter, think about the type of fluid this could be and the laboratory studies that should be done on the fluid to assist in diagnosis.

OVERVIEW

The hematology laboratory usually receives body fluids for cell counts and morphologic evaluation. The types of cells found and their concentration are helpful information for the clinician in arriving at a diagnosis. The cells that can be found in these fluids include white blood cells (WBCs) and red blood cells (RBCs) as well as tissue and tumor cells. The cytocentrifuge is used to prepare slide preparations for morphologic review, and Wright's stain is used to stain the cells on the slide. Identifying and differentiating the various types of cells seen in body fluids requires experience. However, all laboratory professionals who perform body fluid analysis should be able to differentiate most malignant cells from benign cells. This chapter describes the sites where body fluids are found, the methods in which the fluids are obtained, and an explanation of why fluids accumulate at these sites. The focus of the chapter is the description of the types of cells and inclusions that can be found in each fluid. The artifacts that can be found and the way to differentiate them from significant inclusions are also described and depicted. This chapter is presented in atlas format, because this is the most helpful way to discuss the morphology of body fluid cells. This chapter does not discuss other studies, such as those performed in the chemistry and microbiology laboratories.

INTRODUCTION

The hematology laboratory plays an increasingly important role in the morphologic evaluation of body fluids. This is primarily due to the use of the cytocentrifuge, which markedly improves morphology over the previously used direct smear technique. The cytocentrifuge is an instrument used to prepare slides from body fluid specimens other than peripheral blood. The sample is centrifuged directly onto a glass slide and yields a concentrate of cells with excellent morphology.

The Wright-stained, cytocentrifuge-prepared slide is made in the hematology laboratory for the purpose of performing a differential WBC count. However, this slide also is valuable in making many important diagnoses, both benign and malignant. Most malignant cells, including hematopoietic malignancies, carcinomas, and sarcomas, can be recognized microscopically. The hematopoietic malignancies are generally easier to diagnose from the Wright-stained slide than from the routine cytology preparation, which is prepared by alcohol fixation of cells and Papanicolaou stain. Another advantage of the slides made in the hematology laboratory is that these slides are prepared within an hour of specimen receipt, whereas cytology preparations take longer. Additionally, important nonmalignant findings, such as intracellular bacteria and fungi, that can be diagnosed on Wright's stain are frequently not seen on cytology slides. Hematologic slides, however, should not replace cytology preparations, which have better retention of nuclear detail and are superior to hematologic slides when attempting to determine the specific type of carcinoma or sarcoma present. Both techniques are necessary and aid in arriving at the most accurate diagnosis.

► **TYPES OF BODY FLUIDS**

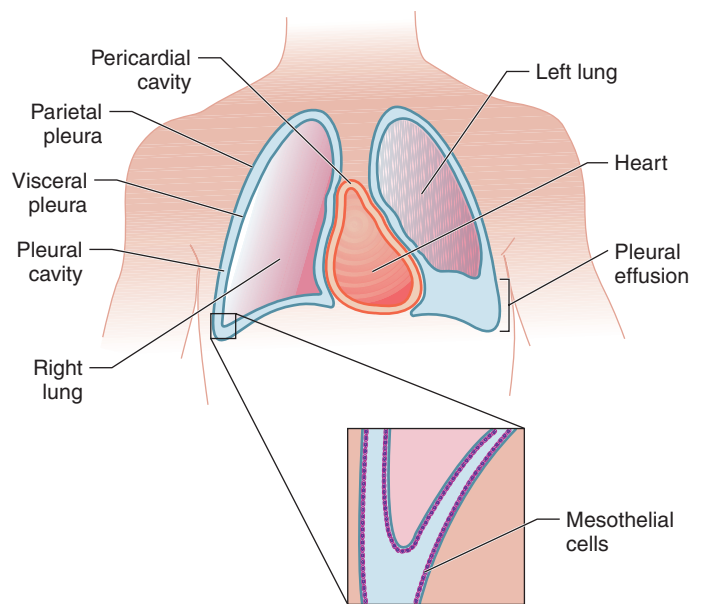

The body fluids discussed in this chapter are most commonly sampled. They are derived from the pleural, pericardial, and peritoneal cavities and from the central nervous system (CNS) and joint spaces (Table 1). The pleural, pericardial, and peritoneal cavities are actually potential spaces and do not contain any appreciable amount of fluid in the normal setting. The CNS, however, normally contains a specific amount of fluid to protect the brain and spinal cord. The joint spaces also have a consistent amount of fluid present for the continual lubrication of the bone surfaces and delivery of nutrients.

The **pleural cavities** (left and right) consist of the space between the lung and the inside portion of the chest wall. A thin membrane, called the **pleura**, lines these cavities. The pleura is composed of a continuous single layer of mesothelial cells (derived from embryonic mesoderm) and subme-

sothelial connective tissue (Figure 1). The pleural lining that covers the lung is the visceral pleura, and the lining that covers the inside of the chest wall is the parietal pleura. The pleural lining's purpose is to provide a moist surface to minimize friction between the lung and chest wall as respiration occurs. In disease states, the mesothelial cells multiply, the lining thickens, and fluid collects in the cavity. The contents of the fluid depend on the pathologic process causing the fluid accumulation.

The heart is enclosed in a saclike structure called the *pericardial sac*, which also is lined by mesothelial cells. The **pericardial cavity** is the anatomic region between the outermost aspect of the heart and the innermost aspect of the pericardial sac. The **pericardium** is a thin membrane that provides a continuous covering of the pericardial cavity composed of a single layer of mesothelial cells and submesothelial connective tissue. The lining covering the outside of the heart is the visceral pericardium, and the lining covering the inside of the pericardial sac is the parietal pericardium (Figure 1).

During certain pathologic events, fluid can accumulate in the pericardial sac. If the fluid accumulates rapidly (a minimum of 250 mL) or if a relatively large amount (1000 mL) accumulates over a longer time, there may be a serious restriction to the normal heart beat and venous return to the heart, creating a life-threatening event. This pathologic compression of the heart due to an accumulation of fluid is called **cardiac tamponade**. In this event, fluid must be removed quickly either by pericardial aspiration or surgery to save the patient's life.

■ **FIGURE 1** Diagram of right lung illustrating the pleural cavity and inset showing mesothelial cells of the parietal and visceral pleura. Illustration of heart shows the pericardial cavity. Diagram of the lung shows the abnormal accumulation of fluid (effusion) in the pleural cavity compressing the lower left lung.

★ **TABLE 1**

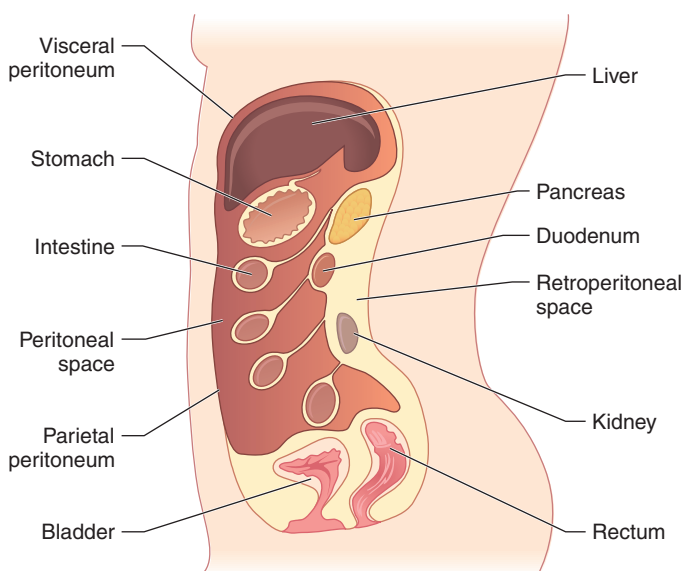

List of Site of Origin of Body Fluids with Terminology of Procedure to Obtain Fluid and Type of Fluid

Anatomic Site	Procedure	Fluid Obtained
Pleural cavity	Thoracentesis	Pleural fluid
Pericardial cavity	Pericardial aspiration	Pericardial fluid
Peritoneal cavity	Paracentesis	Peritoneal fluid (ascitic fluid)
Joint space	Joint aspiration (arthrocentesis)	Synovial fluid
Spinal cord	Spinal tap, lumbar puncture	Cerebrospinal fluid

The **peritoneal cavity** consists of the space between the inside of the abdominal wall and the outside of the stomach, small and large intestine, liver, and superior aspect of the urinary bladder and uterus. The kidneys are positioned posterior to the peritoneal lining (the **peritoneum**) and are referred to as *retroperitoneal*. Other retroperitoneal organs include the pancreas, duodenum, some lymph nodes, and the abdominal aorta. The peritoneal lining, consisting of one layer of mesothelial cells and submesothelial connective tissue, is identical to the pleural lining. The lining covering the inside of the abdominal wall is the parietal peritoneum, and the lining covering the organ surfaces is the visceral peritoneum (Figure 2 ■). In disease states, the cell layers will thicken and fluid can accumulate; this is referred to as **ascitic fluid** or **ascites**.

The **central nervous system (CNS)** consisting of the brain and spinal cord is normally lined by special membranes referred to as *meningeal membranes*, or *meninges*, that protect it. The **meninges** consist of a relatively thick **dura mater**, the outermost membrane; a thinner **arachnoid mater**, the middle membrane; and an innermost **pia mater** that lies directly on the surface of the brain and spinal cord.

The **cerebrospinal fluid (CSF)** occupies the subarachnoid space between the arachnoid mater and pia mater and protects the brain and spinal cord (Figure 3 ■). The choroid plexus cells and ependymal lining cells found in the ventricles produce the CSF. This CSF fluid circulates through the ventricular system in the cerebrum, cerebellum, and brain stem and completely covers the surface of the brain and spinal cord. The CSF is a product of ultrafiltration and active

■ **FIGURE 2** Abdominal cavity illustrating the peritoneal space between the inside of the abdominal wall and the outside of the liver, stomach, intestines, and dome of the bladder.

secretion and is made at a rate of approximately 21 mL/hour.¹ The CSF is reabsorbed by the arachnoid cells. The total volume of CSF in adults is 90–150 mL. Neonates have a CSF volume of 10–60 mL. In certain disease states, the CSF's content changes.

✓ Checkpoint! 1

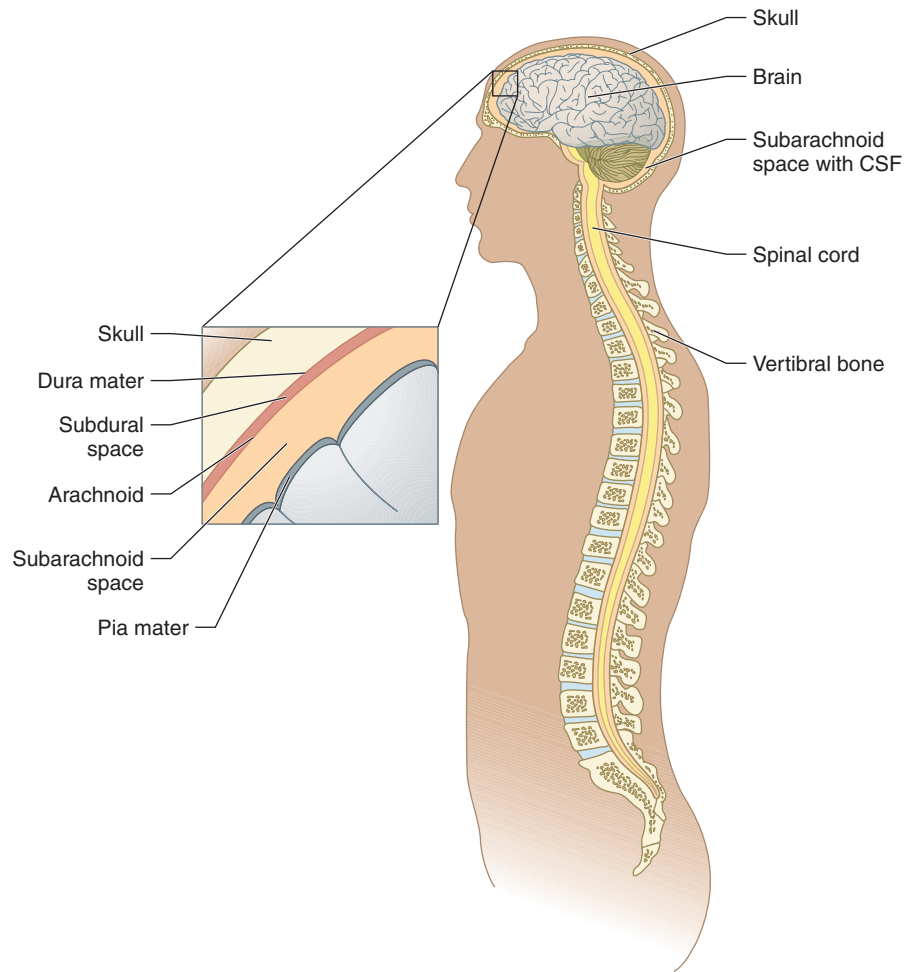

To obtain a sample of CSF for analysis, the needle must be inserted into what area of the central nervous system?

Some bony joints of the body are lined by special membranes called the **synovium** that normally consist of a single layer of synovial cells (Figure 4 ■). The joint space contains synovial fluid that acts as a lubricant and a transport medium for nutrients to get to the joint's bone surfaces. The synovial fluid is produced in part by the synovial cells and is an ultrafiltrate of plasma. Synovial fluid also contains a mucopolysaccharide called *hyaluronic acid*, which sometimes makes the fluid so thick that it hampers laboratory studies.

▶ COMMON CELL TYPES SEEN IN BODY FLUIDS

Segmented neutrophils (segs) are frequently seen in the pleural, pericardial, and peritoneal fluids in varying numbers. The neutrophils have the same appearance as in peripheral blood smears. Sometimes, however, cytocentrifuge artifactual changes can be seen with nuclear segments being thrown to the periphery of the cytoplasm, creating a hypersegmented appearance (Figure 5 ■). Degeneration of neutrophils is seen more frequently in body fluid samples than in peripheral blood smears. The dying cells show cytoplasmic vacuolization and separation of nuclear segments with dense-staining chromatin (Figure 6 ■). These cells can be mistaken for nucleated RBC and even yeast organisms. Neutrophilic precursors, such as promyelocytes, myelocytes, and metamyelocytes, are not commonly seen but if present can represent a chronic inflammatory process or true marrow disorder, such as myeloproliferative disorders, myelodysplastic states, and leukemia. Myeloblasts are usually seen only in the latter three.

Lymphocytes are frequently present in all types of fluids in variable numbers. The lymphocytes vary in morphology from small to large and transformed (reactive). In cytocentrifuge preparations, the lymphocyte nucleoli can be artifactually more prominent than in peripheral blood smears, the nuclear shape can be irregular, and the cytoplasm can have artifactual projections² (Figures 7 ■ and 8 ■). If the lymphocytes are neoplastic (leukemias, lymphomas), the morphology depends on the type of neoplasm, and the cells are homogeneous in appearance. Flow cytometry or immunoperoxidase techniques can be helpful in distinguishing benign versus malignant lymphocytes.

■ **FIGURE 3** Central nervous system showing the subarachnoid space containing cerebral spinal fluid (CSF) covering the brain and spinal cord. Inset illustrates the meninges: dura mater, arachnoid mater, and pia mater.

■ **FIGURE 4** Knee joint illustrating synovial membrane lining and synovial fluid.

■ **FIGURE 5** Artifactual change in neutrophils showing nuclear lobes thrown to the periphery of the cytoplasm. (Slides in this chapter are all cytocentrifuge prepared body fluids, Wright-stained. Magnification 1000× unless otherwise noted.)

■ **FIGURE 6** In the center is a degenerating neutrophil with separation of nuclear lobes and dense staining of the chromatin.

■ **FIGURE 7** Artfactual change in lymphocytes with overly prominent nucleoli.

■ **FIGURE 8** Artfactual change in lymphocytes with cytoplasmic projections.

■ **FIGURE 9** Monocytes in pleural fluid.

Monocytes in body fluids can appear similar to that seen in peripheral blood smears or can be larger with abundant, vacuolated cytoplasm (histiocyte), or they can have actual phagocytosed material (macrophage, phagocyte) (Figures 9 ■, 10 ■, and 11 ■). The distinction among the three morphologic types (monocytes, histiocytes, and macrophages) is not clinically important; however, in some cases, the phagocytosed cells or organisms can be diagnostically important. When large vacuoles fuse, a “signet ring” appearance with the nucleus flattened against the cell membrane occurs (Figure 12 ■). Only a few monocytes are present in CSF, and histiocytes/macrophages usually are seen in the CSF only in pathologic states. Plasma cells are not seen in normal fluids and usually are present only in chronic inflammatory disorders (Figure 13 ■).

Eosinophils, basophils, and mast cells can be present in small numbers in pleural, pericardial, peritoneal, or joint fluids. Increased numbers of these cell types are seen in various disorders and may correlate with peripheral eosinophilia or basophilia.³ Eosinophils are frequently seen in nonspecific or idiopathic effusions but can also be present in effusions caused by various infectious agents, malignancies, and connective tissue disorders. Mast cells can be distinguished from basophils because mast cells have a round (not segmented) nucleus, and mast cells have a higher number of cytoplasmic granules than basophils. The granules in mast cells are smaller than those seen in basophils (Figures 14 ■ and 15 ■). An increase in the number of basophils can correlate with myeloproliferative disorders involving body fluids.

Benign tissue cells can be seen in any of the body fluids and must be differentiated from malignant cells (Table 2 🌟). Benign mesothelial cells can be seen in the pleural, pericardial, and peritoneal fluids. These are large cells that have a moderate to abundant amount of cytoplasm. The cytoplasm can be light or dark blue and occasionally contain

■ FIGURE 10 Histiocyte in pleural fluid.

★ TABLE 2

Normal Existing Tissue Cells Found in the Various Body Fluids

Fluid Type	Normal Tissue Cells
Cerebrospinal	Ependymal, choroid plexus cells, arachnoid
Pleural, pericardial, peritoneal	Mesothelial
Joint	Synovial

granules or phagocytosed debris. The nucleus is eccentric with a homogeneous chromatin pattern. Nucleoli can be seen, and if present, are blue with a smooth membrane (Figure 16■). The tissue cells present in joint fluids are synovial and have a similar appearance to mesothelial cells with a somewhat denser cytoplasm (Figure 17■). The tissue cells (choroid plexus and ependymal) that can be seen in CSF tend to cluster and can have cytoplasmic granules and slightly irregular nuclei (Figure 18■). The arachnoid cells are frequently seen as a syncytium with a mass of cytoplasm containing several nuclei (Figure 19■). These benign tissue cells are usually seen only in CSF from infants and adults who have had recent neurosurgery or a shunt in place.

► MORPHOLOGIC FINDINGS DUE TO ARTIFACT

Some artifactual findings such as peripheral displacement of the nucleus in neutrophils, cytoplasmic extensions of lymphocytes, and overly prominent nucleoli of lymphocytes have already been mentioned (Table 3★). Other artifactual changes can resemble actual pathologic findings, and interpretation must be made cautiously. Starch particles can be an in vitro contaminant in any type of body fluid. This

■ FIGURE 17 Synovial cells in joint fluid.

■ FIGURE 18 Choroid plexus cells in CSF.

■ FIGURE 16 Benign mesothelial cells in pleural fluid.

■ FIGURE 19 Arachnoid cell syncytium in CSF.

TABLE 3

Artifacts That Can Be Seen with Wright-Stained Cytocentrifuge Prepared Slides and the Potential Mistaken Interpretation

Artifact	Mistaken Interpretation
Peripheral localization of nuclear lobes in neutrophils	Hypersegmented neutrophils
Degenerating neutrophil	Yeast organisms, nucleated RBC
Overprominence of nucleoli in lymphocytes	Blast cells
Cytoplasmic projections of lymphocytes	Hairy cell leukemia
Single large vacuole in histiocyte	Signet ring cell carcinoma
Starch particles	Yeast organisms, crystals
Stain precipitate	Bacterial organisms
Degenerating tissue cells	Malignant cells

starch is on sterilized surgical gloves used by the physician obtaining fluid from the patient. Starch particles can look like yeast organisms, even budding yeasts if two particles are closely associated. Starch particles usually have a refractile center that is not a feature of yeast and are birefringent (discussed later), showing up as bright Maltese crosslike figures with polarized light (Figure 20 ■). Stain precipitate can look like bacterial organisms. If the precipitate appears to be intracellular, changing the fine focus usually shows the precipitate to be in a different plane of focus from the cell. True intracellular bacteria are in the same plane of focus as the cell. Stain precipitate is darker than bacteria and variable in size and can be seen extracellularly, sometimes in distant areas of the slide (Figure 21 ■). In difficult cases, an extra slide should be prepared for a gram stain. Early cellular degeneration is exaggerated by the cytocentrifuge and shows irregular nuclear margins and separating chromatin. This can be mistaken for malignant cells (Figure 22 ■).

► PLEURAL, PERICARDIAL, AND PERITONEAL FLUIDS

Fluids obtained from the pleural, pericardial, and peritoneal cavities have similar findings in various pathologic states and are discussed together. The pleural, pericardial, and peritoneal spaces normally contain a minimal amount of fluid (less than 2.5 mL in the pleural cavity), only enough to keep the lining membranes moist. The fluid is produced by the parietal lining and absorbed by the visceral lining. Fluid is produced by plasma filtration through capillary endothelial cells and depends on four factors: capillary hydrostatic pressure, plasma oncotic pressure, lymphatic resorption, and capillary permeability.² Any pathologic state affecting one or several of these four factors can result in abnormal fluid col-

■ **FIGURE 22** Early cell degeneration.

lection, or **effusion**, in the pleural, pericardial, and peritoneal spaces. In the pleural spaces, accumulation of at least 300 mL is necessary to be detected on chest x-ray, and in the peritoneal cavity accumulation of at least 500 mL is necessary to be detected by abdominal x-ray.²

An effusion can accumulate due to a systemic disease state (**transudate**) or a primary pathologic state of the area (**exudate**).⁴ Transudates are frequently a result of increased capillary hydrostatic pressure as seen with congestive heart failure or of decreased plasma oncotic pressure as seen with hypoproteinemia due to nephrotic syndrome or liver failure. A transudate most often has a specific gravity of 1.015 or less, a total protein of 3.0 g/dL or lower, a ratio of effusion total protein to serum total protein of less than 0.5, a ratio of effusion lactate dehydrogenase (LD) to serum LD of less than 0.6, and usually a total leukocyte count $<1000/\mu\text{L}$.^{1,2}

An exudate is formed by increased capillary permeability and/or decreased lymphatic resorption. An exudative effusion can be caused by many different pathologic processes, such as bacterial infections, viral infections, neoplasms, and collagen vascular diseases. An exudate has a specific gravity >1.015 , a total protein >3.0 g/dL, a ratio of total fluid protein to serum protein >0.5 , a ratio of fluid LD to serum LD >0.6 , and usually a total leukocyte count $>1000/\mu\text{L}$.^{1,2}

A **chylous** effusion has a characteristic milky, opaque appearance that remains in the supernatant after centrifugation. Chylous effusions result from leakage of lymphatic vessels. In the pleural cavity (chylothorax), this is due to leakage of the major thoracic duct. In the peritoneal cavity, chylous effusions result from blockage of the lymphatic vessels. In both the pleural and peritoneal cavities, chylous effusion most often results from malignancy such as lymphoma or carcinoma or from trauma. This type of fluid is rich in chylomicrons and has elevated triglycerides (>110 mg/dL), and its predominant cells are lymphocytes.^{2,5} A **pseudo-chylous** effusion is also milky and results from a chronic, long-standing effusion due to such conditions as tuberculosis and rheumatoid pleuritis.² Pseudo-chylous effusions do not contain chylomicrons and usually have triglycerides <50 mg/dL. There is a mixed reactive cell population with many inflammatory and necrotic cells.

CASE STUDY (continued from earlier in this chapter)

Radiologic studies show a large effusion in the right pleural cavity. A thoracentesis is performed, and 1 liter of thick, yellow fluid is aspirated. Laboratory studies show a total protein of 4.5 g/dL (serum = 6 g/dL), lactate dehydrogenase 40 U/L (serum = 50 U/L), and total leukocyte count of $20,000/\mu\text{L}$ with 90% segmented neutrophils, 10% histiocytes, and many degenerating cells.

1. Is this a transudate or exudate?
2. Is this a chylous fluid?

NONSPECIFIC REACTIVE CHANGES

The term *nonspecific reactive changes* refers to effusions that have an inflammatory cell response that is not diagnostic for any specific disorder. In various pathologic states, certain types of WBCs can be present in increased numbers. Bacterial infections have a predominance of segmented neutrophils while viral, fungal, and mycobacterial infections can have a predominance of lymphocytes or show a mixed inflammatory response. As in peripheral blood, neutrophils can have toxic granulation, Döhle bodies, and cytoplasmic vacuoles.

Lymphocytes are frequently reactive and transformed, simulating lymphoma cells. The most helpful feature in distinguishing reactive lymphocytes from lymphoma cells is that the former consist of a heterogeneous population of cells with varying nuclear shape, amount of cytoplasm, and degree of cytoplasmic basophilia (Figures 23 ■ and 24 ■). Lymphoma cells are homogeneous with the same nuclear and cytoplasmic features. The morphology of the lymphoma cells depends on the particular type of lymphoma.

In rare cases, spontaneous formation of lupus erythematosus (LE) cells is apparent. An LE cell is a macrophage, either neutrophil or monocyte, that has phagocytosed a nucleus showing a homogeneous, smooth chromatin pattern (Figure 25 ■). The finding of these cells is suspicious but not diagnostic for systemic lupus erythematosus (SLE). Other autoimmune type disorders can also show the LE cell phenomenon. Nevertheless, the identification of these cells can be extremely helpful in arriving at a difficult diagnosis. The LE cell should not be mistaken for simple phagocytosis of cells by macrophages, which is frequently seen. The chromatin of the usual phagocytosed cell is not smooth or homogeneous.

Mesothelial cells can show nonspecific reactive changes, which include multinuclearity, presence of nucleoli, mitotic activity, and sometimes an increase in cell size (Figures 26 ■ and 27 ■). There also occasionally is an increased

■ **FIGURE 24** Reactive lymphocyte in pleural fluid.

nuclear-cytoplasmic ratio and nuclear folding simulating carcinoma. Reactive mesothelial cells also can tend to cluster and appear cohesive; however, nuclear molding is not seen (Figure 28 ■). In cases when distinguishing reactive mesothelial cells from malignant cells is very difficult, cytology preparations usually are definitive because alcohol fixation and Papanicolaou stain yield better nuclear detail.

✓ Checkpoint! 2

A 32-year-old woman has right-side chest pain and shortness of breath that has worsened over a two-week period. Chest radiologic studies reveal a right pleural effusion, and a thoracentesis is performed. The pleural fluid specimen on a cytocentrifuged, Wright-stained slide reveals cells similar to that seen in Figure 7. What is the best interpretation of this finding? If there is a strong concern that this can represent a low-grade lymphoma, what would be the best way to determine whether these are benign or malignant lymphocytes?

■ **FIGURE 23** Reactive lymphocytes in pleural fluid.

■ **FIGURE 25** Spontaneous LE cell formation in pleural fluid.

■ **FIGURE 26** Reactive mesothelial cells in pleural fluid.

■ **FIGURE 27** Multinucleated reactive mesothelial cells in pleural fluid.

■ **FIGURE 28** Reactive mesothelial cells in pleural fluid.

■ **FIGURE 29** Intracellular and extracellular bacterial cocci, joint fluid.

MICROORGANISMS

Most types of pathogenic bacterial and fungal organisms stain with Wright's stain and are detectable on a routine cytocentrifuge preparation. Bacteria stain blue regardless of the gram stain features. Demonstrating the organisms intracellularly is important because this indicates true pathogenicity rather than *in vitro* contamination (Figures 29 ■ and 30 ■). Once bacteria have been recognized with Wright's stain, preparing a second cytocentrifuge slide for a gram stain is helpful to confirm the presence of bacteria and to be able to give additional information to the physician while cultures are pending.

Most pathogenic yeasts are found in CSF rather than in pleural, pericardial, or peritoneal fluids. These organisms can be found intracellularly. The different types of pathogenic yeast show some distinguishing features on Wright's stain. This morphologic variance can be used as a clue for an ini-

■ **FIGURE 30** Intracellular and extracellular bacteria, bacilli, peritoneal fluid.

■ **FIGURE 31** *Cryptococcus neoformans*, CSF.

■ **FIGURE 33** *Candida albicans*, CSF.

tial impression of the specific type of yeast, but cultures must be obtained for definitive identification. The most frequently seen fungal organisms in fluids are *Cryptococcus*, *Histoplasma*, *Candida albicans*, and *Candida tropicalis* (Figures 31 ■, 32 ■, 33 ■, and 34 ■). Refer to Table 4 🌟 for a comparison of morphology.

CASE STUDY (continued from earlier in this chapter)

A cytocentrifuged, Wright-stained slide is prepared and a photomicrograph is taken (Figure 35 ■).

3. What would be an appropriate next step to determine whether the material seen is debris or true organisms?

Some of the large tissue cells showed features of degeneration and features suspicious for malignancy.

4. How should this be interpreted?

MALIGNANT CELLS IN FLUIDS

The pleural, pericardial, and peritoneal fluids can contain malignant cells, and their identification is critical for making an accurate diagnosis.^{6,7,8} In some patients, a diagnosis of malignancy can already have been established by other tissue sampling (biopsy or excision), and finding the malignant cells in fluid establishes a condition of tumor metastasis. For other patients, finding malignant cells in fluid can be the initial diagnosis of a malignancy, and if a sample is not sent to cytology, the recognition of malignancy on the hematology laboratory preparation is critical in establishing an early diagnosis. Malignant cells in fluids can usually be distinguished as hematopoietic in origin (leukemia, lymphoma) versus nonhematopoietic (carcinoma, sarcoma), and in some cases further specification of cell type is also possible. It is important to look at the entire cellular area of the slide with a low power objective (10×) to detect suspicious

■ **FIGURE 32** *Histoplasma capsulatum*, multiple organisms in histiocyte; buffy coat, peripheral blood.

■ **FIGURE 34** *Candida tropicalis*, peritoneal fluid.

★ TABLE 4

Comparison of Morphology of Pathologic Yeast as Seen with Wright Stain

Histoplasma	Cryptococcus	Candida Albicans	Candida Tropicalis
Usually small, often intracellular, distinct nonstaining cell wall, partially staining interior	Wide variation in size, usually extracellular, capsule not visible on air-dried preparations, either solidly stained with "wrinkled" appearance or partial internal staining	Can be extracellular and intracellular, moderate in size, stain solid, rarely can see pseudohyphae formation	Can be extracellular and intracellular, moderate in size, dark blue with red internal staining

clusters of cells. In any one sample, there may be only a few malignant cells that are difficult to find.

General features that can be seen in almost any type of malignant cell include an irregular nuclear membrane, unevenly distributed chromatin, and nucleoli that also have an irregular membrane (Table 5 ★).⁷ The nuclear-cytoplasmic ratio varies, with small cell carcinoma cells having minimal cytoplasm and adenocarcinoma cells having as much or more cytoplasm as a benign mesothelial cell. The nuclear membrane irregularity can be jagged or show multiple folds. When nucleoli are present, they are frequently prominent and irregular in shape (Figure 36 ■). Mitotic activity by itself is not a reliable sign of malignancy because their reactive mesothelial cells can undergo mitosis, nor are cytoplasmic vacuoles a reliable finding for malignancy because their presence can be seen as a part of early degeneration in many cells. None of the features described can be used alone to diagnose malignancy. All of the features must be looked for and evaluated together. For example, one type of malignancy can show smooth nuclear membranes but with unevenly distributed chromatin and irregular nucleoli (Table 6 ★).

The most common nonhematopoietic malignancies seen in body fluids are small cell carcinoma and adenocarcinoma. Small cell carcinoma cells have the same general morphologic findings of malignant cells but can be distinguished from other types of carcinoma cells because of the characteristic high nuclear-cytoplasmic ratio, blastlike chromatin, ab-

sence of nucleoli or nonprominent nucleoli, and frequent nuclear molding (Figure 37 ■), which is the process of the nucleus of one cell molding around the shape of an adjacent cell. Nuclear molding occurs with cohesive growth of cells requiring the presence of tight junctions between the cytoplasmic membranes of the cells. Therefore, nuclear molding can be seen in any type of carcinoma but is most often seen with small cell carcinoma. Some cells also can have a paranuclear "blue body," which is an inclusion that has not yet been characterized and can represent early cell degeneration or phagocytosed material. Depending on the cell's orientation, the blue body can appear to be intranuclear and has been described in small cell carcinoma and rarely in sarcoma.⁹ The blue body is seen only with air-dried, Wright-stained preparations (Figure 38 ■). If the malignant cells are noncohesive, small cell carcinoma could be mistaken for a hematopoietic malignancy, and the finding of a blue body would be a good clue for the diagnosis of small cell carcinoma.

Adenocarcinoma differs from small cell carcinoma in that the overall size of an adenocarcinoma cell is larger than a small cell carcinoma cell with a moderate to abundant amount of cytoplasm (Figure 39 ■). The nuclear chromatin is partially clumped and heterogeneous and has prominent nucleoli. The presence of cytoplasmic vacuoles is not specific and can represent early cell degeneration.

Other types of carcinoma and sarcoma can be found in body fluids (Figures 40 ■, 41 ■, 42 ■, and 43 ■). The features

★ TABLE 5

Comparison of Morphologic Features of Reactive Mesothelial Cells versus Malignant Cells

Cell Features	Reactive Mesothelial Cells	Malignant Cells
Nuclear membrane	Smooth	Irregular, jagged
Chromatin	Evenly distributed	Unevenly distributed
Nucleoli	Absent or present with smooth membrane	Prominent, frequently multiple, irregular membrane
Nuclear molding	None	Present in nonhematopoietic malignancies

FIGURE 36 a. Malignant cells (adenocarcinoma), pleural fluid. b. Benign mesothelial cell to contrast with features of malignant cell. c. Single malignant cell (adenocarcinoma), pleural fluid.

TABLE 6

General Morphologic Findings of Benign Mesothelial Cells and Malignant Cells

Any given cell can show variable features so that all must be evaluated before deciding whether a body fluid sample is benign or malignant. No single feature can be used to diagnose malignancy.

	Mesothelial Cell	Adenocarcinoma	Small Cell Carcinoma	Large Cell Lymphoma	Leukemic Blasts
Cell size	Large, 15–30 μ	Large to giant	Moderate to large	Moderate to large	Small to moderate
Chromatin	Loose, homogeneous	Partially clumped, heterogeneous	Slightly coarse, homogeneous	Partially clumped, heterogeneous	Smooth, lace-like, homogeneous
Nucleoli	None to small and regular	Prominent, multiple, irregular	None to small, not prominent	Small to prominent, irregular	Variable
Nuclear membrane	Smooth	Irregular, jagged	Irregular, jagged, folded	Irregular, jagged, folded	Smooth or irregular, folded
N:C ratio	Low, 1:3–5	Low, 1:3 or less	High, 1:1.25	High to moderate 1:1.25–1:2	High to moderate 1:1.25–1:1.75
Intercell relationship	Individual or clumped, no nuclear molding	Usually clumped, \pm nuclear molding	Clumped with nuclear molding, occasionally individual	Individual, no clumping, no nuclear molding	Individual, no clumping, no nuclear molding

seen with Wright's stain are not as specific as from a cytology preparation; the latter is necessary to specifically identify the type of malignancy. For example, squamous cell carcinoma can look like adenocarcinoma with Wright's stain; however, in most cases, the two are readily distinguishable on cytology preparations (Figure 44 ■). Certain types of malignant cells can contain clues for the cellular origin. Melanoma cells can have melanin pigment that is demonstrable with Wright's stain, and hepatocellular carcinoma can have bile pigment (Figures 45 ■ and 46 ■). The presence of these pigments can be suspected with Wright's stain but must be confirmed with more specific staining techniques.

■ FIGURE 46 Bile pigment in macrophage in peritoneal fluid due to cholangiocarcinoma.

✓ Checkpoint! 3

When examining a cytocentrifuged, Wright-stained slide of a body fluid specimen, what are the best features to use in determining whether tissue cells are benign or malignant?

Practically any type of hematopoietic malignancy, including lymphocytic and nonlymphocytic leukemias, lymphomas, Hodgkin disease, and plasma cell¹⁰ neoplasms, can be found in body fluids. Generally, the abnormal cells found in the body fluids in these disorders have the same morphologic features as peripheral blood and bone marrow. The acute leukemias only occasionally involve the pleural, pericardial, or peritoneal cavities and more often are seen in the CSF. Blasts appear larger on cytocentrifuge preparations than on peripheral blood smears, and the nuclear membrane can be surprisingly irregular. Auer rods can be seen, and, if necessary, unstained slides can be prepared for cytochemistry stains and terminal deoxynucleotidyl transferase (TdT) to differentiate the blasts. Lymphoblasts have a very high nuclear-cytoplasmic ratio, and the nucleus can be folded or convoluted.

The morphology of non-Hodgkin lymphoma in the body fluids depends on the particular type of lymphoma. Again, the nuclear membrane can be surprisingly irregular. Large cell lymphoma has cells that are moderate to large in size with irregular nuclei, partially clumped chromatin, and sometimes prominent nucleoli (Figure 47 ■). The cytoplasm is low to moderate in amount and basophilic. The cells are discohesive, but if the fluid is very cellular, the cells can be thrown together and have the appearance of carcinoma cell clusters; nuclear molding is not seen. Burkitt lymphoma (small noncleaved cell) has intermediate size cells with more than one nucleoli and an immature blastlike chromatin (Figure 48 ■). Prominent cytoplasmic vacuoles frequently are appar-

■ FIGURE 48 Burkitt lymphoma (small noncleaved cell) in pleural fluid.

ent. Small cell lymphoma is the most difficult to diagnose and can look like a benign lymphocytic infiltrate. In these cases, flow cytometry is valuable in demonstrating a clonal population of cells. T cell lymphoma can show markedly irregular, convoluted nuclei; however, marker studies are necessary to confirm T or B cell origin of the neoplastic cells (Figures 49 ■, and 50 ■). Cell origin can be accomplished by flow cytometry or immunoperoxidase techniques on cytocentrifuge-prepared slides.

Primary effusion (body cavity) lymphoma is a high-grade type found only in a body cavity without an associated solid tumor mass. This unique malignancy has been reported in patients who are immunocompromised, usually HIV positive, and is associated with HHV-8 (human Herpes virus 8, also known as *Kaposi sarcoma* associated Herpes virus, KSHV).^{11,12,13} The morphology of the cells in the effusion is similar to the

■ FIGURE 47 Large cell lymphoma in pleural fluid.

■ FIGURE 49 Lymphoblastic lymphoma, T cell type, in pleural fluid.

■ **FIGURE 50** Small lymphocytic lymphoma.

■ **FIGURE 52** Hodgkin disease with Reed-Sternberg cell, pleural fluid.

morphology of cells found in anaplastic large cell lymphoma, immunoblastic lymphoma, or small noncleaved cell lymphoma. These malignant cells are usually B cell derived but lack surface-associated antigens for T or B cell lineage.

Hodgkin lymphoma can occasionally be seen to involve pleural fluid (Figures 51 ■ and 52 ■). The malignant Hodgkin cell is large with a moderate to abundant amount of cytoplasm, large nuclei, and prominent nucleoli. If the nucleus is bilobated or if the cell has two nuclei, it can be a Reed-Sternberg cell. The other cells present consist of varying numbers of small lymphocytes, eosinophils, histiocytes, and plasma cells. If other tissue biopsy has already established a patient's Hodgkin disease diagnosis, the malignant cells (either Hodgkin, Reed-Sternberg, or multinucleated variants) must still be identified in the effusion sample to diagnose the fluid's involvement.

■ **FIGURE 51** Hodgkin disease, pleural fluid.

CASE STUDY (continued from earlier in this chapter)

After 3 weeks, Carolyn improved significantly, but the chest pain and effusion did not resolve. A repeat thoracentesis was performed. Laboratory studies show protein 4.7 g/dL (serum = 6 g/dL), lactate dehydrogenase 50 U/L (serum = 60 U/L), and total nucleated cell count 3,000/ μ L. A cytocentrifuged, Wright-stained slide is examined, and the differential count shows 30% segmented neutrophils, 20% lymphocytes, 10% histiocytes, and 40% tissue cells. A photomicrograph of the tissue cells is seen in Figure 53 ■.

5. Is this an exudate or transudate?
6. What is the most appropriate interpretation of these findings?

■ **FIGURE 53** Pleural fluid. (Case Study question 6.)

▶ CEREBROSPINAL FLUID

CSF differs from the pleural, pericardial, and peritoneal fluids in that it exists in the normal state. However, CSF is normally acellular so that the presence of any cells even at a low count suggests a pathologic state. A common problem when evaluating CSF is to distinguish a true CNS hemorrhage versus a spinal tap procedure that causes hemorrhage (traumatic tap). Both of these present as grossly bloody fluids. If the total erythrocyte count (RBC count) in the first tube collected is significantly higher than in the last tube collected, it suggests a traumatic tap. Xanthochromia is a pink to orange fluid supernatant produced by the breakdown products of hemoglobin and is usually thought to indicate true CNS hemorrhage. Xanthochromia occurs, however, if a grossly bloody fluid from a traumatic tap sits for some time before it is centrifuged. A definitive sign of CNS hemorrhage is phagocytosis of erythrocytes by histiocytes (erythrophagocytosis) (Figure 54 ■). It takes approximately 18 hours for histiocytes to mobilize and phagocytose erythrocytes after a hemorrhage. If the hemorrhage is older, hematoidin crystals can be seen intracellularly or extracellularly (Figure 55 ■). Hematoidin is a product of hemoglobin catabolism.

✓ Checkpoint! 4

A 47-year-old man is found comatose at home by his wife. During examination in the emergency room, a spinal tap is performed and grossly bloody spinal fluid is obtained. The total RBC count in the first tube is the same as that in the third tube. A cytocentrifuged, Wright-stained slide shows findings similar to that seen in Figure 54. What is the most appropriate interpretation?

■ FIGURE 54 Erythrophagocytosis.

■ FIGURE 55 Hematoidin crystals in macrophage in CSF.

NONSPECIFIC REACTIVE CHANGES

The normal leukocyte counts of CSF have been difficult to determine (Table 7 ■).^{1,2} The reference ranges listed for pediatric ages are somewhat controversial because they have a high upper limit. Most important for interpretation is to consider the types of white blood cells present and to correlate them with clinical findings.

The total WBC count cannot be interpreted without the total RBC count. When a specimen is obtained as a traumatic tap, the WBC and RBC reflect the same WBC/RBC ratio as the patient's peripheral blood. A general rule is to expect 1 to 2 WBC for every 1000 RBC in the CSF. For example, if the total WBC in a CSF specimen is 10/ μ L and the RBC is 10,000/ μ L, there is no significant increase of WBC (pleocytosis). If, however, the total RBC is 100/ μ L with a WBC of 10/ μ L, a significant increase of WBC indicates a pathologic state.¹⁴ When a patient has an elevated or decreased peripheral blood WBC or RBC, it is best to use the following calculation to determine whether the CSF WBC is significant:^{1,2}

■ TABLE 7

Reference Range for Leukocytes in CSF per μ L

Age	Reference Range
Adults	0–5
5–puberty	0–10
1–4	0–20
<1	0–30

Based on data from: Smith GP, Kielsberg CR. Cerebrospinal, synovial, and serous body fluids. In: Henry SB, ed. *Clinical Diagnosis and Management by Laboratory Methods*, 20th ed. Philadelphia: W.B. Saunders; 2001; and Kielsberg C, Knight J. *Body Fluids*, 3rd ed. Chicago: ASCP Press; 1993.

$$\text{Corrected CSF WBC} = \frac{\text{Total WBC of fluid} - \frac{\text{WBC of blood} \times \text{RBC of fluid}}{\text{RBC of blood}}}{\text{Total WBC of fluid}}$$

For example, a 21-year-old man has fever, headache, and a stiff neck. A spinal tap is performed. Laboratory studies reveal the following:

	Total RBC	Total WBC
CSF	50,000/ μL	250/ μL
Peripheral blood	$3.5 \times 10^{12}/\text{L}$	$3.5 \times 10^9/\text{L}$

The physician asks if the CSF WBC count represents peripheral blood contamination or a true increase indicating meningitis. Because the patient has peripheral leukopenia and anemia, the formula should be used to answer this question.

$$\text{Corrected CSF WBC} = 250/\mu\text{L} - \frac{(3.5 \times 10^9/\text{L}) \times (50,000/\mu\text{L})}{3.5 \times 10^{12}/\text{L}}$$

$$\text{Corrected CSF WBC} = 250/\mu\text{L} - 50/\mu\text{L}$$

$$\text{Corrected CSF WBC} = 200/\mu\text{L}$$

Hence, there is a significant increase in the CSF WBC.

In general, the type of predominant WBC present has the same diagnostic indication as is seen in the peripheral blood. For example, a predominance of neutrophils most often indicates a bacterial meningitis, a predominance of lymphocytes correlates with viral or fungal meningitis, and an increase of eosinophils can indicate a parasitic infection or allergic and drug reactions. More detailed correlations of possible diagnosis and type of cell increase is available in other sources.^{1,2,15}

As with the pleural, pericardial, and peritoneal fluids, reactive lymphocytes must be distinguished from lymphoma cells (Figure 56■). Hematopoietic precursors, including megakaryocytes, are present if the spinal tap needle penetrated the vertebral bone, drawing back a portion of bone

■ FIGURE 56 Reactive lymphocytes, CSF.

marrow. This is most often seen in infants but can occur in adults with osteoarthritis.¹⁶

Mesothelial cells are not present in CSF, but other tissue cells such as arachnoid and choroid plexus can be seen. These are most often present in CSF from infants and adults who have had some type of manipulation such as surgery or shunt placement. It is very unusual to see these cells from a simple spinal tap procedure in an adult.

MICROORGANISMS

The same types of microorganisms described in pleural, pericardial, and peritoneal fluids can be present in CSF samples. As mentioned earlier, distinguishing intracellular bacteria from stain precipitate is critical. A Gram stain is most helpful in this situation. The most common yeast organism seen in CSF is cryptococcus (Figure 31). When cryptococcus is suspected from the cytocentrifuge-prepared slide, the microbiology laboratory should perform an India ink preparation to confirm the presence of the characteristic large capsule of cryptococcus. If very few organisms are present, however, the India ink preparation can be negative because unconcentrated CSF is used for the India ink. Cultures must be obtained to confirm the type of organism present.

MALIGNANT CELLS

Much of the description of malignant cells in pleural, pericardial, and peritoneal fluids also holds true for spinal fluid examination.¹⁷ Carcinoma cells tend to be less cohesive in spinal fluid than in other fluids and can simulate hematopoietic malignancies. Because mesothelial cells do not exist in the CSF, the presence of any large tissue cells should be considered suspicious for malignancy (Figures 57■, 58■, and 59■). Malignant cells, however, must be dif-

■ FIGURE 57 Adenocarcinoma, CSF.

■ **FIGURE 58** Large cell undifferentiated carcinoma with intense chemical acute meningitis, CSF.

■ **FIGURE 60** Medulloblastoma, CSF.

ferentiated from the benign choroid plexus cells, ependymal cells, and arachnoid cells by evaluating the cells for standard features of malignancy as described earlier. Cytology preparations are usually definitive. Benign tissue cells usually are seen only in CSF from infants and from adults who have recent neurosurgery or a shunt or reservoir in place.

Cells from primary CNS neoplasms rarely are found in the CSF. Medulloblastoma is a malignant tumor usually occurring in the cerebellum of pediatric patients and has a morphologic appearance similar to that of small cell carcinoma (Figure 60■). Patient history from the physician would be necessary to distinguish the tumor's origin.

Acute lymphocytic leukemia more often involves the CNS than acute nonlymphocytic leukemia (Figures 61■, 62■, and 63■). When erythrocytes are present, care must be

taken not to overinterpret the presence of blasts that simply represent peripheral blood contamination. If no erythrocytes are present, even a low number of blasts (1% to 2%) can indicate CNS involvement.¹⁸ Special studies such as cytochemistry stains, TdT, and surface markers by immunoperoxidase stains or flow cytometry can be helpful.¹⁹

Any type of lymphoma can involve the CNS, but the high-grade lymphomas such as lymphoblastic, immunoblastic, and Burkitt lymphoma (small noncleaved cell) are more often seen. Primary CNS lymphoma is seen more often in patients who are HIV-positive. The lymphomas in these patients are high grade and frequently correspond to Burkitt lymphoma (small noncleaved cell) or B immunoblastic (Figure 64■).

■ **FIGURE 59** Small cell carcinoma, CSF.

CASE STUDY (continued from earlier in this chapter)

After an extensive work up, Carolyn is found to have a primary adenocarcinoma of the right upper lung lobe. A surgical resection is performed. Six months later, the patient has severe headaches. A spinal tap is performed, and a photomicrograph of the cells is as seen in Figure 65 ■.

7. What is the most appropriate interpretation of these cells?

▶ JOINT FLUID

Synovial fluids tend to be thick and viscous due to the presence of hyaluronic acid, a mucopolysaccharide substance secreted by the lining synovial cells. If the fluid is too thick to proceed with cell counts, the use of hyaluronidase can be very helpful to loosen the fluid. Joint fluid is most often aspirated to distinguish crystal-inducing diseases (gout, pseudogout) from septic processes. Other disease states can induce an inflammatory response; however, diagnosing these by joint-fluid examination alone is usually not possible. Certain diagnoses can be suspected when comparing the total WBC count with percent of segmented neutrophils present; however, there is great overlap, and morphologic examination by cytocentrifuge preparations can be extremely helpful (Table 8).^{20,21}

Joint fluids that have a total WBC of 50,000 to 200,000/ μL suggest an infectious or crystal-induced etiology. If the differential count shows 90% or more segmented neutrophils, an infectious agent is most likely and cultures must be obtained. Microorganisms can be seen in joint fluid if present in sufficient numbers and have the same

■ **FIGURE 65** Cerebral spinal fluid. (Case Study question 7)

★ TABLE 8

General Grouping of Diagnosis by Total WBC and Percent Neutrophils in Synovial Fluid Analysis

There is some overlap of diagnostic groups, and other studies are necessary to reach an accurate diagnosis.

Total WBC	% Neutrophils	Diagnostic Groups
0–5,000/ μL	<30% neutrophils	Osteoarthritis, traumatic arthritis, neuropathic arthropathy, pigmented villonodular synovitis
2,000–200,000/ μL	>50% neutrophils	Rheumatoid arthritis, Lupus erythematosus, Reiter's syndrome, rheumatic fever, ankylosing spondylitis
50,000–200,000/ μL	>90% neutrophils	Infectious—bacterial, mycobacterial, fungal
500–200,000/ μL	<90% neutrophils	Crystal induced—gout, pseudogout, apatite arthropathy
50–10,000/ μL	<50% neutrophils, RBC present	Hemorrhagic—trauma, hemophilia, anticoagulant, pigmented villonodular synovitis, neuropathic arthropathy, hemangioma

morphology as previously described. Bacterial organisms are more common, and pathogenic yeasts are only rarely seen.

When the total WBC is in the range of 2,000 to 200,000/ μL with more than 50% neutrophils in the differential count, entities such as rheumatoid arthritis (RA), SLE, and Reiter's syndrome should be considered. Spontaneous LE cell formation rarely occurs. The LE cell suggests SLE; however, it is not diagnostic and can be seen in RA. The so-called RA cell is a neutrophil containing granules of immune complexes. These cells are not specific for a diagnosis of RA. The Reiter's cell is a macrophage with vacuoles containing debris of phagocytosed neutrophils. The debris can also be unrecognizable blue material. These cells are also nonspecific and not diagnostic for Reiter's disease.

Synovial cells can become proliferative in a reactive setting similar to mesothelial cells. Reactive synovial cells also can be multinucleated and occur in clusters, and their nuclei can have small, regular nucleoli. Theoretically, malignant cells can be seen in synovial fluid; however, this is extremely rare.²²

EXAMINATION FOR CRYSTALS

The three most common types of crystals present in joint fluid are monosodium urate crystals seen in gout, calcium pyrophosphate crystals seen in pseudogout, and cholesterol crystals present in different types of chronic arthritides such as

RA.²³ Examination for crystals on a cytocentrifuge-prepared slide is superior to a standard wet preparation because the cytocentrifuge concentrates the specimen. Samples that are negative with wet preparation can actually show crystals on the concentrated cytocentrifuge slide. Using cytocentrifuge prepared slides also decreases the biologic hazard when handling wet preparations. If sufficient numbers of crystals are present, they can be seen with plain light microscopy on a Wright-stained cytocentrifuge slide. However, polarized light must be used to confirm birefringence²⁴ (described later). If fewer crystals are present, polarization is necessary to see them initially. Every joint fluid sent to the hematology laboratory for cell counts should have a crystal examination.²⁵ Some Wright's stain techniques result in the dissolution of the monosodium urate crystals. Therefore, preparing two cytocentrifuge slides, one for Wright's stain and one left unstained, is best. Both slides should be examined for crystals on multiple specimens to determine whether a particular stain technique dissolves the monosodium urate crystals (Table 9).

Birefringence refers to a particular material's ability to refract light rays. It is determined by using a polarizing microscope. A fixed light filter (analyzer) is placed above the specimen and a rotating filter (polarizer) is placed below the specimen. Both filters allow light to pass in only one direction. When the polarizer is rotated 90 degrees to the analyzer, no light can pass, yielding a "dark field." If the specimen contains birefringent material, it changes the direction (refract) of the light rays, allowing them to pass through the analyzer, and the birefringent material is seen as a bright particle or crystal.²⁴ A quartz compensator is used to further identify a crystal by determining the velocity of the light rays passing through the crystal's grain (axis).

Monosodium urate (MSU) crystals should be reported as intracellular and/or extracellular. MSU crystals are typically long, thin, and needlelike with pointed ends (Figure 66a). They can be seen singly or in bundles. MSU crystals are strongly birefringent and are brilliant with polarized light (Figure 66b). A quartz compensator must be used to determine positive or negative birefringence. MSU crystals are negatively birefringent and when aligned parallel to the axis of the compensator, show a yellow color; when turned perpendicular to the axis of the compensator, the color changes to blue (Figure 66c).^{1,2,24}

Calcium pyrophosphate (CPP) crystals also can be seen intracellularly and/or extracellularly. CPP crystals are typically short, rectangular, and weakly birefringent so that they can be difficult to see with polarized light (Figures 67a and 67b). When aligned parallel to the axis of a quartz compensator, the CPP crystals are blue, and the color changes to yellow when they are perpendicular to the axis of the compensator (Figure 67c).^{1,2,24} A joint fluid occasionally has both MSU and CPP crystals; the presence of one does not exclude the other.

Cholesterol crystals have a characteristic notched-plate shape and are birefringent (Figure 68). These crystals are

TABLE 9

Morphologic Comparisons of Commonly Seen Birefringent Crystals and Particles

Crystal	Birefringence	Color Parallel to Quartz Compensator	Morphology
Monosodium urate	Strong	Yellow	Long, thin, needlelike, intra- and extracellular
Calcium pyrophosphate	weak	Blue	Short, rectangular, intra- and extracellular
Cholesterol	Strong	Variable	Large platelike, notched, extracellular
Steroids	Strong	Variable	Amorphous, intra- and extracellular
Talc particles	Strong	Yellow and blue	Maltese cross shape, extracellular

present in chronically inflamed joints as are seen in rheumatoid arthritis.

Starch particles are distinguished from pathogenic crystals by a characteristic Maltese cross shape with polarized light (Figure 20). If a joint has been injected with steroids, the steroid particles can be seen intracellularly and extracellularly. Steroid particles do not have a crystal shape and are amorphous but birefringent.

✓ **Checkpoint! 5**

A 57-year-old man has an acutely swollen, painful, reddened joint in his left great toe. Joint fluid is aspirated, and a photomicrograph is taken (Figure 69 ■). This picture is taken with polarized light using a quartz compensator. What is the most appropriate interpretation of this finding?

SUMMARY

The fluids discussed in this chapter are those most commonly sampled: pleural, pericardial, peritoneal, synovial, and CSF. In pathologic conditions, the amount of fluid can increase (effusion). An effusion can be a transudate or an exudate. Chylous effusions are milky and result from leakage of lymphatic vessels. Common cell types seen in these fluids include white blood cells, tissue cells, and malignant cells. Examination of cellular morphology in body fluids, a critically important procedure for hematology laboratories,

is performed for not only a differential leukocyte count but also a possible demonstration of diagnostic findings such as microorganisms and malignant cells. The cytocentrifuge-prepared Wright-stained slide yields excellent morphology of cells and can significantly aid in making a timely diagnosis of patients with effusions of unknown etiology. The hematology laboratory must take an active role in correlating morphologic findings such as cultures, special stains, and cytology with additional studies that can be necessary.

REVIEW QUESTIONS

LEVEL I

- The types of body fluids other than peripheral blood that are frequently sent to the hematology laboratory include which of the following? (Objective 1)
 - cerebrospinal fluid
 - pleural fluid
 - pericardial fluid
 - all of the above
- The pleura, pericardium, and peritoneum are composed of what type of cell? (Objective 2)
 - white blood cell
 - epithelial cell
 - mesothelial cell
 - squamous cell
- Anatomically, where is the visceral pleura located? (Objective 1)
 - innermost aspect of the abdominal wall
 - outermost portion of the heart
 - innermost aspect of the chest wall
 - outermost portion of the lung
- Which of the following cell type(s) seen in cerebrospinal fluid can be considered normal, not a sign of pathologic disease? (Objective 2)
 - arachnoid cells
 - choroid plexus cells
 - ependymal cells
 - all of the above
- The finding of possible bacterial organisms on a cytocentrifuged, Wright-stained slide would be easiest to confirm by which of the following? (Objective 5)
 - gram stain
 - silver stain
 - culture
 - electrophoresis
- Which of the following can be seen as artifact on a cytocentrifuged, Wright-stained slide? (Objective 3)
 - hypersegmentation of neutrophils
 - stain precipitate
 - cytoplasmic projections of lymphocytes
 - all of the above

LEVEL II

- A specimen labeled "ascites" is sent to the laboratory. What type of procedure was used to obtain this fluid? (Objective 1)
 - thoracentesis
 - lumbar puncture
 - pericardial aspiration
 - paracentesis
- Which of the following cell types is responsible for the production of cerebrospinal fluid? (Objective 2)
 - choroid plexus
 - arachnoid
 - neutrophils
 - mesothelial
- A 25-year-old woman develops a left-sided pleural effusion while recovering from bacterial pneumonia. A thoracentesis is performed, and the following laboratory results are reported:

	Serum	Fluid
Protein	6.5 g/dL	5 g/dL
LD	75 U/L	60 U/L

- These results would be best interpreted as which of the following? (Objective 3)
- chylous
 - exudate
 - pseudochylous
 - transudate
- A 56-year-old woman has a 3-week history of abdominal pain. A peritoneal effusion is found. After paracentesis, a sample is sent to the laboratory. Examination of the cytocentrifuged, Wright-stained slide shows clusters of large cells that have abundant cytoplasm, smooth nuclear membranes, evenly distributed chromatin, and no nucleoli. An occasional multinucleated cell is found with the same features. These cells most likely represent: (Objective 5)
 - reactive mesothelial cells
 - adenocarcinoma cells
 - small cell carcinoma
 - ependymal cells

REVIEW QUESTIONS (continued)

LEVEL I

7. Which of the following best characterizes a chylous fluid? (Objective 4)
 - a. transparent, yellow, low nucleated cell count
 - b. opaque, bloody, many neutrophils
 - c. cloudy, yellowish-green, many histiocytes
 - d. opaque, white, many lymphocytes and chylomicrons
8. A 45-year-old man has pleural effusions on the right and left side. A right-sided thoracentesis is performed and a sample is sent to the laboratory. The fluid-serum protein ratio is 0.3, the fluid-serum LD ratio is 0.4, and the total nucleated cell count is low. Which of the following best describes this fluid? (Objective 4)
 - a. chylous
 - b. exudate
 - c. pseudochylous
 - d. transudate
9. Malignant tissue cells have which of the following morphologic feature characteristic(s)? (Objective 6)
 - a. irregular nuclear membrane
 - b. evenly distributed chromatin
 - c. prominent, irregular nucleoli
 - d. a and c only
10. The finding of which of the following in joint fluid is most helpful to establish a diagnosis of gout? (Objective 7)
 - a. monosodium urate
 - b. cholesterol
 - c. starch particles
 - d. neutrophils

LEVEL II

5. A 60-year-old man who has smoked cigarettes since the age of 16 years has left-sided chest pain. A thoracentesis sample is sent to the laboratory. The cytocentrifuged, Wright-stained slide is examined, and clusters of large cells have irregular, jagged nuclear membranes, prominent and irregular nucleoli, and unevenly distributed chromatin. These cells most likely represent: (Objective 5)
 - a. reactive mesothelial cells
 - b. adenocarcinoma cells
 - c. large cell lymphoma
 - d. reactive histiocytes
6. Referring to the case in question 5, the protein, LD, and other studies would most likely reveal that this is a(n): (Objective 3)
 - a. exudate
 - b. chylous fluid
 - c. transudate
 - d. pseudochylous fluid
7. A 65-year-old woman has a painful, swollen elbow. A joint aspiration is performed, and a sample is sent to the laboratory. A cytocentrifuged slide is examined with polarized light and a quartz compensator. Birefringent crystals are seen intracellular and extracellular; they are needlelike in appearance and are yellow when oriented parallel to the quartz compensator. These crystals would be best identified as which of the following? (Objective 8)
 - a. calcium pyrophosphate
 - b. cholesterol
 - c. monosodium urate
 - d. steroids
8. Referring to the case in question 7, which of the following is the most likely diagnosis? (Objective 8)
 - a. gout arthritis
 - b. pseudogout arthritis
 - c. rheumatoid arthritis
 - d. systemic lupus erythematosus
9. A 55-year-old man is brought to the emergency room in a comatose state. He was found at home by his son and appears to have fallen from a ladder. A spinal tap is performed and reveals the following:

Color	Red
Appearance	Bloody
RBC	$100 \times 10^9/L$
WBC	$0.10 \times 10^9/L$
Differential WBC	80% segmented neutrophils 15% lymphocytes 5% monocytes

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

Which of the following would be the most specific finding in this patient for a true CNS hemorrhage versus traumatic spinal tap? (Objective 6)

- a. crenated red blood cells
 - b. xanthochromia of the supernatant
 - c. erythrophagocytosis by histiocytes
 - d. WBC of $0.1 \times 10^9/L$
10. Referring to the patient in question 9, what is the significance of the WBC count of $0.1 \times 10^9/L$? (Objective 9)
- a. This is diagnostic for bacterial meningitis.
 - b. This is diagnostic for early viral meningitis.
 - c. This is expected for the amount of hemorrhage.
 - d. This is diagnostic for fungal meningitis.

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Radiologic studies show a large effusion in the right pleural cavity. A thoracentesis is performed and 1 L of thick, yellow fluid is aspirated. Laboratory studies show a total protein of 4.5 g/dL (serum = 6 g/dL), lactate dehydrogenase 40 U/L (serum = 50 U/L), and total leukocyte count of 20,000/ μ L with 90% segmented neutrophils, 10% histiocytes, and many degenerating cells.

Question:

1. Is this a transudate or exudate?

Explanation:

This is an exudate because the protein fluid/serum = 0.75, the fluid LD/serum LD = 0.80, and the WBC is >1000 m/L.

Question:

2. Is this a chylous fluid?

Explanation:

No, this is not chylous because the predominant cell is not a lymphocyte. Because of its appearance, it may be considered pseudochylous.

Question:

3. What would be an appropriate next step to determine whether the material seen is debris or true organism?

Explanation:

The quickest and easiest procedure is to make another slide and perform a Gram stain. If there is not a sufficient amount of fluid remaining, a Gram stain can be performed on the original unstained slide. The material seen is degenerating neutrophils.

Question:

4. How should this be interpreted?

Explanation:

In fluids that have findings of severe infection, the reactive changes of the mesothelial cells can be striking, and caution should be taken not to overinterpret them. Also, degenerative changes can simulate changes of malignancy with what appears to be an irregular nuclear membrane.

Question:

5. Is this an exudate or transudate?

Explanation:

This is an exudate because the protein fluid/serum = 0.78, the fluid LD/serum LD = 0.83, and the WBC is >1000 μ /L.

Question:

6. What is the most appropriate interpretation of these findings?

Explanation:

Most of the infection is resolved and the tissue cells show changes suggestive of malignancy, most likely an adenocarcinoma. This needs to be verified by cytology.

Question:

7. What is the most appropriate interpretation of these cells?

Explanation:

These cells initially appear as mesothelial cells; however, the CSF does not have mesothelial cells, and the patient is an adult with no history of recent brain surgery or CSF shunt or reservoir. Therefore, this most likely represents a metastatic carcinoma. This should be verified by cytology.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

To obtain a sample of cerebrospinal fluid for analysis, the needle must be inserted into what area of the central nervous system?

Answer

Subarachnoid space.

Checkpoint! 2

A 32-year-old woman has right-sided chest pain and shortness of breath that has worsened over a 2-week period. Chest radiologic studies reveal a right pleural effusion, and a thoracentesis is performed. The pleural fluid specimen on a cytocentrifuged, Wright-stained slide reveals cells similar to that seen in Figure 28-7. What is the best interpretation of this finding? If there is a strong concern that this may represent a low-grade lymphoma, what would be the best way to determine whether these are benign or malignant lymphocytes?

Answer

These cells are benign lymphocytes with the artifact of a pale staining area resembling nucleoli. These are not blasts because of the mature chromatin. Immunophenotyping by flow cytometry of the pleural fluid would be the best way to determine whether this is a benign or malignant population of lymphocytes.

Checkpoint! 3

When examining a cytocentrifuged, Wright-stained slide of a body fluid specimen, what are the best features to use in determining whether tissue cells are benign or malignant?

Answer

Nuclear features are the best to use to distinguish benign and malignant cells. These include nuclear membrane (smooth or irregular), chromatin pattern (regular or irregular distribution), and nucleoli

(present or absent, nucleolar membrane smooth or irregular).

Checkpoint! 4

A 47-year-old man is found comatose at home by his wife. During examination in the emergency room a spinal tap is performed and grossly bloody spinal fluid is obtained. The total red blood cell count in the first tube is the same as that in the third tube. A cytocentrifuged, Wright-stained slide shows findings similar to that seen in Figure 28-54. What is the most appropriate interpretation?

Answer

There has been a true subarachnoid hemorrhage.

Checkpoint! 5

A 57-year-old man has an acutely swollen, painful, reddened joint in his left great toe. Joint fluid is aspirated, and a photomicrograph is taken (Figure 28-69). This picture is taken with polarized light using a quartz compensator. What is the most appropriate interpretation of this finding?

Answer

Both monosodium urate and calcium pyrophosphate crystals are present.

Primary Hemostasis

Barbara A. O'Malley, M.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define *hemostasis*, *blood coagulation*, and *thrombosis*.
2. Explain the general interaction of the systems involved in maintaining hemostasis.
3. Distinguish the events that occur in primary hemostasis from those that occur in secondary hemostasis.
4. Differentiate the primary hemostatic plug from the secondary hemostatic plug.
5. Name the three types of blood vessels and explain the general roles of the vasculature and normal endothelial cells in aiding and preventing activation of the hemostatic system.
6. Describe the normal morphology and number of platelets on a peripheral blood smear and state the normal concentration in the blood.
7. Name and describe the cell that is the precursor of platelets in the bone marrow.
8. Identify and define the steps in the normal sequence of events of platelet activation following injury to the endothelium.
9. Describe the role of the primary hemostatic plug in the cessation of bleeding.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Identify key histologic features of each type of blood vessel and explain the metabolic functions of endothelial cells in hemostasis.
2. Describe the development of megakaryocytes and platelets in the bone marrow to include the action of humoral factors, the stem cell and progenitor cell compartment, the recognizable features of the morphologic stages, and the mechanism of release from the marrow to peripheral blood.
3. Define *endomitosis* and *polyploidy*.
4. Identify three key substances that are stored in the platelet dense bodies and five key substances stored in the platelet alpha granules and explain the role of each in hemostasis.
5. Outline steps the platelets undergo in forming the primary hemostatic plug, including the biochemical mediators necessary for platelet adhesion, platelet aggregation, and platelet secretion.
6. Correlate various platelet ultrastructural features with their functions.
7. Identify platelet agonists and predict their effect on platelet function.
8. Describe the biochemical roles of the secreted contents of the platelet granules in hemostasis.

OBJECTIVES—LEVEL II (continued)

9. Correlate activation with changes in the platelet ultrastructure and biochemistry.
10. Describe the roles of the platelet in secondary hemostasis.
11. Identify the life span of platelets in the peripheral blood.

KEY TERMS

Agonist
 Alpha granule (α G)
 Arachidonic acid (AA)
 Clot retraction
 Demarcation membrane system (DMS)
 Dense bodies (DB)

 Glycocalyx
 Glycoprotein Ib (GPIb)
 Glycoprotein IIb/IIIa (GPIIb/IIIa)
 Hemostasis
 Open canalicular system (OCS)
 Platelet activation
 Platelet adhesion
 Platelet aggregation
 Platelet procoagulant activity
 Platelet secretion (Platelet release reaction)
 Polyploid
 Primary hemostatic plug
 Secondary hemostatic plug
 Thrombogenic/nonthrombogenic
 Thrombopoietin (TPO)
 Thrombosis

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Describe the bone marrow production of blood cells.

Level II

- ▶ Summarize the hierarchy of stem and progenitor cells in the bone marrow and the growth factors that direct the proliferation and maturation of blood cells.
- ▶ Describe the general biology of integrins and other adhesion molecules.

CASE STUDY

We will refer to this case study throughout the chapter.

Michael, a 20-year-old male with acute lymphocytic leukemia (ALL) is receiving chemotherapy. Two weeks after his second treatment, he notices small reddish-purple spots on his lower legs and ankles. A CBC reveals Hb 9 g/dL; WBC $2 \times 10^9/L$; platelets $19 \times 10^9/L$. Consider what could be responsible for the pancytopenia and the potential consequences of this condition.

OVERVIEW

This chapter is the first of a section describing the processes involved when blood clots in response to vascular injury. The actions of the blood vessels and platelets in hemostasis are collectively called *primary hemostasis*; the actions of the protein coagulation factors are called *secondary hemostasis*. This chapter discusses primary hemostasis and first describes the physical structure and functions of the blood vessels in hemostasis. It discusses platelets in hemostasis next under the major subtopics of production, structure, and functions.

INTRODUCTION

Blood normally flows through the circulatory system, a closed system of vessels. The blood vessels and their constituents are critical in controlling the physiologic functions of the circulatory system. A traumatic injury such as a cut to the finger severs vessels, resulting in bleeding. To minimize blood loss, the normally inert circulating platelets and dissolved plasma proteins mobilize to form a “clot,” an insoluble mass or structural barrier (thrombus), which occludes the injured vessel and prevents further loss of blood. The formation of the clot is limited to the area of injury so that normal circulation is maintained in vessels elsewhere in the body. In other words, the hemostatic system is activated when and where it is needed. The same elements provide a continuous surveillance system that prevents leakage of plasma and cells into the tissues in normal circumstances.

Hemostasis is the property of the circulation that maintains blood as a fluid within the blood vessels and the system’s ability to prevent excessive blood loss upon injury. Hemostasis is from the Greek words *heme*, meaning blood, and *stasis*, meaning to halt. The barrier mass formed to limit

blood loss is known as the *hemostatic plug*, *blood clot*, or *thrombus*. Hemostasis requires the interaction of three compartments: the blood vessels, the platelets, and a group of soluble plasma proteins, the coagulation factors. Blood coagulation (“clotting”) is the mechanism that transforms the fluid plasma into a gel by converting the soluble protein fibrinogen to the insoluble form, fibrin.

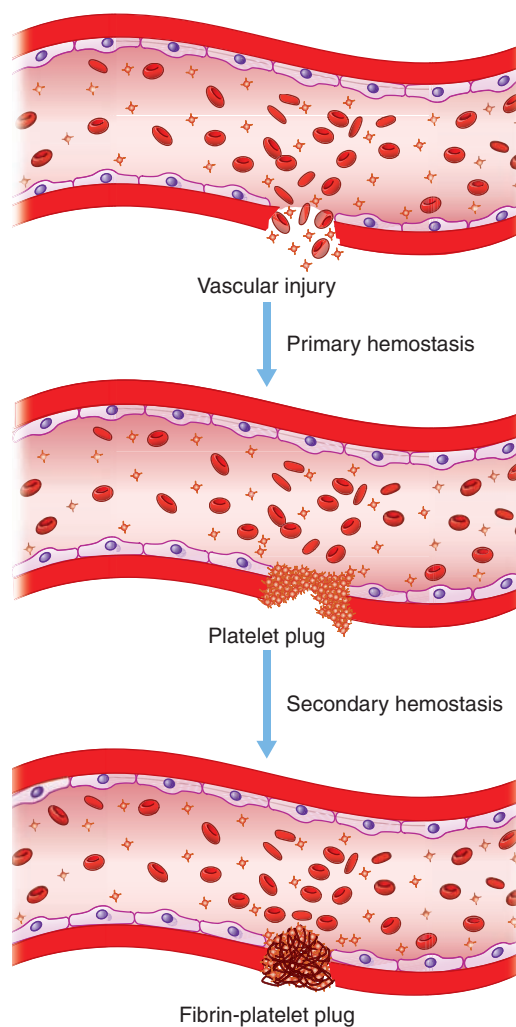

Hemostasis occurs in stages called *primary hemostasis*, *secondary hemostasis*, and *fibrinolysis*. During primary hemostasis, the platelets interact with the injured vessels and with each other. This interaction results in a clump of platelets known as the **primary hemostatic plug**, which temporarily arrests bleeding, but it is fragile and easily dislodged from the vessel wall.

Subsequently, insoluble strands of fibrin become deposited on and within the primary platelet plug to reinforce and stabilize it and to allow the wound to heal without further blood loss. Generation of fibrin constitutes the stage of secondary hemostasis. Fibrin is formed by a series of complex biochemical reactions involving soluble plasma proteins (coagulation factors) as they interact with the injured blood vessels and the platelet plug. The plug, or thrombus, is then called the **secondary hemostatic plug** (Figure 1 ■). The blood has changed from a liquid to a semisolid gel at the site of injury.

After the wound has healed, additional components of the hemostatic system break down and remove the clot in the fibrinolytic stage. Physiologic and biochemical inhibitors control all phases and components of the hemostatic system.

Injury also can occur to intact, unsevered blood vessels. In this case, blood clot formation can occur on an interior surface of the damaged vessel wall and result in the abnormal condition **thrombosis**.

In summary, hemostasis occurs because of the interaction of the blood vessels, platelets, and certain plasma proteins (Table 1 ☆). Proteins of hemostasis include those that form fibrin, those that are involved with fibrinolysis, and those that inhibit all stages of the process. Defects in one hemostatic compartment can be overcome by effective utilization of the other two; defects in two of the three compartments generally results in pathologic hemostasis and bleeding. This chapter focuses on primary hemostasis. It describes the structure and functions of the blood vessels (vascular system, or vasculature) and the platelets as they form the primary hemostatic plug.

■ **FIGURE 1** Stages of hemostasis after vascular injury. Bleeding occurs after an injury to a blood vessel. The hemostatic system is activated to prevent excessive blood loss. Hemostasis occurs in two stages: (1) primary hemostasis when the platelets aggregate at the site of the injury and form the platelet plug (primary hemostatic plug) and (2) secondary hemostasis when fibrin develops to strengthen the platelet plug forming the fibrin-platelet plug (secondary hemostatic plug).

 - Fibrinolytic proteins
 - Inhibitors

CASE STUDY (continued from the previous page)

1. Does Michael have a defect in primary or secondary hemostasis?

► **ROLE OF THE VASCULAR SYSTEM**

The vascular system forms an extensive distribution system for blood, carrying nutrients to all the body’s cells and tissues and transporting waste products for disposal. To perform this function, the system must provide an uninterrupted flow of blood (i.e., a nonleaking circuit) and maintain blood in a fluid state. The vascular system consists of three types of blood vessels: arteries, veins, and capillaries (Table 2). The arteries carry blood from the heart to the capillaries. The veins return blood from the capillaries to the heart. The vessels in which hemostasis occurs are primarily the smallest veins (*venules*) and, to a lesser degree, the smallest arteries (*arterioles*). Venules and arterioles are 20–200 μm in diameter.

STRUCTURE OF BLOOD VESSELS

The structure of all blood vessels is similar (Figure 2) consisting of a central cavity, the lumen, through which the blood flows. The lumen is lined with a continuous, single layer of flattened endothelial cells that separate the blood from the underlying tissues and provide a protective environment for the blood’s cellular elements. Overlapping portions of their cytoplasm interconnect the individual endothelial cells.

The luminal surface of the endothelial cells (on the inside of the vessel) has a thin coating of complex protein and carbohydrate substances (mucopolysaccharides) called the **glycocalyx**. The abluminal surface (on the tissue side) is attached to a basement membrane that consists of a unique form of collagen, type IV, embedded in a matrix of adhesive proteins.

Three layers of tissue in the vessel wall vary in thickness and composition depending on the size and type of vessel. Histologically on cross-section, the layers of the walls of veins and arteries appear distinct (Figure 2a). The innermost layer, tunica intima, consists of the endothelial cell monolayer, the basement membrane, and subendothelial connective tissue that holds them together; arteries also have an organized internal elastic membrane.

The middle layer, tunica media, is thicker in arteries than in veins. In arteries, smooth muscle cells predominate and are surrounded by loose connective tissue primarily consisting of elastin fibers, collagen fibers, reticular fibers, and proteoglycans. The tunica media of veins contains only a few smooth muscle cells, fewer elastin fibers, and a similar matrix of connective tissue. In response to a variety of physiologic stimuli, the smooth muscle cells of the tunica media contract and expand, which constricts or dilates the lumen.

The tunica adventitia, the outer coat, is thicker in veins than in arteries. A few fibroblasts are embedded in collagen and other connective tissues in this layer. The fibroblasts

Structure and Functions of Blood Vessels of the Microcirculation

Blood Vessel	Structural Characteristics	Functions
Arterioles	20–200 μm in diameter Basement membrane Primary component is smooth muscle Fibroblasts Thicker wall of collagen and extracellular matrix	Serve as site of hemostatic activity following injury Regulate blood pressure by change in diameter Perform endothelial cell hemostatic functions
Venules	20–200 μm diameter Basement membrane Few smooth muscle cells Few fibroblasts Primary component, thin layer of collagen and extracellular matrix No elastic fibers	Serve as major site of hemostatic activity following traumatic injury Exchange nutrients, oxygen, and waste products Regulate vascular permeability Perform endothelial cell hemostatic functions
Capillaries	5–10 μm diameter Single endothelial cell lumen Basement membrane No smooth muscle cells No collagen fibers No elastic fibers	Have no hemostatic function except those of endothelial cells Exchange nutrients, oxygen, and waste products

■ **FIGURE 2** Structure and function of the blood vessel wall, comparing and contrasting arterioles, venules, and capillaries. **a.** Arterioles and venules. Endothelial cells, smooth muscle cells, and fibroblasts synthesize and secrete the components of the subendothelial matrix of connective tissue and the basement membrane proteins. The wall of arterioles is primarily composed of smooth muscle cells and contains elastin in contrast to the venule, which has only sparse smooth muscle cells. The media of arterioles is the most prominent layer; the adventitia layer is the largest in venules. **b.** A capillary consists primarily of endothelial cells and basement membrane with very little connective tissue.

synthesize and secrete the fibers and other components of the matrix. Mast cells are present in some layers of veins.

The third type of blood vessel, the capillary (Figure 2b), connects the arterioles and venules. Capillaries collectively compose by far, the largest surface area of all types of blood vessels, although they are individually the smallest. They are approximately 5–10 μm in diameter, just large enough for single blood cells to traverse. Single endothelial cells form the lumen of a capillary with their cytoplasm wrapped around in a circular form. The endothelial cells communicate with surrounding pericytes through gap junctions.¹ The tissue beneath a capillary's basement membrane is sparse and contains no smooth muscle cells.

FUNCTIONS OF BLOOD VESSELS

After an injury, the damaged vessels initiate hemostasis. The first response of vessels to injury is constriction or narrowing of the lumen of the arterioles to minimize the flow of blood into the wound area and the escape of blood from the wound site. Vasoconstriction also brings the hemostatic components of the blood (the platelets and the plasma proteins) closer to the vessel wall, facilitating their interactions. Vasoconstriction occurs immediately and lasts a short time.

The mechanism of vasoconstriction is complex. It is caused in part by neurogenic factors and in part by several regulatory substances that interact with receptors on the surface of cells of the blood vessel wall. The regulating substances include serotonin and thromboxane A_2 (both products of platelet activation) and endothelin-1 (which is produced by damaged endothelial cells). These substances can aid in prolonging vasoconstriction.²

In contrast, healthy intact endothelial cells synthesize and secrete a prostaglandin, PGI_2 , also called *prostacyclin*. PGI_2 counteracts constriction by causing vasodilation of the arterioles.³ Vasodilation increases blood flow into the injured area to bring fresh supplies of plasma-blood clotting substances and causes redness of the skin at the wound site.

Also after injury, endothelial cells of the venules contract, producing gaps between them and allowing plasma leakage into the tissues causing swelling or edema (increased vascular permeability). The increased blood flow into the area (vasodilation) and the increased vascular permeability are components of the *inflammatory response*, a normal physiologic response to injury.

✓ Checkpoint! 1

Think about the last time that you injured your finger with a paper cut. Did your finger bleed immediately? If not, what might have prevented immediate bleeding?

FUNCTIONS OF ENDOTHELIAL CELLS

Endothelial cells lining the lumina of blood vessels are the principal elements regulating many vascular functions. Some functions modulated by the endothelial cells are hemostatic; others are nonhemostatic in nature (Table 3). The endothelial lining of normal, healthy blood vessels is **nonthrombogenic** and antithrombotic, preventing inappropriate clotting. Damaged endothelial cells become **thrombogenic**, promoting the formation of a thrombus or blood clot (Figure 3).

Hemostatic functions that inhibit clot formation include the provision of a nonreactive environment for the components of the hemostatic system. Components of the hemostatic system (platelets and coagulation proteins) are inert in the presence of normal endothelium. Both physiologic and biochemical interactions provide the nonreactive environment.⁴ Physiologically, the surface of the endothelial cells is negatively charged and repels circulating proteins and platelets, which also are negatively charged. Biochemically, a wide variety of substances is synthesized and secreted by the endothelial cells, which contribute to the nonreactive environment. These include substances that:

- inhibit platelet function (PGI_2 , nitric oxide [NO], and ADPase)
- inhibit coagulation (heparan sulfate/glycosaminoglycans [cofactor for antithrombin], thrombomodulin [protein C activation], tissue factor pathway inhibitor [TFPI])
- activate fibrinolysis (tissue plasminogen activator [tPA] and urinary-type plasminogen activator [uPA])

Damaged endothelium becomes thrombogenic, producing substances that activate platelets and coagulation proteins and inhibit fibrinolysis. Damaged endothelial cells:

- produce and secrete von Willebrand factor (VWF), which aids platelets in the initial stage of primary hemostasis
- produce tissue factor that is released during injury and initiates the formation of fibrin for secondary hemostasis
- expose collagen in the subendothelium and secrete platelet activating factor (PAF), which activate platelets
- release plasminogen activator inhibitor (PAI-1), which inhibits fibrinolysis

When endothelial injury occurs and bleeding starts, platelets and coagulation proteins in the plasma physically contact exposed subendothelial tissues. Interactions then occur between the vessel wall, platelets, and hemostatic proteins in the plasma to form a blood clot to stop the bleeding.

The amount of blood lost from a vessel depends on its size and type as well as on the efficiency of the hemostatic

★ TABLE 3

Functions of Endothelial Cells

Component/Characteristic	Function
Hemostatic functions	
Nonthrombogenic	
Negatively charged surface	Repels platelets and hemostatic proteins
Heparan sulfate	Inhibits fibrin formation (cofactor for antithrombin)
Thrombomodulin	Inhibits fibrin formation (cofactor in activation of protein C)
PGI ₂ (Prostacyclin)	Vasodilates; inhibits platelet aggregation
Tissue plasminogen activator (tPA)	Activates fibrinolytic system
Nitric oxide	Vasodilates
Thrombogenic	
Endothelin	Vasoconstricts
von Willebrand factor production and processing	Carries factor VIII (F-VIII) in plasma; causes platelet adhesion
Tissue factor	Initiates fibrin formation
Plasminogen activator inhibitor (PAI-1)	Inhibits activation of fibrinolytic system
Nonhemostatic functions	
Selective blood/tissue barrier	Keeps cells and macromolecules in vessels; allows nutrient and gas exchange
Processing of blood-borne antigens	Contributes to cellular immunity
Synthesis and secretion of connective tissue:	
Basement membrane collagen	Provides backup protection for endothelial cells
Collagen of the matrix	Is responsible for platelet adhesion
Elastin	Vasodilates and vasoconstricts
Fibronectin	Binds cells to one another
Laminin	Contributes to platelet adhesion after injury
Vitronectin	Binds cells to one another; ? platelet adhesion
Thrombospondin	Binds cells to one another; ? platelet adhesion

? = possibly

mechanism. Hemostasis is most effective in arterioles and venules. Capillaries lack the tissue layers beyond the basement membrane and do not effectively contribute to hemostasis. When larger vessels are severed, hemostatic plug formation takes longer and might not be sufficient to stop bleeding. The pressure within arteries is much higher, and the blood flow can be so rapid that clotting cannot occur effectively (e.g., within the upper aorta).

✓ Checkpoint! 2

What actions of the endothelial cells prevent clotting from occurring within the blood vessels?

▶ PLATELETS IN HEMOSTASIS

The second major component of the hemostatic system is the blood platelet. Bizzozero first established the platelet's role in hemostasis in 1882.⁵ He noted that they were

clumped together as part of thrombi in the mesenteric vessels of rabbits and guinea pigs.

Platelets appear on a Romanowsky-stained peripheral blood smear as small, anuclear cells with prominent reddish purple granules (Figure 4 ■). They circulate as discoid-shaped structures, approximately 2–3 μm in diameter and have a lifespan of 9–12 days. The normal concentration of platelets in the blood is $150\text{--}440 \times 10^9/\text{L}$. The spleen and liver remove nonviable or aged platelets.

The following sections of this chapter discuss the production of platelets in the bone marrow, their structure, and the various functions in hemostasis.

PLATELET PRODUCTION

Platelets are produced in the bone marrow from the same progenitor cell as the erythroid and myeloid series (CMP/CFU-GEMM). The bipotential CFU-E/Mk ultimately gives rise to precursor cells committed to megakaryocytic

FIGURE 3 Antithrombotic characteristics of resting endothelium versus the prothrombotic effects of damaged or activated endothelium. Resting endothelium provides an environment that inhibits activation of hemostasis. This includes secretion of substances that (1) inhibit platelet activation (PGI₂, NO, ADPase), (2) inhibit coagulation (heparan sulfate/GAG as a cofactor for AT, TM for activation of Protein C, which inactivates activated F-Va and F-VIIIa, and TFPI), and (3) activate fibrinolysis (tPA, uPA). When endothelium is damaged, it secretes substances that (1) activate platelets (TXA₂, PAF) and bind them to the vessel wall (VWF), (2) activate coagulation (TF, which initiates formation of fibrin), and (3) inhibit fibrinolysis (PAI-1). EC = endothelial cells; PGI₂ = prostacyclin; NO = nitric oxide; GAG = glycosaminoglycans; AT = antithrombin; TM = thrombomodulin; APC = activated protein C; EPCR = endothelial protein C receptor; PS = protein S; tPA = tissue type plasminogen activator; uPA = urinary type plasminogen activator; PAF = platelet activating factor; TXA₂ = thromboxane; TF = tissue factor; VWF = von Willebrand factor; PAI-1 = plasminogen activator inhibitor-1; → = stimulation; ⋯→ = inhibition

development (Figure 5 ■). The morphologically identifiable platelet precursor cell is a megakaryocyte. Platelets are fragments of the cytoplasm of mature megakaryocytes. The cells of the megakaryocytic lineage include actively proliferating progenitor cells and postmitotic megakaryocytes undergoing maturational development.

Megakaryocyte Progenitor Cell Compartment

Megakaryocyte progenitor cells are responsible for expanding the megakaryocyte numbers and proliferating in response to a number of hematopoietic cytokines. The CFU-GEMM differentiates into a committed megakaryocyte progenitor cell. Using cell culture techniques to grow human adult bone marrow precursor cells, researchers have defined

■ **FIGURE 4** Peripheral blood smear. The arrows point to platelets. (Wright-Giemsa stain; 1000× magnification)

a hierarchy of megakaryocyte progenitor cells that develop through stages identified as *BFU-Mk* and *CFU-Mk*. Surface antigens and growth characteristics differentiate the two stages. The *BFU-Mk* is CD34⁺, HLA-DR⁻, c-kit⁺ (SCF receptor), while the *CFU-Mk* is positive for all three antigens. In culture, *BFU-Mk* produce multifocal colonies (bursts) of 100–500 megakaryocytes while the *CFU-Mk* produce single colonies of 4–32 megakaryocytes. A progenitor cell that is more primitive than the *BFU-Mk* has been grown in cultures of fetal bone marrow called the *high proliferative potential cell-*

megakaryocyte (HPPC-Mk).⁶ Morphologically, early progenitor cells appear as small indistinguishable lymphoid-like cells.⁷

Regulation of Platelet Production

A regulatory process maintains an adequate number of platelets in the peripheral blood. Production of platelets by the bone marrow can increase or decrease according to the body's needs. The major stimulus regulating production is the platelet mass in the circulating blood plus the megakaryocyte mass in the bone marrow.⁸

Similar to their action on other myeloid cell lines,^{8,9} cytokines and growth factors such as interleukin-3 (IL-3), GM-CSF, and stem cell factor influence the progenitor stages of megakaryocytes to proliferate. Interleukins-6 and -11 also affect megakaryocyte development, particularly the maturation phases, but only when they work in synergy and with other cytokines.¹⁰

The major humoral factor regulating platelet development is **thrombopoietin (TPO)**, which influences all stages of megakaryocyte production from the HPPC-Mk level to the release of mature platelets from the bone marrow.^{11,12} Megakaryocytes grown in culture undergo apoptosis in the absence of TPO.¹³ The presence of TPO had been suspected since the 1950s, but not until 1994 did several research groups first isolate it.⁹ The gene for TPO was cloned shortly after its discovery. By 1997, TPO was made by recombinant DNA techniques, and its effects have been studied in vitro and in clinical trials to treat patients with certain platelet

■ **FIGURE 5** Production of platelets. Progenitor cells become committed to the megakaryocyte lineage. Committed progenitor stages are *BFU-Mk* and *CFU-Mk*. Megakaryoblasts undergo a series of endomitoses until nuclear maturation is complete at 8N to 64N ploidy levels. Cytoplasmic maturation occurs at ploidy levels of 8N or higher. Morphologic features of each stage of cytoplasmic maturation are described in the text. Growth factors SCF, GM-CSF, and IL-3 influence proliferation of the stem and progenitor cells. Thrombopoietin influences all stages of megakaryocyte production. IL-6 and IL-11 also support megakaryocyte production, primarily maturation. Platelets are first released between the endothelial cells of the marrow sinuses as proplatelets. Proplatelets break into mature platelets and are released into the peripheral blood.

disorders.¹⁴ TPO is produced in the liver, the kidneys, and the spleen, and possibly in the bone marrow in patients who have low platelet counts.^{8,11} Thrombopoietin is structurally related to the erythrocyte growth factor, erythropoietin.⁸

TPO maintains a constant number of platelets in the peripheral blood via a unique mechanism. Cellular production of TPO is relatively consistent from day to day. TPO binds to its receptor, Mpl (CD110), on circulating platelets and bone marrow megakaryocytes and progenitors.⁸ TPO bound to circulating platelets is internalized and degraded and is not available to stimulate proliferation of bone marrow progenitor cells. Therefore, the higher the peripheral platelet count, the more TPO is bound and less TPO remains free in the plasma. This reduces both the stimulation of megakaryocyte progenitor cells in the bone marrow and platelet production. When the platelet count decreases, more TPO is free to bind to megakaryocyte progenitor cells in the bone marrow, increasing platelet production.¹¹ TPO appears to work both independently and in synergy with the other growth factors mentioned. The effects of TPO in patients with low platelet numbers are to increase the number of megakaryocytes in the bone marrow, the size and DNA content (ploidy level) of megakaryocytes, and the rate of maturation of the megakaryocytes.¹² The number of circulating platelets can increase from 3 to 10 times the baseline level by administration of TPO.¹¹ (To access more information on the Mpl receptor online, see <www.ncbi.nlm.nih.gov/prow/guide/11586825_g.htm>.)

Checkpoint! 3

What would be the effect on the platelet count if a patient had a mutation in the gene for thrombopoietin that resulted in the gene's inability to code for functional mRNA?

CASE STUDY (continued from earlier in this chapter)

2. If Michael were given TPO, how would you expect his bone marrow and peripheral blood picture to change?

Stages of Megakaryocyte Development

When TPO and other growth factors stimulate progenitor cell receptors, megakaryocyte differentiation results. The blast cell undergoes a maturation sequence that differs from that of other marrow lineages in that nuclear maturation takes place first and is largely complete before cytoplasmic maturation begins. Following an initial series of proliferative (mitotic) cell divisions, the precursor cells begin a unique nuclear maturation process consisting of a series of endomitoses. With each **endomitosis**, the cell's DNA content doubles, but cell division and nuclear division do not take place.¹⁰ The resulting cells become **polyploid**, meaning that the DNA content, or ploidy level within a single nuclear envelope (normally 2N), can range from 4N to 64N or higher.

Endomitosis begins in megakaryoblasts and is completed by the end of stage II megakaryocytes. The 8N stage is generally the first recognizable stage on a bone marrow smear because by this stage, the megakaryocytes are becoming significantly larger than other cells in the bone marrow. The 16N stage is the most common ploidy class in adult humans.

Cytoplasmic maturation can be initiated at nuclear ploidy levels of 8N or more, but the stage at which maturation occurs varies from cell to cell. In general, nuclear maturation ceases when cytoplasmic maturation begins. The reason for variability in cytoplasmic maturation at different ploidy levels is not known. Clinical conditions associated with the presence of large platelets on the peripheral blood smear are noted to have more megakaryocytes with lower ploidy (shifted left). These large platelets are sometimes called *stress platelets* analogous to stress reticulocytes seen in anemias. Increased ploidy of an individual megakaryocyte's nucleus generally results in more cytoplasm and, thus, more platelets from that megakaryocyte.

Four arbitrary stages of megakaryocyte development are described according to their morphologic appearance on Romanowsky-stained bone marrow smears. Differentiating characteristics include nuclear morphology, cytoplasmic appearance, and relative size of the cell as determined by the ploidy class. The four stages are described in Table 4. Figure 6 shows an early megakaryocyte and a mature megakaryocyte. The nucleus transforms from a single (round) lobe with fine chromatin and visible nucleoli to lobulated with coarse chromatin and no visible nucleoli. In general, as the megakaryocyte matures, the cytoplasm increases in volume and changes from basophilic, nongranular, and scant in the blast stage (Stage I) to completely granular and acidophilic in the mature stage. The cytoplasm in the early stages (Stage I and II) may have a few granules appearing in the region of the Golgi apparatus whereas the cytoplasm of the mature cell (Stage IV) appears completely filled with azurophilic granules.

In addition to granules, the cytoplasm of a maturing megakaryocyte develops an internal membrane system of channels called the **demarcation membrane system (DMS)**. The demarcation membrane is not visible in the light microscope and is first seen in electron micrographs at the promegakaryocyte stage. It is derived by invagination of the megakaryocyte's outer membrane and eventually develops into a highly branched, interconnected system of channels that maintain open communication with the extracellular space. As the DMS forms, small areas of the megakaryocyte cytoplasm are compartmentalized (Figure 7a). These areas eventually become the platelets, and the DMS becomes the outer membrane of the platelets.⁹ The separated cytoplasmic areas can be seen on the edges of the cell pictured in Figure 6b.

In the practical day-to-day evaluation of bone marrow specimens, distinguishing the maturation stages of megakaryocytes is not necessary. It is, however, important to recognize a cell as being of the megakaryocyte lineage.

★ TABLE 4

Developmental Stages of Megakaryocytes

	Name	Characteristics
Stage I	Megakaryoblast	6–24 μm diameter Scant basophilic cytoplasm No visible granules Round nucleus Visible nucleoli
Stage II	Promegakaryocyte (basophilic megakaryocyte)	14–30 μm diameter Increased cytoplasm, primarily basophilic Few visible azurophilic cytoplasmic granules Indented or bilobed nucleus Beginning of demarcation membranes (visible with electron microscopy)
Stage III	Granular megakaryocyte	25–50 μm diameter Numerous cytoplasmic granules Abundant acidophilic cytoplasm Large, multilobed nucleus No visible nucleoli
Stage IV	Mature megakaryocyte	40–60 μm diameter Abundant acidophilic, very granular cytoplasm Demarcation zones present Multilobulated nucleus No visible nucleoli

✓ Checkpoint! 4

If a patient has a mutation in the gene for TPO that resulted in the inability to code for mRNA, how would you expect the number of megakaryocytes on bone marrow smears to be affected?

Release of Platelets

The primary site of megakaryocyte development and platelet production (megakaryocytopoiesis) is in the bone marrow. Mature megakaryocytes are typically situated less than 1 μm from the abluminal surface of the marrow sinus endothelial cells and shed platelets directly into the sinuses. Platelets appear to be released from megakaryocytes in groups called *proplatelets*, which are long slender protrusions of megakaryocyte cytoplasm called *pseudopods* or *filopodia* (Figure 7b ■). Each megakaryocyte extrudes multiple cytoplasmic extensions between endothelial cells into the marrow sinuses as proplatelets, which then break up into individual platelets. The megakaryocyte nucleus remains in the marrow and is engulfed by the marrow macrophages. Localized apoptosis (caspase activation) is thought to play a role in the final stages of platelet formation and release.^{15,16} Whole intact megakaryocytes occasionally are released from the marrow, circulate in the peripheral blood, and become trapped in capillary beds in the spleen and lungs. These cells also can release platelets to the peripheral blood.¹⁷ One mature megakaryocyte produces between 1000–3000 platelets.

Development of a megakaryoblast to the platelet-producing stage requires approximately 7 days. Two-thirds of the platelets that are released into the peripheral blood circulate in the bloodstream; the remaining third is sequestered in the spleen and is in equilibrium with those platelets in the circulation. The average life span of platelets in peripheral blood is ~9.5 days.

Outward extrusion of cytoplasm, eventually breaking up into individual platelets delineated by demarcation membrane system (arrow). Expelled nucleus is phagocytized by marrow macrophages.

PLATELET STRUCTURE

Circulating inert platelets are disc shaped anucleate cell fragments with smooth surfaces. Unlike the exterior surfaces of erythrocytes and leukocytes, the surface membranes of platelets have several openings resembling holes in a sponge. The openings are membranous channels that extend deep into the interior of the cells.

Circulating platelets repel one another and the surfaces of the endothelial cells that line the interior lumen of blood vessels. After an injury, many changes affecting the platelet morphology and biochemistry occur, causing the platelets to become “activated” after which they interact with the vessel wall and other platelets to form the primary hemostatic plug. To understand the activation process, the ultrastructure of normal platelets must be considered.

The platelet ultrastructure is divided into four arbitrary regions or zones: peripheral zone, structural zone, organelle zone, and membrane systems¹² (Figure 8■ and Table 5🟢). The components of each region have specific functions in activated platelets and are discussed in the following sections.

Peripheral Zone

The peripheral zone of the platelet consists of a phospholipid membrane covered on the exterior by a fluffy surface coat and on the interior by a thin submembranous region

between the cytoplasmic membrane and the next layer. Microfilaments are present in the submembranous region, the nature of which is described below.

The surface coat, or glycocalyx, is thicker on platelets than on most other cells (~14–20 nm). It consists of glycolipids, membrane glycoproteins, proteins, mucopolysaccharides, and adsorbed plasma proteins, including coagulation factor V (F-V), VWF, and fibrinogen. The glycocalyx is responsible for the platelet surface’s negative charge and is found on the surface membrane of the interior channels. Some surface proteins are receptors for substances that cause **platelet activation**.

The cytoplasmic membrane has a typical trilaminar structure of a bilayer of phospholipid and embedded integral proteins. It functions to maintain cytoplasmic integrity and to mediate interactions between platelets and the vasculature and plasma proteins. The membrane is the former demarcation membrane of the parent megakaryocyte. The surface membrane of platelets invaginates to give rise to a system of channels, the *surface-connected open canalicular system (OCS)*.

An asymmetrical arrangement of the phospholipids is an important factor in the function of platelets. Phosphatidylcholine (PC) and sphingomyelin (SM), which are neutral in charge, are concentrated on the outer half while negatively charged phospholipids (phosphatidylserine [PS], phosphatidylinositol [PI], and phosphatidylethanolamine [PE]) predominate on the inner half of the bilayer.² The phospholipid

■ **FIGURE 8** Diagram of platelet ultrastructure. (Modified, with permission, from Thompson AR, Harker LA. *Manual of Hemostasis and Thrombosis*, 3rd ed. Philadelphia: F.A. Davis; 1982.)

asymmetry is maintained in resting platelets by an ATP-dependent amino phospholipid translocase that actively pumps PE and PS from the outer to the inner leaflet.¹⁸ The negatively charged phospholipids accelerate several steps in the plasma protein coagulation sequence. The placement of these phospholipids on the platelet membrane's inner leaflet separates them from the plasma coagulation proteins and prevents inappropriate coagulation. However, during platelet activation, these phospholipids become exposed on the platelet surface, facilitating their interactions with plasma procoagulant proteins.

The cytoplasmic membrane contains integral proteins that are receptors for stimuli involved in platelet function. Approximately 30 proteins have been identified as glycoproteins, and a nomenclature system has been developed using GP for glycoprotein and a Roman numeral from I to IX according to electrophoretic migration by decreasing molecular weight. Glycoproteins Ib, IIb, IIIa, and IX play a major role in platelet function and pathophysiology.

Glycoprotein Ib (GPIb) is the major platelet receptor for VWF (Figure 9a■). It is noncovalently associated with GPIX and GPV in the membrane (in a ratio of 2:2:1). The function of GPV is not known, and no clinical bleeding problems are associated with its absence. GPV is not required for either membrane expression of the GPIb/IX complex or for interaction between GPIb/IX and VWF. The function of GPIX is also unknown, but it is required for efficient surface expression of GPIb. Rare bleeding disorders are associated with abnormalities of GPIb and with GPIX. The complex (also known as CD42) is referred to in this text as *GPIb/IX*.

Glycoprotein Ib consists of two chains, α and β . The GPIb α chain is larger and contains the binding sites for

VWF, thrombin, and ristocetin (used in the platelet aggregation test). The binding sites are located on the major extracellular portion of GPIb called *glycocalicin*. The glycocalicin portion of the chain extends from the platelet surface and can be cleaved by proteolytic enzymes. Plasma levels of glycocalicin correlate with platelet production and can be used to differentiate thrombocytopenia due to decreased platelet production (low plasma glycocalicin) from that resulting from increased platelet destruction (elevated glycocalicin).^{19,20} The remainder of GPIb α is associated with the GPIb β chain and spans the phospholipid bilayer. On the cytoplasmic side, both the α and the β portions are associated with actin-binding protein. Each platelet contains approximately 25,000 GPIb/IX complexes.¹⁷ GPIb/IX functions in the platelet adhesion process (as explained later).

Glycoproteins IIb and IIIa associate in the membrane, forming a complex (**GPIIb/IIIa**), which is the major plasma membrane receptor for fibrinogen (Figure 9b■). The GPIIb/IIIa complex also binds other subendothelial adhesive proteins such as VWF, thrombospondin, vitronectin, and fibronectin. Each platelet has approximately 80,000–100,000 copies of this receptor on its external membrane, and another 30,000 copies are present within platelets on the internal membranes of the α -granules, dense bodies, and OCS.²¹ These internal receptors join the plasma membrane when platelets are activated and undergo secretion.¹⁸

Glycoprotein IIb, the larger of the two subunits, is a two-chain protein. The α chain is embedded in the phospholipid bilayer, and the β chain protrudes from the platelet surface. Part of the β chain carries the HPA-3 (formerly Bak^d) platelet

TABLE 5

Platelet Ultrastructure and Functions

Zone and Component	Function/Role
Peripheral zone	Adhesion and aggregation
Glycocalyx	
Proteins, glycoproteins, mucopolysaccharides	
Phospholipid bilayer	
Phospholipids	Asymmetric arrangement; source of arachidonic acid
Integral proteins	
Glycoproteins Ib/IX, IIb/IIIa	Adhesion and aggregation
Enzymes	Activation
Structural zone	Structure and support
Microtubules (tubulin)	
Cytoskeletal network	
Microfilaments (Actin)	
Intermediate filaments (filamin/actin-binding protein, talin, vimetin)	
Organelle zone	Secretion and storage
Granules	
Dense bodies	Nonprotein mediators (ADP, ATP, serotonin)
Alpha granules	Protein mediators

Glycogen	
Membrane systems	Secretion and storage
Open canalicular system	Secretion of granule contents
Dense tubular system	Storage of calcium

alloantigen. Glycoprotein IIIa is a single chain polypeptide and is associated with the GPIIb portion that lies within the phospholipid bilayer. The small surface portion of GPIIIa contains the HPA-1 (formerly PI^{A1}) alloantigen. The cytoplasmic tails of the two proteins are associated with actin in the platelet cytoskeleton. The GPIIb/IIIa complex is a latent receptor “hidden” in resting platelets and has low affinity for fibrinogen binding. When agonists activate platelets, the GPIIb/IIIa complex is converted to a high-affinity ligand-binding conformation. The high-affinity configuration is required for platelet aggregation (described later). GPIIb/IIIa is an $\alpha_{IIb}\beta_3$ integrin (CD41/CD61). The GPIIb/IIIa receptors appear to be responsible for the uptake of fibrinogen from plasma into megakaryocytes and platelets.

FIGURE 9 Structure of platelet membrane glycoproteins. **a.** Glycoprotein Ib is composed of an alpha and a beta chain. Both span the phospholipid bilayer. The alpha chain is larger and contains the binding sites for thrombin, ristocetin, and VWF. Actin-binding protein is attached to the cytoplasmic side. Glycoprotein IX and glycoprotein V associate with glycoprotein Ib in the platelet membrane. **b.** Glycoproteins IIb and IIIa associate in a complex after platelet activation. Binding sites for fibrinogen as well as platelet-specific antigens are present. Cytoplasmic portions of each component have binding areas for actin.

Checkpoint! 5

If a patient inherited a mutation of the gene for glycoprotein IIIa that resulted in its absence, what two platelet antigens would be decreased or absent?

Structural Zone

The structural zone consists of *microtubules* and a submembranous and cytoplasmic network of *microfilaments* and *intermediate filaments*. The structural zone’s functions are to

support the plasma membrane, stabilize the resting discoid shape of the platelet, and provide a means of shape change when the platelet is activated.

Microtubules (MT) are composed of the protein tubulin. Each is a bundle of 8 to 24 hollow tubules (25 nm diameter) located beneath the submembranous region of microfilaments and completely surrounds the circumference of the resting platelet.

The submembranous protein network consists of actin microfilaments, actin-binding protein, and several other structural proteins (intermediate filaments) that form a cytoskeleton supporting the plasma membrane (Web Figure 1 ■). Actin, the most abundant protein in platelets, accounts for 15–20% of the total protein content. It has two forms, monomeric G (globular) actin and F (filamentous) actin. The F form consists of several polymerized G molecules. Approximately 30–40% of the actin in a resting platelet is in the F form with the remainder in the G form. Actin-binding protein is attached to the cytoplasmic side of the GPIb/IX complex and anchors actin to the membrane.¹⁹ Upon platelet activation, the submembranous microfilaments and intermediate filaments reorganize, polymerize, and form the characteristic filopodia (pseudopods) seen in activated platelets.

Actin also is part of a network of structural support proteins dispersed throughout the cytoplasm. In the cytoplasm, actin is associated with myosin and several other contractile proteins similar to those of smooth muscle. Unlike smooth muscle, in which the ratio of actin:myosin is about 7:1, the platelet ratio is ~100:1. This network also undergoes significant changes in structure and location when platelets become activated, resulting in the central contraction of MT and relocation of organelles during platelet activation and shape change.

Organelle Zone

The organelle zone is beneath the MT layer and consists of mitochondria, glycogen particles (which support the platelet's metabolic activities), and four types of granules dispersed within the cytoplasm. The granules are *dense bodies*, *alpha granules*, *lysosomal granules*, and *peroxisomes*; they serve as storage sites for proteins and other substances essential for platelet function. Generally, mature platelets have very little ribosomes or rough endoplasmic reticulum.

Platelets contain 3–8 electron-dense organelles, 20–30 nm in diameter. These **dense bodies (DB)** are so named because they appear denser in electron microscope preparations than the other types of granules due to their high Ca^{2+} content. These bodies contain mediators of platelet function and hemostasis that are not proteins: ADP, ATP, and other nucleotides as well as phosphate compounds, calcium ions, and serotonin (Table 6 🔄). The ADP in the dense bodies is known as the *nonmetabolic*, or *storage*, *pool* of ADP to distinguish it from metabolic ADP found in the cytoplasm. The ratio of ADP:ATP in the DB is higher than that found in the cytoplasm (3:2 vs 1:8 in the cytoplasm). The metabolic pool

TABLE 6

Composition and Functions of Platelet Dense Body Contents

Component	Role
ADP (nonmetabolic)	Agonist for platelets
ATP (nonmetabolic)	Agonist for cells other than platelets; activates Ca^{2+} influx channel in outer membrane
Other nucleotides	Unknown
Inorganic phosphates	Unknown
Calcium	Platelet activation
Serotonin	Vasoconstriction; platelet agonist

provides energy for normal platelet metabolism, whereas the storage pool is important in the platelet aggregation reactions. Serotonin is taken up from the plasma and stored in the DB.

Alpha granules (αG) are the most numerous of the four types of granules, numbering ~50–80 per platelet. They contain two major groups of proteins (Table 7 🔄): One group consists of proteins similar to hemostatic proteins found in the plasma. Some, such as VWF, are synthesized in the megakaryocyte as the platelets develop.²² Others, such as fibrinogen, immunoglobulins, and albumin, are absorbed from the plasma by megakaryocytes and packaged in the αG during thrombopoiesis.¹⁰ The second group includes proteins with a variety of functions. Some are found exclusively in platelets (e.g., platelet factor 4 and β -thromboglobulin). Some proteins are growth factors that affect the growth and gene expression of smooth muscle cells in the blood vessel wall (e.g., platelet derived growth factor). Plasminogen activator inhibitor is present in platelet αG in addition to being synthesized by endothelial cells. Platelet αG also contain a number of adhesive proteins including fibronectin, VWF, vitronectin, and thrombospondin.

Lysosomal granules contain several hydrolytic enzymes and are similar to the lysosomes found in other cells. The peroxisomes are thought to be involved in lipid metabolism.¹⁸

Platelets contain all of the necessary enzymes for the glycolytic and tricarboxylic acid cycles and for glycogen synthesis and degradation. About 50% of the platelet's energy (ATP) is derived from the glycolytic pathway, and about 50% is derived from the tricarboxylic acid cycle.

Membrane Systems

The fourth structural zone of the platelet is composed of two systems of membranes. One, the **surface-connected open canalicular system (SCCS or OCS)** is an elaborate, interconnected series of conduits leading from the platelet surface to its interior. This OCS is derived from the demarcation membrane system of the parent megakaryocyte and serves several functions in platelets. It provides for both the entry of external substances into the interior of platelets and a

TABLE 7

Composition and Functions of Platelet Alpha Granule Proteins

Protein	Role
Group I—hemostatic proteins	
Fibrinogen	Platelet aggregation Conversion to fibrin
F-V, F-XI	Fibrin formation
Protein S, tissue factor pathway inhibitor, α_1 protease inhibitor, C1 esterase inhibitor	Inhibition of coagulation
von Willebrand factor	Platelet adhesion Carries F-VIII in plasma
Plasminogen	Conversion to plasmin (fibrinolysis)
PAI-1, α_2 -PI	Fibrinolytic inhibitors
Group II—nonhemostatic proteins	
Platelet-specific	
β -thromboglobulin	Chemoattractant for neutrophils, fibroblasts Neutralizes heparin
Platelet factor 4	Neutralizes heparin Weak neutrophil and fibroblast chemoattractant
Platelet-derived growth factor (PDGF)	Promotes regrowth of smooth muscle cells (wound repair)
Transforming growth factor—beta (TGF_β), epidermal growth factor (EGF), insulin-like growth factor (IGF)	Mitogenic factors
Vascular endothelial growth factor (VEGF)	Angiogenic factor
Not platelet specific	
Albumin	Unknown
Thrombospondin, fibronectin, vitronectin	Adhesive glycoproteins

route for the release of granule contents to the outside. The OCS also represents an extensive internal store of membranes. Activated platelets undergoing shape change, filopodia formation and spreading require a dramatic increase in surface membrane compared to resting platelets, which OCS membranes provide. Because the OCS membranes contain many of the same glycoproteins as the surface membrane, it also serves as a source for additional plasma membrane glycoproteins during platelet activation.¹⁸

A second type of membrane is the **dense tubular system (DTS)**, which originates from the residual endoplasmic reticulum of the megakaryocyte. The channels of the DTS do not connect with the surface of the platelet. The DTS is a

storage site for ionized calcium within platelets analogous to the sarcoplasmic reticulum of muscle cells and releases Ca^{2+} when platelets are activated.²³ The concentration of calcium ions within the platelet cytoplasm is important in regulating platelet metabolism and activation. The DTS is also a major site of prostaglandin and thromboxane synthesis.²⁴

PLATELET FUNCTION

Platelet Roles in Hemostasis

Platelets are involved in several aspects of hemostasis (Table 8). One role appears to be performing passive surveillance of the blood vessel endothelial lining for gaps and breaks. Although the exact nature of this role is somewhat controversial, it has been shown that platelets maintain the vessels' continuity or integrity by filling in the small gaps caused by the separation of endothelial cells. Platelets attach to the underlying exposed collagen fibers of the subendothelium and prevent blood from escaping. A decrease in the number of platelets in the peripheral blood results in blood leaking through these gaps into the tissues.

When injury occurs and an actual break in the continuity of the lining of the vessels occurs, the platelets react by forming the primary hemostatic plug. By sticking first to exposed collagen and other components of the subendothelium and then to each other, the platelets form a mass that mechanically fills openings in the vessels and limits the loss of blood from the injury site.

Following platelet plug formation, membrane phospholipids of the aggregated platelets provide a reaction surface for the proteins that make fibrin. Fibrin stabilizes the initial platelet plug, and the entire mass of fibrin and platelets constitutes the secondary hemostatic plug.

As a fourth role, platelet-derived growth factors stimulate smooth muscle cells and fibroblasts to divide and replace the cells that were damaged, thus promoting healing of the injured tissues.

The steps and mechanisms that result in primary and secondary hemostatic plug formation are described next.

Formation of the Primary Hemostatic Plug

Platelets circulating in blood vessels do not interact with other platelets or other cell types. Circulating platelets are disc-shaped and inert in the environment of normal endothelium (Figure 10a). Injury to the blood vessels causes a

TABLE 8

Platelet Roles in Hemostasis

change in the normal environment, and in response, activate the platelets. The primary hemostatic plug is the result of the transformation of the platelets from an inactive to an active state. The formation of a platelet plug requires several platelet activation events, including adhesion, contraction or shape change, secretion, and aggregation (Figure 11 ■).

Platelet Adhesion The major function of platelets is to seal openings in the vascular network. The initial stimulus for platelet activation and deposition is exposure of subendothelial components of the vessel walls that are normally hidden from circulating platelets. The subendothelium contains a large number of adhesive proteins, and the platelet has receptors for many of them. The first step in primary hemostatic plug formation, **platelet adhesion**, is the attachment of platelets to collagen and other components of the subendothelium. Platelets contain two collagen receptors: GPIIb/IIIa and GPVI, which mediate direct collagen binding at low shear rates. Platelet adhesion to collagen at high shear

■ **FIGURE 11** Diagram of platelets forming the primary hemostatic plug. Tissue injury causes platelets to adhere to subendothelial collagen. Shape change, secretion of granule contents, and aggregation follow. Additional platelets become activated by the secreted substances and clump together, eventually forming a mechanical barrier that halts the flow of blood from the wound.

rates, however, requires the presence of VWF and the platelet VWF receptor, GPIb/IX.

VWF, which is synthesized by endothelial cells and megakaryocytes, is both stored in intracellular granules (Weibel Palade bodies in endothelial cells and α G in platelets) and secreted into the plasma. It is deposited in the subendothelium, where it is bound to collagen (Web Figure 2■). VWF is a multimeric protein made up of a series of identical subunits, each containing binding sites for both GPIb/IX on the platelet surface and collagen in the subendothelium. Circulating VWF will not bind to GPIb/IX. However, high shear rates cause conformational changes in immobilized VWF and/or GPIb, and platelets readily adhere to VWF immobilized on collagen via their GPIb/IX receptors.^{25,26} VWF thus becomes a “bridge” connecting the platelet to the collagen fibers (Web Figure 2).

While the tissues have numerous other adhesion molecules and the platelet surface has many other receptors, their contributions to platelet adhesion *in vivo* remain uncertain. Platelets preferentially bind to collagen via VWF under conditions of high shear rates. The GPIb/IX receptor is functionally available in the resting platelet, and binding does not require platelet activation or Ca^{2+} . Once its ligand becomes available, adhesion occurs; it is a passive, non energy-requiring process and is potentially reversible in its early stages. Many platelets adhere in a similar manner until a monolayer of platelets covers the exposed surface of the subendothelium (Figure 10d■).

Much of what is known about this phase of platelet function has been learned from studying patients with two diseases in which platelets fail to adhere properly: Bernard-Soulier disease and von Willebrand disease (VWD). Patients with Bernard-Soulier disease have mutations in one of the genes of the GPIb/IX complex that cause either decreased

amounts of the receptor complex on the platelet surface or abnormal function of the complex. Patients with VWD have mutations in the gene encoding VWF.

✓ Checkpoint! 6

If a patient with Bernard-Soulier disease or VWD cut a finger, would you expect bleeding to stop as fast as the bleeding stops when you cut your own finger? Why or why not?

Platelet Activation Adhesion of platelets to subendothelial components via VWF triggers a series of morphologic and functional changes known as *platelet activation*. Activation is a complex process that includes changes in metabolic biochemistry, platelet morphology (shape), surface receptors, and membrane phospholipid orientation. Key outcomes of activation are the generation of active GPIIb/IIIa receptors for fibrinogen binding, the secretion of the contents of the platelet granules into the surrounding tissue, and the formation of platelet aggregates. Only activated platelets are able to proceed with the subsequent steps in the formation of the primary hemostatic plug. Once activated, the platelet response becomes self-perpetuating and irreversible. Through strict control mechanisms, platelet activation remains localized to the injured area. The cellular changes associated with activation are described first, followed by the changes in platelet biochemistry. Activation of platelets is summarized schematically in Figure 12■ and in Web additional files.

Platelet Agonists A number of substances have been shown to stimulate platelets and to activate them. An agent

■ **FIGURE 12** Platelet shape change after stimulation by an agonist. Pseudopods develop on the platelet surface and contain a network of actin and myosin; the microtubule circumferential ring contracts; the membrane phospholipids are activated; glycoprotein IIb/IIIa receptors appear; internal biochemical changes occur; and granule secretion follows.

that induces platelet activation is called an **agonist**. Each agonist binds to the platelet surface at its specific platelet receptor. A signal is transmitted (transduced) internally by the receptor, and a series of reactions in the interior of the platelet leads to subsequent platelet responses. The signal transduction mechanisms in the platelet are similar to those of other cells.

Some agonists (Table 9 ) are generated by the platelets themselves and some by other cells or molecules at the site of injury. Some agonists are normally present within cells and are released when the cells are injured or activated; others are synthesized de novo with activation. Agonists are often grouped as “strong” or “weak.” Strong agonists (e.g., collagen, thrombin) can activate the full range of platelet functions themselves (shape change, secretion, aggregation). Weak agonists initiate platelet activation but require platelet synthesis and release of endogenous TXA₂ (i.e., activation of the platelet cyclooxygenase pathway) to drive full activation through secretion and aggregation. Thrombin is probably the most potent activator of platelets in vivo.¹⁷

Platelet Shape Change Activation of platelets by a number of agonists is accompanied by a change in the platelet’s shape from flattened disc-shaped cells to spiny spheres with long projections from the surface called *pseudopods* or *filopodia* (Figure 10b). Shape change involves reorganization of proteins in the structural zone including the MT, submembranous cytoskeletal proteins, and actin and myosin cytoplasmic filaments. The MTs contract centrally within the activated platelet, concentrating the platelet organelles in the center of the cell (causing the change to a spherical rather than flattened cell). This brings the platelet granules into closer proximity to the OCS, facilitating secretion. The protrusive force for developing filopodia is due to actin polymerization and is an energy-requiring process. After platelets adhere to the subendothelium, they undergo variable degrees of “spreading,” resulting in the development of broad lamellipodia rather than spikelike filopodia.²⁷ As a result of the shape change, each platelet has

a larger membrane surface area for biochemical reactions and a larger area for contact with the injured tissue and other platelets.

The cytoskeletal rearrangements, resulting in shape change and spreading, alter membrane glycoproteins. GPIIb/IX receptors are moved from the platelet surface to the OCS and internalized while active GPIIb/IIIa receptors increase in density on the platelet surface as they are mobilized from αG and OCS membranes.²⁸ The result is to convert the activated platelet from an “adhesive” state to an “aggregation” state.

Shape change leads to succeeding responses if the stimulus from the agonists is strong enough. In the absence of a sufficiently strong stimulus, the platelet returns to its original discoid shape.

Platelet Secretion (Release) Following the centralization of organelles by the contractile process responsible for shape change, platelets begin to discharge granule contents into the surrounding area, a process known as **platelet secretion** or **platelet release reaction**. Secretion is an energy-dependent process requiring ATP. The open canalicular system fuses with membranes of granules that have been centralized deep within the platelets interior during platelet shape change, and the contents are then extruded through the OCS to the exterior of the platelet. Alternatively, secretion can occur by direct fusion with the plasma membrane.¹⁸

Secretion provides a positive feedback mechanism in platelet activation. Some of the substances released from the platelet granules (e.g., serotonin, ADP) function as agonists that stimulate membrane receptors on additional platelets. The binding of secreted ligands to platelet receptors repeats itself, resulting in the recruitment of additional layers of platelets and ultimately the formation of a platelet plug. These positive feedback mechanisms ensure an adequate hemostatic response.

Roles of the Granule Contents The DB release their contents into the surrounding tissue (Table 6). The DB release of ADP is considered to be of primary importance because ADP functions as an agonist, producing a positive feedback mechanism in the continued stimulation and recruitment of additional platelets. The receptors for ADP are designated P2Y₁, P2Y₁₂, and P2X1 receptors.¹⁸ Stimulation by ADP results in the typical response of increased cytoplasmic calcium, more platelet release, and the appearance of active fibrinogen receptors (GPIIb/IIIa).

DB release calcium extracellularly with the ADP. This calcium is nonmetabolic and is not involved in the internal stimulation processes. The extruded calcium is believed to provide a high concentration outside the platelets necessary for fibrinogen attachment and for other enzymatic reactions that take place on the platelet exterior surface. Other components and their functions are listed in Table 6.

The αG contain a wide variety of proteins (see Table 7 for a partial list of αG components). Some are specific for the

platelet, and others are similar to hemostatic proteins found in the plasma. The platelet-specific proteins include platelet factor 4 (PF4) and β -thromboglobulin (β TG). Both have heparin-neutralizing activity, although β TG does not bind heparin as avidly as PF4. Heparin is an anticoagulant used to treat patients who are hypercoagulable (have increased tendency to form clots) or who are at increased risk of thrombosis. PF4 performs many other actions including chemotactic activity for neutrophils, monocytes, and fibroblasts. β TG, which is actually a family of proteins, also is a chemoattractant for fibroblasts and can promote wound healing.

Thrombospondin constitutes about 20% of the protein released from the platelet α G. It is also synthesized by other cells including endothelial cells and is found in the extracellular connective tissue. It may function to stabilize the aggregated platelets.²¹

Platelets contain a number of growth factors, including PDGF, TGF β , EGF, and IGF. All function as mitogens and are thought to contribute to healing injured tissue.¹⁸

F-V, VWF, and fibrinogen are proteins in the α G that are similar to hemostatic proteins of the plasma. F-V can function as a receptor on the platelet surface for hemostatic proteins (F-Xa and prothrombin, ∞ Chapter 30) and is a cofactor in the process of fibrin formation. Platelets contain \sim 20% of the F-V in whole blood,²⁹ which, like fibrinogen, appears to be taken up from plasma.³⁰ The functions of VWF and fibrinogen have been discussed previously. Plasminogen activator inhibitor (PAI-1) and α_2 -antiplasmin, when released from activated platelets, appear to protect newly formed clots from lysis. When released from the platelet granules, these hemostatic proteins can serve as an additional source of these components for secondary hemostasis.

Platelet Aggregation During platelet adhesion, VWF binding to GPIb/IX triggers intracellular signaling that results in activation of GPIIb/IIIa in the platelet membrane, which then binds soluble fibrinogen. The active GPIIb/IIIa complex appears soon after platelet activation with any agonist. Resting platelets do not express functional GPIIb/IIIa complex and are unable to bind fibrinogen. This prevents unactivated platelets from aggregating as they circulate in the plasma. With the development of the high-affinity, ligand-binding form of GPIIb/IIIa, the platelet is functionally able to undergo platelet aggregation.¹⁸

Platelet aggregation is the attachment of platelets to one another (Figure 10c). Newly arriving platelets flowing into the area become activated by contact with agonists such as ADP and TXA₂ (released by the initial adherent and activated platelets), products from the damaged tissue and endothelial cells, and thrombin (a procoagulant enzyme generated by tissue factor/F-VIIa). With activation, the new platelets undergo shape change and exposure of their active GPIIb/IIIa sites. The fibrinogen bound to activated platelets serves as a bridge, cross-linking GPIIb/IIIa molecules on two adjacent platelets.

Fibrinogen is able to link two platelets because of its molecular structure. Briefly, it is a dimeric molecule composed of two each of three polypeptide chains: A α_2 ,B β_2 , γ_2 . One fibrinogen molecule attaches to the GPIIb/IIIa receptors on two adjacent platelets via binding sites at the carboxy terminal end of each of the γ chains³¹ (Figure 13 ■). The α chains also contain sequences for platelet binding. Approximately 40,000–50,000 molecules of fibrinogen are bound to each activated platelet. Fibrinogen binding is reversible for a time, but after about 10 to 30 minutes, it becomes irreversible. Ca²⁺ is needed for platelet aggregation to occur whereas platelet adhesion does not require Ca²⁺.

Fibrinogen and Ca²⁺ are supplied by both the plasma and internal platelet storage sites (α G, DB, DTS), which provide high concentrations of both constituents in the injured area.

The importance of GPIIb/IIIa receptors in platelet aggregation was demonstrated by studying patients with Glanzmann thrombasthenia. Persons with this rare disease lack functional GPIIb/IIIa receptors, and their platelets do not aggregate in response to various agonists in platelet aggregation tests. Patients who have decreased levels of fibrinogen also have abnormal platelet aggregation. Other adhesive proteins such as VWF, thrombospondin, and fibronectin also bind to the GPIIb/IIIa receptor, but their roles in platelet aggregation in vivo are unclear.

Within in vitro test systems, aggregation occurs in two phases, primary and secondary aggregation. During primary

■ **FIGURE 13** Platelet aggregation. Agonist stimulation in the presence of Ca²⁺ causes high-affinity fibrinogen receptors, activated glycoprotein IIb/IIIa, to appear on the platelet surface. Fibrinogen binds horizontally to two platelets by peptide sequences at the terminal end of its gamma and alpha chains in the D domains, one gamma chain to GPIIb/IIIa receptors on each platelet. Fibrinogen thus becomes a bridge between the two platelets.

aggregation, platelets adhere loosely to one another. If the stimulus by agonists is weak, primary aggregation is reversible. Secondary aggregation follows and results in irreversible platelet aggregation. It begins as the platelets start to release their own ADP and other granule contents and to synthesize and release TXA₂ (to be described). The released substances act as additional agonists, which supplement the platelet stimulation. If platelets are unable to release ADP and/or to synthesize TXA₂, secondary aggregation does not occur, and the platelets disaggregate. Generally, the *in vivo* result in such situations increases the time to stop bleeding from a wound.

✓ Checkpoint! 7

Your finger is still bleeding at this point, but the platelets are aggregating to form the primary hemostatic plug. Let's review the key events:

- To what do platelets first adhere?
- What bridge and what platelet membrane receptor are needed for platelet adhesion?
- What bridge and what platelet membrane receptor are needed for platelets to attach to one another?
- What is the attachment of platelets to one another called?

Biochemistry of Platelet Activation Platelets become activated after agonists bind to receptors on the platelet surface, initiating signaling events within the platelets. These signaling events eventually lead to the reorganization of the platelet cytoskeleton, granule secretion, and aggregation.

G Proteins Actions of most of the familiar agonists (collagen, ADP, thrombin, epinephrine, TXA₂, and arachidonic acid) and their receptors are linked with guanine nucleotide-binding (G) proteins on the inner leaflet of the phospholipid membrane. G proteins are molecular switches, which are inactive when GDP is bound, but active after GTP is bound. When the platelet adheres to collagen, G proteins are acti-

vated and, in turn, activate enzymes in the platelet membrane and cytoplasm. Some activated enzymes cleave specific membrane phospholipids. The resulting lipid products are “second messengers” that transmit the signal to interior parts of the cells.

Phospholipase C and the Phosphoinositide Pathway

One second messenger pathway important in platelet activation involves activation of the enzyme phospholipase C (PLC) (Figure 14 ■). Activated G proteins activate PLC, which cleaves phosphatidyl inositol bis-phosphate (PIP₂) into IP₃ and DAG. PIP₂ is the doubly phosphorylated product of the membrane lipid phosphatidyl inositol (PI) produced by PI kinase. The cleavage products released from PIP₂ by PLC function to mobilize calcium ions from storage sites in the DTS (IP₃) and to activate a kinase enzyme, protein kinase C/PKC (DAG). Activated PKC in turn phosphorylates proteins, contributing to granule secretion and fibrinogen receptor exposure.¹⁸

Role of Ca²⁺ Platelet activation is accompanied by an increase in the cytosolic free Ca²⁺ concentration. Ca²⁺ serve as intracellular second messengers and affect enzyme activity and protein-protein interactions. Resting platelets have very low levels of ionic calcium in the cytoplasm (Figure 15 ■). Many cellular enzyme systems that are inactive at the Ca²⁺ concentration in resting platelets become activated by the increase in Ca²⁺ that occurs with platelet activation. These enzymes include phospholipase A₂ (PLA₂), phospholipase C (PLC), PI kinase, and myosin light chain kinase (MLCK), important in the assembly of the contractile mechanism responsible for platelet shape change. The increase in calcium ions is due to both the release from internal stores (by IP₃) and the influx from outside the cell. A direct relationship exists between the amount of cytoplasmic-free calcium and the extent of platelet stimulation.

Arachidonate Pathway Phospholipase A₂ is activated by the increase in cytoplasmic calcium and hydrolyzes arachidonic acid from the second carbon of the glycerol backbone of membrane phospholipids. **Arachidonic acid**

■ **FIGURE 14** Phospholipase C/phosphoinositide pathway. Activated G proteins activate PLC. Activated PLC cleaves PIP₂, releasing IP₃ and DAG. IP₃ in turn triggers release of Ca²⁺ from the DTS. DAG activates PKC, inducing granule secretion and activation of GP IIb/IIIa, the fibrinogen receptor. PLC = phospholipase C; PIP₂ = phosphatidyl bis-phosphate; IP₃ = inositol triphosphate; DAG = diacyl glycerol; DTS = dense tubular system; PKC = protein kinase C

■ **FIGURE 15** Ca^{2+} regulation in platelets. Resting platelets maintain low levels of cytoplasmic Ca^{2+} via active uptake by the DTS and active extrusion, probably via a Ca^{2+} pump. These mechanisms counter a passive diffusion of Ca^{2+} into the platelet along a concentration gradient. With activation, platelets increase intracellular cytoplasmic Ca^{2+} due to release from the DTS (by IP_3) and increase Ca^{2+} influx (probably mediated via ATP). DTS = dense tubular system

(AA) is an unsaturated fatty acid and once released from the membrane phospholipids serves as a precursor of a variety of regulatory substances including prostaglandins and leukotrienes. In the platelet, thromboxane A_2 (TXA_2) is synthesized from AA by the enzymes cyclo-oxygenase and thromboxane synthase. In endothelial cells, prostacyclin (PGI_2) is synthesized from AA by cyclo-oxygenase and prostacyclin synthase (Figure 16 ■).

TXA_2 is a potent platelet agonist and can stimulate platelet activation and secretion. Platelet activation by “weak” agonists does not produce platelet secretion if TXA_2 synthesis is blocked, which seriously impairs subsequent steps in platelet function. Aspirin (acetyl-salicylic acid) irreversibly inhibits cyclooxygenase and prevents affected platelets from synthesizing TXA_2 . Because aspirin’s inhibition of cyclooxygenase is irreversible, the effect lasts for the lifetime of the platelets exposed. TXA_2 also is released from activated platelets and enhances vasoconstriction and functions as a platelet agonist, perpetuating the activation process. TXA_2 is a labile compound quickly converted into an inert form, TXB_2 , shortly after its synthesis.

Cyclic AMP (cAMP) Pathway cAMP is an important negative regulator of platelet activation (Figure 17 ■). It inhibits shape change, platelet secretion, and integrin activation (conversion of GPIIb/IIIa to an active form). The

platelet membrane enzyme adenylyl cyclase is activated when PGI_2 from endothelial cells contacts platelet membrane receptors. Activated adenylyl cyclase produces cAMP within the platelet cytoplasm, resulting in the activation of protein kinase enzymes that, in turn, inhibit platelet aggregation. This is one way to limit and localize the formation of the primary hemostatic plug.¹⁸ ADP functions as a platelet agonist by inhibiting adenylyl cyclase, thus lowering cAMP levels and permitting platelet activation. The platelet inhibitory drug, dipyridamole, inhibits phosphodiesterase, the enzyme responsible for the degradation of cAMP to AMP, thus stabilizing platelet cAMP levels and inhibiting platelet activation.

Platelet activation and biochemical reactions leading to aggregation are summarized in Figures 16 and 18 ■.

Primary Hemostatic Plug The platelets eventually form a barrier (the primary hemostatic plug) that seals the injury and prevents further blood loss. When the primary hemostatic plug is formed, the bleeding stops. The time for bleeding to cease depends on the depth of the injury and the size of the blood vessel involved. Superficial wounds in which only capillaries and small vessels are affected usually stop bleeding within 10 minutes.

✓ Checkpoint! 8

Your finger has now stopped bleeding. Outline the steps of primary hemostasis that have occurred.

📖 CASE STUDY (continued from earlier in this chapter)

- The physician explained to Michael that the reddish purple spots on his legs and ankles were tiny pinpoint hemorrhages into the skin. Explain the relationship of these hemorrhages to the platelet count.

Platelets and Secondary Hemostasis

The final aspect of platelet activation involves the changes in the platelet membrane that allow platelets to function in secondary hemostasis. Activated platelets accelerate thrombin formation, a function known as **platelet procoagulant activity**. Fibrin-forming proteins (coagulation factors) bind to the surface of activated platelets by binding either to specific receptors on platelets or nonspecifically to negatively charged phospholipids.¹⁸ The resulting platelet-coagulation factor interactions result in formation of the secondary hemostatic plug.

The primary platelet plug is relatively unstable and is easily dislodged. During secondary hemostasis, fibrin forms amid and around the aggregated platelets. Platelets enhance the fibrin-forming processes by mechanisms explained in ∞ Chapter 30. The proteins that interact enzymatically to

■ **FIGURE 16** Biochemical pathways of TXA₂ formation in the platelet. Stimulation of platelet membranes (both intracellular granule and cytoplasmic membranes) by agonists (e.g., collagen, thrombin, arachidonic acid) results in liberation of arachidonic acid from membrane phospholipids. Cyclo-oxygenase incorporates two molecules of oxygen-forming prostaglandin PGG₂ (PGH₂ in the reduced form). Thromboxane synthetase converts PGG₂ to TXA₂ and TXA₂ is spontaneously converted to inactive thromboxane B₂. Alternatively, PGG₂ can be converted to (PGI₂) in endothelial cells, a powerful platelet inhibitor. TXA₂ = thromboxane A₂; PGI₂ = prostacyclin

form fibrin must be assembled on a lipid surface where the reactions take place. The membrane phospholipids of activated platelets are the primary source of this lipid surface.

Fibrin-forming proteins do not bind to resting platelet surfaces in the circulation. In resting platelets, the negatively

charged phospholipids are almost exclusively found in the inner half of the membrane bilayer. During the activation of platelets, the membrane phospholipids flip-flop, and the negatively charged phospholipids move to the outer leaflet, perhaps via a Ca²⁺-activated “scramblase” enzyme that reverses the asymmetric distribution of phospholipids.¹⁸ This phospholipid rearrangement provides the phospholipid surface allowing coagulation factors to bind, become activated, and initiate fibrin formation. Platelets can assemble both the Xase and prothrombinase complexes. *Platelet factor 3* activity is an older name for this platelet procoagulant activity. The fibrin-platelet plug is the secondary hemostatic plug.

The entire platelet-fibrin mass then contracts to a firmer, more cohesive clot. This contraction is called **clot retraction**. An adequate number of functional platelets are needed for clot retraction to occur, a process that can be observed in a test tube of blood when no anticoagulant is added. After blood is placed into the test tube, the formation of fibrin results in a network or mesh of fibrin strands that extends throughout, trapping essentially all of the blood cells with some serum. The mass of fibrin and trapped cells

■ **FIGURE 17** Role of cAMP in platelets. cAMP is a negative regulator of platelet function, inhibiting various steps of platelet activation. Adenyl cyclase converts ATP or ADP to cAMP. Subsequently, phosphodiesterase breaks cAMP down into inactive AMP. PGI₂, a platelet-activation antagonist, activates adenyl cyclase, while ADP, a potent platelet agonist, inhibits adenyl cyclase. Dipyridamole, a platelet inhibitory drug, functions by inhibiting phosphodiesterase, thereby stabilizing cAMP and preventing platelet activation. cAMP = cyclic AMP; → = stimulation; —| = inhibition.

■ **FIGURE 18** Schematic diagram showing platelet biochemical changes after activation. An agonist (A) binds to a receptor (R) on the platelet. The GPIIb/IIIa complex appears soon after platelet activation with an agonist. Gp on the inner part of the phospholipid membrane (linked with R) becomes activated which in turn activates PLC. PLC cleaves PIP₂ to form IP₃ and DAG. Subsequently, Ca²⁺ is mobilized into the cytoplasm from the DTS. Many enzymes are activated by the increase in Ca²⁺ including phospholipase A2. Arachidonic acid released from the membrane phospholipids is converted to thromboxane which stimulates platelet secretion. DAG activates PKC which contributes to granule secretion. Coagulation factors (e.g., Xa, Va) bind to the platelet surface leading to fibrin formation. Key: IIb, IIIa = GPIIb/IIIa receptor; FIB = fibrinogen; DAG = diacylglycerol; Gp = guanine nucleotide binding protein; IP₃ = inositol-3-phosphate; PLC = phospholipase C; PKC = protein kinase C; PIP₂ = phosphatidylinositol phosphate.

contracts over a period of 2–24 hours, extruding much of the serum from the fibrin mass.

Clot retraction is believed to occur by the association of adjacent platelet pseudopods with each other and the fibrin strands. Actin and other contractile proteins within the pseudopods cause the platelets to retract. A comparable phenomenon is believed to occur *in vivo*, consolidating the thrombus into a cohesive mass of platelets and fibrin that seals the wounded vessel and prevents further blood loss. Contraction can also decrease thrombolysis efficiency and enhance wound healing.³² The stabilized platelet-fibrin mass remains in place until fibroblast repair of the wound results in permanent healing, and fibrinolysis dissolves the mass.

Physiologic Controls of Platelet Activation

Several inhibitory mechanisms balance platelet activation and prevent excessive platelet deposition (Table 10). The platelet contacts with agonists are minimized due to the endothelial cell (EC) barrier. The flowing blood produces a dilutional effect, removing platelet agonists, loosely associated platelets, and coagulation proteins from the developing platelet aggregate. ECs produce NO and PGI₂, two potent inhibitors of platelet activation. ECs also have an ADPase enzyme that cleaves ATP and ADP to AMP, limiting the agonist effects of ADP. Physiologic controls that limit thrombin activity also limit platelet aggregation because thrombin is a potent platelet activator. Many agonists have short half-lives,

★ TABLE 10

Physiologic Controls of Platelet Activation

- Minimal platelet contact with agonists (endothelial cell barrier)
- Dilutional effect of flowing blood
- Limited platelet responsiveness to agonists (endothelial cell production of NO; PGI₂ → ↑ cAMP; ADPase; antithrombin)
- Limited duration of agonist receptor activity (short half-life of agonists)
- Maintenance of tight controls on cytosolic [Ca²⁺]
- Inability of “resting” GPIIb/IIIa to bind fibrinogen

limiting their effects, and platelets can become desensitized to stimulation by some agonists. Intraplatelet calcium levels are tightly controlled as is the availability of the active form of the platelet receptor GPIIb/IIIa.

 CASE STUDY (continued from earlier in this chapter)

4. What is the most likely cause of Michael's pancytopenia?
5. Why would the administration of growth factors such as erythropoietin (EPO) and TPO be considered in this case?

SUMMARY

After an injury, blood clots as the result of a series of complex biochemical reactions called *hemostasis*. Its purpose is to temporarily reconstruct continuity of injured vessels to minimize loss of blood. The components of hemostasis are found in the plasma and in the tissues that compose the blood vessel walls. All of the components are inert until the injury activates them.

Hemostasis occurs in phases called *primary hemostasis*, *secondary hemostasis*, and *fibrinolysis*. This chapter discussed the primary hemostasis phase during which the blood vessels and the platelets cooperatively form an aggregate of platelets that mechanically fills the openings in the injured blood vessels and stops bleeding from the wound site. The injured blood vessels contribute by constricting and secreting a variety of biochemical mediators that affect all of the subsequent hemostasis steps.

The roles of the platelets are to adhere to the injured areas of the blood vessel walls and to aggregate by attaching to one another and by secreting substances stored in their granules. The secreted substances help to attract and activate new platelets that are added to the aggregate and that help the growth of new tissue to permanently heal the wound. The surface of the aggregated platelets is required for the reactions of secondary hemostasis; it is discussed in the next chapter.

REVIEW QUESTIONS

LEVEL I

1. The definition of hemostasis is the: (Objective 1)
 - a. process of maintaining the body temperature
 - b. termination of bleeding following a traumatic injury
 - c. process of forming a hematoma
 - d. regulation of kidney function
2. Which of the following is the primary element that prevents blood from clotting inside blood vessels? (Objective 5)
 - a. fibrinogen
 - b. arteriole
 - c. endothelial cells
 - d. platelets
3. What bone marrow cell is the precursor of platelets? (Objective 7)
 - a. neutrophil
 - b. erythrocyte
 - c. endothelial
 - d. megakaryocyte
4. What is the action of the blood vessels in hemostasis immediately after an injury? (Objective 5)
 - a. thrombosis
 - b. aggregation
 - c. vasoconstriction
 - d. vasodilation

LEVEL II

1. What are the cells called that line the central cavity of all blood vessels and related tissues? (Objective 1)
 - a. epithelial cells
 - b. endothelial cells
 - c. capillaries
 - d. smooth muscle cells
2. What is the normal life span of platelets in the peripheral blood? (Objective 11)
 - a. 8 hours
 - b. 1 day
 - c. 10 days
 - d. 100 days
3. Platelet dense bodies are storage organelles for which of the following that are released after activation? (Objective 4)
 - a. calcium, ADP, and serotonin
 - b. fibrinogen, glycoprotein Ib, and VWF
 - c. ADP, thromboxane A₂, and F-V
 - d. lysosomal granules, ATP, and factor-VIII
4. Which of the following is the platelet receptor needed for platelet adhesion? (Objective 5)
 - a. glycoprotein IIb/IIIa
 - b. actin
 - c. VWF
 - d. glycoprotein Ib/IX

REVIEW QUESTIONS (continued)

LEVEL I

5. Which of the following has happened when a cut finger initially stops bleeding? (Objectives 8, 9)
 - a. vasoconstriction of vessels proximal to the cut
 - b. vasodilation of vessels distal to the cut
 - c. formation of the primary hemostatic plug by aggregated platelets
 - d. completion of fibrin formation and formation of the secondary hemostatic plug
6. What is a reasonable reference range for platelets in the peripheral blood? (Objective 6)
 - a. $1.5\text{--}4.0 \times 10^9/\text{L}$
 - b. $150\text{--}400 \times 10^9/\text{L}$
 - c. $4.0\text{--}11.0 \times 10^{12}/\text{L}$
 - d. $4.0\text{--}11.0 \times 10^9/\text{L}$
7. What is the first step in platelet function after an injury? (Objective 8)
 - a. fibrin formation
 - b. release of ADP
 - c. platelet aggregation
 - d. platelet adhesion to collagen
8. What is the process called when platelets bind to one another? (Objective 8)
 - a. platelet secretion
 - b. fibrin formation
 - c. platelet adhesion
 - d. platelet aggregation
9. Which of the following best describes the normal morphology of platelets on a peripheral blood smear? (Objective 6)
 - a. They are larger than erythrocytes.
 - b. They are filled with azurophilic granules.
 - c. They are light blue in color without granules.
 - d. They have large nuclei.
10. Each of the following is involved in hemostasis *except*: (Objective 2)
 - a. vasoconstriction by the blood vessels
 - b. adhesion and aggregation by the platelets
 - c. fibrin formation by proteins in the plasma and platelets
 - d. regulation of blood pressure

LEVEL II

5. The platelet glycoprotein IIb/IIIa complex is: (Objective 5)
 - a. a membrane receptor for fibrinogen
 - b. secreted from the DB
 - c. secreted by endothelial cells
 - d. also called *actin*
6. The formation of thromboxane A₂ in the activated platelet: (Objective 8)
 - a. is needed for platelets to adhere to collagen
 - b. is caused by the alpha granule proteins
 - c. requires the enzyme cyclooxygenase
 - d. occurs via a pathway involving VWF
7. What effect does thrombopoietin have on the megakaryocyte? (Objective 2)
 - a. decreases the number of platelets formed
 - b. speeds maturation in the bone marrow
 - c. induces the cell's release to the peripheral blood
 - d. decreases the rate of endomitosis and ploidy
8. The function of microtubules in the resting platelet is to: (Objective 6)
 - a. keep a high level of calcium in the cytoplasm
 - b. store and sequester calcium
 - c. provide a negative charge on the platelet surface
 - d. maintain the disc shape
9. The contents of the platelet granules are released from the platelet: (Objective 5)
 - a. through the open membrane system after fusion with the granules
 - b. through the microtubules after fusion with the granules
 - c. by disintegration of the platelet plasma membrane
 - d. by the mitochondria
10. Which of the following is true about the relationship between ADP and platelets? (Objective 7)
 - a. ADP is necessary for platelet adhesion.
 - b. ADP released from the DB is required for adequate platelet aggregation.
 - c. ADP is synthesized in the platelet from arachidonic acid.
 - d. ADP is released from the alpha granules of the platelets.

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Michael was diagnosed with ALL and received chemotherapy as a part of his treatment regimen. His CBC showed pancytopenia after several treatments. He had pinpoint hemorrhages on his legs and ankles as a result of the severe thrombocytopenia.

Question:

1. Does Michael have a defect in primary or secondary hemostasis?

Explanation:

He has a defect in primary hemostasis as a result of thrombocytopenia.

Question:

2. If Michael were given TPO, how would you expect his bone marrow and peripheral blood picture to change?

Explanation:

Because TPO influences megakaryocytes to proliferate, you would expect to see an increase in megakaryocytes in the bone marrow and an increase in platelets in the peripheral blood.

Question:

3. The physician explained to Michael that the reddish-purple spots on his legs and ankles were tiny pinpoint hemorrhages into the skin. Explain the relationship of these hemorrhages to the platelet count.

Explanation:

The platelet count is severely decreased. Thus, there is a defect in the formation of the primary hemostatic plug allowing blood to leak from small vessels.

Question:

4. What is the most likely cause of Michael's pancytopenia?

Explanation:

Acute leukemia is associated with thrombocytopenia and anemia. The WBC may be normal or increased. Treatment for leukemia includes

chemotherapy, which destroys not only leukemic cells but also normal hematopoietic cells.

Question:

5. Why would the administration of growth factors such as EPO and TPO be considered in this case?

Explanation:

EPO and TPO stimulate the proliferation of erythroblasts and megakaryoblasts, respectively, in the bone marrow. This will increase the number of red blood cells and platelets in the peripheral blood.

ANSWERS TO CHECKPOINTS**Checkpoint! 1**

Think about the last time that you injured your finger with a paper cut. Did your finger bleed immediately? If not, what might have prevented immediate bleeding?

Answer

No, vasoconstriction of the blood vessels prevented it.

Checkpoint! 2

What actions of the endothelial cells prevent clotting from occurring within the blood vessels?

Answer

Their negatively charged surface repels clotting factors and platelets in the normal peripheral blood circulation. They synthesize heparan sulfate and thrombomodulin, which inhibit fibrin formation. They synthesize PGI₂, which inhibits platelet activation. They synthesize tPA and PAI-1, which control fibrinolysis.

Checkpoint! 3

What would be the effect on the platelet count if a patient had a mutation in the gene for thrombopoietin that resulted in inability of the gene to code for functional mRNA?

Answer

The platelet count would be decreased.

Checkpoint! 4

If a patient has a mutation in the gene for thrombopoietin that resulted in inability of the gene to code for mRNA, how would you expect the number of megakaryocytes seen on bone marrow smears to be affected?

Answer

The number of megakaryocytes in the bone marrow would be decreased.

Checkpoint! 5

If a patient inherited a mutation of the gene for glycoprotein IIIa that resulted in its absence, what two platelet antigens would be decreased or absent?

Answer

The HPA-1 and HPA-3 would be decreased or absent.

Checkpoint! 6

If a patient with Bernard-Soulier disease or von Willebrand disease cut a finger, would you expect bleeding to stop as fast as the bleeding stops when you cut your own finger? Why?

Answer

No, because their platelets would be unable to adhere to collagen and the primary hemostatic plug would take longer to form to halt the bleeding.

Checkpoint! 7

Your finger is still bleeding at this point, but the platelets are aggregating to form the primary hemostatic plug. Let's review the key events:

- To what do platelets first adhere?*
- What bridge and what platelet membrane receptor are needed for platelet adhesion?*
- What bridge and what platelet membrane receptor are needed for platelets to attach to one another?*
- What is the attachment of platelets to one another called?*

Answer

- Collagen
- Von Willebrand factor and glycoprotein Ib/IX
- Fibrinogen and glycoprotein IIb/IIIa
- Platelet aggregation

Checkpoint! 8

Your finger has now stopped bleeding. Outline the steps of primary hemostasis that have occurred.

Answer

The blood vessels have undergone vasoconstriction and are by now possibly beginning to dilate. Platelet adhesion, platelet secretion, platelet aggregation, and formation of the primary hemostatic plug have occurred.

Secondary Hemostasis and Fibrinolysis

J. Lynne Williams, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define *hemostasis*. Identify the three physiologic compartments involved in the hemostatic mechanism.
2. Differentiate primary and secondary hemostasis.
3. List the coagulation factors using Roman numerals and determine how each is evaluated in lab testing.
4. Classify the coagulation factors into groups and discuss their characteristics.
5. Evaluate the importance of vitamin K in hemostasis.
6. Describe the mechanism of action of the coagulation proteins.
7. Diagram the sequence of reactions in the coagulation cascade according to the historic concepts of intrinsic, extrinsic, and common pathways.
8. Identify the factors involved in contact activation.
9. Diagram the physiologic pathway of blood coagulation.
10. Define *fibrinolysis*, identify the major components of the fibrinolytic system, and explain why fibrinolysis is a necessary component of hemostasis.
11. List the fragments resulting from fibrinolytic degradation; compare and contrast the fragments resulting from the degradation of fibrinogen and fibrin.
12. List the major biochemical inhibitors that regulate secondary hemostasis.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Explain the interactions of the three physiologic compartments involved in hemostasis.
2. Describe the domain structure of the coagulation factors, determine how this structure affects the action of the serine proteases, and explain the significance of the noncatalytic regions.
3. Summarize the formation of complexes on a phospholipid surface and explain the significance of these complexes to hemostasis.
4. Integrate the role of contact factors with other systems (complement activation, fibrinolysis, inflammation).
5. Describe the multiple roles of thrombin in hemostasis.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Coagulation mechanism
- ▶ Procoagulant factors
- ▶ Coagulation cascade
- ▶ Fibrinolytic system
- ▶ Physiologic control of hemostasis
- ▶ The physiologic pathway of coagulation
- ▶ Summary
- ▶ Review questions
- ▶ References

From Chapter 30 of *Clinical Laboratory Hematology, 2/e*. Shirlyn B. McKenzie. J. Lynne Williams. Copyright © 2010 by Pearson Education. All rights reserved.

OBJECTIVES—LEVEL II (continued)

6. Explain the physiologic functions of ADAMTS-13, LRP, EPCR, UPAR.
7. Compare and contrast physiologic and systemic fibrinolysis.
8. Describe the physiologic controls of hemostasis including blood flow, feedback inhibition, liver clearance, and inhibitors (antithrombin, tissue factor pathway inhibitor, protein C, protein S, and TAFI).
9. Evaluate a case study from a patient with a defect in hemostasis and, using the medical history and laboratory results, determine the diagnosis.

KEY TERMS

ADAMTS-13
 Coagulation factor
 Common pathway
 Contact group
 Endothelial cell protein C receptor (EPCR)
 Extrinsic pathway
 Extrinsic Xase complex
 Fibrin degradation (split) products (FDP or FSP)
 Fibrinogen group
 Fibrinolysis
 γ -Carboxylation
 Intrinsic pathway
 Intrinsic Xase complex
 LRP receptor (LDL receptorlike protein)
 PIVKA
 Plasminogen activator inhibitor (PAI)
 Plasminogen activator (PA)
 Prothrombinase complex
 Prothrombin group
 Serine protease
 Serpin
 Thrombin activatable fibrinolysis inhibitor (TAFI)
 Thrombomodulin (TM)
 Tissue factor pathway
 Tissue factor pathway inhibitor (TFPI)
 Tissue-type plasminogen activator (tPA)
 Transglutaminase
 Urokinase-type plasminogen activator (uPA)
 (Urokinase)
 UPAR (uPA receptor)
 Vitamin K dependent
 Zymogen

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Define and summarize the events in *primary hemostasis*.

Level II

- ▶ Describe the structure of the platelet phospholipid membrane.
- ▶ Review protein structure, protein domains, and properties of enzymes.

CASE STUDY

We will address this case throughout the chapter.

Shawn, a 10-year-old boy, was seen by his physician for recurrent nosebleeds and anemia. History revealed that the epistaxis began when he was about 18 months old. The nosebleeds occurred one or two times a month and began spontaneously. His mother reported that he seemed to bruise easily. No lesion was found in the nose. No history of drugs was noted. The family history indicated that the boy's grandparents were cousins. The patient had a brother who died of intracranial hemorrhage at 10 years of age. Parents and all other relatives showed no bleeding problems.

OVERVIEW

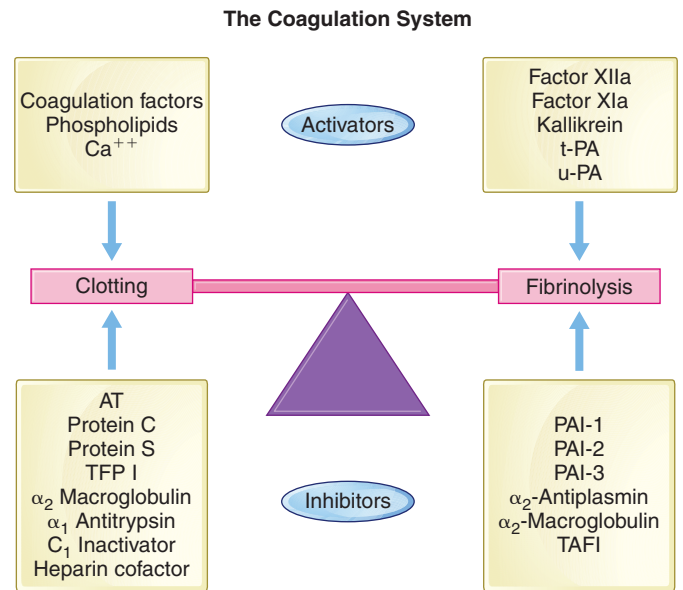

Hemostasis requires the interaction of platelets, blood vessels, and coagulation proteins. The previous chapter described primary hemostasis (platelets and blood vessels). This chapter introduces the plasma protein systems contributing to secondary hemostasis. It begins with an overview of hemostasis and discusses the distinctions between primary and secondary hemostasis. The coagulation proteins are presented in related groups for initial discussion of general properties, mechanisms of action, and protein structure. The chapter describes the functional interactions of these procoagulant proteins from the classical perspective of intrinsic, extrinsic, and common pathways. The fibrinolytic system (components, activators, and inhibitors) is presented, and the products of fibrinolytic degradation are defined. The various components contributing to the control of hemostasis are discussed including physiologic processes (blood flow, liver clearance), positive and negative feedback mechanisms, and natural inhibitors. The chapter concludes with an updated perspective of the hemostatic system referred to as the *physiologic pathway*.

INTRODUCTION

Hemostasis is a carefully balanced process by which the body maintains blood in a fluid state within the vasculature and prevents loss of blood from the vascular system upon injury. Although often thought of as “clot” formation, hemostasis also includes fibrin (clot) dissolution and vessel repair. Hemostasis involves a series of complex and highly regulated events linking platelets, vascular endothelial cells, and coagulation proteins (**coagulation factors**). The interaction of these three components at the cellular and molecular levels determines whether the equilibrium between bleeding (hemorrhage) and clotting (thrombosis) is maintained (Figure 1 ■).

As discussed, hemostasis consists of two stages: primary and secondary. Primary hemostasis, the formation of the unstable platelet plug, is the first response to vascular injury. Secondary hemostasis, the rapid reinforcement of the unstable platelet plug with chemically stable fibrin, follows and includes a series of interdependent, enzyme-mediated reactions. The endpoint of these reactions is the generation of thrombin that transforms the soluble protein fibrinogen to insoluble fibrin to stabilize the platelet plug.

The process of fibrin formation is well balanced and controlled, limiting fibrin formation to the area of vessel injury. This localization prevents widespread or systemic coagulation activation. The procoagulant reactions are amplified to the appropriate degree, while natural inhibitors limit the proteolytic activity of the activated clotting factors. Negative feedback also controls fibrin formation: large amounts of thrombin, the last enzyme formed, destroy coagulation cofactors in

■ **FIGURE 1** The coagulation system is kept in balance by activators and inhibitors of clotting and fibrinolysis. Clotting occurs when blood vessels are damaged and activators of coagulation factors are exposed or released. Clotting is controlled because fibrinolysis is initiated in response to clotting activation. Inhibitors of both clotting and fibrinolysis serve to bring the system back into balance. An imbalance in the activation or inhibition of either clotting or fibrinolysis causes thrombosis or bleeding.

the rate-limiting steps of its own production. The platelet-fibrin plug seals the injured vessel preventing blood loss, the vessel begins to repair itself, and the fibrin is ultimately digested by plasmin, an enzyme of the fibrinolytic system.

Hemostasis is complex, involving many interrelating components and control mechanisms. No part of the system acts alone. However, each part is discussed individually and then the concepts are integrated into a cohesive theory of hemostasis.

COAGULATION MECHANISM

The reactions involved in coagulation were originally described as occurring in a cascade¹ or waterfall-like² fashion in which circulating, inactive coagulation factor precursors, called **zymogens**, are sequentially activated to their active enzyme forms. Each zymogen serves first as the substrate for the preceding enzyme in the cascade and, when activated, serves as an enzyme for the subsequent zymogen. A simplified diagram of the cascade is shown in Figure 2 ■. In vitro, initiation of the cascade occurs via two pathways: The **intrinsic pathway** requires enzymes and protein cofactors that are present in plasma; the **extrinsic pathway** requires enzymes and protein cofactors present in plasma as well as

■ **FIGURE 2** A simplified version of the coagulation cascade showing the cascade or waterfall-like sequence of reactions. Boxes indicate complex formation. PL = platelet phospholipid; TF = tissue factor

an activator—tissue factor—not found in blood under normal conditions. Both converge in a third path called the **common pathway** to generate the fibrin clot. The traditional analysis of the coagulation process assigns each of the coagulation factors to the intrinsic, extrinsic, or common pathway as indicated in Table 1 🌟.

The concept of intrinsic, extrinsic, and common pathways evolved from observations of reactions occurring in vitro (in test tubes) and has contributed to our knowledge of how coagulation occurs in vivo. For clinical laboratory professionals, understanding hemostasis from an in vitro diagnostic perspective is important. The concept of the three pathways, combined with available tests for in vitro evaluation of the intrinsic system (activated partial thromboplastin

time [APTT]) and the extrinsic system (prothrombin time [PT]) are invaluable in diagnosing clinical hemorrhagic disorders. Although the model of intrinsic, extrinsic, and common pathways still serves as the basis of our understanding of this complicated system, the system in vivo functions quite differently and is not so compartmentalized. Physiologic hemostasis is basically a single pathway, now called the **tissue factor pathway**.³

✓ **Checkpoint! 1**

What is the major distinction between the so-called extrinsic and intrinsic pathways?

🌟 **TABLE 1**

**CASE STUDY** (continued from earlier in this chapter)

Screening tests for evaluating hemostasis were done on Shawn. The child was found to have a platelet count of $242 \times 10^9/L$. Bleeding time was 8 minutes. The PT was 29.5 seconds with a control of 12.0 seconds. The APTT was 51.0 seconds with a control of 55.4 seconds. Liver function tests were normal.

1. What do the results of the screening tests (platelet count, bleeding time, PT, and APTT) indicate?
2. What component of the hemostatic mechanism is most likely affected?

▶ PROCOAGULANT FACTORS

The coagulation factors are the procoagulant proteins involved in hemostasis. The International Committee on Nomenclature of Blood Coagulation Factors⁴ has assigned Roman numerals I through XIII to some of the factors. Each Roman numeral was assigned according to the order of discovery of the respective factor, not its place in the reaction sequence. Each factor had one or more common names or synonyms in addition to the Roman numeral designation, although the common names are rarely used today (Table 2). The letter *a* following the Roman numeral indicates the activated form of the factor (i.e., it is no longer a zymogen but has enzymatic activity). There are, however, several exceptions to this terminology. In its activated form, factor II (prothrombin) is preferentially known as *thrombin* rather than F-IIa. When fibrinogen (F-I) is cleaved by thrombin, it is preferentially called *fibrin*. Tissue factor (TF) was assigned F-III, and calcium was assigned F-IV, but these Roman numeral designations are seldom used. F-VI is no longer included in the coagulation sequence because it was originally assigned to a procoagulant activity subsequently found to be activated F-V. High molecular weight kininogen (HK) and prekallikrein (PK) were never assigned Roman numerals.

Most coagulation factors were discovered when physicians saw patients with a life-long history of bleeding problems. Studies of the affected patient's blood revealed that certain proteins were functionally deficient. These proteins have been isolated and characterized as to their composition (including full amino acid sequences), biochemical functions, and the chromosomal location of their genes, providing useful information for understanding hereditary problems (Table 2).

**CASE STUDY** (continued from above)

3. What evidence exists to indicate that Shawn has a hereditary bleeding disorder?
4. Are the nosebleeds significant in considering the diagnosis?

PROPERTIES OF THE BLOOD COAGULATION FACTORS

Similarities among the structural and functional properties of the coagulation factors permit division into three groups: the **prothrombin group**, the **fibrinogen group**, and the **contact group** (Table 3).

Prothrombin Group

The prothrombin group of proteins includes prothrombin (F-II) and factors VII, IX, and X. These factors have a molecular mass ranging from 50,000 to 100,000 Daltons (Da.). The factors in the prothrombin group are produced in the liver, and all contain the γ -carboxyglutamic acid-rich region called the *GLA-domain* that is critical for the calcium-binding properties of these proteins. The prothrombin group is also referred to as **vitamin K dependent** because its members require vitamin K (see later section) to be functional. Other vitamin K-dependent proteins include protein C, protein S, and protein Z (see section on biochemical inhibitors).

Fibrinogen Group

The fibrinogen group includes fibrinogen (F-I) and F-V F-VIII, and F-XIII. Thrombin acts on all during coagulation. They have the highest molecular weights of all the factors, ranging from 300,000 to 350,000 Da. These factors are not found in serum because they are consumed during clotting.

Contact Group

The contact group includes F-XI and F-XII, PK, and high molecular weight kininogen (HK). The proteins have molecular weights ranging from 80,000 to 173,000 Da. The contact group is involved in the initial activation of the intrinsic pathway and requires contact with a negatively charged surface for activation. With the exception of F-XI, the contact factors do not appear to play an essential role in hemostasis *in vivo*.⁵ However, this group of factors is integrally related to other physiologic systems. In addition to the coagulation system, the activated forms of the contact group can activate the fibrinolytic, kinin, and complement systems and play an important role in the inflammatory response. These factors are found in serum because they are not consumed during clotting.

MECHANISM OF ACTION OF THE COAGULATION FACTORS

The coagulation proteins can be grouped functionally as cofactors, substrates, or enzymes. The enzymes can be further grouped as either serine proteases or a transglutaminase.

Cofactors

F-V and F-VIII function as *cofactors* for activated coagulation proteases F-Xa and F-IXa, respectively. F-Va and F-VIIIa have no enzymatic activity of their own. HK functions as a cofactor for the contact activation phase of coagulation (F-XIIa and F-XIa), protein S is a cofactor for activated protein C (see

★ TABLE 2

Summary of the Properties of Coagulation Factors

Factor	Common Name(s)	Description	T _{1/2} (hours)	Role	Plasma Concentration	Chromosome
I	Fibrinogen	6-chain glycoprotein MW 340,000	72–120	Substrate; fibrin precursor	2000–4000 µg/mL 10 nM	4
II	Prothrombin	Single-chain glycoprotein MW 72,000	60–70	Serine protease Thrombin precursor	100–150 µg/mL 1.4 nM	11
III	Tissue factor	Single-chain, transmembrane lipoprotein MW 45,000	NA	Cofactor in extrinsic Xase complex not found in circulation	NA	1
IV	Calcium	Element	NA	Cofactor in some coagulation reactions	8.8–10.5 mg/dL	—
V	Proaccelerin	Single-chain glycoprotein MW 330,000	12–36	Cofactor in prothrombinase complex	5–10 µg/mL 30 nM	1
VII	Proconvertin, stable factor	Single-chain glycoprotein MW 50,000	3–6	Serine protease; constituent of extrinsic Xase complex	0.5 µg/mL 30 nM	13
VIII	Antihemophilic factor	Heterodimer glycoprotein MW 80,000 (light chain) 90–200,000 (heavy chain)	8–12	Complex with VWF in the circulation; cofactor in intrinsic Xase complex	0.15 µg/mL	X
VWF	von Willebrand factor	Multimeric glycoprotein MW 250,000 (subunit)	12	Platelet adhesion; stabilization of circulating F-VIII	8–10 µg/mL	12
IX	Plasma thromboplastin component	Single-chain glycoprotein MW 57,000	18–24	Serine protease; constituent of intrinsic Xase complex	4 µg/mL 70 nM	X
X	Stuart factor	Two-chain glycoprotein MW 56,000	30–40	Serine protease; constituent of prothrombinase complex	4–6 µg/mL 100 nM	13
XI	Plasma thromboplastin antecedent	Two-chain glycoprotein MW 160,000	52	Serine protease; contact factor	4–6 µg/mL 30 nM	4
XII	Hageman factor	Single-chain glycoprotein MW 80,000	60	Serine protease; contact factor	23–39 µg/mL 375 nM	5
XIII	Fibrin-stabilizing factor	Multimeric glycoprotein MW 320,000	240	Transglutaminase; stabilizes fibrin	14–28 µg/mL 65 nM	6 (A-chain) 1 (B-chain)
HK	Fitzgerald factor, Williams factor, Flaujeac factor	Monomeric α-globulin MW 120,000	156	Cofactor; complexed with PK and F-XI; contact factor	70–90 µg/mL 670 nM	3
PK	Fletcher factor	Monomeric γ-globulin MW 100,000	35	Serine protease complexed with HK; contact factor	35–45 µg/mL 410 nM	4

T_{1/2} = biologic half-life; MW = molecular weight in da.; HMWK = high molecular weight kininogen; PK = prekallikrein

★ TABLE 3

Coagulation Factor Groups Based on Physical Characteristics

	Contact Group	Prothrombin Group	Fibrinogen Group
Characteristics	Requires contact with a surface for activation	Requires vitamin K for synthesis; needs Ca ⁺⁺ to bind to a phospholipid surface; is adsorbed from plasma by BaSO ₄	Has large molecules; is absent from serum (consumable)
Factors/Proteins included	XII, XI, PK, HK	II, VII, IX, X, protein C, protein S, protein Z	I, V, VIII, XIII

later section), and TF is a cofactor for F-VIIa. Each protease has some activity in the absence of its cofactor, but interaction with cofactor significantly enhances proteolytic function. The full activity of F-VIIa, F-IXa, and F-Xa is expressed only when they are a part of a procoagulant complex named for their physiologic substrate. Thus, the F-VIIa/TF complex is termed *extrinsic tenase* (named for the extrinsic factor complex's enzymatic action on F-X), the F-IXa/F-VIIIa complex is termed the *intrinsic tenase* (named for the intrinsic factor complex's enzymatic action on F-X), and the F-Xa/F-Va complex is termed the *prothrombinase* complex (named for the complex's enzymatic action on prothrombin).

Substrate

Fibrinogen is classified as a *substrate* because it is acted upon by the enzyme thrombin. It is the only coagulation protein that, as a substrate, does not become an activated enzyme.

Enzymes

The coagulation proteins that have enzymatic activity are secreted as zymogens, which are proenzymes or inactive precursors that must be modified to become active. Activation can involve either (1) a conformational change of the molecule or (2) proteolytic cleavage of one or more specific zymogen peptide bond(s). The coagulation zymogens are rapidly activated in a cascade-like sequence. Initially, a small number of zymogens are activated, and each sequentially activates the next zymogen in the cascade, resulting in the amplification of the initial stimulus.

Members of the family of **serine proteases**, including thrombin, factors VIIa, IXa, Xa, XIa, and XIIa, have a functional serine in their active sites and a common catalytic mechanism. They selectively hydrolyze arginine- or lysine-containing peptide bonds in their substrates. Each serine protease involved in the coagulation cascade is highly specific for its substrate(s).

F-XIIIa is the only coagulation protein with **transglutaminase** activity. It catalyzes the formation of isopeptide bonds between glutamine and lysine residues on fibrin, forming stable covalent cross-links.

VITAMIN K-DEPENDENT COAGULATION PROTEINS

Seven of the blood coagulation proteins, including prothrombin, factors VII, IX, and X, and proteins C, S, and Z, require vitamin K to become functional. Vitamin K is a fat-soluble vitamin found in green leafy vegetables, fish, and liver. Some gram-negative intestinal bacteria also synthesize it. Vitamin K is necessary for the **γ -carboxylation** of glutamic acid residues in the GLA domains of these proteins. The addition of an extra carboxyl group (COOH) to the γ -carbon of the glutamic acid residues (a reaction known as γ -carboxylation) is a post-translational modification of the protein carried out by a

specific γ -glutamyl carboxylase in the endoplasmic reticulum (ER) of the liver. The γ -carboxylation is essential for binding the factor to negatively charged phospholipid surfaces (e.g., exposed phospholipids on activated platelets) via Ca^{2+} bridges.⁶ The carboxylase requires the reduced form of vitamin K (hydroquinone form) for its action. The carboxylation reaction converts reduced vitamin K to the epoxide form, which is converted back to the reduced form by the enzyme vitamin K epoxide reductase. Conversion back to the reduced form allows recycling of the vitamin K. Vitamin K antagonist drugs such as warfarin/coumadin inhibit the activity of the vitamin K epoxide reductase and prevent recycling of vitamin K back to the reduced form. Warfarin/coumadin overdose can be reversed by vitamin K administration (Figure 3 ■).

In the absence of vitamin K, the liver synthesizes the proteins, which can be found in the plasma. However, they are nonfunctional because they lack the γ -COOH groups necessary for Ca^{2+} /phospholipid binding. The vitamin K-dependent factors lacking the COOH modification have previously been referred to as **PIVKA** (**p**rotein **i**nduced by **v**itamin **k** **a**bsence or antagonists) or des- γ -carboxy form. The International Committee on Thrombosis and Haemostasis recommends using the term *acarboxy* form. Warfarin/coumadin, which inhibits the γ -carboxylation process, results in the production of inactive proteins by the liver. The nonfunctional and functional forms of the factors are identical with respect to amino acid composition and antigenic determinants.

■ **FIGURE 3** The vitamin K-dependent γ -carboxylation of glutamic acid. The coagulation factors in the prothrombin group must undergo this postribosomal carboxylation of glutamic acid residues in order to become functional. A specific carboxylase converts glutamyl residues to γ -carboxy glutamyl residues in a reaction requiring oxygen, carbon dioxide, and reduced vitamin K (hydroquinone). In the process, reduced vitamin K is converted to an epoxide and must be recycled to its reduced form by the enzyme epoxide reductase. This latter reaction is blocked by vitamin K antagonist drugs such as warfarin or coumadin.

✓ Checkpoint! 2

Will a patient who is vitamin K-deficient produce any of the vitamin K-dependent factors? Why is vitamin K so vital to the formation of coagulation complexes?

STRUCTURE OF THE BLOOD COAGULATION PROTEINS

The blood coagulation proteins are made up of multiple functional units called *domains*, which can be classified as catalytic or noncatalytic depending on their function.⁷ Catalytic domains contain the active site of the enzyme and are involved in activating other proteins. Noncatalytic domains contain regulatory elements. Structural similarities occur among proteins involved in the hemostatic mechanism, many of which are believed to be derived from common ancestral genes (Web Figure 1 ■).

The *catalytic domain* of the serine proteases involved in blood clotting is highly homologous to trypsin. The main function of this domain is the conversion of an inactive proenzyme to an active enzyme by cleavage of a peptide bond in its target substrate, a process known as *zymogen activation by limited proteolysis*.

The noncatalytic domains give each coagulation factor its own unique identity, making each highly specific in its activity and activation. They are regulatory elements serving to bind calcium and promoting interaction with phospholipids, cofactors, receptors, and substrates. Some of the more common types of noncatalytic domains include the signal peptide, propeptide, γ -carboxyglutamic acid-rich (GLA) domain, epidermal growth factor domain, apple domain, finger domain, and kringle domain.

The *signal peptide* is a short domain that permits translocation of the protein to the endoplasmic reticulum. Vitamin K-dependent proteins have a *propeptide* between the signal peptide and the GLA domain, which contains the recognition site that directs γ -carboxylation of the vitamin K-dependent proteins after synthesis. The GLA domain contains 9–12 γ -carboxyglutamic acid residues and is essential for Ca^{2+} binding. When bound, Ca^{2+} mediates the association of a coagulation factor with a phospholipid surface.

The *epidermal growth factor (EGF) domain*, *finger domain*, and *apple domains* are thought to be involved in binding to cofactors, activators, or substrates. The *kringle domain* is a lysine-binding site responsible for the affinity of certain proteins (plasminogen, plasmin, tissue plasminogen activator) for fibrin. There are other domains whose functions are as yet unknown (Web Figure 2 ■).

✓ Checkpoint! 3

Why are the domains of the serine proteases involved in blood clotting so important in the hemostatic mechanism?

▶ COAGULATION CASCADE

The coagulation cascade is composed of four interacting sets of reactions: complex formation on phospholipid membranes, intrinsic pathway activation, extrinsic pathway activation, and the common pathway.

COMPLEX FORMATION ON PHOSPHOLIPID MEMBRANES

The coagulation cascade occurs on cell surface membranes. Clotting factors bind to the phospholipid membrane surface, forming a complex including enzyme, substrate, and cofactor.⁸ Subendothelial tissue, exposed when blood vessel injury occurs, and the activated platelet surface provide the critical phospholipids for coagulation *in vivo*. The phospholipid surface serves to decrease the K_m of the reaction between enzyme and substrate and to localize the reaction to the site of injury.⁹

Three procoagulant complexes, the **extrinsic Xase** (also called *extrinsic tenase*), **intrinsic Xase** (also called *intrinsic tenase*), and **prothrombinase complexes** assemble on the phospholipid membrane (Figure 4 ■). Extrinsic Xase is formed when TF, an integral membrane lipoprotein, is exposed to blood when vessel injury occurs. TF binds F-VII or F-VIIa in the presence of Ca^{2+} , giving rise to the F-VIIa/TF complex that activates F-X. The intrinsic Xase is formed on membrane surfaces when F-IXa and F-VIIIa bind to phospholipid in the presence of Ca^{2+} . This complex also activates F-X to Xa. In a similar way, F-Xa and F-Va bind to negatively charged membranes in the presence of Ca^{2+} to form the prothrombinase complex. This complex converts prothrombin, also bound to the membrane, to thrombin. The rate of prothrombin activation by the prothrombinase complex is about 300,000 times faster than activation by F-Xa alone.¹⁰

THE INTRINSIC PATHWAY

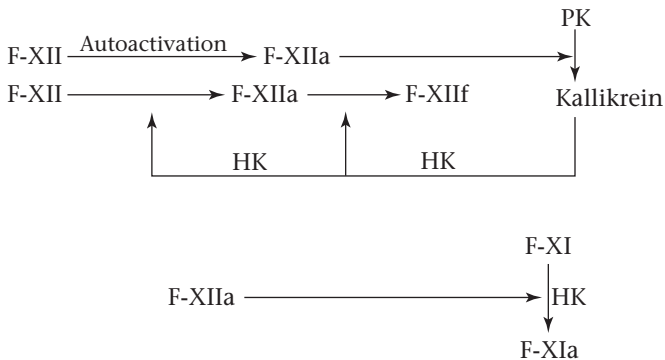

Contact Factors/the Surface Mediated Pathway

The four contact factors include F-XII, F-XI, PK, and HK. The contact factors are activated when exposed to and adsorbed on negatively charged surfaces such as glass, kaolin, celite, and ellagic acid. Activation of these factors does not require Ca^{2+} ; thus, *in vitro* activation (or “pre-activation”) can occur in citrated patient samples stored in glass tubes for prolonged periods before testing. Patients deficient in F-XII, PK, and HK have no apparent clinical bleeding disorder despite a markedly prolonged APTT; thus, it is unlikely that these factors play an important role in coagulation *in vivo*. They do, however, contribute significantly to fibrinolysis, inflammation, complement activation, angiogenesis, and kinin formation. About 50% of patients with F-XI deficiency have clinically evident bleeding abnormalities, suggesting that F-XI

■ **FIGURE 4** Schematic illustration of the coagulation complexes forming on a phospholipid surface. The vitamin K-dependent proteases (F-VIIa, F-IXa, and F-Xa and thrombin) are shown associated with their cofactors (TF, F-VIIIa, F-Va, and thrombomodulin [TM], respectively) and substrates (F-IX and F-X, prothrombin, and protein C [PC], respectively) on the membrane surface. APC = activated protein C

could be an important accessory to blood coagulation, but it is probably not essential.

Factor XII The liver produces F-XII (Hageman factor). Zymogen single-chain F-XII is converted into the two-chain active serine protease F-XIIa by proteolysis by kallikrein, plasmin (PLN), or by “autoactivation.” Autoactivation of F-XII occurs by contact with negatively charged surfaces. Binding to the negatively charged surface induces a conformational change that makes the protein more susceptible to autocatalysis. Many nonphysiologic substances (glass, kaolin, ellagic acid)¹¹ have been associated with in vitro F-XII autoactivation. The nature of the physiologic surfaces responsible for autoactivation is still in question but is most likely negatively charged cellular membranes or subendothelial structures (collagen, basement membrane).

Bound F-XIIa proteolytically cleaves PK to kallikrein, which with HK as a cofactor can then reciprocally proteolytically activate surface-bound F-XII to F-XIIa (Web Figure 3 ■). The generation of F-XIIa and kallikrein by reciprocal activation amplifies the reactions. F-XIIa can be further cleaved by kallikrein yielding smaller F-XII fragments (F-XII_f) that have little or no procoagulant activity.¹²

In addition to activating PK to kallikrein, F-XIIa has other enzymatic functions in hemostasis. As the first enzyme in the intrinsic pathway, it converts F-XI to its active form, F-XIa, in a reaction that requires HK as a cofactor. Second, F-XIIa activates the fibrinolytic and complement systems. F-XIIa, F-XIa, and kallikrein activate plasminogen directly, although much less efficiently than tissue plasminogen activator (tPA) or urokinase (uPA) (see later section) (Figure 5 ■). F-XIIa also activates the first component of the complement cascade (C-1).

Prekallikrein PK predominantly circulates in plasma bound to HK (75% bound, 25% free).¹² F-XIIa activates PK to the serine protease kallikrein. In addition to reciprocal activation of F-XII and initiation of “intrinsic” coagulation, kallikrein can activate the kinin, fibrinolytic, and complement systems. Kallikrein cleaves bradykinin from HK. It directly activates plasminogen to PLN and converts prourokinase (scuPA) to uPA, which in turn can activate plasminogen. PLN subsequently can activate the first and third components of the complement cascade (Figure 5). Kallikrein also serves as a chemoattractant and activator for neutrophils and monocytes, facilitating the inflammatory response.

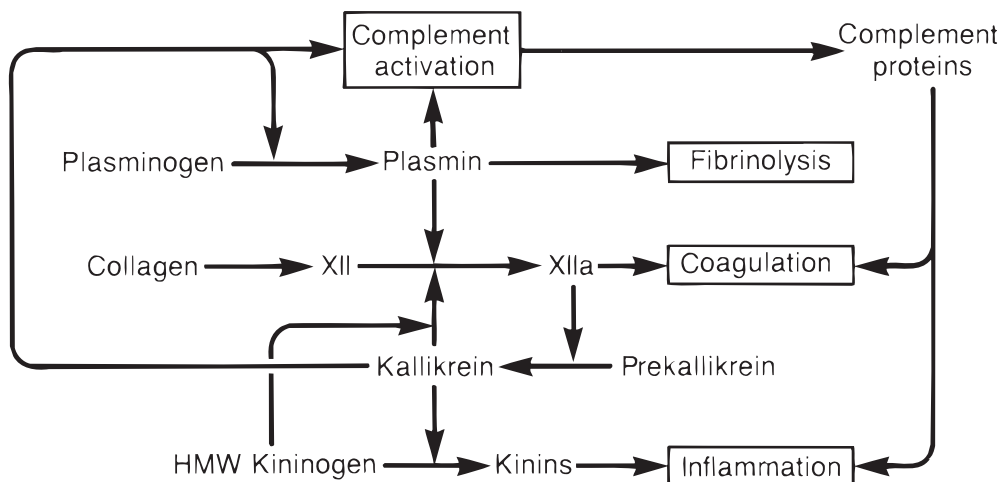

High Molecular Weight Kininogen (HK) HK serves as a nonenzymatic cofactor in activation of the contact factors and is the source of kinins. HK accelerates the rate of surface-dependent activation of F-XII and the rate of PK activation by F-XIIa. HK binds to platelets, endothelial cells, and granulocytes, assembling the other components of the con-

tact activation pathway. Two forms of kininogen are found in plasma, HK and low molecular weight kininogen (LK). The liver produces both forms by alternative splicing of a single gene. In addition, HK is found in endothelial cells, platelets, and granulocytes. HK, the preferred substrate for kallikrein, is a single-chain glycoprotein that can be cleaved by kallikrein into a two-chain disulphide-bonded molecule with the release of a small nonapeptide, bradykinin, a potent bioactive peptide. Bradykinin has many functions including increasing vessel permeability, dilating small vessels, contracting smooth muscle, and causing pain. Bradykinin stimulates vasodilation, increasing blood flow, and stimulates endothelial cell profibrinolytic, antithrombotic and antiplatelet properties by stimulating endothelial cell prostacyclin (PGI₂), nitric oxide (NO) and tPA synthesis and secretion.

Factor XI F-XI is activated to a serine protease by F-XIIa and cofactor HK (Web Figure 4 ■).

Like PK, F-XI circulates in the plasma primarily as a complex with HK. In addition to activation by F-XIIa, F-XI can be activated by both thrombin and F-XIa itself in a positive feedback reaction. Thrombin is likely the physiologically relevant activator of F-XI with minimal need for activation by F-XIIa in vivo. Both F-XI and thrombin bind to the surface of activated platelets where in vivo activation most likely occurs.¹³ The substrate for F-XIa is F-IX. Although patients with deficiencies of other contact factors (F-XII, PK, and HK) do not have bleeding problems, about 50% of patients with a F-XI deficiency experience abnormal bleeding after surgery or injury. Plasma levels of F-XI are not the only determinant of whether bleeding occurs because patients who have bleeding problems and those who do not have similar plasma concentrations of F-XI.

■ FIGURE 5 Role of contact factors in physiologic systems.

Other Factors in the Intrinsic Pathway

Factor IX F-IX is a single-chain vitamin K-dependent zymogen containing 12 Gla residues. F-IX is activated by F-XIa in the presence of Ca^{2+} and does not require any other cofactor (Web Figure 5 ■). Activation is associated with cleavage of two bonds in F-IX, releasing a 35 amino acid activation peptide and a two-chain molecule, F-IXa.

When activated, F-IXa forms a complex (intrinsic Xase) with cofactor F-VIIIa and Ca^{2+} on the surface of activated platelets to activate F-X (Figure 6 ■).

The extrinsic pathway complex F-VIIa/TF also activates F-IX (see later section). This extrinsic pathway for F-IX activation bypasses the contact activation system.

F-IXa (but not F-IX) binds to phospholipid surfaces on activated platelets in the presence of calcium; it does not bind to resting platelets. It is one of two coagulation proteins (F-VIII and F-IX) whose genes are encoded on the X chromosome. The severe bleeding that results from a deficiency of F-IX (Hemophilia B) indicates that it plays a critical role in blood coagulation.

■ **FIGURE 6** The complex formed by the sequential activation of the intrinsic pathway (F-IXa, F-VIIIa, Ca^{2+}) activates F-X. The cofactor, F-VIIIa, binds to the platelet phospholipids and serves to orient F-IXa and F-X to enhance activation of F-X. F-IXa and F-X are bound to the platelet surface via Ca^{2+} bridges. Spikes on platelet indicate activated platelet.

Factor VIII F-VIII is synthesized primarily in the liver and circulates in plasma in association with von Willebrand factor (VWF). Each protein in this complex is under separate genetic control and has distinct biologic functions and immunologic properties. Binding to VWF stabilizes F-VIII and protects it from inhibition or degradation. F-VIII circulates in the plasma in an inactive form until it is activated by thrombin (or F-Xa), yielding F-VIIIa, which serves as a cofactor for the F-IXa activation of F-X.

F-VIII is synthesized as a large precursor protein consisting of the linear array of A1:A2:B:A3:C1:C2 domains. A signal peptide is cleaved on translocation into the lumen of the ER. F-VIII is further processed on secretion from the cell with the cleavage of part of the B domain and the release of a heterodimer composed of heavy-chain (A1:A2 and part of B domain) and light-chain (A3:C1:C2 domains) polypeptides. In the plasma, F-VIII associates with VWF, which stabilizes F-VIII and prolongs its circulating half-life from ~2 hours to ~12 hours.¹⁴ In addition to increasing F-VIII survival, VWF also is involved in regulating F-VIII activity. VWF prevents F-VIII from binding to phospholipids and activated platelets and protects against inactivation by activated protein C. It does not, however, prevent thrombin activation of F-VIII but rather facilitates thrombin proteolytic activation.¹⁵ Thrombin cleaves both the heavy and the light chains of F-VIII, creating a three polypeptide molecule (F-VIIIa) with subunits derived from the A1, A2, and A3:C1:C2 domains). The A1 and A3:C1:C2 subunits remain linked as a stable dimer while the A2 subunit, associated primarily by weak electrostatic interactions, readily dissociates. As a result, F-VIII is labile, and its activity is rapidly lost at room temperature. Thrombin activation of F-VIIIa by proteolytic cleavage dissociates F-VIIIa from VWF, permitting F-VIIIa interaction with the platelet surface. F-VIIIa has no enzymatic activity but as part of the intrinsic Xase complex functions as a cofactor for F-IXa activation of F-X. However, large amounts of F-Xa and thrombin destroy the procoagulant function of F-VIIIa. Like F-IX, the gene for F-VIII is located on the X chromosome, and the factor is critical for normal blood coagulation. A deficiency of F-VIII results in Hemophilia A.

von Willebrand Factor (VWF) VWF is a large multimeric glycoprotein synthesized by endothelial cells and megakaryocytes. VWF is synthesized as a proprotein with a signal peptide, a propeptide (pp), and the mature VWF protein. VWF undergoes extensive intracellular modifications during trafficking through the ER and Golgi including removal of the signal peptide, formation of dimers and subsequently higher multimers, glycosylation, and protein folding.¹⁶ In the Golgi, the propeptide is cleaved from pro-VWF, releasing the VWFpp and the mature VWF monomer.¹⁷ The VWF monomer consists of areas of internal homology or domains, resulting in a structure with A-, B-, C-, and D-domains. The propeptide, also called VWF antigen II, is required for the VWF multimerization process as well as the

regulated intracellular storage of VWF. Although synthesized as a monomer of 250,000 Da, VWF circulates in the plasma as a family of molecules (multimers) of a wide range of sizes (0.5– > 20 million Da.) with the largest forms being most effective in promoting platelet adhesion. However, all multimers can bind F-VIII in a 1:1 molar ratio.

Mature VWF multimers are stored within α -granules (α G) of platelets and in Weibel-Palade bodies of endothelial cells. They are released from these intracellular stores following injury or stimulation by thrombin, histamine, or the vasopressin analog 1-desamino-8-D-arginine vasopressin (DDAVP). Platelet and endothelial cell VWF generally consists of larger multimers, called *ultralarge VWF multimers (ULVWF)*, than are found in plasma. Degradation of ULVWF to the normal plasma forms is accomplished by the VWF-cleaving protease, ADAMTS-13 (a member of the **a disintegrinlike and metalloprotease with thrombospondin repeats** proteins).¹⁸ The ULVWF are released from the Weibel-Palade bodies and remain tethered to the endothelial cell surface, forming long stringlike structures. When tethered, ULVWF is exposed to the shear forces of the flowing blood, and the protein unfolds and exposes the cleavage site for ADAMTS-13.¹⁹ If the ULVWF is released directly into plasma, platelets can spontaneously aggregate, resulting in thrombosis.

VWF contributes to both primary and secondary hemostasis. It mediates adhesion of platelets to the vessel wall in areas of high flow rate and high shear force by the simultaneous binding of VWF to GPIb/IX on platelet surfaces and to collagen and elastin in the subendothelium. High molecular weight multimers of VWF contain the highest number of platelet and other cell surface-binding sites. VWF also can bind to the GPIIb/IIIa receptor on platelets (the normal physiologic receptor for fibrinogen) and thus can promote platelet aggregation. These molecules serve as *intercellular bridges* between platelets, between platelets and subendothelium, and between platelets and endothelial cells. In secondary hemostasis, VWF carries F-VIII in the plasma, binding to and stabilizing F-VIII via a noncovalent interaction between the two molecules. The two proteins circulate as a VWF/F-VIII complex.

✓ Checkpoint! 4

Which components of the intrinsic pathway are believed to be essential for *in vivo* hemostasis?

THE EXTRINSIC PATHWAY

F-X can also be activated by the extrinsic pathway involving F-VII and its cofactor, TF, or tissue thromboplastin. When vessel injury occurs, nonvascular cells (fibroblasts, smooth muscle cells) with TF on their surface are exposed to the blood. TF binds F-VII and F-VIIa in the presence of calcium,

forming the F-VIIa/TF complex. Once formed, this complex initiates the extrinsic pathway of blood coagulation. The F-VIIa/TF complex (extrinsic Xase) converts F-X to F-Xa, similarly to the intrinsic Xase complex. The F-VIIa/TF complex also can activate F-IX of the intrinsic pathway, bypassing the need for contact activation of this pathway. F-Xa can feed back to activate more F-VII to F-VIIa.

Tissue Factor

TF is the cellular receptor and cofactor for F-VII and F-VIIa. It is a transmembrane lipoprotein originally named *F-III* or *tissue thromboplastin*. TF is expressed constitutively on the plasma membrane of most nonvascular cells. It is not normally expressed by cells that are in contact with flowing blood, but monocytes and endothelial cells can be stimulated to produce TF by endotoxin, complement component 5a, immune complexes, interleukin-1, and tumor necrosis factor.²⁰ TF and the platelet phospholipid surface have similar functions in coagulation; both attract calcium ions to facilitate the formation of procoagulant enzyme complexes at the injury site.

Factor VII

F-VII is one of the vitamin K-dependent proteins produced by the liver and has 12 Gla residues. F-VII circulates in two forms: the inactive zymogen, F-VII, and low levels of the active enzyme, F-VIIa (~1% of the total plasma F-VII).²¹ Free F-VIIa is a weak enzyme in the absence of TF. However, these trace levels of circulating F-VIIa are sufficient to initiate the coagulation cascade when injury exposes TF. F-VII is a single-chain molecule activated to two-chain F-VIIa by proteolytic cleavage of a single peptide bond, with the two cleavage peptides remaining tethered by a disulfide bond. No cleavage peptide is released.

As with intrinsic activation of coagulation, there is positive feedback in activating the extrinsic pathway. When TF and F-VII are bound in a complex, F-VIIa can autocatalyze more F-VII to F-VIIa. Additionally, F-Xa associated with a phospholipid surface can feed back to activate F-VII, increasing the amount of F-VIIa formed.²²

✓ Checkpoint! 5

Historically, the major importance for initiating coagulation was assigned to either the intrinsic or extrinsic pathway. What are some observations that suggest that the classic concepts were not accurate?

THE COMMON PATHWAY

The intrinsic and extrinsic pathways converge on the common pathway as both pathways activate F-X.

Factor X Activation

F-X can be activated by the F-VIIa/TF/Ca²⁺ complex (extrinsic Xase) or the F-IXa/F-VIIIa/Ca²⁺/phospholipid complex (intrinsic Xase).

Thrombin Generation

F-Xa then forms a complex with cofactor F-Va, phospholipid, and Ca²⁺. This prothrombinase complex acts to optimally activate prothrombin to thrombin.

Factor X F-X is another vitamin K-dependent protein produced by the liver; it contains 11 Gla residues. It circulates as a two-chain disulfide-linked zymogen. A 52-amino acid activation peptide is released from the F-X heavy chain to generate F-Xa.

Factor V F-V is a large glycoprotein produced by the liver. It is also called *labile factor* because, like F-VIIIa, its activity deteriorates quickly at room temperature. About 25% of F-V in the blood is found in the α G of platelets from which it is secreted during platelet activation.²³ F-V circulates in the plasma as a single-chain molecule with a domain organization similar to F-VIII (A1:A2:B:A3:C1:C2). Activation of F-V to F-Va, with full cofactor activity, requires cleavage of several bonds. Both thrombin and F-Xa can activate F-V, although thrombin is the primary activator in vivo. Cleavage produces a two-chain heterodimer consisting of a heavy chain (A1:A2 domains) noncovalently linked through Ca²⁺ to a light chain (A3:C1:C2 domains). The B domain is released as a result of activation. F-Va binds to specific sites on the activated platelet surface, serving as the attachment site for F-Xa (Figure 7 ■). Most of the F-V that participates in the prothrombinase complex on the platelet membranes probably is supplied as the result of secretion from activated platelet α G.

Prothrombin Prothrombin is a vitamin K-dependent protein produced by the liver; it contains 10 Gla residues. Zymogen F-II circulates as a single-chain molecule and is cleaved by the prothrombinase complex in two places. Cleavage releases the C-terminal half of the molecule that contains the catalytic domain (prethrombin) from the remainder of the molecule (the activation peptide, prothrombin fragment 1.2). Assays for fragment 1.2 reflect the level of in vivo prothrombin activation. Prethrombin (single-chain)

■ **FIGURE 7** The prothrombinase complex (F-Xa, F-Va, Ca²⁺, PL) activates prothrombin to thrombin. F-Va binds to the platelet phospholipid surface and orients F-Xa and prothrombin to enhance the formation of thrombin. F-Xa and prothrombin are bound to the platelet surface via Ca²⁺ bridges. This complex is very similar to the complex formed by the intrinsic pathway (F-IXa, F-VIIIa, Ca²⁺, PL). Spikes on platelet indicate activated platelet.

is cleaved to thrombin, which is composed of an α - and a β -chain linked by a disulfide bond. It does not contain the GLA domain of prothrombin and thus does not bind to negatively charged phospholipids (Figure 8 ■). As a result, thrombin does not remain tethered to the phospholipid surface on which it was formed but can dissociate and move to other areas or surfaces (e.g., thrombomodulin on nearby intact endothelial cells).

Roles of Thrombin

Thrombin generation is critical for normal hemostasis and it has a number of diverse roles (Figure 9 ■). This protein functions as a procoagulant by cleaving fibrinopeptides A and B from fibrinogen to create fibrin monomer; it also generates other procoagulant activities, activating factors Va, VIIIa, and XIIIa to greatly amplify its own formation; it stimulates endothelial cells to release VWF and plasminogen activator inhibitor (PAI-1) and to express TF²⁴; it also activates platelets, stimulating platelet aggregation. Thrombin can suppress fibrinolysis by activating the **thrombin activatable fibrinolysis inhibitor (TAFI)**. Conversely, thrombin also has antithrombotic functions that dampen its own formation. Thrombin binds to thrombomodulin and activates protein C, and it stimulates endothelial cells to release tissue plasminogen activator and endothelium-derived relaxing factor (EDRF, also known as nitric oxide). In addition to its role in hemostasis, thrombin has mitogen and cytokine-like activities and plays a role in inflammation, wound healing, and atherosclerosis.

Prothrombin Conversion to Thrombin

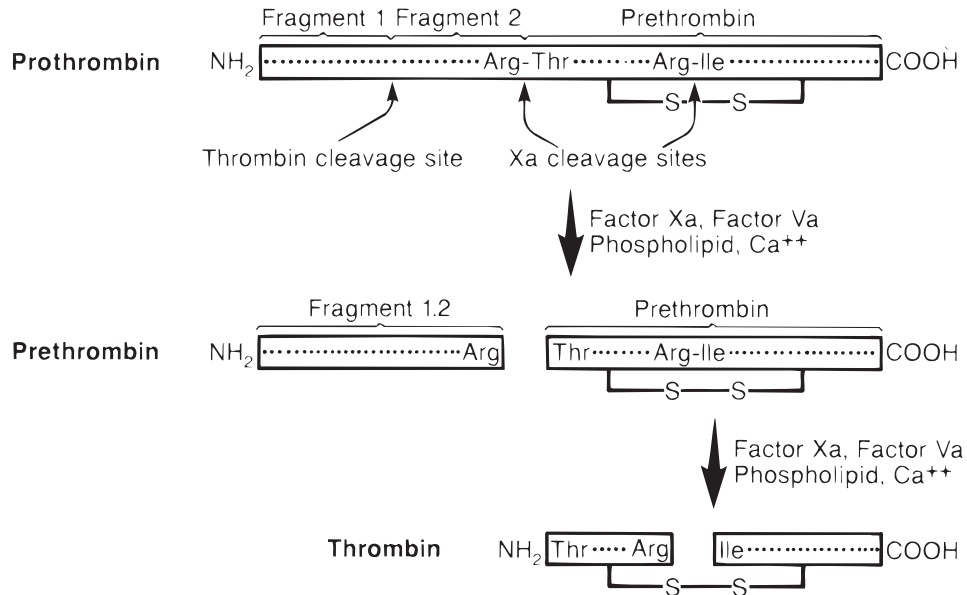

FIGURE 8 The prothrombin molecule is a single-chain glycoprotein that can be divided into the “pro” portion (fragments 1 and 2 or fragment 1.2) and the thrombin portion (prethrombin). Factor Xa proteolytically cleaves the molecule between the “pro” and thrombin portions releasing fragment 1.2 and prethrombin. Prethrombin is further cleaved into two disulfide bonded chains forming the potent enzyme thrombin.

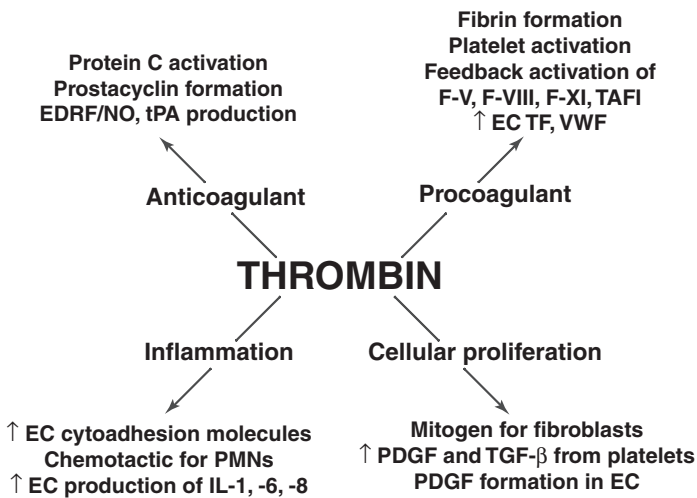

FIGURE 9 The multifactorial roles of thrombin. In addition to its multiple roles as a procoagulant protease, thrombin also has anticoagulant functions as well as important activities in promoting inflammation and cellular proliferation. (EDRF= endothelium-derived relaxing factor; NO = nitric oxide; tPA= tissue plasminogen activator; TAFI = thrombin activable fibrinolysis inhibitor; EC = endothelial cell; TF = tissue factor; VWF = von Willebrand factor; PMNs = polymorphonuclear neutrophils; PDGF = platelet-derived growth factor)

7. What factors are included in the common pathway?
8. An abnormal PT and a normal APTT would indicate a problem with which factor?

Formation of Fibrin

The insoluble fibrin clot is formed from soluble fibrinogen in three distinct steps:

1. *proteolytic cleavage* of arginine-glycine bonds by thrombin, releasing fibrinopeptides A and B from the α and β chains, forming fibrin monomer
2. spontaneous *polymerization* of fibrin monomers to form fibrin polymers
3. *stabilization* of the fibrin polymers by F-XIIIa-catalyzed cross-linking.

Fibrinogen The fibrinogen molecule is a large (350,000 Da.), trinodular glycoprotein found in plasma and platelet

α G. Megakaryocytes and platelets do not synthesize the protein but absorb it from plasma. Fibrinogen is the most abundant coagulation protein with a plasma concentration of 2–4 mg/mL (representing about 2% of the total plasma protein concentration). Fibrinogen is encoded by three separate genes located on chromosome 4, and the production of the three chains is coordinately regulated. Fibrinogen is also one of several hepatic proteins whose production is increased as part of the acute phase response mediated by IL-6.

Fibrinogen is a dimeric protein composed of three pairs of nonidentical polypeptide chains referred to as $A\alpha$, $B\beta$, and γ -chains (a molecule of fibrinogen would be described as $A\alpha_2B\beta_2\gamma_2$)²⁵ (Figure 10■). This nomenclature refers to the fact that small polypeptides (fibrinopeptides A and B) are released from $A\alpha$ and $B\beta$ chains by thrombin, producing a single molecule of fibrin, $\alpha_2\beta_2\gamma_2$. Twenty-nine disulfide bonds join the three pairs of chains. Electron microscopy has demonstrated the folding of the molecule into a trinodular structure.²⁶ The central nodule, the E domain, is referred to as the *N-terminal disulfide knot (N-DSK)* because the amino terminal ends of all six polypeptide chains join to form this region. The E domain contains the fibrinopeptides A and B. The two outer nodules, the D domains, are made up of the

carboxy-terminal ends of the β and γ chains and a short sequence of the α chain. The $A\alpha$ chain has a long polar appendage at the carboxy-terminal end that folds back toward the N-DSK, which is the site of initial PLN hydrolysis (see below). The D and E domains are separated from each other by 111–112 amino acids forming a triple-stranded α -helical structure called the *coiled-coil domain* (supercoiled region).

Release of FPs A and B. Thrombin binds to the central E domain of fibrinogen and cleaves specific arginine-glycine bonds, releasing four peptides from the fibrinogen molecule. It releases a short peptide containing 16 amino acids from each $A\alpha$ chain (fibrinopeptide A [FPA]) as well as a 14 amino acid peptide from each $B\beta$ chain (fibrinopeptide B [FPB]). The resulting molecule is called a *fibrin monomer*. Release of FPA alone is sufficient for the fibrin assembly process.

Assembly of Fibrin Polymers. The cleavage of FPA and FPB exposes binding sites in the central E domain that interact with complementary sites on the γ -chain of the D domain of other fibrin monomers, creating a D-E contact. The polymerization sites on the D domain are always available and interact with complementary sites on the E domain

■ **FIGURE 10** Fibrinogen is a trinodular structure composed of three pairs ($A\alpha$, $B\beta$, γ) of disulfide bonded polypeptide chains. The central nodule is known as the *E domain*. Thrombin cleaves small peptides, A and B, from the α and β chains in this region to form fibrin. The central nodule is joined by supercoiled α -helices to the terminal nodules also known as the *D domains*.

after thrombin cleavage. The polymerization continues by the addition of a third monomer forming a D-D contact as well as another D-E contact. The use of x-ray crystallography to study fibrinogen has provided insights into the mechanism by which fibrin self-assembles. The crystal structures show a mechanism for electrostatic steering to guide the alignment of fibrin polymers during polymerization.²⁷ The noncovalent interaction of the nodules leads to the initial formation of two-stranded polymers termed *protofibrils*. The polymer strands aggregate in an overlapping pattern called *half-staggered array* in which the second strand is offset from the first by half of the length of a single fibrin molecule. The protofibrils then aggregate into thick fibers through lateral associations held together by weak noncovalent and electrostatic interactions. During fibrin monomer polymerization, other plasma proteins including components of the fibrinolytic system (plasminogen, plasminogen activators, and fibrinolytic inhibitors) can also bind to the fibrin surface. Thrombus extension *in vivo* can be blunted by unactivated fibrinogen molecules or fibrin degradation products (FDPs) which can bind to and cap the ends of a protofibril.

Fibrin Stabilization. Spontaneously polymerized fibrin strands are unstable, but the α and γ chains of adjacent fibrin strands are subsequently covalently cross-linked by F-XIIIa. The cross-linking strengthens the clot and provides resistance to chemical (5 M urea) and enzymatic (plasmin) digestion compared to the uncross-linked polymer (Figure 11 ■).

Factor XIII The final reaction in fibrin formation is the stabilization of the fibrin polymer catalyzed by F-XIIIa. F-XIII circulates as a heterotetramer (A_2B_2), which is the product of two separate genes coding for the A and B chains. F-XIII is found evenly distributed between plasma and platelets. Platelet F-XIII exists as an A_2 dimer lacking the B subunit. The plasma F-XIII A chain is primarily synthesized by bone marrow cells, megakaryocytes, monocytes, and macrophages and is stored in the soluble (nongranular) fraction of the platelet. The A chain contains the active site of the enzyme, the fibrin binding and substrate recognition domains. The B chains are secreted by hepatocytes and complex rapidly with the A chains in the plasma, stabilizing them and prolonging their plasma survival. The B chains also promote plasma F-XIII association with fibrinogen.

When fibrin is polymerized, plasma F-XIII is bound as the A_2B_2 complex. Fibrin binding provides a mechanism to localize F-XIII to sites of thrombin generation and fibrin polymerization, allowing for efficient activation of the zymogen F-XIII. Thrombin cleavage of the A chains, dissociating the B chains and releasing an activation peptide, activates F-XIII to F-XIIIa. The expression of F-XIIIa activity requires its interaction with calcium ions, which induce a conformational change, exposing its active center and promoting catalysis.

F-XIIIa is thus a calcium-dependent transglutaminase that catalyzes the formation of covalent isopeptide bonds within

■ **FIGURE 11** Thrombin cleaves the A and B fibrinopeptides from the E domain of fibrinogen to form fibrin monomer. The cleavage apparently changes the negative charge of the E domain to a positive charge. This permits the spontaneous growth of fibrin polymers as the positively charged E domain assembles with the negatively charged D domains of other fibrin monomers. The polymer is initially joined by hydrogen bonds. F-XIIIa in the presence of Ca^{2+} is responsible for catalyzing the formation of covalent bonds between glutamine and lysine residues of adjacent monomers (D domains), thus stabilizing the lattice formation.

the fibrin polymer. These bonds are formed between the terminal domains of γ chains of two adjacent fibrin monomers within a protofibril, forming longitudinal end-to-end cross-links. More slowly, cross-links form between polar appendages of α chains of neighboring monomers. The covalently cross-linked fibrin network produces a fibrin clot with increased mechanical strength and increased resistance to proteolytic digestion by plasmin. The presence of these unique bonds is responsible for the liberation of specific fibrin degradation products (D-dimers, see below) when plasmin digests the clot. In contrast to the hydrogen-bonded polymers, the F-XIIIa-stabilized fibrin polymer is not soluble in 5M urea or monochloroacetic acid. In addition to forming covalent cross-links between molecules of fibrin, F-XIIIa also cross-links fibrinolytic inhibitors to the fibrin clot, including α_2 -antiplasmin, plasminogen activator inhibitor-2 (PAI-2), and TAFI.²⁸ The localization of these fibrinolytic inhibitors to the fibrin clot results in the inhibition of plasmin formation and augmentation of fibrin stabilization. F-XIIIa also cross-links fibrin to extracellular matrix molecules, helping to anchor the fibrin clot to the vessel wall and promoting wound healing.

✓ Checkpoint! 6

What are the three steps in the formation of an insoluble fibrin clot?

▶ THE FIBRINOLYTIC SYSTEM

The fibrinolytic system is activated in response to the activation of the coagulation cascade. This system functions to remove fibrin from the vascular system in a controlled manner once it has fulfilled its function and to prevent excessive fibrin accumulation. This system, which digests the fibrin clot through proteolysis, must be regulated so that proteolytic activity is limited to the area of fibrin formation and does not occur prior to healing of the vascular lesion.

INTRODUCTION

Fibrin formation occurs both intravascularly and extravascularly as a consequence of coagulation, inflammation, and tissue repair. When no longer needed, fibrin must be removed so that normal vessel and tissue structure and function can be restored. The process of removing fibrin is called **fibrinolysis**. The fibrinolytic system is responsible for dissolving thrombi and maintaining a patent vascular system. The key components in this system are (1) the inactive proenzyme, plasminogen, (2) plasminogen activators (PA), (3) the active enzyme PLN, (4) fibrin, (5) fibrin/fibrinogen degradation (split) products, and (6) inhibitors of plasminogen activators and PLN (Table 4 🌟).

Like the coagulation system, the fibrinolytic system normally acts locally at sites of fibrin accumulation without causing systemic effects. If the fibrinolytic system's activity increases (e.g., deficiencies of inhibitors α_2 -antiplasmin or PAI-1), stability of the hemostatic plug can be compromised or premature dissolution can occur resulting in an increased bleeding tendency. Conversely, decreased activity of the system (e.g., deficiency of plasminogen, plasminogen activators, or elevated inhibitors) can result in delayed or inadequate fibrin dissolution and thromboembolic tendencies.

Fibrin formation essentially initiates fibrinolysis. Fibrin acts to assemble the various fibrinolytic components to optimize and localize their interactions. When clotting begins, the zymogen plasminogen binds to fibrin throughout the developing thrombus. tPA also binds to fibrin, which increases its enzymatic activity so it can efficiently convert plasminogen (PLG) to PLN. The formation of a ternary complex between the activator (tPA), the zymogen (PLG), and the substrate (fibrin) results in the targeted, specific degradation of fibrin (not fibrinogen or other plasma proteins). PLN then digests fibrin to soluble degradation products, producing several well-characterized fibrin fragments. The system is inhibited by the action of PAIs and by the PLN inhibitor, α_2 -antiplasmin (α_2 -AP).

When associated with the fibrin surface, plasmin is protected from rapid inhibition by α_2 -AP so that efficient degra-

dition of a fibrin clot can occur (Figure 12 ■). If free PLN leaks into the circulation, these PLN molecules are rapidly inactivated by α_2 -AP. Thus, the activity of this potentially dangerous proteolytic enzyme is localized to the fibrin clot. The relative proportions and locations of profibrinolytic (PLG and PA) molecules and the antifibrinolytic molecules influence the timing and degree of clot dissolution.

✓ Checkpoint! 7

Why is the process of fibrinolysis a vital part of the hemostatic mechanism? Why must it be closely regulated and controlled?

PLASMINOGEN AND PLASMIN

PLG is a single-chain glycoprotein synthesized by the liver. It has five kringle domains that are critical in regulating fibrinolysis. The kringles contain lysine-binding sites that are responsible for the binding affinity of PLG and PLN for fibrin, cell surface receptors, and other proteins including α_2 -antiplasmin. PLG preferentially binds to C-terminal lysines as opposed to intramolecular lysines. **Plasminogen activators (PA)** convert PLG into its active two-chain form, the serine protease PLN, by hydrolysis of a single peptide bond. PLN exhibits much broader substrate specificity than the procoagulant serine proteases and has the potential to degrade and destroy most proteins. In addition to fibrin, PLN can degrade essentially all proteins susceptible to trypsin including fibrinogen, F-V and F-VIII, complement, and several hormones. However, PLN formation and inactivation is highly regulated in vivo, and the enzyme is active only temporarily and locally (in the vicinity of the fibrin clot). PLG binds to fibrin, and activation occurs much more efficiently at the fibrin surface, targeting the proteolytic action of the enzyme PLN to its substrate.

The active enzyme PLN has a positive feedback effect on fibrinolysis. Intact plasma PLG has an amino terminal glutamic acid residue (Glu-PLG). PLN can cleave the Glu-PLG, producing a smaller PLG molecule with a lysine N-terminal amino acid (Lys-PLG). Lys-PLG has a higher affinity for binding to fibrin and greater reactivity with PAs, thus accelerating and improving the efficiency of PLN formation.²⁹

ACTIVATORS OF FIBRINOLYSIS

The two major PA that occur in the circulating blood are tissue-type PLG activator (tPA) and urokinase-type PLG activator (uPA), also called *urokinase* (UK). The contact phase of coagulation produces serine proteases (F-XIIa and kallikrein), which also can promote PLG activation.

Contact Phase PA

PAs are generated during the contact phase of the intrinsic pathway, although the physiologic importance of these

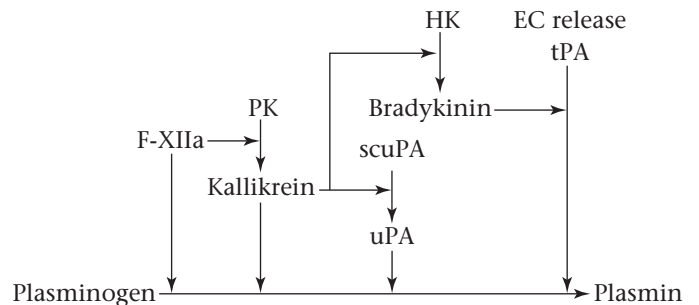

★ TABLE 4

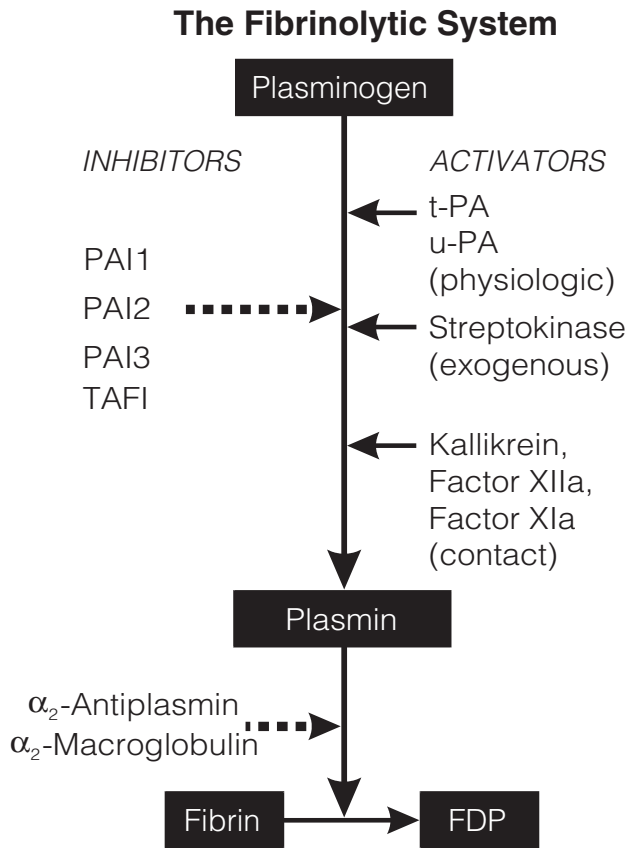

Summary of Properties of the Components of the Fibrinolytic System

Component	Description	Role	t1/2	Concentration	Chromosome
I. Fibrinolytic component					
Plasminogen (PLG)	Single-chain glycoprotein MW 92,000	Zymogen; precursor of plasmin	2.2 days	200 µg/mL 2000 nM	6
Plasmin (PLN)	Dimeric glycoprotein MW 92,000	Serine protease; cleaves fibrin	0.1 sec	—	—
II. Activators of plasminogen					
Tissue plasminogen activator (tPA)	Glycoprotein MW 70,000	Serine protease; complexed with inhibitor PAI-1; activates plasminogen	4 min	0.005 µg/mL 0.07 nM	8
Urokinase type plasminogen activator (uPA)	Single-chain glycoprotein (scuPA) MW 54,000	Serine protease; low enzymatic activity until cleaved to tcuPA by PLN; activates plasminogen	7 min	0.004 µg/mL 0.07 nM	10
III. Inhibitors					
Plasminogen activator Inhibitor-1 (PAI-1)	Single-chain glycoprotein MW 52,000	Proteinase inhibitor (SERPIN): inhibits tPA and uPA	8 min	0.001–0.04 µg/mL 0.1–0.4 nM	7
Plasminogen activator inhibitor-2 (PAI-2)	Glycoprotein—Two forms: MW 60,000 (secreted); 47,000 (intracellular)	Proteinase inhibitor (SERPIN): inhibits tPA, uPA	—	Trace (normal plasma) 0.250 µg/mL in late pregnancy	18
α ₂ -antiplasmin (AP)	Single-chain glycoprotein MW 70,000	Complexes with PLN; also inhibits kallikrein, thrombin, tPA	3 days	70 µg/mL 1000 nM	17
Thrombin activated fibrinolysis inhibitor (TAFI)	Single-chain protein MW 60,000	Carboxypeptidase B: inhibits plasminogen activation by cleaving lysine AA from fibrin	10 min	5 µg/mL 75 nM	13
IV. Cell surface receptors					
UPAR	Glycoprotein receptor MW 60,000	Binds uPA—localizes on surface of EC, monocytes, and macrophages	—	—	19
Annexin 2	Heterotetramer MW 36,000	Binds tPA, PLG; found on EC, monocytes, and macrophages, SMC	—	—	15
Low-density-lipoprotein Receptor-like protein (LRP)	MW 600,000	Clearance receptor for uPA/PAI-1 & PAI-2, tPA/PAI-1, PLN/α ₂ PI	—	—	12

MW = molecular weight in Da.; SERPIN = serine protease inhibitor; UPAR = urinary plasminogen activator (uPA) receptor; EC = endothelial cells; SMC = smooth muscle cells

activators is uncertain. F-XIIa, F-XIa, and kallikrein all have the ability to directly activate PLG to PLN, although somewhat slowly. They normally account for no more than 15% of total PLN-generating activity in plasma.³⁰ Kallikrein can affect fibrinolysis by converting scuPA to its more active two-chain form, uPA, and by liberating bradykinin from HK. Bradykinin can then stimulate release of tPA from endothelial cells, further enhancing fibrinolysis. In vivo, the importance of intrinsic activators is likely mediated via kallikrein conversion of scuPA to uPA, which has increased ability to activate plasminogen.

■ **FIGURE 12** The fibrinolytic system can be activated by the physiologic activators, tissue plasminogen activator (tPA) derived from endothelial cells, and urokinase-type plasminogen activator (uPA) or the contact activators, kallikrein, F-XIIa, and F-XIa. Exogenous activator, streptokinase, can also activate the system. Plasmin (PLN), the product of activation, controls coagulation by digesting fibrin to fibrin degradation products (FDP) and by degrading factors V, VIII, and XII. The inhibitors of plasminogen activation, plasminogen activator inhibitor-1 (PAI-1), plasminogen activator inhibitor-2 (PAI-2), plasminogen activator inhibitor-3 (PAI-3), thrombin activatable fibrinolysis inhibitor (TAFI), and the inhibitors of plasmin (α_2 -antiplasmin and α_2 -macroglobulin) serve to control the fibrinolytic system. The fibrinolytic system, like the clotting system, is intricately regulated by these activators and inhibitors.

Physiologic PLG Activators

The two important physiologic plasma PAs are **tissue-type plasminogen activator (tPA)** and **urokinase-type plasminogen activator (uPA)**. Both are serine proteases that have a high degree of specificity for converting PLG to PLN by cleavage of a single bond (Arg561-Val). Each has different structural, functional, and immunologic properties.

Vascular endothelial cells of small vessels mainly produce tPA, which seems to be the predominant PA activity in the circulatory system. In vivo, single-chain tPA (sctPA) is released from the endothelial cells by stimuli such as thrombin, bradykinin, histamine, exercise, venous stasis, shear

stress, and DDAVP administration.³¹ tPA has two kringle domains containing lysine-binding sites (LBS). LBS are involved in fibrin binding, fibrin-specific plasminogen activation, rapid clearance in vivo, and binding to endothelial receptors.³² tPA is unique among the serine proteases because it does not circulate as a zymogen but is fully active toward its substrate plasminogen in its single-chain form. However, PLG activation by tPA in plasma (in the absence of fibrin) is relatively inefficient. The activation of PLG by tPA is markedly increased when both proteins are bound to fibrin via their respective LBS. Single-chain tPA can be converted to a two-chain molecule by cleavage of a single peptide bond by kallikrein, PLN, or F-Xa. However, the single-chain form is nearly as effective as the two-chain form in the presence of fibrin.³³

In addition to binding to and functioning on a fibrin surface, tPA also associates with the membrane of endothelial cells. The endothelial cell receptor for tPA is annexin II, which functions as a coreceptor for both tPA and PLG. Binding and activation of tPA and PLG help maintain a fibrinolytic potential on undamaged vascular surfaces.

uPA is produced primarily by renal tubular epithelium and vascular endothelium and is found in urine and plasma. However, it functions mainly in the tissues where it plays an important role in digesting the extracellular matrix, enabling cells to migrate.³⁴ This process is important in wound healing, embryogenesis, inflammation, and cancer metastasis. uPA is secreted as a single-chain molecule (scuPA) but has little proteolytic activity until it is converted to a two-chain form by PLN, F-XIIa, or kallikrein.³⁵ uPA differs from tPA because it lacks high-affinity binding for fibrin, although it can activate both fibrin-bound and circulating PLG. The localized generation of small amounts of fibrin-bound PLG converts scuPA to uPA, bringing about the reciprocal activation of PLG and scuPA.

A specific receptor for uPA, **urokinase plasminogen activator receptor (uPAR)**, plays an important role in localizing uPA-catalyzed PLG activation. The receptor binds scuPA and uPA to the endothelial cell surface and facilitates activation of scuPA to uPA and of PLG. Binding uPA to uPAR increases the activation of plasminogen sixfold by colocalization of uPA and PLG and contributes to a fibrinolytic potential on undamaged endothelium.

Lipoprotein(a) (Lp[a]), an LDL-like particle similar in structure to PLG, has been shown to inhibit the activation of PLG by tPA and uPA.³⁶ Lp(a), which also possesses LBS, competes with PLG and tPA for fibrin binding, interfering with PLG activation. Thus, elevated levels of Lp(a) are antifibrinolytic and are considered a thrombotic risk factor.

Exogenous Activators

In addition to these physiologically important endogenous PLG activators, several bacterial species also produce efficient PLG activators. Streptokinase (SK), derived from

β -hemolytic streptococci, is not a serine protease but acts by forming a 1:1 complex with PLG. When bound to SK, PLG undergoes a conformational change, exposing an altered active site in PLG, which can then autocatalytically convert to PLN. SK is used as a therapeutic agent to dissolve clots. However, SK has no preferential action toward PLG bound to fibrin and thus acts equally well on plasminogen molecules in the circulation, resulting in extensive systemic plasmin activation and a generalized proteolytic state. Plasminogen activators are also produced by *Staphylococcus aureus* (staphylokinase [SAK]) and by *Yersinia pestis*. Like SK, SAK is not an enzyme but forms a 1:1 complex with PLG. However, SAK does not activate PLG in the absence of fibrin. Trace amounts of PLN can convert the SAK:PLG complex to SAK:PLN that is a highly fibrin-specific PA.

FIBRIN DEGRADATION

PLN is responsible for the asymmetric, progressive degradation of fibrin (or fibrinogen), forming distinct protein fragments referred to as **fibrin degradation (split) products (FDP or FSP)**. The liver rapidly clears these fragments from the circulation. Their detection in the plasma is of diagnostic value for some hemostatic disorders.

The sites of PLN proteolytic action are similar in fibrinogen and cross-linked fibrin. PLN digestion of fibrinogen has been widely studied and has been used as the model to explain the digestion of fibrin. The products formed include fragments X, Y, D, and E (Figure 13). Fragment X is formed when plasmin cleaves a few small peptides from the exposed polar appendages in the C-terminal region of the α chains of fibrinogen and liberation of β 1-42 from the N-terminal portion of the β chain occurs. Next, cleavage in one coiled region midway between one D terminal domain and the E central domain produces a uninodular fragment D and a binodular fragment E-D (fragment Y). PLN then cleaves fragment Y in the coiled region between the remaining E and D domains, producing free fragment E and another fragment D. Each fibrinogen molecule ultimately is degraded into two D fragments, one E fragment, and a few small peptides.

PLN degradation of fibrin monomer and noncross-linked fibrin polymer is essentially identical to that of fibrinogen. PLN degradation of cross-linked fibrin, however, is slower and produces unique degradation products because of the intermolecular bonds induced by F-XIIIa. The smallest unique degradation product, the D-D fragment, consists of two fragment D segments of two adjacent cross-linked fibrin monomers. To completely separate adjacent D and E domains on neighboring molecules, six cleavages must occur (2α , 2β , and 2γ chains cleaved). Digestion severing all connections is not always complete. Therefore, some of the cross-linked D-D degradation products are found within molecules of various molecular weights. They can consist of X, Y, D, and E fragment complexes from two or more cross-linked fibrin monomers (e.g., DD/E, YD/DY, YY/DXD) (Figure 14). A test for breakdown products, the

Plasmin Degradation of Fibrinogen

■ **FIGURE 13** The degradation of fibrinogen by plasmin occurs in well-defined sequential steps. First, small peptides are cleaved from the carboxyl ends of α -chains producing fragment X. The E domain retains the A and B peptides. The fragment X is still capable of reacting with thrombin to form fibrin. Next, one of the D domains is cleaved from the fragment X, producing fragment Y (DE) and a fragment D. Further cleavage of the fragment Y produces D and E fragments.

D-dimer test, is a specific marker for PLN degradation of fibrin.

The fibrin fragments, if present in sufficient concentration, can exert an anticoagulant effect on the clotting system. Fragment X can still react with and bind thrombin but very slowly. Fragment X can compete with fibrinogen for thrombin so that less fibrin is formed. Fragments Y, D and E inhibit the polymerization of fibrin monomers. The fragments can also interfere with primary hemostasis by inhibiting platelet aggregation.

If free in plasma, PLN can cause proteolytic degradation of numerous plasma proteins including fibrinogen; factors V, VIII, and XII; and components of the kinin and complement systems. The rapid formation of complexes between free PLN and its inhibitor, α_2 -antiplasmin (P-AP), controls this potentially dangerous proteolytic process. If inactivation of PLN is not sufficiently controlled, a systemic fibrinolytic state results, characterized by PLG activation, depletion of α_2 -antiplasmin, and fibrinogen breakdown. Physiologic fibrinolysis, which occurs when PLN is attached to fibrin, is highly fibrin specific and not associated with a systemic fibrinolytic/proteolytic state.

✓ Checkpoint! 8

Why are the PLN degradation products of fibrinogen and fibrin different?

■ **FIGURE 14** Fibrin digestion by plasmin occurs at cleavage sites identical to those of fibrinogen. However, because of the covalent bonds of the F-XIIIa-stabilized polymer, digestion is slower. Derivatives also are different as some sites are not accessible in the lattice formation. This schematic drawing depicts some of the derivatives of plasmin digestion of fibrin. (Adapted, with permission, from: Beutler E et al., eds. *Williams Hematology*. New York: McGraw Hill; 1995).

INHIBITORS OF FIBRINOLYSIS

The fibrinolytic proteins are held in check by fibrinolytic inhibitors, which modulate the fibrinolytic system to prevent systemic proteolysis (Table 4). They act at the PLG activation step or directly on plasmin.

Plasminogen Activator Inhibitors (PAI)

Several inhibitors control the activation of PLG. Most belong to a family of serine-protease inhibitors called **serpins** that inhibit target molecules by formation of a 1:1 stoichiometric complex. The primary regulators are the **plasminogen activator inhibitors (PAIs)**. Five proteins with PAI activity have been identified: PAI-1, PAI-2, PAI-3, protease nexin-1, and neuroserpin. Of these, only PAI-1 appears to play a significant role in regulating PA activity in blood and most tissues.²⁹ The interaction of PAI-1 with tPA is >1000 times higher than the interaction of tPA with the other PAIs.

PAI-1, which appears to be the primary physiological inhibitor of tPA and uPA, is produced by endothelial cells, monocytes, macrophages, megakaryocytes, hepatocytes, smooth muscle cells, and adipocytes. PAI-1 reacts with tPA, sctPA, and uPA but not scuPA. In plasma, about 70% of the tPA circulates in complex with PAI-1. Release of PAI-1 from activated platelets into the developing hemostatic plug ensures that the initial fibrin matrix is not prematurely lysed by tPA activation of PLG. PAI-1 is an acute phase reactant protein. Thrombin, IL-1, TGF- β , TNF α , and endotoxin all induce dramatic increases in plasma PAI-1 levels. Elevated PAI-1 results in a decrease in tPA activation of PLG and a shift in the hemostatic balance toward hypercoagulability. Deficiency of PAI-1 results in a serious bleeding disorder due to unregulated and excessive fibrinolysis.

PAI-2, the second plasminogen activator inhibitor, is found in greatest amounts in placentas and in macrophages. Plasma levels are very low except in pregnancy when it is

drastically elevated. PAI-2 inhibits both tPA and uPA but is less effective toward sctPA.

PAI-3 is probably the activated protein C (APC) inhibitor. These two molecules are immunologically and functionally identical.

PA/PAI complexes are removed from the circulation by binding to the low-density lipoprotein receptor-like protein (LRP) receptors on hepatocytes and macrophages. LRP mediate clearance of free tPA, tPA/PAI-1, uPA/PAI-1, tPA- or uPA-PAI-2, and α_2 macroglobulin/protease complexes.²⁹

Thrombin Activatable Fibrinolysis Inhibitor (TAFI)

TAFI is a recently discovered plasma protein that inhibits fibrinolysis when activated. TAFI is a procarboxypeptidase B, activated to TAFIa by the thrombin/thrombomodulin complex.³⁷ Activation requires formation of a ternary complex involving TAFI-thrombin-thrombomodulin. PLG binding to fibrin occurs primarily at carboxy-terminal lysine residues. New C-terminal lysines are generated during initial plasmin degradation of fibrin. TAFIa suppresses fibrinolysis by removing C-terminal lysine and arginine residues from fibrin, thereby eliminating the fibrin-binding sites for plasminogen³⁸ (Figure 15 ■). TAFIa protects the fibrin clot from degradation by inhibiting binding and activation of PLG. Because of TAFIa's short half-life, this effect is temporary, delaying activation of fibrinolysis until the fibrin clot can be established and stabilized. Thus, thrombin generation initially results in the suppression of fibrinolysis by activating TAFI. TAFIa, in turn, plays a major role in the balance between fibrin deposition and removal. Thrombomodulin also has a role in down-regulating coagulation by activating protein C (see later section).

α_2 -Antiplasmin

The liver produces and secretes α_2 -antiplasmin (AP), which is also found in platelet α G. It is the principal physiologic

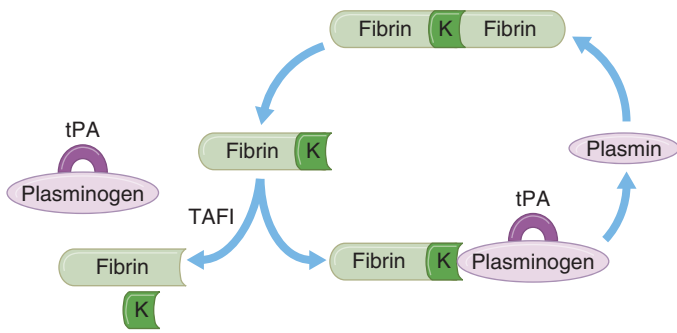

FIGURE 15 Down regulation of plasmin formation by TAFI. Fibrinolysis is initiated when plasminogen is converted to plasmin by tPA. Both plasmin and tPA preferentially bind to carboxy-terminal lysine (K) residues of fibrin. The formation of plasmin is enhanced by a positive feedback loop. New C-terminal lysine residues generated after limited plasmin cleavage provide new binding sites for continued tPA and plasminogen binding. TAFIa cleaves off the C-terminal lysine residues from partially degraded fibrin and thereby eliminates/decreases the fibrin cofactor function in the tPA/plasminogen/fibrin complex, inhibiting the formation of plasmin and the degradation of the fibrin clot. (TAFI = thrombin activatable fibrinolysis inhibitor; tPA= tissue plasminogen activator)

inhibitor of PLN, binding via LBS on PLN and rapidly inhibiting the enzyme. In the circulation, AP reacts quickly with free PLN, but PLN bound to fibrin is protected from inactivation because fibrin occupies the same binding sites on PLN as would AP. Circulating AP thus makes an important contribution to limiting systemic fibrinolysis. AP can also bind PLG, interfering with the absorption of PLG to fibrin. Some AP molecules are cross-linked to fibrin by F-XIIIa during clotting, thus increasing the initial resistance of fibrin to the action of PLN. This allows repair processes to start before clot lysis is initiated.

α_2 -Macroglobulin

α_2 -Macroglobulin is an inhibitor with wide specificity that reacts with many different proteases. It is a backup inhibitor for several proteases including PLN and the other hemostatic serine proteases. If the fibrinolytic system has been extensively activated and a large amount of PLN has been generated, inhibitory capacity of AP's would be exhausted. α_2 -Macroglobulin then operates as a second line of defense to inactivate remaining PLN. Antithrombin, α_1 -antitrypsin, and C1 inhibitor all have some antiplasmin activity in vitro but are probably of minimal significance in vivo.

CASE STUDY (continued from earlier in this chapter)

9. Does any evidence exist to indicate a problem with Shawn's fibrinolytic system?

PHYSIOLOGIC CONTROL OF HEMOSTASIS

The dynamic process of fibrin formation is normally limited to the site of vascular injury. However, the disruptive force of blood flow presents an extraordinary problem for regulating hemostasis. Activated factors and/or platelets must be kept at the site of injury and must be controlled so they are inactive when distant from the site of vessel damage. Cellular localization and plasma protease inhibitors are essential in confining the coagulation reactions to sites of injury so that blood remains fluid in uninvolved vessels. Other physiologic mechanisms involved in controlling hemostasis include the control of blood flow, liver clearance of activated proteins, and negative and positive feedback of activated clotting factors.

BLOOD FLOW

Vasoconstriction and activation of clotting factors are necessary for clot formation to begin. Vessel constriction initially enhances clot formation by slowing blood flow through the injured vessel. As blood pools, creating an area of stasis, platelets and coagulation factors are brought in proximity to the vessel wall, promoting the initiation of primary and secondary hemostasis. Neither stasis alone nor the activation of circulating coagulation factors in flowing blood results in clot formation. Vasoconstriction of the injured vessel is an important initial step for adequate fibrin formation. Return to normal blood flow through an area of injury then limits coagulation by diluting the concentration of activated factors. Activated factors carried away from the fibrin clot are bound by inhibitory proteins with loss of their coagulant potential.

LIVER CLEARANCE

The liver is the site of production of many clotting factors, making it a vital organ for normal hemostasis. The liver removes activated coagulation factors complexed with their inhibitors from the circulation as well as PLN-antiplasmin complexes and fibrin degradation products. A major receptor for removal of these complexes is the LRP receptor found on hepatocytes and liver macrophages. Liver disease can result in hemorrhage due to decreased production of coagulation factors. It can also contribute to systemic fibrinolysis or thrombosis associated with the failure to remove activated proteases.

POSITIVE FEEDBACK AMPLIFICATION

The hemostatic system has several positive feedback mechanisms. Some of the most important are (1) thrombin, which, as a major activator of platelets, promotes the release of platelet F-Va and the exposure of negatively charged phospholipids.

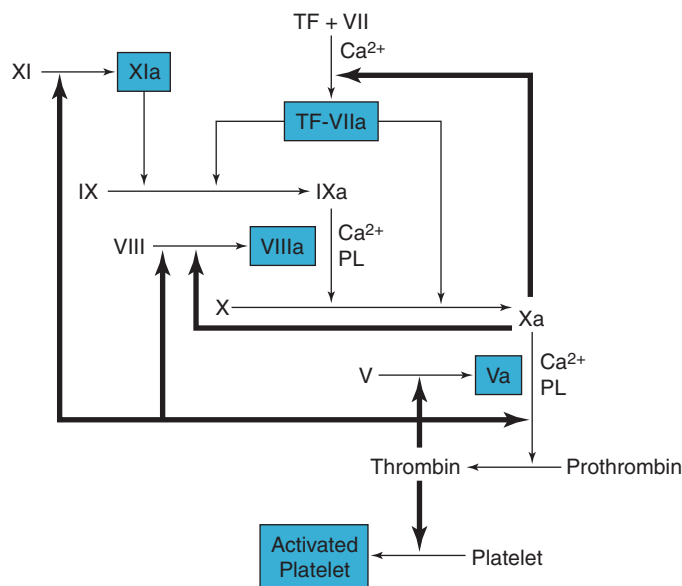

pholipid surfaces used for assembly of coagulation protein complexes, (2) thrombin activates F-Va and F-VIIIa, (3) F-Xa feeds back to activate F-VII, and (4) F-Xa has limited ability to activate F-VIII in a reaction that can be important before significant quantities of thrombin are produced (Figure 16■).

NEGATIVE FEEDBACK INHIBITION

Some of the activated factors have the potential to destroy other factors in the coagulation cascade. This process of feedback inhibition limits further production of the enzymes and dampens the coagulation cascade. Thrombin has the ability to activate F-Va and F-VIIIa but at higher concentrations can inactivate them via activated protein C (APC). F-Xa first activates F-VIIa and then, through the action of tissue factor pathway inhibitor, is itself inactivated in a reaction that requires F-VIIa/TF. Fibrin, the end product of the cascade, also indirectly controls clotting. Fibrin has a strong affinity for thrombin. Once adsorbed onto the fibrin meshwork, thrombin is very slowly released, limiting the amount of thrombin available to cleave more fibrinogen to fibrin. In addition, FDPs produced by PLN digestion function as inhibitors of fibrin formation by interfering with the conversion of fibrinogen to fibrin and the polymerization of fibrin monomers.

BIOCHEMICAL INHIBITORS

Naturally occurring inhibitors are soluble plasma proteins that regulate the enzymatic reactions of serine proteases.

■ **FIGURE 16** Positive feedbacks in coagulation. Positive feedbacks are indicated by heavy arrows. Shaded boxes indicate targets. (Adapted, with permission, from: Beutler E et al., *William's Hematology*. New York: McGraw-Hill; 1995)

They prevent the initiation or amplification of the coagulation cascade (Table 5★) (Figure 17■). The natural inhibitors include:

1. antithrombin (AT)
2. heparin cofactor II (HCII)
3. protein C (PC) and protein S (PS)
4. tissue factor pathway inhibitor (TFPI)
5. protein Z-dependent protease inhibitor (ZPI) and protein Z (PZ)
6. α_2 -Macroglobulin (α_2 -M)
7. α_1 -antitrypsin (α_1 -protease inhibitor [α_1 PI])
8. C1-inhibitor
9. Thrombin activatable fibrinolysis inhibitor (TAFI see under fibrinolysis)
10. α_2 -antiplasmin (α_2 AP; see under fibrinolysis)

Antithrombin, α_1 -antitrypsin, heparin cofactor II, C1-inhibitor, ZPI and AP are all members of the serpin family of **serine protease inhibitors** (Serpins), which inhibit their target enzymes by forming a covalent complex between the active site serine of the enzyme and the reactive center of the serpin. Conformational changes are induced in both molecules, trapping the enzyme with the serpin and resulting in loss of activity of both proteins.

Antithrombin

AT, formerly called *AT III*, is a serpin protease inhibitor and is clinically the most important inhibitor of procoagulant serine proteases. AT can neutralize all serine proteases including thrombin; factors XIIa, XIa, IXa, and Xa; kallikrein; and plasmin. AT molecules circulating in the blood have limited inhibitory activity. AT forms a 1:1 complex with each target protease, but the reaction is slow in the absence of heparin. Inhibition of the target proteases is accelerated three to four orders of magnitude by the cofactor heparin. Originally, two antithrombin activities, the progressive antithrombin (in the absence of heparin) and heparin cofactor (in the presence of heparin) activities, were described and were thought to be due to two separate plasma proteins. Subsequently, however, both activities were shown to be associated with a single protein, AT.³⁹ Procoagulant proteases associated with surface-activating complexes (prothrombinase, tenase) are protected against AT/heparin inactivation.

AT is produced by hepatocytes, endothelial cells, and possibly megakaryocytes. In vivo, heparin is located in the granules of mast cells and basophils although under normal circumstances, it is not released from these cells into the circulation and cannot be detected in plasma. While only small amounts of naturally occurring heparin are found in the plasma, vascular endothelium is rich in heparan-like molecules called *heparan sulfate proteoglycans* (HSPGs). These endothelial cell-associated proteins have heparan side chains with the correct carbohydrate sequences needed for AT recognition. Both thrombin and AT can bind to HSPGs and

★ TABLE 5

Summary of Naturally Occurring Inhibitors

Component	Description	Role	Concentration in Plasma	t _{1/2}	Chromosome
Protein C (PC)	Two-chain glycoprotein MW 62,000	Serine protease: inactivates F-Va and F-VIIIa	4–6 $\mu\text{g/mL}$ 70 nM	6 hr	2
Protein S (PS)	Single-chain glycoprotein MW 75,000	Cofactor for APC inhibition of F-Va and F-VIIIa	20–25 $\mu\text{g/mL}$ 300 nM	42 hr	3
Thrombomodulin (TM)	Transmembrane protein MW 450,000	Cofactor/modulator: EC receptor for thrombin; cofactor for thrombin activation of PC; stimulates EC to release tPA and EDRF	0.02 $\mu\text{g/mL}$	—	20
Antithrombin (AT)	Single-chain glycoprotein MW 58,000	SERPIN: inhibits thrombin, factors Xa, IXa XIa, XIIa, kallikrein, plasmin, tPA	150–400 $\mu\text{g/mL}$ 2500 nM	61–72 hr	1
Heparin cofactor II (HCII)	Glycoprotein MW 66,000	SERPIN: inhibits thrombin	40–70 $\mu\text{g/mL}$ 1000 nM	60	22
C1 esterase inhibitor	Single-chain glycoprotein MW 105,000	SERPIN: inhibits kallikrein, plasmin, C1, factors XIIa, XIa	180 $\mu\text{g/mL}$ 1700 nM	70	—
Protein C inhibitor (PAI-3)	Single-chain protein MW 57,000	Proteinase inhibitor (SERPIN): inhibits APC	5.3 $\mu\text{g/mL}$ 100 nM	23 days	—
α_1 -antitrypsin (α_1 - proteinase inhibitor, α_1 PI)	Protein MW 55,000	SERPIN: inhibits F-XIa, thrombin, kallikrein, plasmin, tPA	2500 $\mu\text{g/mL}$ 45,000 nM	144 hr	—
Tissue factor pathway Inhibitor (TFPI)	MW 40,000	Proteinase inhibitor: inhibits F-VIIa and F-Xa	0.05–0.15 $\mu\text{g/mL}$ 2.5 nM	1–2 min	—
α_2 -Macroglobulin	Dimeric protein MW 725,000	Proteinase inhibitor: inhibits kallikrein, PLN, thrombin, tPA	2500 $\mu\text{g/mL}$ 3400 nM	—	12
Protein Z dependent Protease Inhibitor (ZPI)	Single-chain glycoprotein MW 72,000	SERPIN: inhibits F-Xa with cofactor Protein Z; inhibits F-XI	1.0–1.6 $\mu\text{g/mL}$ 20 nM	—	—
Protein Z	Vitamin K-dependent glycoprotein MW 62,000	Cofactor for ZPI inhibition of F-Xa	2–3 $\mu\text{g/mL}$ 50 nM	60	13

are brought close together. Upon binding, AT undergoes a conformational change, making its reactive site more accessible to the active site serine of thrombin (or other protease targets). The thrombin/AT (TAT) complex then dissociates from the proteoglycan, and the heparan sites are free to bind other thrombin/AT molecules. Dermatan sulfate, another glycosaminoglycan located in the vessel wall and the tissues, has little catalytic effect on AT but is a potent catalyst for heparin cofactor II. Vessel wall HSPGs bind and localize plasma AT, which contributes to the anticoagulant and antithrom-

botic properties of the endothelium by inhibiting free thrombin and other activated proteases.

As an anticoagulant, heparin molecules are structurally and functionally heterogeneous, ranging in size from 5000 to 30,000 Da. In commercial preparations of heparin, only about one-third of the molecules have catalytic activity. Among naturally occurring heparin-like proteoglycans, less than 10% are active. Heparin inhibits platelet function by inhibiting VWF binding and reducing platelet adhesion to subendothelium and thus can produce hemorrhagic side ef-

■ **FIGURE 17** Major naturally occurring inhibitors of coagulation. Solid lines indicate proteolytic pathways. Dashed lines show direction of inhibition. Shaded ovals indicate inhibitors. TFPI = tissue factor pathway inhibitor

fects if not monitored during therapeutic administration. Also, heparin can produce a mild thrombocytopenia (heparin-associated thrombocytopenia [HAT]), resulting from direct interactions between heparin and platelets. The low-molecular-weight (LMW) heparins (alternative therapeutic antithrombotic agents) can inactivate F-Xa but are less effective in inactivating thrombin. As the size of the heparin molecules decreases, the ratio of inactivation of F-Xa versus thrombin increases. LMW heparins are also less likely to induce thrombocytopenia and HAT. Heparin has no action as an anticoagulant in the absence of AT. When AT levels are significantly reduced, patients can become unresponsive to antithrombotic therapy with heparin.

Heparin Cofactor II

HCII is a second plasma protease inhibitor whose activity is accelerated by heparin. Unlike AT, HCII is not a broad-spectrum inhibitor. It inhibits thrombin but has little activity against other coagulation proteases (F-Xa, F-IXa, F-VIIa). Because HCII's affinity for heparin is less than that of AT, a higher concentration of heparin is needed to accelerate its thrombin inhibition. Therefore, HCII probably contributes a minimal anticoagulant effect in heparinized patients. It has been suggested that HCII might function as a second-line inhibitor of thrombin. It likely is to be involved in thrombin inhibition in extravascular locations because its activity (unlike that of AT) is accelerated significantly by extravascular dermatan sulfate. HCII can also play a role in protection from thrombosis during pregnancy.⁴⁰

Protein C and Protein S

The protein C (PC) pathway is a major inhibitory mechanism involved in controlling blood coagulation. Unlike the other inhibitory mechanisms directed at the proteases of the coagulation cascade, activated protein C (APC) inhibits two of the nonproteolytic regulatory cofactors of coagulation: Va and VIIIa.

PC and its cofactor, protein S (PS), are vitamin K-dependent proteins synthesized in the liver. PC circulates as a two-chain disulfide-linked zymogen containing 9 Gla residues. PS is a single-chain glycoprotein with 11 Gla residues. Unlike the other vitamin K-dependent factors, PS does not contain a serine protease domain and thus lacks protease activity. The protein C pathway is illustrated in Figure 18.■

Thrombin is generated at the site of injury. Excess thrombin binds to thrombomodulin on adjacent EC surfaces. **Thrombomodulin (TM)** is an integral membrane protein named for its ability to change the activity of thrombin from procoagulant to anticoagulant so that thrombin loses its ability to clot fibrinogen, activate F-V, or activate platelets but instead rapidly activates PC in the presence of Ca^{2+} .^{41,42} TM binding appears to cause a conformational change in the thrombin molecule that accounts for its altered activity. APC is released from the T:TM complex and in association with its cofactor PS, proteolytically inactivates F-Va and F-VIIIa. The precursor F-V and F-VIII molecules are resistant to the action of APC. The inactivation of these cofactors prevents effective, sustained thrombin generation. Thus, via activation of PC, thrombin creates a self-dampening effect that limits the growth of the fibrin clot.

To function effectively, APC must interact with PS, forming a 1:1 stoichiometric complex in the presence of Ca^{2+} and a phospholipid surface. PS circulates in the blood in two forms: (1) free PS (40% of the total circulating protein) and (2) protein that is noncovalently associated with the complement regulatory protein, C4b-binding protein (C4b-BP). The free form of PS is the only effective cofactor for APC. When bound to a cell surface, the complex of PC-PS is capable of inactivating F-Va and F-VIIIa. APC cleaves Arg 306 and Arg 506 in F-Va, dissociating the A2 fragment, and the analogous Arg 336 and Arg 562 in F-VIIIa. Inactivation of F-VIIIa is stimulated significantly by F-V. APC also produces a profibrinolytic effect, presumably due to the decreased generation of thrombin resulting in the lack of activation of TAFI.

An **endothelial protein C receptor (EPCR)** is found on the endothelial cells of larger vessels.⁴³ When EPCR binds PC, it augments PC activation by increasing the affinity of the T:TM complex for PC.⁴⁴ When activated by the T:TM in the microcirculation, APC rapidly dissociates from the endothelial cells but dissociates more slowly from the endothelium of larger vessels because of binding to EPCR. When bound to EPCR, APC is not capable of inactivating F-Va (and probably F-VIIIa). When APC dissociates from EPCR, APC can bind PS and then inactivate F-Va. APC bound to EPCR induces a profound anti-inflammatory effect, mediated at least in part via activation of protease-activated receptor-1 (PAR-1) on the EC membrane.⁴⁵

APC is neutralized by PC inhibitor (PCI, or PAI-3), α_1 -antitrypsin, and α_2 -M. PCI is a serpin that produces a procoagulant effect due to its blocking the anticoagulant effect of the PC system. Deficiency of either PC or PS results in a tendency for thromboembolic disease. Patients have been

■ **FIGURE 18** Protein C pathway. Thrombin forms on the vessel wall at the site of injury. Thrombomodulin on the endothelial cell forms a complex with thrombin. This complex activates protein C, which then in association with free protein S inactivates F-Va and F-VIIIa. described with normal amounts of PC and PS in their plasma yet activation of PC fails to inactivate F-Va. This abnormality (F-V Leiden), referred to as *APC resistance*, is due to a mutation in one of the cleavage sites of F-Va.⁴⁶

Tissue Factor Pathway Inhibitor

TFPI, also called *extrinsic pathway inhibitor*, *lipoprotein-associated coagulation inhibitor*, and *antithromboplastin*, inhibits the F-VIIa-TF complex, suppressing the activity of the extrinsic pathway.

The endothelium is the major source of TFPI synthesis in vivo. A significant portion of TFPI is bound to heparan sulfate on the surface of endothelial cells with most of the remainder in blood bound to low density lipoproteins (LDL).⁴⁷ Heparin administration releases the EC-bound TFPI and raises the plasma level severalfold.⁴⁸ The range of TFPI concentrations is broad among normal individuals. Plasma concentrations of TFPI activity vary with LDL levels because the interaction of TFPI with lipoproteins reduces the measurable anticoagulant activity.⁴⁹

TFPI is unique among the protease inhibitors because it is a potent inhibitor of both F-Xa and F-VIIa. First, TFPI binds to and inhibits the active site of F-Xa. Subsequently, this binary complex reacts with F-VIIa in complex with TF, forming a quaternary compound (VIIa-TF-Xa-TFPI) on a membrane surface, inactivating both proteases.⁵⁰ TFPI can neutralize F-Xa when bound in a prothrombinase complex, but its activity against F-VIIa requires F-VIIa to be complexed with TF⁵¹ (Figure 19 ■).

The molecular basis for TFPI's capacity to neutralize two proteases simultaneously is due to the fact that TFPI has three inhibitor domains: the first domain binds to and inhibits the F-VIIa/TF complex and the second inhibits F-Xa. The target of the third inhibitory domain is unknown.⁵²

Because TFPI inhibition of F-VIIa/TF requires F-Xa, the extrinsic pathway is not shut off until a significant amount of

■ **FIGURE 19** The inhibition of F-VIIa/TF by tissue factor pathway inhibitor (TFPI) occurs as the result of a multistep process. First, TFPI binds to F-Xa and neutralizes it, resulting in a conformational change of TFPI that promotes binding of the F-Xa/TFPI complex with the F-VIIa/TF complex in a calcium-dependent reaction.

F-Xa is generated. Once F-Xa is produced, TFPI prevents continued activation of F-X by the F-VIIa/TF complex, and further activation of F-X must occur through the intrinsic pathway by the F-IXa-F-VIIIa complex. While initial activation of F-Xa occurs via the extrinsic pathway, sustained activation requires activation of F-IXa via the intrinsic pathway.⁵³ This explains the bleeding associated with factor deficiencies of the intrinsic pathway. Even in the event of tissue damage and tissue factor generation, deficiencies of factors VIII and IX will not permit sufficient activation of F-Xa to maintain normal hemostasis.

α_2 -Macroglobulin

α_2 -M is capable of inhibiting several serine proteases including thrombin, F-Xa, plasmin, and kallikrein. The inhibition rate is relatively slow when compared to other inhibitors, and protease activity is not completely neutralized. It serves as a secondary or backup inhibitor for many coagulant and fibrinolytic enzymes.

The glycoprotein α_2 -M is widely distributed in the body. Its concentration changes with age with the highest levels in infants and children. It also can be elevated in pregnancy, in women using oral contraceptives, and in a number of other disorders. Following initial binding to the target enzyme, α_2 -M undergoes a conformational change essentially trapping the enzyme within the inhibitor, preventing binding to its substrate. However, the catalytic site of the protease is left intact. This suggests that α_2 -M may function primarily as a clearance mechanism for serine proteases rather than as an inhibitor of enzymatic activity because the α_2 -M/protease complexes are rapidly cleared from plasma via binding to LRP receptors in the liver.

α_1 -Antitrypsin

The glycoprotein α_1 -antitrypsin (α_1 protease inhibitor [α_1 PI]) has the capacity to inhibit a number of proteases and is the major inhibitor of F-XIa. Its activity is thought to be more important at the tissue level, particularly in its role as an inhibitor of neutrophil elastase. α_1 PI deficiency results in emphysema due to unopposed elastase activity damaging lung alveoli.⁵⁴

C1-Inhibitor

C1-inhibitor was first recognized as an inhibitor of the esterase activity of C1 from the complement cascade. As well, it inhibits the contact system proteases F-XIIa, F-IXa, kallikrein, and PLN. C1-inhibitor is the major plasma protease inhibitor of F-XIIa, accounting for more than 90% of the plasma inhibitory activity.

Protein Z and ZPI

PZ is a vitamin K-dependent protein that markedly enhances the inhibitory function of protein ZPI against F-Xa. ZPI is a plasma serpin that inhibits F-Xa in a PZ-dependent manner.⁵⁵ It also inhibits F-XIa in the absence of PZ. The physio-

logic importance of ZPI and PZ in the regulation of coagulation is still unclear.

Checkpoint! 9

Why are naturally occurring inhibitors important in the hemostatic mechanism?

11. What is the significance of normal results in a patient with hemostatic disease?

▶ THE PHYSIOLOGIC PATHWAY OF COAGULATION

Although it has been traditional to divide the coagulation mechanism into intrinsic and extrinsic pathways, it is now accepted that the two pathways do not operate independently of each other. Current thought is that TF is the key initiator of coagulation in vivo because it can activate both F-X and F-IX (Figure 20 ■).

TF is not normally expressed on cells in contact with blood but is found on the surface of a variety of cell types outside the vasculature. Upon injury, cells expressing TF are exposed to the blood. Membrane-bound TF binds F-VII or F-VIIa with high affinity, anchoring the complex to the site of injury. F-VIIa/TF then activates F-X to F-Xa, and the common pathway continues. The extrinsic activation of F-X seems to make the activation of F-X by the intrinsic Xase complex (F-IXa, F-VIIIa, PL, and Ca^{2+}) unnecessary, but clinical observations have demonstrated the absolute necessity of these factors for normal hemostasis. Patients with F-VIII and F-IX deficiencies have major bleeding problems as do patients with severe deficiencies of factors II, V, VII, and X. The observation that F-VIIa/TF also activates F-IX to IXa demonstrates that extrinsic pathway activation could result in activation of F-X through both “intrinsic” and “extrinsic” mechanisms (Figure 20). The roles of TFPI and the positive feedback effects of thrombin also contribute to explaining physiologic coagulation.

When coagulation is triggered, a series of events occurs, described as the *initiation*, *propagation*, and *termination* phases of coagulation. Coagulation is initiated when TF-bearing cells are exposed to blood at a site of vascular injury. TF binds and activates F-VII, and the TF-VIIa complex binds and activates F-X and F-IX on the surface of the TF-bearing cells. The result is the generation of a small amount of thrombin, which may or may not be sufficient to induce fibrin formation. However, it is sufficient to set in motion the events that will result in a subsequent burst of thrombin generation.

■ **FIGURE 20** Tissue factor initiation of the physiologic pathway by activation of F-IX and F-X. Dotted lines indicate positive feedback activation of TF-F-VII by F-Xa and activation of F-XI by thrombin. TF = tissue factor

The small amounts of thrombin formed during the initiation phase initiate a series of events, associated with the multiple roles of thrombin in hemostasis that culminate in the acceleration or propagation of the coagulation mechanism. These events include the activation of (1) platelets, (2) F-V, F-VIII, and F-XIII, and (3) F-XI. The F-Xa that is produced on the TF-bearing cell is almost immediately inhibited by TFPI, which quickly inhibits the F-VIIa/TF complex. Formation of thrombin through the extrinsic pathway is transient and subsequent propagation of the coagulation cascade occurs on the surface of activated platelets (activated by either the initial injury or thrombin generated during the initiation phase). Further activation of F-X and the coagulation cascade occurs through the “intrinsic” pathway by the F-IXa-F-VIIIa complex generated by F-VIIa/TF activation of F-IXa and thrombin activation of F-XIa. The result is massive prothrombin activation and with the surge in thrombin generation, activation of protein C and TAFI (via thrombin binding to thrombomodulin).

Once the platelet/fibrin clot has formed, the coagulation process must be terminated to prevent clot extension into noninjured areas of the vasculature. The termination phase is the phase in which the coagulation reactions subside. Activated by the burst of thrombin generation in the propagation phase, the PC/PS/TM system inactivates F-Va and F-VIIIa, preventing the generation of additional thrombin. The intact endothelium adjacent to the area of injury also has AT and TFPI bound to heparin sulfate molecules on the surface, which inactivates any proteases that venture beyond the injury area. Circulating protease inhibitors directly inhibit proteases that escape into the fluid phase.

Thus, patients with hereditary deficiencies of F-XII, PK, and HK have a markedly prolonged partial thromboplastin time (PTT), suggesting an abnormality in the intrinsic pathway, but they do not have abnormal bleeding in vivo because in vivo hemostasis requires only F-VIIa/TF activation of F-IX and F-X and thrombin activation of F-XI. The severe bleeding seen in patients with deficiencies of F-VIII or F-IX is due to their inability to generate the “burst” of thrombin generation associated with the propagation phase of coagulation. Linked to a level of thrombin generation insufficient to generate an adequate fibrin clot is the failure to activate TAFI and its suppression of fibrinolysis.

CASE STUDY (continued from earlier in this chapter)

A specific assay for F-VII activity was done on Shawn and both of his parents. His F-VII activity was found to be 3% of that in normal plasma. Prothrombin and F-X activities were normal. The F-VII activity of Shawn's father and mother was 50% and 47%, respectively. (The reference range of F-II activity is 70–120%.)

12. Do these findings explain the patient's bleeding history?

SUMMARY

The hemostatic system functions to keep blood fluid within the vasculature and to prevent excessive blood loss upon vascular injury. Platelets, vascular endothelial cells, and numerous coagulation proteins interact to maintain a balance between bleeding and clotting in vivo. Primary hemostasis occurs through activation of platelets and results in the formation of an unstable platelet plug. The formation of

fibrin (coagulation) subsequently reinforces this resulting in stabilization of the platelet plug, or secondary hemostasis.

The process of fibrin formation is carefully controlled, limited to areas of damage within the vascular network. Localization of the response to the site of injury prevents widespread coagulation activation. Activation of the coagulation system occurs on phospholipid membrane surfaces (activated platelets) or on exposed subendothelial tissue at sites of vessel injury. Coagulation involves a series of sequential activations of inactive proenzymes to active enzyme products. Classically, activation of the coagulation system has been described as being initiated via one of two possible pathways, the intrinsic and the extrinsic. Currently, however, it is believed that this distinction, while useful in discussing the system, is probably not physiologically relevant. In vivo, activation of coagulation is believed to be initiated by F-VIIa/TF activation of F-X and IX.

Each sequential activation step in the coagulation cascade, involving the generation of an active clotting enzyme, is modified

and/or controlled by cofactors that accelerate the activation and inhibitory mechanisms that slow activation. The net result of these two opposing forces is a well-balanced physiologic process designed to control activation of the system to an appropriate degree. The final activation step results in the formation of the enzyme thrombin, which is responsible for converting the soluble plasma protein, fibrinogen, into an insoluble state, fibrin.

Once the fibrin clot has been formed and hemostasis achieved, repair of the damaged vascular tissue is initiated. The final step in the process requires the dissolution of the fibrin clot once it is no longer needed by the plasma fibrinolytic system. Like clotting, fibrinolysis involves the activation of an inactive proenzyme precursor (plasminogen) to the active enzyme plasmin. This process is also regulated by both activators (plasminogen activators) and inhibitors (plasminogen activator inhibitors and α_2 -antiplasmin).

REVIEW QUESTIONS

LEVEL I

- Which of the following is (are) involved in hemostasis? (Objective 1)
 - only blood clotting
 - clot formation, clot dissolution, vessel repair
 - only blood clotting and bleeding
 - only keeping blood in the fluid state
- Which describes the events involved in secondary hemostasis? (Objective 2)
 - lead to the formation of a chemically stable fibrin clot
 - usually occur independently of primary hemostasis
 - are uncontrolled
 - occur in a random fashion
- Which factor is known as the antihemophilic factor? (Objective 3)
 - F-IX
 - F-XI
 - F-VIII
 - F-XII
- The prothrombin group includes which of the following coagulation proteins? (Objective 4)
 - factors I, V, VIII, XIII
 - PK, HK, F-XI, F-XII
 - factors II, VII, IX, X
 - factors I, II, V, X
- Which of the following function as cofactors in hemostasis? (Objective 6)
 - fibrinogen, prothrombin
 - F-Va, F-VIIIa
 - factors IXa, XIa, XIIa
 - platelet phospholipid, Ca^{2+}

LEVEL II

- Hemostasis depends on the balance of which of the following? (Objective 1)
 - the interaction of blood vessels, platelets, and coagulation proteins
 - the interaction between platelets and coagulation proteins
 - the interaction between blood vessels and coagulation proteins
 - the rate of complex formation
- Which statement most accurately describes the domains of coagulation proteins? (Objective 2)
 - The catalytic region distinguishes each of them from trypsin.
 - The catalytic region gives each protein its own identity.
 - The noncatalytic regions are identical in all coagulation proteins.
 - The domains impart specificity and recognition to control hemostasis.
- Which of the following is true concerning the formation of protein complexes that occur during coagulation? (Objective 3)
 - slows the rate of reaction
 - does not require the presence of Ca^{2+} ions
 - is not necessary for normal coagulation
 - localizes the reaction to the site of injury

REVIEW QUESTIONS (continued)

LEVEL I

6. What activates the extrinsic pathway? (Objective 7)
 - a. exposure to negatively charged surfaces
 - b. contact with tissue factor
 - c. the intrinsic pathway
 - d. F-XIIa
7. Which factors are involved in the initial activation of the coagulation system and require contact with a negatively charged surface for their activation? (Objectives 7, 8)
 - a. factors II, V, VII, X
 - b. factors XII, XI, PK, HK
 - c. factors II, VII, IX, X
 - d. factors I, V, VIII, XIII
8. Which of the following is *not* involved in the fibrinolytic system? (Objective 10)
 - a. plasminogen activator inhibitors
 - b. plasmin
 - c. thrombin
 - d. F-XII, kallikrein
9. Which of the following is (are) end products in the breakdown of fibrin? (Objective 11)
 - a. fragment X
 - b. fragments Y and D
 - c. fragments D and E
 - d. fibrin monomer
10. Which of the following pairs the correct protein with its inhibitor? (Objective 12)
 - a. thrombin–antithrombin
 - b. tissue factor–TFPI
 - c. heparin–heparin cofactor II
 - d. fibrin–TAFI

LEVEL II

4. Which of the following describes the contact factors (PK, HK, F-XI, F-XII)? (Objective 4)
 - a. have a significant role in initiating hemostasis in vivo
 - b. all cause a serious bleeding problem when defective or deficient
 - c. contribute to fibrinolysis, inflammation, and complement activation
 - d. can be assayed by the prothrombin time
5. What is the role of ADAMTS-13 in hemostasis? (Objective 6)
 - a. activate protein C to activated protein C
 - b. cleave ULVWF to multimers normally found in the circulation
 - c. serve as a receptor for uPA on hepatocytes
 - d. inhibit activated hemostatic proteases
6. What is the hepatic cell receptor which binds and clears tPA/PAI-1, plasmin/AP, and uPA/PAI-1 complexes from the circulation? (Objective 6)
 - a. UPAR
 - b. LRP
 - c. annexin-2
 - d. thrombomodulin
7. What is the procoagulant function of thrombin? (Objective 5)
 - a. activate of F-XII
 - b. inactivate protein C
 - c. suppress platelet activation
 - d. activate F-V and F-VIII
8. What is needed for fibrinolysis to occur at a physiologically significant rate? (Objective 7)
 - a. tPA must bind to fibrin
 - b. circulating plasminogen must be activated to plasmin
 - c. PAI-1 must be inhibited by α_2 -antiplasmin
 - d. plasminogen must be bound to fibrinogen
9. Which is true of TFPI? (Objective 8)
 - a. is found in platelets
 - b. is unique because two different proteases are inhibited at the same time
 - c. does not require Ca^{2+}
 - d. inhibits the entire coagulation cascade by inhibiting the extrinsic pathway
10. The following results were reported on a 10-year-old male with a history of bleeding problems: prothrombin time—29.5 seconds (control 12.5 seconds); partial thromboplastin time—51.0 seconds (control 55.4 seconds). What do these results indicate? (Objective 9)
 - a. a F-VII defect or deficiency exists
 - b. a defect in the intrinsic system exists
 - c. the child has hemophilia A
 - d. platelet testing should be done

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Shawn, a 10-year-old boy, had recurrent nosebleeds and anemia. Epistaxis began when he was about 18 months old. The nosebleeds occurred one or two times a month and began spontaneously. He bruised easily. The family history indicated that the boy's grandparents were cousins. The patient had a brother who died at 10 years of age of intracranial hemorrhage. Laboratory testing revealed a prolonged PT but an APTT in the reference range. This suggests a defect in one of the coagulation factors in the extrinsic pathway.

Question:

1. What do the results of the screening tests platelet count, bleeding time, prothrombin time (PT), and activated partial thromboplastin time (APTT) indicate?

Explanation:

Screening tests indicate the platelet compartment (primary hemostasis) is likely normal. The problem probably is a defect of the plasma proteins (secondary hemostasis).

Question:

2. What component of the hemostatic mechanism is most likely affected?

Explanation:

A normal APTT and a prolonged PT indicate a defect of the extrinsic pathway.

Question:

3. What evidence exists to indicate that Shawn has a hereditary bleeding disorder?

Explanation:

This patient's bleeding history began when he was just 18 months old and has occurred regularly since that time. Nosebleeds begin spontaneously (in the absence of trauma), and the patient has a history of easy bruisability. One brother also had a bleeding diathesis and died of intracranial hemorrhage at age 10.

Question:

4. Are the nosebleeds significant in considering a diagnosis?

Explanation:

Nosebleeds in the absence of trauma are significant; although they often indicate a platelet defect, platelet screening tests in this patient were normal.

Question:

5. What coagulation factors are included in the extrinsic pathway?

Explanation:

F-VII and tissue factor.

Question:

6. What factors are included in the intrinsic pathway?

Explanation:

F-XII, F-XI, prekallikrein, high molecular weight kininogen, F-IX, and F-VIII are included.

Question:

7. What factors are included in the common pathway?

Explanation:

F-X, F-V, prothrombin, and fibrinogen are included.

Question:

8. An abnormal PT and a normal APTT would indicate a problem with which factor?

Explanation:

F-VII.

Question:

9. Does any evidence exist to indicate a problem with Shawn's fibrinolytic system?

Explanation:

No.

Question

10. Why were liver function tests done on Shawn?

Explanation:

They were done to rule out an acquired deficiency of coagulation proteins.

Question

11. What is the significance of normal results in a patient with hemostatic disease?

Explanation:

Deficiency of one or more coagulation factors in the absence of liver disease or overt clinical thrombosis suggests a genetic deficiency of the factor being evaluated.

Question

12. Do these findings explain the patient's bleeding history?

Explanation:

Yes, the boy has a homozygous F-VII deficiency, and his parents are heterozygous. Because homozygosity for F-VII is rare, the family history proved to be significant. The nosebleeds (more commonly associated with platelet dysfunction) are probably due to the reduction of thrombin generation upon hemostatic activation and the resultant loss of thrombin-catalyzed platelet activation.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

What is the major distinction between the so-called extrinsic and intrinsic pathways?

Answer

Both pathways require enzymes and protein cofactors originally present in plasma; however, the extrinsic pathway also requires an activator (tissue factor) that is not found in the blood under normal circumstances.

Checkpoint! 2

Will a patient who is vitamin K-deficient produce any of the vitamin K-dependent factors? Why is vitamin K so vital to the formation of coagulation complexes?

Answer

A patient who is vitamin K-deficient still synthesizes the proteins but fails to attach the extra carboxyl group to the γ -carbon of glutamic acid residues in the GLA domains of the protein, which is required for full functional activity of the proteins. The γ -carboxy form of the proteins is required for Ca^{2+} -mediated interaction with phospholipid surfaces, which is required for forming the coagulation activation complexes.

Checkpoint! 3

Why are the domains of the serine proteases involved in blood clotting so important in the hemostatic mechanism?

Answer

The catalytic domain of the protease cleaves the substrate(s) of this protease. The various noncatalytic domains of the serine proteases contain the regulatory elements of the proteins and are responsible for conferring the specificity of activation and activity of each enzyme. They bind calcium and promote interaction with phospholipids, cofactors, receptors, and substrates.

Checkpoint! 4

Which components of the intrinsic pathway are believed to be essential for in vivo hemostasis?

Answer

Factors IX, VIII, and possibly factor XI are the components. Factor XII, prekallikrein, and HMW kininogen are not essential for normal in vivo hemostasis.

Checkpoint! 5

Historically, the major importance for initiating coagulation was assigned to either the intrinsic or the extrinsic pathway. What are some observations that suggest that the classic concepts were not accurate?

Answer

Thrombin can activate factor XI, bypassing the need for contact activation by factor XII/kallikrein/HK. Factor IX can be activated by factor VIIa as well as factor XIa (again, bypassing the need for contact activation). Thus, initiation of coagulation by tissue factor/factor VII is sufficient to initiate activation of both pathways. However, full escalation of the coagulation system requires proteins of both pathways.

Checkpoint! 6

What are the three steps in the formation of an insoluble fibrin clot?

Answer

(1) Proteolytic cleavage of fibrinopeptides A and B by thrombin, forming a fibrin monomer, (2) spontaneous polymerization of fibrin monomers to form fibrin polymers, and (3) stabilization of the fibrin polymers by F-XIIIa.

Checkpoint! 7

Why is the process of fibrinolysis a vital part of the hemostatic mechanism? Why must it be closely regulated and controlled?

Answer

Fibrinolysis is needed to restore the blood vessel structure and function to normal when the fibrin clot is no longer needed. It is essential

to balance the activity of the procoagulant proteins. If activity of fibrinolysis is deficient, the result is thrombosis; if fibrinolysis is excessive, the result is hemorrhage.

Checkpoint! 8

Why are the plasmin degradation products of fibrinogen and fibrin different?

Answer

Plasmin cleaves at the same place on molecules of either fibrin or fibrinogen (at the coiled regions, midway between the terminal D domains and the C-central domain). In fibrinogen, this produces separate D and E fragments. However, because fibrin monomers have been covalently crosslinked by F-XIIIa, complexes of various combinations (particularly the so-called D-dimer) are formed. The presence of D-dimer confirms that both the procoagulant system (thrombin) and the fibrinolytic system (plasmin) have been activated.

Checkpoint! 9

Why are naturally occurring inhibitors important in the hemostatic mechanism?

Answer

Naturally occurring inhibitors help control the activity of the coagulation and fibrinolytic proteases. They are inactive when distant from a site of vessel damage, helping to limit clot formation to areas of vessel injury. They are essential in preventing unwarranted initiation or excessive amplification of the coagulation cascade.

Disorders of Primary Hemostasis

Barbara A. O'Malley, M.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define and differentiate among *thrombocytopenia*, *thrombocytosis*, and *thrombocythemia* and state an expected range of platelet count in each.
2. Define and differentiate among *petechiae*, *purpura*, *ecchymosis*, *hematoma*, and *easy bruisability*.
3. Identify laboratory tests that can be ordered to screen for abnormalities of the hemostatic system.
4. Explain the expected clinical consequences when a patient has an abnormality of platelets or blood vessels.
5. Correlate quantitative variations in the platelet count with disease manifestations.
6. Recognize hematologic disorders that are characterized by the presence of thrombocytopenia or thrombocytosis.
7. Describe the etiology, pathophysiology, and laboratory findings of the thrombocytopenias.
8. Differentiate primary (malignant) from secondary (reactive) thrombocytosis.
9. Explain the effect of aspirin and its duration on platelet function.
10. Identify the cause and describe the clinical and laboratory features of hereditary disorders of platelet function.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Categorize each specific disorder of hemostasis by body system affected (e.g., vasculature, platelets).
2. Predict the type of bleeding symptoms in patients with disorders of primary hemostasis.
3. Describe the expected symptomatology, etiology, pathophysiology, and laboratory test results in patients with disorders of the vasculature.
4. Organize thrombocytopenic and thrombocytosis conditions by etiology and pathophysiology and explain laboratory findings in each condition.
5. Differentiate acute from chronic immune thrombocytopenic purpura by significant clinical and laboratory data.
6. Explain the pathophysiology of thrombocytopenia and thrombocytosis in hematologic disorders.
7. Organize the hereditary and acquired qualitative platelet defects by etiology and pathophysiology, and predict the clinical and laboratory features.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Diagnosis of bleeding disorders
- ▶ Disorders of the vascular system
- ▶ Platelet disorders
- ▶ Summary
- ▶ Review questions
- ▶ References

OBJECTIVES—LEVEL II (continued)

8. Explain the biochemical mechanism of the effect of aspirin on platelet function and recommend a time frame for patients to refrain from taking aspirin and related anti-inflammatory drugs prior to platelet function testing.
9. Summarize the effect of aspirin, alcohol, and antibiotics on platelet function.

KEY TERMS

Bernard-Soulier syndrome (BSS)
 Congenital amegakaryocytic thrombocytopenia (CAMT)
 Congenital thrombocytopenia with radioulnar synostosis (CTRUS)
 δ -storage pool disease
 Disseminated intravascular coagulation (DIC)
 Ecchymoses
 Epistaxis
 Fanconi anemia (FA)
 Glanzmann's thrombasthenia (GT)
 Gray platelet syndrome (α storage pool disease)
 Hematoma
 Hemolytic uremic syndrome (HUS)
 Heparin-associated thrombocytopenia (HAT)
 Heparin-induced thrombocytopenia (HIT)
 Immune thrombocytopenic purpura (ITP)
 Ischemia
 May-Heggelin anomaly (MHA)
 Necrosis
 Neonatal alloimmune thrombocytopenia (NAIT)
 Nonthrombocytopenic purpura
 Petechiae
 Primary thrombocytosis
 Purpura
 Quebec platelet disorder
 Scott syndrome
 Secondary (reactive) thrombocytosis
 Thrombocytopenia with absent radii (TAR)
 Thrombotic thrombocytopenic purpura (TTP)
 Vasculitis
 Wiskott-Aldrich syndrome (WAS)
 X-linked thrombocytopenia (XLT)

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Hemostasis: Describe how a blood clot forms after an injury, especially the role of platelets in cessation of bleeding.
- ▶ Immunology: Define and describe antigen/antibody reactions, classes of immunoglobulins, and the process of immune complex formation.
- ▶ Immune hemolytic anemia: Summarize the pathophysiology of the immune hemolytic anemias.
- ▶ Laboratory methods: Correlate the automated platelet count with the platelet count estimate on a peripheral blood smear.
- ▶ Laboratory methods: Identify artifacts that can cause spuriously increased or decreased automated platelet counts.

Level II

- ▶ Hemostasis: Correlate the functions of the blood vessels, platelets, and coagulation factors in forming a blood clot.
- ▶ Neoplastic leukocyte disorders: Summarize the consequences of malignant diseases of the bone marrow, particularly as they relate to the production of platelets.
- ▶ Cytokines: Describe how cytokines and growth factors regulate the production of blood cells.
- ▶ Flow cytometry: Recognize and correctly utilize the CD nomenclature of cellular antigens.

CASE STUDY

We will address this case study throughout the chapter.

Mohammed, a 15-year-old male from Saudi Arabia, was admitted to the emergency room after an automobile accident with several superficial cuts and bruises to the head and arms. He was bleeding profusely, having more severe bleeding than would be expected from the nature of his wounds. Consider possible causes of this abnormal bleeding and the laboratory tests that might be used to differentiate and diagnose the cause.

OVERVIEW

This chapter is the first of two that describe abnormalities of the hemostatic system that result primarily in bleeding. It begins with a discussion of general clinical and laboratory aspects of hemostatic disorders. Following the general topics, defects in primary hemostasis, including the vascular system and platelets, are discussed. The pathophysiologic basis and clinical manifestations for each defect are presented, but the major emphasis is on laboratory involvement in the diagnosis and/or treatment of the conditions. It is important to correctly identify the cause of the hemostatic defect so that appropriate treatment or preventive measures can be implemented.

INTRODUCTION

Hemostasis minimizes blood loss from disruptive injuries to blood vessels and prevents blood loss from intact vessels. The hemostatic response includes vasoconstriction of blood vessels, primary hemostatic plug formation by platelet activation, fibrin formation by activation of soluble plasma proteins, and function of inhibitors that prevent inappropriate or excessive activation of hemostasis and regulate the system to allow activation only when and where it is needed. Adequate hemostasis depends on a large number of intricately balanced mechanisms. Abnormalities of one or more components in the process of clot formation (i.e., the blood vessels, platelets, or clotting factors) can lead to excessive bleeding. Failure to regulate excessive clot formation leads to thrombosis.

DIAGNOSIS OF BLEEDING DISORDERS

CLINICAL MANIFESTATIONS OF BLEEDING DISORDERS

A patient with a clinically significant bleeding disorder presents to the physician with hemorrhagic symptoms. Bleeding symptoms can range from easy bruisability to life-threat-

ening hemorrhage. The severity of the bleed is generally proportional to the severity and type of hemostatic defect.

The type of bleeding can indicate which component of the hemostatic system is defective. A defect in a component of primary hemostasis (vasculature, platelets) usually results in bleeding from the skin or mucous membranes, such as epistaxis (nose bleeds), gingival mucosa (gums), or menorrhagia (abnormal menstrual bleeding). Bleeding symptoms in patients with coagulation factor abnormalities, on the other hand, are usually internal, involving deeper tissues and joints.

Bleeding from subcutaneous blood vessels (capillaries) into intact skin can be visualized as petechiae, ecchymoses, or hematomas (Figure 1 ■). **Petechiae** are small red to purple spots in the skin less than 3 mm in diameter resulting from blood leakage through the endothelial lining of capillaries. Petechiae usually occur on the extremities because of the high venous pressure. When arising spontaneously, without trauma, they are painless. Several petechiae in one area can merge into a larger bruised area. Petechial lesions are characteristic of abnormalities of platelets and blood vessels and usually are not seen in coagulation factor disorders.

Ecchymoses are bruises that are larger than 1 cm in diameter and are caused by blood escaping through the endothelium into subcutaneous tissue, commonly from a vessel larger than a capillary. They are red or purple when first formed and become yellowish green as they heal and hemoglobin degrades into bilirubin and biliverdin. Ecchymoses can appear spontaneously or with trauma and can be painful and tender. They can occur when there are abnormalities of blood vessels, platelets, or coagulation factors.

Intermediate lesions (>3 mm but <1 cm) are called *intermediate purpura*. The word **purpura**, meaning purple, is used ambiguously but generally refers to all bruises from petechiae to ecchymoses. Purpura is also used as part of the name of diseases in which these typical symptoms occur such as immune thrombocytopenic purpura (ITP). A bruise is called a **hematoma** when blood leaks from an opening in a vessel and collects beneath intact skin. It is blue or purple and slightly raised. Hematomas can occur in any organ or tissue.

■ **FIGURE 1** Schematic drawing of bleeding manifestations in intact skin. **a.** Petechiae. **b.** Ecchymosis. **c.** Hematoma.

When ecchymoses and petechiae are found in higher than normal numbers and with less than usual trauma, the condition is termed *easy bruisability*. Another term used often in describing clinical manifestations of bleeding disorders is *excess bleeding*, which occurs from superficial cuts and scratches when platelets fail to form an effective primary hemostatic plug. Excess bleeding means that the bleeding is more prolonged and/or is more profuse than normal for the patient or as compared with a normal person. Blood can escape from visceral organs into any body cavity or from mucous membranes into any body orifice. Frank bleeding is characteristic of both platelet and coagulation abnormalities.

PHYSICIAN EVALUATION OF A PATIENT WITH ABNORMAL BLEEDING

Excessive bleeding can be caused by a local disruption of the vasculature, such as a bleeding ulcer, or by generalized failure of the hemostatic mechanism. In some cases both are present, compounding the effect of the vascular disruption. It is the physician's responsibility to determine the cause of the bleeding and to institute proper treatment. This requires obtaining an accurate medical history, performing a thorough physical examination, and ordering and interpreting the results of appropriate laboratory tests.

The patient's history should include:

- age of onset of hemorrhagic symptoms
- type of symptoms
- family history
- presence of other diseases
- complete drug history (including over-the-counter drugs and herbal supplements)
- exposure to toxins

The answers should enable the physician to decide whether a bleeding disorder exists, determine the probability of an inherited versus an acquired condition, and help define the affected portion of the hemostatic system. The age at which symptoms first appeared provides a clue to the disorder's etiology. Bleeding occurring at birth or shortly thereafter often indicates an inherited disorder, although onset later in life does not rule this out. Bleeding from the umbilical cord and/or from the circumcision site suggests a coagulation factor defect.

The persistence and severity of symptoms—whether occurring throughout life, a single event, or intermittently—is also informative. Bleeding in excess of that expected from a tonsillectomy, tooth extraction, trauma, injury, surgery, or childbirth can provide clues.

Family history is helpful in determining whether other family members have had similar symptoms. A pedigree analysis can help to establish the pattern of inheritance (X-linked, autosomal, dominant, or recessive). Patients with inherited abnormalities do not always have a positive family history, however, because spontaneous mutations occur in several hemostatic disorders.

The presence of an associated disease, such as a malignancy, aplastic anemia, leukemia, liver disease, uremia, or infection, must be considered. These conditions can be associated with secondary or acquired platelet disorders and/or coagulation defects.

A history of drug exposure is important to consider because many drugs are known to affect the hemostatic mechanism, and various drugs affect different portions of the system. Aspirin, chemotherapeutic drugs, coumadin, and other anticoagulants are examples, but there are many others. The reader is referred to the Website and to other texts that provide extensive lists of specific drugs that have been implicated in acquired hemostatic defects.^{1,2}

Finally, past or present exposure to toxic chemicals such as benzene, insect sprays, and hair dyes should be investigated.

On physical examination, the type and sites of bleeding are noted, as well as whether the bleeding is from single or multiple sites, and whether it is spontaneous or the result of trauma. Using the information from the history and physical examination, the physician orders appropriate laboratory tests to confirm and classify the presence of abnormal hemostasis.

LABORATORY EVALUATION OF ABNORMAL BLEEDING

Although laboratory testing plays an important role in evaluating a patient with a suspected hemostatic abnormality, it should never be a substitute for good clinical assessment of the patient. No single laboratory test can fully evaluate defective hemostasis, so initially a battery or group of screening tests is usually ordered. Based on their results, the physician can determine whether a detectable abnormality of hemostasis does exist and order the confirmatory tests necessary to define the disorder. Minimum screening tests include:

- platelet count
- prothrombin time (PT)
- activated partial thromboplastin time (APTT)

The results of one or more of these tests is abnormal in most patients with hemostatic disorders, and they are usually within the reference ranges if the patient does not have a defect in the hemostatic system. However, screening tests are not helpful in predicting *bleeding risk* for the patient. In patients with disorders of primary hemostasis, the PT and APTT are usually normal, and the platelet count may or may not be abnormal.

When the results of these screening tests are normal in a patient with a history of clinically significant bleeding, a vascular disorder or functional platelet defect is likely. Confirmatory tests of platelet function can then be ordered. These include the closure time (measured by platelet function analyzer, PFA-100®), platelet aggregation tests, flow cy-

tometry for platelet antigens, and the template bleeding time, which measures the time it takes for an incision to stop bleeding (if available on the laboratory test menu). The PFA-100 is an alternative or supplement to the bleeding time test. It provides automated assessment of platelet dysfunction. It aspirates a blood sample through a capillary at high shear flow to simulate the hemodynamic conditions of platelet adhesion and aggregation at a vascular lesion. The instrument uses cartridges with membranes that are coated with collagen and ADP or collagen and epinephrine. When the blood encounters the coated membranes, platelet adhesion, activation, and aggregation are triggered, leading to the occlusion of an aperture and cessation of blood flow. In the absence of abnormal results of platelet function testing, the physician can investigate the possibility of a vascular disorder.

Abnormality of the PT and/or APTT denotes a coagulation factor disorder. Numerous confirmatory tests are available to specify the diagnosis.

In some patients with mild hemostatic disease, the screening tests may not be sensitive enough to detect an abnormality. Other patients may have conditions that do not affect the screening tests. In such cases, a knowledgeable physician in the field of bleeding disorders can direct the clinical investigation using the information obtained from the clinical history and physical examination.

Laboratory testing for the hemostatic system consists of a number of tests, each of which evaluates a specific part of the hemostatic system. It is important for a clinical laboratory professional to correlate and understand the significance of the results of all hemostasis tests and to correlate the results with the patient's history, if available. In this way, potentially erroneous results can be identified, and/or additional testing procedures can be recommended.

✓ Checkpoint! 1

Assume that you are the clinical laboratory professional collecting a blood specimen from a patient with a suspected bleeding disorder. You noticed petechiae and several bruises on the patient's arm. What screening tests would the physician likely have ordered? What results of these tests would you expect (normal or abnormal) in this patient?

▶ DISORDERS OF THE VASCULAR SYSTEM

Because the blood vessels are actively involved in hemostasis in a variety of ways, a structural abnormality or damage either to the endothelial lining of blood vessels or the subendothelial structures can result from, or lead to, a variety of clinical manifestations and disease conditions. These disorders can be either inherited or acquired secondary to another condition. The hereditary vascular diseases are caused by abnormal synthesis of subendothelial connective tissue components³⁻⁸ (Table 1 🌱). Either abnormal subendothelium or altered endothelial cells cause acquired vascular disorders (Table 2 🌱).

Symptoms seen in vascular disorders are, for the most part, superficial bleeding, such as easy bruising, petechiae, or lesions that mimic them but are actually not caused by bleeding. In the majority of patients with a primary vascular disorder, hemostatic testing is entirely normal. Thus, the diagnosis of blood vessel disorders is most often made by exclusion (i.e., by finding no positive evidence for a disorder of platelets, coagulation factors, or fibrinolysis in a patient who has a history or physical examination suggesting a bleeding problem). The platelet count and screening tests for coagulation factors are usually normal in blood vessel disorders. The

🌱 TABLE 1

Characteristics of Inherited Disorders of the Vascular System

Disorder	Gene	Effect	Chromosome	Laboratory Findings

template bleeding time and other platelet function testing are also usually normal but can be prolonged in some vascular disease states.

When platelets are normal in number and function, purpura are considered to be caused by damage to the blood vessels, a condition called **nonthrombocytopenic purpura**.

HEREDITARY DISORDERS OF THE VASCULAR SYSTEM

Table 1 summarizes the hereditary disorders of the vascular system. They are very rare, and although bleeding is a common symptom, hemostasis tests are not informative in making the diagnosis. Some vascular disorders are associated with abnormal vessel wall integrity, but others manifest as vascular proliferative lesions. *Hemangiomas* are arteriovenous malformations caused by either upregulation of growth-promoting factors and/or inhibition of apoptosis. Most hemangiomas appear in infancy and spontaneously involute over the next several years. In contrast, the telangectasia lesions seen in hereditary hemorrhagic telangectasia slowly progress over decades. A more complete description of these disorders is available on this chapter's Companion Website.

ACQUIRED DISORDERS OF THE VASCULAR SYSTEM

Acquired disorders of the vascular system are seen quite often and are characterized by bruising and petechiae. Defects of either the vessel wall or the endothelial cells can be

caused by (1) conditions that decrease the supportive connective tissue in blood vessel walls, (2) presence of abnormal proteins in the vascular tissues, (3) infections or allergic conditions, and (4) mechanical stress. Acquired disorders of the vasculature are shown in Table 2.

Purpura Due to Decreased Connective Tissue

The diseases in this category are due to a decreased amount of supportive connective tissue in the blood vessel walls.

Senile Purpura Senile purpura are ecchymoses that appear with unrecognized or minor trauma in older individuals. With age, the extracellular matrix components of the skin degenerate, especially in body areas that have been exposed to sunlight. This decreases the supportive collagen fibrils and allows small blood vessels, particularly capillaries, to burst and form bruises with minor pressure. The bruises do not heal easily and can last for months.

Cushing Syndrome and Corticosteroid Therapy

Excess endogenous glucocorticosteroids (Cushing syndrome) or exogenous (therapeutic) glucocorticoids result in excessive breakdown of collagen, thin fragile skin, vessel wall fragility, and bruising.⁹ Small blood vessels can be mechanically broken and bleed into the skin.

Scurvy Scurvy is a disease caused by a deficiency of vitamin C, which is needed for collagen synthesis. In its absence, collagen production is abnormal, resulting in vascular fragility and bleeding. Bleeding gums and bleeding around hair follicles on arms and legs are characteristic; ecchymoses and intramuscular hemorrhages are also seen. Treatment is oral vitamin C.

Purpura Associated with Paraprotein Disorders

The diseases in this category are due to the presence of abnormal proteins in the vascular system.

Paraproteins Paraproteins are monoclonal immunoglobulins produced by monoclonal neoplastic plasma cells. They occur in a variety of malignant conditions such as multiple myeloma, Waldenström's macroglobulinemia, and lymphoproliferative disorders. Hemostatic symptoms include purpura, bleeding, and thrombosis. The mechanisms leading to these symptoms are varied and complex including qualitative platelet defects, acquired inhibitors and deficiencies of coagulation factors, binding of calcium by paraprotein leading to interference with coagulation, and deposition of light chain protein in the vascular wall. Thrombocytopenia can be present because of the underlying disease and contributes to the bleeding. Bleeding symptoms include epistaxis, petechiae, purpura, and hemorrhages into other organs, particularly the retina.⁹ Puncture wounds, such as a finger stick, bleed profusely.

Amyloidosis Amyloidosis occurs as a primary disorder, as well as secondary to paraproteinemias, such as multiple

myeloma. It is a condition in which deposits of amyloid (modified or misfolded proteins) form in the skin, perivascular tissue, and vessel walls. It leads to fragility of the vessels and to bruising. Bleeding into visceral organs can also occur, and thrombosis is common.

Purpura Due to Vasculitis

Vasculitis is inflammation of the small blood vessels. It occurs when immune complexes attach either to the endothelial cells or the underlying subendothelial structures and activate complement.⁵ The activation fragments of complement initiate several processes: (1) Neutrophils migrate to the area by chemotaxis and phagocytize the immune complexes. Enzymes, free oxygen radicals, and other substances are then released from the neutrophils and damage the vascular tissue. (2) Complement components C3a and C5a cause increased vascular permeability, resulting in vasodilation and edema. (3) The lytic complement cascade can be completed, resulting in damage to the vascular cell membranes.

Antigen–antibody complexes also cause aggregation of platelets and activation of factor XII (F-XII), both of which contribute to thrombosis. Thrombi can occlude blood vessels (**ischemia**) and could result in the destruction of the tissue supplied by the occluded vessels (**necrosis**). Activated F-XII results in the activation of kallikrein and the release of kinins from high molecular weight kininogens, which contribute to the vasodilation and edema associated with inflammation. The damaged vessels can rupture and produce localized purpura. The purpura caused by vasculitis are called *palpable purpura* because small nodules form at the site of the inflammation.¹⁰

The cause of the vasculitis in most patients is never found. Some conditions that are associated with vasculitis are:

- Henoch-Schönlein purpura
- infections
- drugs

Details of these conditions can be found on this text's Companion Website.

Miscellaneous Causes of Purpura

Other causes of purpura may or may not be related to abnormalities of the hemostatic system.

Mechanical Purpura Increased pressure within the lumen of capillaries after intense exercise, coughing spasms, or epileptic seizures can cause petechial hemorrhages in the skin.

Artificially Induced Purpura Artificially induced bruises can be self-inflicted (factitious purpura) or result from abuse by others. The cause is difficult to distinguish from a true physiologic (pathologic) process. Artificially induced purpura and bleeding occasionally are the result of unnecessary, secretive overuse of anticoagulant drugs such as

heparin and coumadin. Health professionals with psychological problems who are aware of the consequences of anticoagulant drugs and have the means to obtain them have been guilty of abusing these drugs. Petechial purpura can be induced by placing negative pressure on the skin for a prolonged period as, for instance, sucking the air from a glass held to the mouth. Petechiometers used for the capillary fragility test were based on this principle.

Easy Bruising Syndrome A benign condition called *easy bruising syndrome* (or *purpura simplex*) commonly occurs in young women. Spontaneous small ecchymoses appear on the skin of the thighs or upper arms and have been called *devil's pinches*. The cause of this condition is not fully understood at the molecular level but is thought to be due to hormonal effects on the blood vessel and/or its surrounding tissue.¹¹

Purpura Fulminans Purpura fulminans is a devastating type of purpura seen in newborns and others associated with abnormalities of certain clotting factors or their inhibitors and in some patients who are on therapy for thrombotic conditions. In purpura fulminans, thrombi form in the small vessels supplying the skin and subcutaneous tissues. The vessels become occluded, the skin becomes necrotic, and the condition can rapidly lead to death.

Psychogenic Purpura Psychogenic purpura refers to severe recurrent erythema and ecchymoses, often accompanied by pain and swelling. This was once theorized to be an allergic reaction to blood cells or DNA but no longer. It is generally believed to be a form of factitious purpura associated with a psychiatric illness. Most patients have normal coagulation studies and no evidence of underlying medical illness.⁵

CASE STUDY (continued from earlier in this chapter)

Petechiae were noted on Mohammed's extremities. Blood work was ordered.

1. What laboratory tests, hematology and hemostasis, that would be most informative in interpreting the cause of the patient's bleeding would likely be ordered immediately?
2. Does the patient most likely have a disorder of primary or of secondary hemostasis? Why?

▶ PLATELET DISORDERS

Platelets function in hemostasis to maintain the integrity of the blood vessels and to form the primary hemostatic plug in response to injury so that blood loss is minimized. Bleeding from a cut finger stops when the primary hemostatic plug has sealed the openings in the injured vessels. Formation of the primary hemostatic plug requires an adequate number of normally functioning platelets. If platelet numbers are de-

★ TABLE 3

Types of Bleeding in Disorders of Primary Hemostasis

- Petechiae
- Ecchymoses

- Excessive bleeding from superficial wounds
- Bleeding into the retina
- Gastrointestinal bleeding
- Bleeding in the urinary tract
- Hypermenorrhea
- Gingival bleeding (gums)
- Increased bleeding after tooth extraction
- Intracranial bleeding

creased or if platelet function is abnormal, an injury can bleed excessively.

Platelet disorders are classified as quantitative (numerical) or qualitative (functional). *Quantitative disorders* are those in which the platelet count is either below (thrombocytopenia) or above (thrombocytosis) the reference range. *Qualitative disorders* involve an abnormality of some aspect of platelet function.

Characteristic manifestations of the hemostatic defect seen in patients with platelet disorders are petechiae and excess bleeding from superficial areas of the body such as the skin and mucous membranes. **Epistaxis** (nose bleeds), excessive bleeding from cuts in the skin, and easy bruisability

are commonly experienced. Other possible sites of bleeding are listed in Table 3 ★. The bleeding symptoms reflect the decreased ability of the platelets to form the primary hemostatic plug.

Manifestations of increased platelet counts generally reflect the underlying problem that caused the thrombocytosis; occasionally there is increased likelihood of thrombosis (or rarely, hemorrhage).

QUANTITATIVE PLATELET DISORDERS

Quantitative abnormalities of platelets include thrombocytopenia or thrombocytosis. A reference range of $150\text{--}450 \times 10^9/\text{L}$ (Table C, front cover) is similar to that established by most laboratories. Platelets are usually counted by automated instruments, although some laboratories use manual counting methods as a backup.

The blood smear can also include the presence of morphologically abnormal forms of platelets, such as platelets larger (macrothrombocytes) or smaller (microthrombocytes) than normal, those with decreased or absent granules (hypogranular or agranular), or a combination of variables. Platelet variants should be recognized and reported by the clinical laboratory professional. Platelets are reported as macrothrombocytes if they are larger than normal and as giant forms (megathrombocytes) if they are larger than erythrocytes. Some laboratories use the term *giant platelet* to describe all abnormally large platelets (Figure 2).

a

b

Significant Laboratory Tests in Defects of Primary Hemostasis

	Screening Tests			
	Platelet Count	Prothrombin Time	APTT	Template BT
<i>Vascular disorders</i>	Normal	Normal	Normal	Normal or abnormal
<i>Thrombocytopenia</i>	Decreased	Normal	Normal	Abnormal
<i>Platelet dysfunction</i>	Usually normal	Normal	Normal	Normal or abnormal

✓ Checkpoint! 2

If you observed an average of 14 platelets per high power field on a peripheral blood smear prepared from the needle tip and your laboratory allowed correlation between the direct instrument count and the blood smear estimate of 20%, what range would you expect the instrument count to be? Is this platelet estimate within an acceptable reference range?

Thrombocytopenia

The lower limit of the reference range for platelets is approximately $150 \times 10^9/L$, but clinical symptoms are usually not seen unless the count falls below $50 \times 10^9/L$. When it is below $50 \times 10^9/L$, the severity of clinical manifestations can, to some degree, parallel the platelet count. At levels less than $30 \times 10^9/L$, possible symptoms include petechiae, menorrhagia, or spontaneous bruising with little or no trauma. The possibility of severe and spontaneous bleeding is quite high when the platelet count is below $10 \times 10^9/L$.¹¹ Fatal bleeding into the central nervous system as well as spontaneous bleeding from mucous membranes (e.g., the gastrointestinal tract, the genitourinary tract, and the nose) can occur. The extent of symptoms at all platelet levels varies from patient to patient and can be affected by medications, the blood vessel status, platelet activity, and concurrent disease.

When the patient has thrombocytopenia without other complicating factors, the bleeding time is generally prolonged proportionately at platelet counts between 10 and $100 \times 10^9/L$. The linear relationship is altered, however, if patients have abnormalities of platelet function in addition to the thrombocytopenia. The bleeding time is no longer available in most hospital laboratories. Laboratory tests for coagulation factors (PT and APTT) and for fibrinolysis are unaffected by thrombocytopenia. Table 4 ★ compares typical laboratory screening test results in thrombocytopenia, disorders of abnormal platelet function, and vascular disorders.

Thrombocytopenia, the most common cause of excess or abnormal bleeding, is not a disease per se but a symptom of an underlying condition as is anemia. The finding of a decreased platelet count with or without abnormalities of

other hematologic parameters alerts the physician to search for a cause so that the condition can be appropriately treated. A decreased platelet count can be the primary feature or a secondary manifestation of several conditions. This text classifies thrombocytopenia into five major categories based on pathophysiology (Table 5 ★).

Increased Destruction The most common cause of thrombocytopenia is increased destruction of platelets, resulting in a decreased platelet life span after they have been released into the peripheral blood. If the bone marrow is normal, it attempts to compensate for the decreased platelet numbers in the peripheral blood by increasing production. Consequently, bone marrow megakaryocytes are normal to increased in number. However, the platelets may be eliminated from the circulation faster than the bone marrow can produce them, resulting in thrombocytopenia (Figure 3 ■).

★ TABLE 5

Classification of Quantitative Platelet Abnormalities

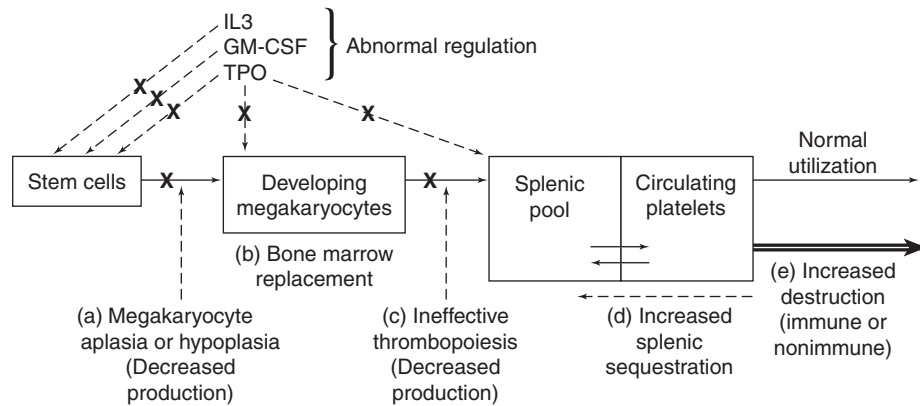

Thrombocytopenia

- Increased destruction
 - Immune
 - Nonimmune
- Decreased production
 - Megakaryocyte hypoplasia
 - Replacement of normal marrow
 - Ineffective thrombopoiesis
 - Inherited disorders
- Increased splenic sequestration
- Dilutional thrombocytopenia
- Conditions with multiple mechanisms of thrombocytopenia

Thrombocytosis

- Primary thrombocytosis
- Secondary thrombocytosis
- Transient thrombocytosis

Artifacts in the quantitative measurement of platelets

■ **FIGURE 3** Schematic drawing showing various causes of thrombocytopenia. IL3 = Interleukin 3; GM-CSF = granulocyte macrophage colony-stimulating factor; TPO = thrombopoietin; X = abnormal or absent

Causes of increased destruction include both immune mediated destruction and those processes that are nonimmune in nature (Table 6 🌟).

Immune Mediated Destruction. Immune platelet destruction is caused by antibodies and is analogous to the destruction of erythrocytes in immune hemolytic anemias. Platelets become sensitized with antibody, and the mononuclear phagocyte system, primarily in the spleen, destroys them. Monocytes and macrophages possess Fc receptors (Fc γ R) by which they recognize platelets coated with anti-

body (Figure 4 ■). In addition, liver macrophages can remove platelets when coated with large amounts of antibody. The length of time that antibody-coated platelets survive in the peripheral blood can range from a few minutes to 2 or 3 days as measured by ^{51}Cr assays.

Antibodies attach to platelets either by their Fab regions, binding to specific epitopes on GP IIb/IIIa or Ib/IX, or by nonspecific attachment of immune complexes to platelet Fc receptors (Figure 4). The antibodies can be IgG, IgA, or rarely IgM,¹² and complement may become activated. The level to which the platelet count becomes decreased depends on the concentration and activity of the antibody, the function of the macrophages Fc and complement receptors, and the ability of the bone marrow to increase platelet production to compensate for the increased loss.¹³

Unlike the immune hemolytic anemias, routine laboratory tests designed to quantitate the amount of immunoglobulin on platelets of thrombocytopenic patients are not available. Several laboratory procedures have been developed to measure the immunoglobulin on the surface (**platelet associated immunoglobulin [PAIg]**), as well as the total platelet immunoglobulin. Circulating platelets contain two distinct pools of IgG: surface associated and intracellular, within α -granules (αG). Normally, the platelet surface has fewer than 200 Ig molecules, while the αG contain approximately 20,000 Ig molecules. The internal immunoglobulin is absorbed from the plasma in proportion to the plasma concentration and, therefore, does not necessarily correlate with an immune process that is destroying the platelets.¹ Although the amount of platelet immunoglobulin is increased in many patients with immune thrombocytopenia, platelet immunoglobulins are also increased in several conditions not associated with the immune destruction of platelets.²

If performed, bone marrow aspiration evaluates the megakaryocytes and rules out other causes of thrombocytopenia.¹ The granulocyte and erythrocyte precursors show

🌟 **TABLE 6**

Classification of Thrombocytopenia Caused by Increased Destruction

Immune mechanisms of destruction

- Immune thrombocytopenic purpura
 - Acute
 - Chronic
 - Transplacental
- Alloimmune thrombocytopenia
 - Neonatal (NAIT)
 - Post-transfusion purpura
- Drugs
 - Quinidine/quinine
 - Heparin
- Other diseases

Nonimmune mechanisms of destruction

- Disseminated intravascular coagulation
- Thrombotic thrombocytopenic purpura
- Hemolytic uremic syndrome
- Mechanical destruction by artificial heart valves

■ **FIGURE 4** Mechanisms of thrombocytopenia caused by immune destruction of platelets. In immune thrombocytopenic purpura, antibody-sensitized platelets are recognized by Fc receptors of the splenic mononuclear phagocyte system and eliminated from the circulation. The bone marrow is stimulated by thrombopoietin and produces increased numbers of megakaryocytes. Thrombocytopenia develops if immune destruction exceeds the compensatory capacity of the marrow. The antibody can also injure megakaryocytes.

normal development with no abnormal cells present. Megakaryocytes are increased, often markedly, reflecting stimulation by thrombopoietin (TPO) to increase platelet production. In cases of severe thrombocytopenia, the marrow can increase production up to five times normal. The ploidy of megakaryocytes also can be increased, resulting in a larger cytoplasmic mass and an increased number of platelets produced per megakaryocyte. However, a majority

of the megakaryocytes often are young forms showing scant cytoplasm and lack of lobulation of the nucleus. Vacuoles in the cytoplasm have been described, which likely reflect the rapid turnover of megakaryocytes rather than abnormal morphology.

The mean platelet volume (MPV), as measured electronically, is increased in immune thrombocytopenia and can be a helpful clue for diagnosis. The peripheral blood smear has increased numbers of platelets that are $>2.5 \mu\text{m}$ in diameter.¹ An inverse relationship generally exists between the platelet count and the number of large platelets when the count is less than $50 \times 10^9/\text{L}$. TPO levels are generally normal in immune thrombocytopenias.

Autoimmune Thrombocytopenia The most common form of thrombocytopenia is **immune thrombocytopenic purpura (ITP)**, formerly called idiopathic thrombocytopenic purpura. ITP is an autoimmune disorder in which autoreactive antibodies bind to platelets, shortening the platelet life span. The clinical presentation can vary from an asymptomatic thrombocytopenia to severe mucosal bleeding. Because of the difficulty in identifying platelet-specific antibodies, the diagnosis of ITP is made by exclusion (i.e., ruling out all other causes of thrombocytopenia). It is based on the patient's history and physical examination, complete blood counts, and examination of the blood smear. Except for thrombocytopenia, the findings on a peripheral blood smear are within normal limits for the age of the patient unless an underlying condition exists. Other tests are usually not indicated.

The clinical features of ITP in children and adults are different. Children usually have an acute form of ITP, while adults have a chronic form of the disease (Table 7). Acute ITP occurs most often in children 2–4 years of age, shows no gender preference, and often follows a viral infection by 1–3 weeks. Nonspecific upper respiratory infections, chickenpox, rubella, cytomegalovirus, and viral hepatitis are some diseases that have been associated with ITP in children.

The platelet count is often less than $20 \times 10^9/\text{L}$. There can be an increase in the number of lymphocytes or mild eosinophilia in some cases, most likely related to the preceding infection. The marrow typically shows normal to increased numbers of megakaryocytes,¹⁴ but it is recommended that a bone marrow examination not be done on children with acute ITP unless the thrombocytopenia has persisted for at least 6 months and unless therapy was not helpful.

Symptoms of acute ITP include the abrupt onset of easy bruising, petechiae on the extremities, and bleeding from mucous membranes. Spontaneous bleeding into the central nervous system occurs in fewer than 1% of children whose platelet count is less than $20 \times 10^9/\text{L}$ but is the most dreaded consequence of ITP.¹⁵ The spleen is not enlarged, and the patient is afebrile.

Most patients (93%) with acute ITP experience a spontaneous remission within 2–6 weeks of the onset of the illness,^{1,14} and the disease does not recur in these patients.

★ TABLE 7

Comparative Features of Acute and Chronic ITP

Feature	Acute ITP	Chronic ITP
Peak age incidence	Children 2–4 years	Adults 20–40 years
Platelet count, initial	$<20 \times 10^9/L$	$30\text{--}80 \times 10^9/L$
Onset of bleeding	Abrupt	Insidious
Type of bleeding	Petechiae and superficial	Petechiae and superficial
Antecedent infection	Common 1–3 weeks prior	Unusual
Gender predilection	None	Females 3:1
Eosinophilia	Common	Rare
Lymphocytosis	Common	Rare
Hemorrhagic bullae in mouth	Present in severe cases	Usually absent
Duration	2–6 weeks	Months or years (lifetime)
Spontaneous remissions	Occur in 93% of cases	Rare; course of disease fluctuates
Therapy	Corticosteroids, anti-D, IVIg	Corticosteroids, splenectomy

IVIg = intravenous immunoglobulin

Some patients fail to achieve a remission by 6 months and are then said to have the chronic form of the disease.

Treatment for patients with acute ITP includes prevention of trauma to reduce the risk of bleeding and simple observation to see that the symptoms subside and the platelet count increases. Because of the high spontaneous remission rate, most patients usually require no specific treatment. The goal of treating patients, if needed, is to raise the platelet count to a level that supports adequate hemostasis as rapidly as possible while preventing life-threatening bleeding. The type of therapy recommended depends on whether the patient is actively bleeding or is *at risk* of bleeding. In general, replacement therapy with platelet transfusions should be used only in life-threatening situations. Some physicians give steroids in an attempt to reduce the risk of bleeding into the central nervous system, but steroids have undesirable side effects.¹ The platelet count increases at a faster rate if a pooled preparation of immunoglobulins (IVIg) or anti-D prepared from donors with high titers of anti-D antibodies (WinRho®) is given. Anti-D binds to D-positive erythrocytes, and splenic mononuclear phagocytes then destroy the sensitized red cells instead of the sensitized platelets.¹⁶ This therapy is limited, therefore, to Rh positive individuals.

✓ Checkpoint! 3

How many platelets per $1000\times$ field would you expect to observe on the peripheral smear of a patient with acute ITP?

Chronic ITP is defined as persistent thrombocytopenia lasting more than 6 to 12 months.¹⁴ The chronic form of ITP differs from acute ITP in several aspects including typical patient age, female predominance, insidious onset, and initial

platelet count (Table 7). Chronic ITP rarely has a spontaneous resolution.

The diagnosis is made based on the patient's history, physical examination, peripheral blood counts, and blood smear examination. From 30% to 40% of adult patients with ITP are asymptomatic and are diagnosed only by the incidental finding of a low platelet count.¹⁷ Bleeding symptoms are rare unless the thrombocytopenia is severe. As in acute ITP, the erythrocyte and leukocyte morphology are usually normal with thrombocytopenia being the only significant finding.¹⁴ Bone marrow examination is not recommended unless it is necessary to rule out other diseases with similar presentation, such as acute leukemia, aplastic anemia, or myelodysplastic syndrome. No other testing is recommended unless the patient is at risk for HIV infection.¹⁸

Antiplatelet autoantibodies can be identified in 58–80% of patients with chronic ITP. Most are directed toward epitopes on either GPIIb/IIIa or GPIb/IX; however, the exact antigenic stimulation is unknown.¹³ Although the numbers of megakaryocytes in the bone marrow are normal or increased, platelet production is generally decreased to low normal (rather than a compensatory increase as might be expected) probably due to the effect of antiplatelet antibodies on the marrow megakaryocytes.¹⁷ Most patients have normal platelet function, but some patients have impaired platelet function, likely due to antibody binding to the GPIIb/IIIa or GPIb/IX receptors (producing in essence an “acquired” Glanzmann thrombasthenia or Bernard Soulier syndrome).

The goal of ITP treatment is to reach a safe platelet count, not a normal platelet count.¹⁷ Patients with chronic ITP are treated only if their platelet counts are less than $30 \times 10^9/L$ or if symptoms necessitate it. Corticosteroids are recommended and result in a durable complete response in two-thirds of patients. Splenectomy is advised for patients who

are unresponsive and symptomatic after treatment with corticosteroids because the spleen is a major site of antibody production as well as the destruction of the platelets.¹⁸ Splenectomy is successful in a majority of patients, although relapse occurs in 10% to 12% within 1–5 years. The decision to splenectomize the patient usually rests on the patient's previous responses to different treatment modalities. The major risk of splenectomy is overwhelming bacterial sepsis; thus, immunization against encapsulated bacteria at least two weeks prior to surgery is recommended.¹³

Some patients are refractory to both corticosteroid therapy and splenectomy. IVIg improves the platelet count temporarily, but anti-D is not recommended for patients with chronic ITP.¹⁴ For patients who are refractory to this therapy, the most aggressive treatments include chemotherapeutic agents such as vincristine or vinblastine or immunosuppressive therapies such as cyclosporin. Rituximab, an anti-CD20 monoclonal antibody, is a targeted immunotherapy directed specifically toward B lymphocytes. It has been reported to induce complete or partial response in 50% of patients.

The clinical course of ITP in some patients consists of alternate periods of remission within 6 months of the onset followed by relapse after at least 3 months. This is referred to as an *intermittent* form of the disease.

Transplacental (or neonatal) ITP is an immune form of thrombocytopenia that occurs in newborn infants of mothers with ITP. It is estimated to affect 1–2 of every 10,000 pregnancies.¹⁹ Approximately 15% to 65% of newborns of mothers with ITP have thrombocytopenia at birth. Between 6% and 70% of them will have severe thrombocytopenia with platelet counts of less than $50 \times 10^9/L$. The maternal platelet count does not correlate with that of the fetus, so there is no way to predict which neonates will be at risk. The major hazard is intracranial bleeding during delivery. Thrombocytopenia lasts an average of 3–4 weeks postdelivery until the maternal antibody is cleared from the newborn's system.¹⁹

Alloimmune Thrombocytopenias Immune platelet destruction can be caused by alloantibodies stimulated by foreign antigens during pregnancy or after blood transfusions. **Neonatal alloimmune thrombocytopenia (NAIT)** is similar to hemolytic disease of the newborn except that the antibodies are directed toward platelet antigens rather than erythrocyte antigens. Platelet destruction in the newborn is due to maternal alloantibodies formed against a platelet-specific antigen the baby inherited from the father and that the mother lacks.¹³

The most frequently encountered platelet antigen causing NAIT is HPA-1a (PLA1). Approximately 97% of Caucasian people have the HPA-1a antigen, but 3% are homozygous for the alternate allele HPA-1b (PLA2) and will be immunized if exposed to HPA-1a.¹³ When maternal IgG antiplatelet antibodies cross the placenta, immune destruction of the infant's platelets occurs. Figure 5a ■ shows a proposed mechanism

of attaching alloimmune or autoimmune antibodies to the platelet surface.

Symptoms appear at or shortly after birth and are self-limited. There is, however, a high mortality rate due to bleeding into the central nervous system. This may be a result of birth trauma that is complicated by the natural low levels of certain coagulation proteins in the fetus and newborn. Thus, it is important to recognize NAIT and treat it with IVIg or transfusion with HPA-1a negative platelets as soon as possible.¹²

Rarely patients develop severe alloimmune thrombocytopenia 7–10 days after blood transfusion (post-transfusion purpura). Symptoms such as bleeding from mucous membranes and purpura begin abruptly and last 2–6 weeks. The alloantibody is usually directed against the HPA-1a antigen, but other platelet-specific antigens have been implicated as well. The mechanism of alloantibody destruction of autologous platelets negative for the antigen is controversial, and more than one mechanism may be operative.¹³

Drug-Induced Thrombocytopenia Drug-induced thrombocytopenia is relatively common, and a number of drugs have been implicated as a cause of thrombocytopenia in a small percentage of patients who take them.^{1,2} A list of the drugs that have been identified as causing thrombocytopenia is accessible at <http://w3.ouhsc.edu/platelets>. There is little experimental evidence to establish that some drugs are the actual cause of the decreased platelet count because the thrombocytopenia occurs weeks to months after the drug was first taken. Some drugs can cause a generalized hematopoietic suppression; others cause selective suppression of platelet production. Other drugs cause thrombocytopenia by increasing platelet destruction with circulating immunoglobulins apparently being the cause of the platelet destruction.

More than 200 drugs have been reported to cause thrombocytopenia. Some most commonly reported to cause immunologic thrombocytopenia are quinidine, quinine, gold salts, sulfonamides and derivatives, and heparin. The experimental and clinical association for these drugs is more substantial. In some cases, the offending agent is a metabolite of the drug formed in vivo rather than the original form of the drug.

Symptoms of excess bleeding appear suddenly and can be severe. The platelet count can be very low, often less than $10 \times 10^9/L$. Bleeding manifestations include petechiae, purpura, and, occasionally, intracranial hemorrhage. On first exposure, symptoms appear 6–7 days after taking the drug. After the patient has been sensitized, symptoms can occur immediately after taking a dose. Usually the only necessary treatment is withdrawal of the offending drug. When the drug is removed, the drug-dependent antibody cannot bind to the platelets, and the platelet count rises and symptoms subside.²⁰ The exception is the thrombocytopenia induced by α -methyl dopa and gold, a condition in which the antibodies bind to platelets even in the absence of the drug.

■ **FIGURE 5** Variations in antibody binding to platelets. **a.** Platelet autoantibodies or alloantibodies bind to epitopes on GPIIb/IIIa, GPIb/IX, most frequently, or to other glycoproteins resulting in ITP. **b.** Quinine/quinidine-dependent antibodies bind to a complex of drug and glycoprotein, usually either GP-Ib/IX or IIb/IIIa. **c.** Heparin binds platelet factor 4 and the heparin/PF4 complex attaches to IgG antiheparin antibodies via the Fab combining site. The Fc portion of the antibody binds to platelet IgG Fc₁/IIa receptors.

Three pathways have been proposed to explain drug-induced immune-mediated platelet destruction. The first mechanism, the *hapten theory*, proposes that the drug binds covalently with platelets to form a drug-platelet antigenic complex, and the drug acts as a hapten. A drug-dependent antibody is formed that recognizes and binds to this complex. However, few studies support the hapten model of antibody formation except for perhaps the thrombocytopenia seen with large doses of penicillin. The second model was the *innocent bystander mechanism* in which the drug binds to a plasma protein and elicits an antibody response. Antibody binding to the drug-protein complex forms an immune complex that nonspecifically binds to circulating platelet Fc receptors (Figure 5c■). Again, with the exception of some heparin-induced thrombocytopenias, most drugs do not appear to work via this mechanism.

The most common mechanism is the formation of drug-dependent antibodies against epitopes created by the association of the drug with proteins on the platelet surface. The

association can be a specific ligand-receptor interaction, often with GPIIb/IIIa molecules, or a nonspecific noncovalent interaction. Some drugs can create neoepitopes for antibody formation by interacting with the platelet surface glycoproteins. Antibodies to quinidine and quinine bind to either drug/GPIb/IX or drug/GPIIb/IIIa complexes on the platelet surface by their Fab portions (Figure 5b■).

The mechanism of platelet destruction is similar to that described previously: antibodies bind to the platelet, and the mononuclear phagocyte system removes the platelet. Drug-induced thrombocytopenias occasionally are caused by inhibition of megakaryocyte proliferation and platelet production as well as destruction of platelets in the circulation.

Heparin can cause thrombocytopenia via two mechanisms, one immune mediated (**heparin-induced thrombocytopenia [HIT]**) and the other nonimmune mediated (**heparin-associated thrombocytopenia [HAT]**). Heparin is used for the prevention or treatment of thrombosis. In some patients, heparin causes a direct platelet activation

effect, a nonimmune mediated thrombocytopenia, resulting in HAT. *HIT* refers to the situation characterized by immune-mediated destruction of platelets due to heparin-dependent, platelet-activating IgG antibodies that recognize complexes of platelet factor 4 (PF-4) bound to heparin. PF-4 is released from platelet α G during platelet activation, binds to heparin in the circulation, and antibodies are produced to the heparin/PF-4 complex. The antibody/heparin/PF-4 complex then attaches to the platelet surface via the platelet Fc γ IIa receptors, resulting in increased platelet clearance and thrombocytopenia. Occasionally the antibody-heparin-PF4 complexes can induce platelet activation (Figure 5c). The most serious complication of HIT is the activation of the clotting system and thrombosis. Thrombocytopenia develops in approximately 3% of patients who receive heparin, and thrombosis occurs in one-third of those.²¹ For this reason, patients receiving heparin therapy should be monitored with daily platelet counts. For a complete discussion of the role of HIT in inducing thrombosis.

Miscellaneous Immune Thrombocytopenias Immune thrombocytopenia occurs as a secondary feature in many diseases. Although a variety of mechanisms can contribute to thrombocytopenia in these disease states, there appears to be an immune element in collagen diseases, other autoimmune disorders including systemic lupus erythematosus and rheumatoid arthritis, lymphoproliferative disorders such as Hodgkin disease and chronic lymphocytic leukemia, and solid tumors.

Patients with infections can develop an immune-mediated thrombocytopenia. Many infectious agents have been implicated, including the Epstein-Barr virus in infectious mononucleosis, cytomegalovirus, rubella, mumps, HIV, hepatitis, and nonspecific viral infections. Thrombocytopenia occurs in more than one-third of patients with bacterial septicemia, although the platelet count is usually not less than $50 \times 10^9/L$ and resolves when the infection is treated. Typical features of an immune process accompany the reduced platelet count in infections: shortened platelet survival, increased megakaryocytes in the bone marrow, and large platelets on the peripheral blood smear.²¹

Checkpoint! 4

A 6-year-old boy was brought to his pediatrician because the mother noticed small pinkish spots on his legs. Examination discovered several bruises on his arms and legs. Laboratory tests were ordered. His platelet count was $20 \times 10^9/L$, and the PT and APTT were within normal limits. The CBC was normal except for the low platelet count. The boy had no previous history of bleeding. The mother said she had noted the spots after he was given the hepatitis vaccine. What is the most probable type of thrombocytopenia? Should other coagulation tests be performed at this time?

Nonimmune Destruction. Increased destruction of platelets may occur by processes other than immune-related mechanisms. Platelets can be activated and consumed by aggregation within the circulation. **Disseminated intravascular coagulation (DIC)** is a disorder in which fibrin formation within the blood vessels is associated with platelet activation and consumption. **Thrombotic thrombocytopenic purpura (TTP)** and **hemolytic uremic syndrome (HUS)** are conditions in which platelets are activated without generalized activation of the coagulation cascade.

Mechanical destruction of platelets occurs in patients with artificial heart valves or vascular grafts. Platelets are destroyed by adhering to the artificial prosthesis or by mechanical rupture as the valves open and close against them.

Decreased Production A second category of disorders causing thrombocytopenia is characterized by failure of the bone marrow to deliver adequate numbers of platelets to the peripheral blood. The bone marrow function in these disorders is abnormal, and thrombocytopenia develops secondarily. Examination of bone marrow smears and sections aids in the identification of the primary condition. The decreased platelet count occurs because of one of the following: (1) megakaryocyte hypoplasia exists in the bone marrow, (2) there is ineffective thrombopoiesis, or (3) the patient has a hereditary condition that affects the ability of the bone marrow to support megakaryocyte growth (Table 8 .

Megakaryocyte Hypoplasia Syndromes. Hypoplasia of megakaryocytes (Figure 3) can result from either decreased proliferation of megakaryocytes in the bone marrow or replacement of the bone marrow by neoplastic disease, fibrosis, or granulomatous inflammation. All three myeloid cell lineages can be affected or only the megakaryocytes.

Decreased Megakaryocyte Proliferation The most frequent cause of marrow hypoplasia is drug or radiation therapy for malignant disease. Chemotherapeutic agents and radiotherapy produce generalized marrow suppression affecting all three lineages. The marrow usually regenerates shortly after the therapy is stopped, but the megakaryocytes are often the last lineage to recover.

Aplastic Anemia Megakaryocytes are decreased in aplastic anemia, a bone marrow disease characterized by pancytopenia and bone marrow hypoplasia. In acquired aplastic anemia, a decreased platelet count may appear before hypoplasia of other cell lineages and may be the last lineage to return to normal after recovery. Platelet size (mean platelet volume [MPV]) is normal in aplastic conditions in contrast to the increased MPV seen in immune-mediated thrombocytopenia. Platelets can, however, demonstrate an increased

★ TABLE 8

Causes of Decreased Platelet Production

Hypoplasia of megakaryocytes

- Decreased megakaryocyte proliferation
 - Chemotherapy and radiation therapy for malignant disease
 - Aplastic anemias
 - Acquired
 - Congenital/Hereditary
 - Fanconi anemia
 - Congenital amegakaryocytic thrombocytopenia (CAMT)
 - Congenital thrombocytopenia with radioulnar synostosis (CTRUS)
 - Isolated megakaryocyte hypoplasia
 - Thrombocytopenia with absent radii (TAR)
- Replacement of normal marrow

 - Fibrosis or granulomatous inflammation

Ineffective thrombopoiesis

- Megaloblastic anemia

Hereditary thrombocytopenia

- Wiskott-Aldrich syndrome/X-linked thrombocytopenia
- Bernard-Soulier syndrome
- May-Hegglin anomaly

variation in size as indicated by the platelet distribution width (PDW) on electronic instruments. TPO levels are increased in patients with aplastic anemia in contrast to normal levels in immune-mediated platelet destruction.

Several hereditary disorders result in a congenital aplastic anemia. **Fanconi anemia (FA)** is a congenital disorder characterized by chromosomal instability, defective DNA repair mechanisms, and progressive bone marrow hypoplasia, eventually resulting in aplastic anemia in ~90% of affected patients. At least eight different genes have been associated with the development of FA.²²

Congenital amegakaryocytic thrombocytopenia (CAMT) presents with isolated hypomegakaryocytic thrombocytopenia during the first years of life but eventually converts into bone marrow failure and aplastic anemia, usually between the ages of 3–20.²³ The molecular basis for most patients has been identified as a mutation within the gene for the thrombopoietin receptor, TPO-R (c-mpl). The evolution from an isolated thrombocytopenia to complete marrow hypoplasia underscores the importance of TPO and its receptor in the maintenance of hematopoietic stem cells.

Congenital thrombocytopenia with radioulnar synostosis (CTRUS) is also a congenital disorder present-

ing as an isolated amegakaryocytic thrombocytopenia that evolves into aplastic anemia.²³ Most patients have a mutation within the *HOXA11* gene, resulting in a truncated HOXA11 protein, an important regulatory protein for development of both hemopoietic and bone tissue. The abnormal bone morphology usually presents as a union of the ulna and radius by osseous tissue.

Thrombocytopenia with absent radii (TAR) is an inherited condition characterized by isolated hypoplasia of the megakaryocyte lineage, thrombocytopenia, and bilateral radial aplasia. Other skeletal malformations occasionally may be seen. The thrombocytopenia is usually severe only during the first years of life with a gradual improvement in platelet count to within normal values in adulthood. No mutations within the genes for TPO or TPO-R have been identified, and the defect is assumed to be an abnormality in the TPO/TPO-R signaling pathway.²³

Replacement of Normal Marrow. Abnormal cells, malignant or nonmalignant, can replace normal marrow causing decreased numbers of megakaryocytes (as well as the precursor cells for the other marrow lineages). Some myelodysplastic syndromes have decreased platelets as part of their pathology. The bone marrow may have normal or increased numbers of megakaryocytes, many of which are micromegakaryocytes and dysplastic forms. Peripheral blood platelets also can have abnormal morphology and abnormal function as indicated in the platelet aggregation tests. Marrow replacement by solid tumors or by fibrous tissue, as in chronic idiopathic myelofibrosis, sometimes results in thrombocytopenia, although thrombocytosis is more common. Abnormal platelet morphology, such as large and/or hypogranular forms, can be present.

Ineffective Thrombopoiesis. Megaloblastic anemias caused by a deficiency of vitamin B₁₂ or folic acid are characterized by ineffective thrombopoiesis as well as ineffective erythropoiesis and granulopoiesis (Figure 3). Pancytopenia is often seen in these diseases. The bone marrow contains normal or increased numbers of megakaryocytes, but the number of platelets entering the peripheral blood is decreased.

Hereditary Thrombocytopenia. Wiskott-Aldrich syndrome, Bernard-Soulier syndrome, and May-Hegglin anomaly are inherited disorders in which platelet production is decreased. These disorders also demonstrate other abnormalities.

The **Wiskott-Aldrich Syndrome (WAS)**, an X-linked disorder, is characterized by very small platelets, thrombocytopenia, and severe immune dysregulation (eczema and infections) due to a progressive decline in T lymphocyte number and function.²³ The *WAS* gene codes for a protein expressed exclusively in hematopoietic cells that is involved in cell signaling and regulation of the cytoskeleton. **X-linked thrombocytopenia (XLT)** results from mutations within the *WAS* gene, which manifest as an isolated throm-

bocytopenia without the immune dysfunction seen in WAS. WAS platelets show decreased aggregation to ADP, epinephrine and collagen, and reduced numbers of dense granules.

Bernard-Soulier syndrome (BSS) is characterized by both thrombocytopenia and dysfunctional platelets and is discussed later in this chapter. **May-Hegglin anomaly (MHA)** is characterized by a moderate macrothrombocytopenia and Döhle-like inclusions in leukocytes and is one of a group of disorders associated with abnormalities of the *MYH9* gene (nonmuscle myosin gene).

Checkpoint! 5

What is the pathophysiology of thrombocytopenia in megaloblastic anemia?

Increased Splenic Sequestration The spleen normally stores ~one-third of the platelets produced and released by the bone marrow in a pool that is in equilibrium with circulating platelets. In some conditions in which the spleen is enlarged (congestive splenomegaly and reactive splenomegaly or hypersplenism), the proportion of platelets sequestered also is increased and can reach 90% of the total platelet mass.¹⁹ Because the bone marrow production remains constant, the number of circulating platelets decreases. The platelet count is usually above $20 \times 10^9/L$, and symptoms of excess bleeding usually are not seen.

Most causes of thrombocytopenia resulting from splenomegaly are complicated by other factors that also contribute to it. It is rare for splenomegaly to occur as an isolated event. Examples of diseases in which splenomegaly is found include hepatic cirrhosis with portal hypertension, hemolytic anemia, Gaucher's disease and other storage diseases, Felty's syndrome, leukemias, and lymphomas. Bone marrow infiltration with the malignant cells can complicate the decreased platelet count in lymphomas.

Some myeloproliferative disorders are characterized by splenomegaly but increased platelet counts. In these conditions, the number of platelets sequestered increases, but the spleen also can be involved in producing platelets (extramedullary hematopoiesis).

Hypersplenism is a condition in which the spleen is enlarged and is hyperactive with an increase in the number of macrophages. Platelets are removed by increased pooling and by increased phagocytosis. Platelet size in hypersplenism is normal. The enlarged spleen can simultaneously sequester erythrocytes and neutrophils.

Dilutional Thrombocytopenia Patients who experience massive hemorrhage requiring replacement of 10 or more units of blood within 24 hours can develop thrombocytopenia if stored banked blood alone is used for transfusion. Because of the relatively short half-life of platelets, minimal viable platelets are in banked blood. Bleeding occurs in 20% to 60% of patients who receive 20 units or more

of transfused blood. Certain coagulation factors are also deficient in stored blood, possibly contributing to the bleeding diathesis. Recommendations for patients receiving massive transfusions are to monitor the platelet count, PT, and APTT and to administer platelet concentrates to maintain the platelet count at $75 \times 10^9/L$.²⁴

Conditions with Multiple Mechanisms of Thrombocytopenia Thrombocytopenia in some conditions is the result of more than one mechanism (Table 9). In alcoholic patients without cirrhosis, the major effect of ethanol is on the platelets. When cirrhosis is present, coagulation factors can also be affected. Alcohol reduces platelet numbers and causes defects of aggregation, release, and procoagulant activity. Platelet production is suppressed by a direct toxic effect of alcohol on the bone marrow, which can be compounded by ineffective production associated with a deficiency of folate. Also, decreased TPO production by the liver contributes to a reduced thrombopoiesis. Patients with cirrhosis have enlarged spleens due to passive congestion, also contributing to thrombocytopenia.

In lymphoproliferative disease, when the tumor affects the bone marrow, production of platelets is impaired. Additionally, the production of autoantibodies can enhance platelet destruction. If splenomegaly is present, increased sequestration by the spleen can contribute to the thrombocytopenia.

During cardiopulmonary bypass surgery, the patient's blood circulates through a pump outside the body to be oxygenated. Hemostasis is altered in a variety of ways. The platelet count is decreased to approximately one-half of the presurgical level because of the dilution by IV fluids and donor blood if transfusions were necessary. Platelet counts

★ TABLE 9

Conditions with Multiple Mechanisms of Thrombocytopenia

Alcoholism

- Suppress platelet production

- Inadequate neutralization of heparin

usually remain above $100 \times 10^9/L$ during the procedure but can take several days to correct to the patient's normal concentration. Platelets can be activated or mechanically damaged by the artificial surfaces encountered during the procedure.²⁵ Additional effects of extracorporeal circulation are discussed in later sections.

CASE STUDY (continued from earlier in this chapter)

Mohammed's laboratory results were:

Hematology	Hemostasis
WBC $10.5 \times 10^9/L$	Prothrombin time 11.2 sec
RBC $2.3 \times 10^{12}/L$	APTT 25.6 sec
Hb 6.6 g/dL (66 g/L)	
Hct 0.193 L/L	
Platelet count $133 \times 10^9/L$	

3. Explain how these laboratory tests confirm that the patient's bleeding is related to a defect in primary hemostasis rather than secondary hemostasis.
4. Is the bleeding more likely related to problems with the vascular system or with platelets? Why?
5. Is this profuse bleeding with the presence of petechiae consistent with the platelet count? Why?
6. What additional testing would be helpful to identify the cause of the patient's excess bleeding?

Thrombocytosis

Thrombocytosis is the general term for a platelet count that is elevated above the established reference range. On the peripheral smear, more than 20 platelets are seen per $100 \times$ oil immersion field, and they can appear in large clumps on capillary or first drop smears. They can be more concentrated on the featheredge of a smear.

Sustained increases in platelet numbers are the result of increased production by the bone marrow because the platelet's life span is not increased. Bone marrow megakaryocytes are increased on histologic sections and can be found in clusters. On buffy coat smears from the marrow, significant numbers of megakaryocytes can be present on the featheredge and throughout the body of the smear. Table 10⁺ shows primary and secondary conditions associated with thrombocytosis.

Primary Thrombocytosis In **primary thrombocytosis**, megakaryocyte proliferation and maturation bypass the normal regulatory mechanisms. Uncontrolled or autonomous production of megakaryocytes in the bone marrow results in a marked increase in the number of circulating platelets. The platelet count is usually more than $1000 \times 10^9/L$. In the bone marrow, megakaryocyte hyperplasia as well as giant megakaryocytes with increased ploidy are seen.

TABLE 10

Causes of Thrombocytosis

Primary thrombocytosis

- Essential thrombocythemia
- Chronic myelogenous leukemia
- Polycythemia vera
- Chronic idiopathic myelofibrosis
- Refractory anemia with ringed sideroblasts
- 5q- syndrome

Secondary (reactive) thrombocytosis

- Acute hemorrhage
- Surgery
- Post splenectomy
- Recovery from thrombocytopenia
 - Alcohol-induced thrombocytopenia
 - Chemotherapeutic drugs
 - Therapy of cobalamin deficiency
- Malignant diseases
- Chronic inflammatory diseases
- Iron-deficiency anemia
- Hemolytic anemia

Transient thrombocytosis

- Vigorous exercise
- Epinephrine
- Childbirth

Thrombocytosis occurs in both the chronic myeloproliferative disorders and myelodysplasia. In essential thrombocythemia, the megakaryocyte lineage predominates. Thirty-five percent of patients with refractory anemia with ringed sideroblasts and some patients with the 5q- syndrome have thrombocytosis, but the platelet count is usually less than $1000 \times 10^9/L$.²⁶

Patients with myeloproliferative disorders can have either hemorrhagic or thrombotic episodes; the cause of these episodes is not always known. Although thrombotic complications are slightly more frequent than bleeding symptoms in general, patients with chronic myelogenous leukemia only rarely develop thrombosis. Hemorrhagic symptoms are present in approximately one-fourth of patients despite the increased numbers of platelets. Epistaxis and bleeding from the gastrointestinal tract and from other mucous membranes can be quite profuse.

The bleeding time is only rarely prolonged, even in patients with bleeding symptoms, but most patients have abnormal in vitro platelet aggregation. Abnormal platelet aggregation has been demonstrated most frequently with

epinephrine but can also be abnormal with ADP and collagen.²⁶ Screening tests for clotting factors are normal.

Secondary (Reactive) Thrombocytosis **Secondary, thrombocytosis** is also called **reactive thrombocytosis** because another disease or condition causes the increased platelet count by normal regulatory mechanisms. The platelet count returns to the reference range by treating the primary condition. The clinical picture is generally related to the underlying condition rather than the thrombocytosis.

Differentiating primary from secondary thrombocytosis can be difficult. Although platelet counts are usually lower than $1000 \times 10^9/L$ in reactive thrombocytosis, they can be as high as in primary thrombocytosis. The bleeding time and platelet aggregation tests are normal, and hemorrhagic and thrombotic complications are infrequent.²⁷ IL-6 is increased in most patients with secondary thrombocytosis but not in primary thrombocytosis, however routine testing procedures are not available for this cytokine.

Several conditions associated with reactive thrombocytosis are shown in Table 10. The etiology of the increased platelet count varies. After acute hemorrhage or surgery, the platelet count can rise to $600 \times 10^9/L$ or more but returns to the reference range within a short time. After splenectomy, the platelet count rises, sometimes to more than $1000 \times 10^9/L$ and can remain elevated for several months. The rise in platelet count exceeds that expected for the loss of the splenic reservoir function, indicating that the spleen plays a role in regulating platelet production. Rebound thrombocytosis can follow recovery from thrombocytopenia in alcoholics and patients on chemotherapeutic drugs, or after therapy for vitamin B₁₂ deficiency. Platelet counts in patients with iron deficiency anemia vary from thrombocytopenic to $>1000 \times 10^9/L$. In adults with iron deficiency anemia due to chronic blood loss, thrombocytosis is commonly reported (50–75% of patients), and the platelet count returns to normal after iron replacement. Thrombocytosis is thought to occur in hemolytic anemias due to the stimulation of the bone marrow by hematopoietic growth factors to produce erythrocytes resulting in stimulation of other lineages as well.

Transient Thrombocytosis Platelet counts rise transiently in the conditions listed in Table 10.

Checkpoint! 6

Explain why primary thrombocytosis is often associated with abnormal platelet function while secondary thrombocytosis is not.

Artifacts in the Quantitative Measurement of Platelets

The laboratory must be aware of artifacts responsible for erroneously (spuriously) low or high platelet counts in automated electronic platelet counting.²⁸ Recognition of these

artifacts can prevent misdiagnosis and inappropriate or unnecessary diagnostic procedures and therapy. In many cases, these errors can be reduced by examining a blood smear. Pseudothrombocytopenia is an in vitro artifact of automated cell counting seen when blood is collected in EDTA. Aggregates of platelets, or platelet satellitism (platelets bound to neutrophils), are common findings on the peripheral smear.

CASE STUDY (continued from the previous page)

Mohammed's hematology report included a finding that at least 65% of the platelets were large and giant forms with intense granulation.

7. Is there a possibility that the patient's platelet count is spuriously increased or decreased? Why?

QUALITATIVE (FUNCTIONAL) PLATELET DISORDERS

The platelet's roles in hemostasis include platelet adhesion, contraction, release of ADP, generation of thromboxane A₂, aggregation, and procoagulant activity. Inherited or acquired abnormalities in any phase of platelet function can lead to defective formation of a primary hemostatic plug and abnormal bleeding.

Clinical symptoms vary from asymptomatic to mild, easy bruisability to severe, life-threatening hemorrhaging depending on the nature of the defect. The type of bleeding is similar to that seen in thrombocytopenic disorders. Common manifestations include petechiae, easy and spontaneous bruising, bleeding from mucous membranes such as the nose or gastrointestinal tract, abnormal vaginal bleeding, and prolonged bleeding from trauma.

Laboratory screening test results are similar to those found in thrombocytopenia except that the platelet count is usually normal. A mildly decreased platelet count, however, is characteristic of some conditions. The bleeding time is often prolonged, and in patients who are also thrombocytopenic, is increased more than expected for the degree of thrombocytopenia. Screening tests for coagulation factors (PT, APTT) and tests for fibrinolysis are normal. Special laboratory tests for platelet function reflect the nature of the platelet defect.

Platelet functional disorders are classified as hereditary or acquired. The inheritance pattern in the hereditary types is usually autosomal recessive.

Hereditary Disorders of Platelet Function

Hereditary platelet defects are rarely encountered clinically. However, much of the present knowledge of platelet function has been derived from the study of patients with

★ TABLE 11

Inherited Disorders of Platelet Function**Disorders of adhesion (defects in platelet-vessel wall interaction)**

- von Willebrand disease (deficiency/defect in plasma VWF)
- Bernard-Soulier syndrome (deficiency/defect in GPIb/IX)

Disorders of aggregation (defects in platelet-platelet interaction)

- Congenital afibrinogenemia (deficiency of plasma fibrinogen)
- Glanzmann thrombasthenia (deficiency/defect in GP IIb/IIIa)

Disorders of platelet secretion and abnormalities of granules

- Storage pool deficiency (δ SPD; α SPD)
- Quebec platelet disorder

Disorders of platelet secretion and signal transduction

- Receptor defects (defects in platelet-agonist interaction) (Receptor defects: TXA_2 , ADP, collagen, epinephrine, serotonin)
- Defects in G-protein activation
- Defects in phosphatidylinositol metabolism (phospholipase C deficiency)
- Defects in protein phosphorylation (PKC deficiency)
- Abnormalities in arachidonic acid pathways and TXA_2 synthesis (deficiency of phospholipase A₂, cyclooxygenase, thromboxane synthase)

Disorders of platelet coagulant-protein interaction (Scott syndrome)

such anomalies. Defects in each phase of platelet function have been described (Table 11 ★). A convenient classification scheme is based on the steps in platelet function. Abnormalities in function can be related to affected portions of the platelet ultrastructure (Figure 6 ■).

Disorders of Platelet Adhesion Adhesion to collagen requires the presence of both an adequate amount of functional von Willebrand factor (VWF) and the presence of functional GPIb/IX on the platelet membrane. VWF is a bridge binding the platelet via GPIb/IX to collagen. Disorders of platelet adhesion include deficiencies of either VWF (von Willebrand Disease) or GP Ib/IX (Bernard-Soulier syndrome). Because adhesion to collagen is the major mechanism initiating platelet function, aggregation and formation of the primary hemostatic plug are also defective.

Bernard-Soulier Syndrome. **Bernard-Soulier syndrome (BSS)** is a rare autosomal-recessive disorder first described by Bernard and Soulier in 1948.²⁹ The incidence is less than 1 in 1,000,000.³⁰ BSS is characterized by a moderate to severe thrombocytopenia and abnormal platelet function. Homozygous patients have a lifelong bleeding tendency that can begin in infancy. Bleeding symptoms are similar to those

■ FIGURE 6 Ultrastructural components associated with inherited disorders of platelet function.

■ **FIGURE 7** Platelet morphology in Bernard-Soulier syndrome. (Peripheral blood, Wright-Giemsa stain, 1000× magnification)

described for thrombocytopenia. Heterozygous persons usually have no significant bleeding symptoms.³⁰

BSS is sometimes called the *giant platelet syndrome* because of the appearance of the platelets on a peripheral blood smear. More than 60% and up to 80% of platelets are increased in size with a diameter between 2.5 and 8.0 μm , occasionally up to 20 μm (Figure 7 ■). The cause and signifi-

cance of the large size is unknown. Platelets also have an increase in the number of dense granules proportional to their increase in size.³⁰

The defect in BSS is a quantitative decrease or abnormal function of the GPIb/IX complex. It results from a mutation in one of the genes that code for the proteins in the complex: GPIb α , GPIb β , or GPIX. Lack of functional GPIb/IX prevents interaction of the platelets with VWF and the subsequent platelet adhesion to collagen (Figure 6a). More than 600 genetic mutations associated with BSS have been identified (see www.bernardsoulier.org).

Laboratory tests are required to diagnose this disease and differentiate it from other platelet functional disorders and other causes of thrombocytopenia (Table 12 🌱). Examination of the peripheral blood smear typically reveals thrombocytopenia and the abnormal platelet morphology. The platelet count can be normal or slightly decreased and is variable over time in the same patient. The bleeding time is prolonged more than expected for the degree of thrombocytopenia, indicating a coexistent disorder of platelet function. Platelet aggregation studies are normal with ADP, collagen, and epinephrine. However, agglutination with ristocetin, which requires VWF and GPIb/IX, is abnormal³⁰ (Figure 8a ■).

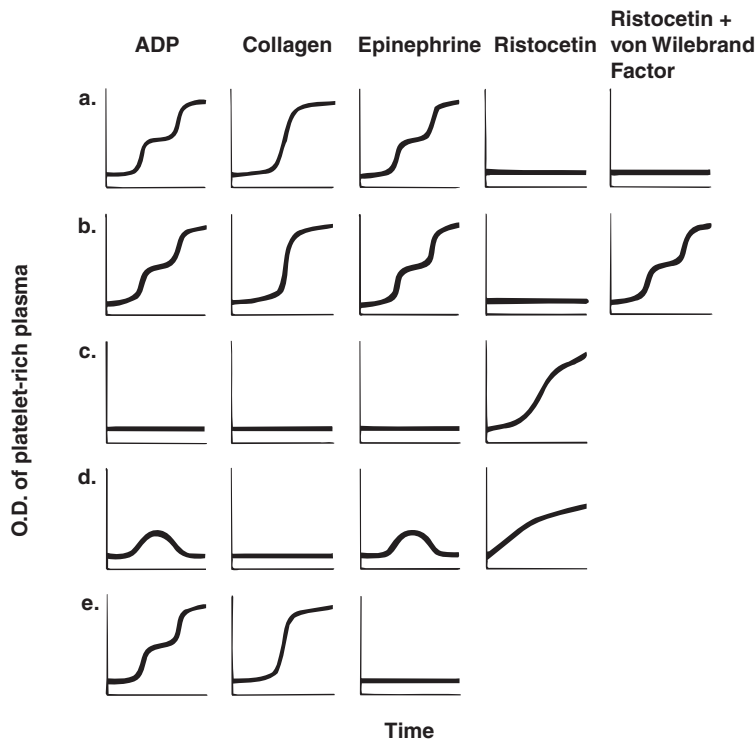

Similar platelet aggregation results are obtained in patients with VWD. To differentiate them, a modification of

🌱 **TABLE 12**

Laboratory Test Results in Selected Platelet Disorders

Disorder	Defective Platelet Component	Platelet Count	Bleeding Time Test	Platelet Aggregation	Closure Time (PFA*)	Other
Bernard-Soulier syndrome	Glycoprotein Ib/IX	Normal or decreased	Increased	Abnormal with ristocetin Normal with ADP, collagen, epinephrine	Increased	Giant platelets
Glanzman thrombasthenia	Glycoprotein IIb/IIIa	Normal	Increased	Abnormal with ADP, collagen, epinephrine Normal with ristocetin	Increased	
δ -storage pool disease	Dense granule deficiency	Normal	Increased	Abnormal secondary aggregation with ADP, epinephrine; abnormal with collagen Normal primary aggregation	Variable	
Gray platelet syndrome	Alpha granule deficiency	Variably decreased	Variable	Normal	Variable	Agranular platelet
Defective thromboxane A ₂ synthesis	Deficiency of cyclooxygenase, or TXA ₂ synthase	Normal	Increased	Abnormal secondary aggregation with ADP, abnormal with collagen Normal primary aggregation	Increased	

*PFA = Platelet Function Analyzer

■ **FIGURE 8** Platelet aggregation patterns in disorders of platelet function. **a.** Bernard-Soulier syndrome. **b.** von Willebrand disease. **c.** Glanzmann's thrombasthenia. **d.** δ -storage pool disease, aspirin ingestion, uremia, thromboxane A_2 deficiency. **e.** Myeloproliferative disease.

the ristocetin agglutination test is used. The addition of VWF (e.g., normal plasma) to the patient's platelet suspension does not correct the abnormal ristocetin agglutination in BSS patients but corrects the agglutination defect in VWD (Figure 8b■). Also, flow cytometry can characterize the platelet surface GPIb/IX proteins (CD42b/CD42a).

BSS has no specific treatment. Supportive measures such as erythrocyte and platelet transfusions are used as needed.

von Willebrand Disease. VWD is characterized by a decrease in production of VWF or production of a dysfunctional protein (Figure 6b). It is a plasma protein disorder rather than a platelet functional disorder.

Disorders of Platelet Aggregation Platelet aggregation requires the presence of fibrinogen and the GPIIb/IIIa receptor on the platelet membrane. In the absence of either of these components, platelets do not interact with one another to produce primary or secondary aggregation. The congenital disorder in which the GPIIb/IIIa complex is defective is **Glanzmann's thrombasthenia (GT)**.

GT is a rare autosomal recessive disease first described in 1918.³¹ Clinical manifestations are apparent only in homozygotes.³² Platelets of patients with GT are deficient in the GPIIb/IIIa complex (Figure 6c), the site of attachment

of fibrinogen to the platelet surface. Fibrinogen "bridges" two platelets in the presence of calcium, initiating platelet aggregation.

Glycoproteins IIb and IIIa are encoded by separate genes closely linked on the long arm of chromosome 17. A deficiency of the whole complex in the platelet membrane occurs when either gene is defective because both proteins are required to form a functional complex. More than 100 different molecular defects of the two genes have been identified (see www.sinaicentral.mssm.edu/intranet/research/glanzmann). Three subtypes of GT³³ have been described: GT Type I is characterized by undetectable or trace amounts (<5%) of GP-IIb/IIIa; GT Type II patients have GPIIb/IIIa of up to 15% of normal; GT Type III is a qualitative defect of GPIIb/IIIa with laboratory diagnostic features of GT except that GPIIb/IIIa levels are 50–100% of normal. Obligate carriers (heterozygotes) of a quantitative defect have 50% to 60% of the complex but are phenotypically normal.³⁴

Aggregation in GT does not occur because the platelets lack the site for attachment of fibrinogen. Aspects of platelet function that do not depend on aggregation, such as adhesion and secretion, are usually normal. At low agonist concentrations, however, decreased secretion and TXA₂ synthe-

sis can occur. Additional abnormalities of platelets occur in patients with GT, including deficiencies of antigens such as HPA-1a and HPA-1b that are normally present on the GPIIb/IIIa complex. Some patients have a deficiency of fibrinogen in the α Gs, presumably due to decreased GPIIb/IIIa-mediated endocytosis of fibrinogen from the plasma.

Bleeding symptoms can begin in infancy and involve superficial areas of the body characteristic of platelet abnormalities. Although they are usually described as moderate in severity, deaths have occurred.

Laboratory tests are necessary to differentiate this disorder from other platelet defects (Table 12). The platelet count and morphology are normal, but the bleeding time is markedly prolonged, and clot retraction is abnormal, indicating platelet dysfunction. Platelet aggregation tests show no response to agonists such as ADP, epinephrine, or collagen because the platelets lack the site of attachment of fibrinogen; thus, aggregation cannot occur. Normal agglutination, however, occurs with ristocetin (Figure 8c■). Deficiencies of GPIIb or IIIa are identified by flow cytometry of platelets utilizing anti-CD41 or anti-CD61 antibodies and/or observing a quantitative decrease of the proteins using polyacrylamide gel electrophoresis to separate platelet glycoproteins.

No specific treatment is available for thrombasthenic patients. Supportive platelet transfusions are used when needed, and bone marrow transplantation has been performed in rare cases.

Disorders of Platelet Secretion, Granule Abnormalities, and Signal Transduction Disorders of platelet secretion and signal transduction include a heterogeneous group of disorders that have in common impaired secretion of granule contents and abnormal aggregation during platelet activation. In aggregation studies, the second wave of aggregation has been found to be reduced or absent. The abnormal platelet functions occur either because the granules or their contents are decreased (storage pool deficiency) or because of an abnormality in the activation mechanisms regulating secretion and aggregation. Symptoms vary from moderate to mild bleeding tendencies depending on the abnormality. Manifestations can be easy bruising, hemorrhage, and excess bleeding after surgery or childbirth.³⁵ The platelet count is normal, and the bleeding time is variable.

Deficiencies of Granules (Storage Pool Diseases/SPD). An autosomal dominant trait characterized by an isolated decrease in dense granules (DG) is called **δ -storage pool disease**. The platelets in this disorder show a decrease or absence of platelet DG on electron microscopy (Figure 6d), but the morphologic appearance of the platelets on stained peripheral blood smears is normal. The bleeding time is usually prolonged (Table 12), and platelet aggregation tests are abnormal with ADP, epinephrine (normal primary wave of aggregation, absent or blunted secondary wave) and low levels of collagen (markedly reduced re-

sponse) (Figure 8d■). The platelet aggregation abnormalities are due to the lack of ADP release from the DG so that secondary aggregation does not occur with ADP or epinephrine. The platelet aggregation curve induced by collagen is normally produced by release of endogenous DG products (“secondary aggregation” only) and is therefore absent. The ratio of total platelet ATP:ADP is increased (>2.5).³⁴ Platelet agglutination studies using ristocetin demonstrate normal results.

Deficiencies of DG also occur as one of the features of several rare autosomal recessive disorders including Chediak-Higashi syndrome, Hermansky-Pudlak syndrome, Wiscott-Aldrich syndrome, and TAR syndrome.

Gray Platelet Syndrome (GPS). Selective deficiency of platelet α -granules is called the **gray platelet syndrome**, or **α -storage pool disease**. Because α G are so numerous, their absence causes the platelets to appear agranular on a peripheral blood smear. By electron microscopy, α G are absent or markedly decreased. Recent studies indicate that megakaryocyte synthesis of α G contents is normal, and the defect may be in targeting endogenously synthesized proteins to the developing α G.³⁵ In contrast to δ -storage pool disease, platelet aggregation studies are generally normal, and clinical manifestations are usually mild. Patients can have a mild thrombocytopenia, and the bleeding time can be prolonged (Table 12).

Quebec Platelet Disorder. **Quebec platelet disorder** is a rare autosomal dominant disorder associated with abnormal proteolysis of α G proteins due to increased levels of platelet urinary-type plasminogen activator.³⁵ In contrast to GPS, the structure of the α G is preserved, and platelets are morphologically normal by light microscopy. Platelet counts often are moderately decreased, and patients experience a variable bleeding history.

Abnormalities of the Platelet Secretory Mechanism. These disorders are typically associated with a mild to moderate bleeding history. Patients usually have a prolonged bleeding time, absence of second wave of platelet aggregation with ADP or epinephrine, and decreased aggregation with collagen. They must be differentiated from acquired abnormalities of platelet secretion induced by drugs such as aspirin (see below). Although rare, these disorders as a group are far more common than thrombasthenia (GT), BSS, or SPD.³⁶

Defective Thromboxane A₂ (TXA₂) Synthesis. Liberation of arachidonic acid from membrane phospholipids and its conversion to TXA₂ is an important positive feedback loop enhancing the platelet activation process. A defect in the pathway of TXA₂ synthesis produces a platelet aggregation pattern similar to that seen in δ -storage pool disease (Figure 6d, Table 12). Defects can occur in the liberation of arachidonic acid from phospholipids (phospholipase A₂ deficiency) and in TXA₂ synthesis (cyclooxygenase deficiency or thromboxane

synthase deficiency).³⁷ Platelet secretion and secondary aggregation do not occur.

Signal Transduction Defects. Various heterogeneous disorders are grouped together as signal transduction defects. The defect can involve platelet-agonist interaction (i.e., defect of the platelet receptor for a specific agonist). In these disorders, patients typically have impaired platelet responses to a single agonist in platelet aggregation assays. Documented receptor defects include receptors for TXA₂(TP α), ADP (P2Y₁₂), collagen (GPIa/IIa or GP-VI), epinephrine, and serotonin.^{35,36} Other potential defects in platelet secretion and signal transduction are listed in Table 11.

Disorders of Platelet Procoagulant Activity Defective procoagulant activity of platelets has been described as an additional finding in several of the previously mentioned disorders and as a single entity in some patients. **Scott syndrome** is a rare autosomal recessive disorder characterized by abnormal Ca²⁺-induced phospholipid scrambling. The activated platelets secrete and aggregate normally but fail to transport phosphatidyl serine from the inner to the membrane's outer phospholipid leaflet. As a result, the platelet

✓ Checkpoint! 7

Compare the results of platelet aggregation studies in platelet adhesion, aggregation, and secretion disorders.

Acquired Disorders of Platelet Function

Platelet dysfunction is induced in a variety of conditions and with the ingestion of certain drugs. Clinical manifestations and the results of laboratory tests vary with the cause and the resulting effect on the platelet mechanism.

Chronic Renal Failure A bleeding tendency in uremia recognized for many years was first associated with a platelet functional abnormality in 1956. The platelet defect's pathogenesis and severity is related to the accumulation of waste products in the blood, although which of the metabolites produces harmful effects is unclear. The bleeding time is prolonged and seems to correlate with the severity of the renal failure. The platelet aggregation test with collagen and secondary aggregation with ADP and epinephrine is decreased, indicating an abnormal secretory response (Figure 8d). Platelet procoagulant activity also is defective.

Bleeding symptoms in uremic patients can be severe. Ecchymoses, gastrointestinal bleeding, and hemorrhages into serous cavities can be seen. The bleeding time shortens, and clinical symptoms decrease with dialysis treatment.

Hematologic Disorders The bleeding and thrombotic problems in myeloproliferative disorders were described earlier in this chapter. An abnormal response to epinephrine in the platelet aggregation test is a fairly consistent abnormality as well. The response to ADP and collagen appears to be variable (Figure 8e ■).

Defective platelet aggregation has been noted in patients with acute leukemia and myelodysplasia. Bleeding problems in these conditions, however, are usually the result of thrombocytopenia.

In addition to impaired vascular function in patients with dysproteinemias such as multiple myeloma and macroglobulinemia described earlier, abnormal platelet function is observed. Severe bleeding symptoms can result. Thrombocytopenia and hyperviscosity are the major causes of the bleeding tendency, but platelet function is abnormal because the paraprotein coats the platelet surface and interferes with the membrane reactions of platelet activation. The bleeding symptoms and the abnormal platelet function are proportional to the amount of abnormal protein in the plasma. Abnormal tests include bleeding time, platelet aggregation, and platelet procoagulant activity. The results of the abnormal tests, however, do not correlate with the severity of clinical bleeding.

Drugs Many drugs have been shown to contribute to platelet dysfunction. The effect of drugs on platelets of persons with normal hemostatic function is usually clinically unnoticeable. However, those with significant abnormalities of the hemostatic system are at greater risk for developing severe bleeding symptoms.

Drugs can variably alter the bleeding time and platelet aggregation studies, but the effects on these laboratory tests do not necessarily correlate with clinical symptoms. The mechanisms of inhibiting platelet function also are variable and are not completely understood. The effects of three drugs— aspirin, alcohol, and certain antibiotic agents—are discussed next.

Aspirin. Aspirin affects platelet function by irreversibly acetylating, and thus inactivating, the cyclooxygenase enzyme, thereby preventing the formation and release of TXA₂. As a result, platelet secretion is decreased. A single dose of 650 mg of aspirin can inhibit 95% of the function of cyclooxygenase in circulating platelets. The platelets affected by aspirin continue to circulate but are nonfunctional. Laboratory tests of platelet function, therefore, can be altered in patients taking aspirin. Platelet function tests return to normal as new platelets are produced and released from the marrow. Tests typically become normal 7 days after the last dose.

The bleeding time in normal persons can be increased by 1–2 minutes after taking a single dose of aspirin and can be affected for as long as 7 days. In healthy persons, though, it rarely becomes prolonged beyond the reference range. In persons with a functional abnormality of platelets (either hereditary or acquired) or VWD, aspirin ingestion can lead to serious bleeding complications. It is recommended that patients should not ingest aspirin or any of the numerous aspirin-containing products for 7 days before having platelet function tests.

Abnormalities in platelet aggregation tests reflect the lack of TXA₂ synthesis and are similar to results from patients

with hereditary deficiencies of enzymes in this pathway. A first wave of aggregation is seen with ADP and epinephrine, but no secondary wave is present. Aggregation does not occur with collagen, and agglutination is normal with ristocetin (Figure 8d).

✓ Checkpoint! 8

Why are the bleeding time test and closure time abnormal for up to 7 days following ingestion of aspirin?

Alcohol. Ingestion of large amounts of alcohol over a long period of time can lead to platelet dysfunction in some individuals. Several mechanisms have been proposed: inhibition of prostaglandin synthesis and alteration of the storage pool of nucleotides or membrane stabilization. The platelet aggregation test can show decreased primary aggregation with ADP.

Antibiotics. Antibiotics, particularly penicillins and cephalosporins (which affect bacterial cell wall synthesis), alter platelet function. Patients taking these drugs show no aggregation with ADP either in the primary or secondary wave. Bleeding time can also be prolonged. The drug is believed to coat the platelet membrane, blocking ADP and epinephrine receptors, and resulting in platelet inability to respond to agonist. Serious bleeding complications can occur.

Cardiopulmonary Bypass Surgery In addition to thrombocytopenia, as discussed previously, platelet function is altered during cardiopulmonary bypass surgery. The platelets are believed to become activated temporarily by the abnormal surfaces to which they are exposed.

Significant bleeding develops in approximately 3% to 5% of patients after bypass surgery. In approximately one-half of these cases, the bleeding is due to inadequate surgical technique and can require additional surgery to correct. The remaining one-half can be due to a variety of defects of hemostasis, the most common of which is acquired abnormal platelet function.

Flow cytometry has been used to study platelet activation during cardiopulmonary bypass surgery in pediatric patients. Results using monoclonal antibodies to CD62P and GPIb/IX are correlated with the extent of platelet activation and with the risk of bleeding. CD62P is contained within the α G and is expressed on the platelet surface only after platelets have undergone the release reaction. After platelets have been activated, GPIb decreases in density on the platelet surface.⁴⁰

CASE STUDY (continued from earlier in this chapter)

When asked if he had had bleeding problems in the past, Mohammed recounted having petechiae, lots of bruises off and on since childhood, frequent nosebleeds, and bleeding for a long time after cuts. A bleeding time, platelet function analyzer closure time, and platelet aggregation studies were ordered. The results are bleeding time, greater than 20 minutes and closure time increased. Platelet aggregation studies showed normal aggregation with ADP, collagen, epinephrine and thrombin. Agglutination with ristocetin was abnormal and was not corrected when VWF was added.

8. Is Mohammed's problem more likely acquired or inherited? Why?
9. What is the significance of these platelet function tests?
10. What is Mohammed's most likely condition?
11. What additional testing would be considered?

SUMMARY

This chapter described disorders of primary hemostasis. Patients affected by these conditions usually have an imbalance in the hemostatic system and experience bleeding of some type. Although bleeding can occur in any organ, most patients experience excess bleeding from superficial cuts, easy skin bruising, and the presence of petechiae. Occasional disorders result in excess clotting, that is, thrombosis rather than excess bleeding.

Vascular disorders are diverse in origin and can be inherited or acquired. Diagnosis of vascular disorders is usually done by excluding other causes of bleeding and observing symptoms consistent with the underlying disorders. Laboratory tests of hemostasis with the exception of the bleeding time are usually normal.

Platelet disorders are broadly categorized as quantitative disorders in which the platelet count is too low or too high or as functional abnormalities in which an aspect of platelet function is altered. Thrombocytopenia is caused by conditions that affect the bone marrow production of megakaryocytes, conditions that cause increased destruction of platelets after they are released into the peripheral blood, conditions in which the spleen is increased in size or by dilution during transfusion of multiple units of banked blood within a short period of time. Thrombocytosis is seen in myeloproliferative disorders and a number of other diseases. Functional platelet abnormalities are caused by mutations in genes that produce platelet membrane or granule constituents or can be acquired by ingestion of certain drugs such as aspirin. Laboratory tests that are helpful in establishing the cause of a platelet disorder include platelet counts, template bleeding time, closure time (PFA-100®), and platelet aggregation studies.

REVIEW QUESTIONS

LEVEL I

- Which of the following platelet counts indicates thrombocytopenia? (Objective 1)
 - $200 \times 10^9/L$
 - $2000 \times 10^9/L$
 - $200 \times 10^{12}/L$
 - $20.0 \times 10^9/L$
- What laboratory test(s) is (are) most often ordered to screen for abnormalities of the hemostatic system? (Objective 3)
 - platelet count
 - prothrombin time
 - activated partial thromboplastin time
 - all of the above
- An average of 20 platelets per field was counted on a blood smear from an EDTA specimen with a $1000\times$ magnification. What is the platelet count estimate? (Background Basics 4)
 - $300 \times 10^9/L$
 - $150 \times 10^9/L$
 - $400 \times 10^9/L$
 - $200 \times 10^9/L$
- What are purple lesions that are larger than 1 cm in diameter that are *not* raised called? (Objective 2)
 - petechiae
 - ecchymoses
 - hematoma
 - thrombocytosis
- In which hematologic disorder would you expect to observe a decreased platelet count? (Objective 6)
 - acute leukemia
 - chronic myelocytic leukemia
 - hemolytic anemia
 - iron-deficiency anemia
- How long should a patient be off aspirin or aspirin-containing products before having platelet function testing? (Objective 9)
 - 2 hours
 - 2 days
 - 7 days
 - 30 days
- Which of the following can result in a falsely decreased platelet count on an automated hematology counter? (Background Basic)
 - large number of schistocytes
 - iron-deficiency anemia
 - aplastic anemia
 - platelet satellitism

LEVEL II

Use the following history for questions 1–5.

The mother of a 4-year-old boy noticed several bruises on his arms, legs, and torso. Upon closer examination, she saw several pinpoint, brownish purple spots on his ankles. Just before leaving home for the doctor's office, the child had a moderately severe nosebleed. There had been no previous episodes of this type.

The child's physical examination was unremarkable except for the bruises. The child had not recently taken any medication but was recovering from the chicken pox.

Laboratory results showed:

RBC	$4.25 \times 10^{12}/L$
Hb	10.8 g/dL (108 g/L)
Hct	.34 L/L
MCV	80 fL
MCH	25.4 pg
MCHC	301 g/L
WBC	$5.2 \times 10^9/L$
Platelet count	$4.0 \times 10^9/L$

A bone marrow examination was scheduled but was later cancelled.

- What disorder is most probably indicated by the boy's history? (Objectives 4, 5)
 - acute leukemia
 - Bernard-Soulier syndrome
 - idiopathic thrombocytopenic purpura
 - Marfan syndrome
- If a bone marrow examination had been performed, what morphology would it likely have shown? (Objective 4)
 - normal to increased numbers of megakaryocytes
 - large numbers of blast cells
 - decreased numbers of erythrocyte precursors
 - absence of all myeloid precursors and replacement by fat
- What is the mechanism of platelet destruction in immune thrombocytopenia? (Objective 4)
 - lysis by complement in the peripheral blood
 - increased sequestration of platelets by the spleen
 - removal of antibody-coated platelets by splenic macrophages
 - activation and increased utilization by forming aggregates in the blood stream

REVIEW QUESTIONS (continued)

LEVEL I

8. What level of platelet count is associated with a risk of life-threatening bleed into the central nervous system? (Objective 5)
 - a. $200 \times 10^9/L$
 - b. $500 \times 10^9/L$
 - c. $100 \times 10^9/L$
 - d. $5 \times 10^9/L$
9. Thrombocytosis is: (Objective 8)
 - a. a platelet count within the reference range for age
 - b. abnormal platelet function
 - c. the presence of a blood clot in a leg vein
 - d. a platelet count above the reference range
10. Platelet satellitism and platelet agglutination seen on a peripheral blood smear occur only: (Background Basic 5)
 - a. in blood collected in sodium citrate anticoagulant
 - b. in blood collected in EDTA anticoagulant
 - c. after the blood has sat on the countertop for 24 hours
 - d. on a smear made from a capillary puncture

LEVEL II

4. The small purple spots seen on this boy's ankles are most probably: (Objective 2)
 - a. petechiae
 - b. ecchymoses
 - c. allergic purpura
 - d. hematoma
5. What is the boy's expected prognosis? (Objective 2)
 - a. imminent death from overwhelming infection
 - b. complete spontaneous recovery within 6 months
 - c. similar problems for the rest of his life
 - d. recovery after a long period of steroid therapy
6. Which of the following is characteristic in a patient with Bernard-Soulier syndrome? (Objective 7)
 - a. abnormal glycoprotein IIb/IIIa
 - b. increased prothrombin time
 - c. increased platelet count
 - d. abnormal platelet aggregation with ristocetin
7. Which of the following is found in Glanzmann's thrombasthenia? (Objective 7)
 - a. mutation in the gene for VWF
 - b. acquired abnormality of fibrinogen
 - c. genetic abnormality of glycoprotein IIb or IIIa
 - d. acquired vascular disorder
8. Hereditary telangiectasia is characterized by which of the following? (Objective 3)
 - a. abnormal platelet adhesion to collagen
 - b. thrombocytosis
 - c. deficiency of platelet dense bodies
 - d. skin lesions that are arterioles connected directly to venules
9. Platelet aggregation studies were performed and showed a primary wave of aggregation with ADP that returned to the baseline with no secondary wave. Which of the following conditions are consistent with these results? (Objectives 7, 8)
 - a. senile purpura
 - b. chronic idiopathic thrombocytopenic purpura
 - c. aspirin effect
 - d. Bernard-Soulier syndrome
10. Reactive thrombocytosis is associated with: (Objectives 4, 6)
 - a. post-surgery
 - b. MPD
 - c. aspirin ingestion
 - d. heparin therapy

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Mohammed experienced increased bleeding from superficial wounds acquired from an automobile accident. Petechiae were also noted. With these symptoms, a platelet disorder is most likely. His laboratory tests confirmed this. His platelet count was slightly decreased but not so low as to cause his bleeding symptoms. His bleeding and closure times were prolonged, which indicated a platelet function disorder. Coagulation factor screening tests were normal. Platelet aggregation studies showed abnormal aggregation with ristocetin that was not corrected by vWf. This confirmed that his disorder was Bernard-Soulier disease.

Question:

1. What laboratory tests, hematology, and hemostasis would likely be ordered immediately that would be most informative in interpreting the cause of the patient's bleeding?

Explanation:

Platelet count, prothrombin time, and activated partial thromboplastin time are the screening tests ordered most often. These tests will detect the presence of a problem either in the platelet numbers or in fibrin formation in most patients with hemorrhagic symptoms.

Question:

2. Does the patient most likely have a disorder of primary or of secondary hemostasis? Why?

Explanation:

The patient most likely has a disorder of primary hemostasis. The presence of petechiae and excess bleeding from superficial cuts are seen in primary hemostatic disorders and are unlikely in disorders of secondary hemostasis.

Question:

3. Explain how these laboratory tests confirm that the patient's bleeding is related to a problem in primary hemostasis rather than secondary hemostasis.

Explanation:

Most disorders of secondary hemostasis are ruled out when the results of the prothrombin time and activated partial thromboplastin time are within the reference ranges (see Table E, inside cover). The platelet count is slightly decreased.

Question:

4. Is the bleeding more likely related to problems with the vascular system or with platelets? Why?

Explanation:

Both hereditary and acquired vascular disorders have characteristic abnormalities that are not included in the history, and therefore we will assume them to be absent. A platelet problem is most likely.

Question:

5. Is this profuse bleeding with the presence of petechiae consistent with the platelet count? Why?

Explanation:

Profuse bleeding and petechiae are not usually evident until the platelet count is below $50 \times 10^9/L$. Therefore, the amount of bleeding is not consistent with the platelet count.

Question:

6. What additional testing would be helpful in identifying the cause of the patient's excess bleeding?

Explanation:

The patient should be questioned for recent ingestion of drugs that affect platelet function, for example, aspirin or aspirin-containing products. In the absence of a history of ingestion of drugs, platelet aggregation testing to identify abnormal platelet function would likely be ordered.

Question:

7. Is there a possibility that the patient's platelet count is spuriously increased or decreased? Why?

Explanation:

This is unlikely because the patient's peripheral smear report does not indicate platelet satellitism, platelet agglutination, or the presence of abnormally small erythrocytes or other features that could cause a spuriously increased platelet count.

Question:

8. Is this patient's problem more likely acquired or inherited? Why?

Explanation:

The patient's problem is most likely inherited because he has had bleeding problems all of his life.

Question:

9. What is the significance of these platelet function tests?

Explanation:

Both the bleeding time and closure time are prolonged, which indicates abnormal platelet function. The platelet aggregation studies with ristocetin are abnormal, but aggregation is normal with other agonists. Abnormal aggregation with ristocetin is characteristic of either von Willebrand disease or Bernard-Soulier disease.

Question:

10. What is the most likely condition?

Explanation:

The patient's platelet aggregation studies were not corrected with the addition of von Willebrand factor. This indicates that the problem is unlikely to be von Willebrand disease. Because the patient had large platelets on the blood smear and typical platelet aggregation studies, the most likely diagnosis is Bernard-Soulier disease.

ANSWERS TO CHECKPOINTS**Checkpoint! 1**

Assume that you are the clinical laboratory scientist collecting a blood specimen from a patient with a suspected bleeding disorder. You noticed petechiae and several bruises on the patient's arm. What screening tests would the physician likely have ordered? What results of these tests would you expect (normal or abnormal) in this patient?

Answer

The physician would likely have ordered a platelet count, prothrombin time, and activated partial thromboplastin time as screening tests. The presence of petechiae indicates a platelet abnormality, the most common of which is thrombocytopenia. Therefore, you would expect the platelet count to be decreased. The prothrombin and activated partial thromboplastin times are normal in platelet abnormalities that are not complicated or accompanied by abnormalities of fibrin formation.

Checkpoint! 2

If you observed an average of 14 platelets on a peripheral blood smear prepared from the needle tip and your laboratory allowed correlation between the direct instrument count and the blood smear estimate of 20%, what range would you expect the instrument count to be? Is this platelet estimate within an acceptable reference range?

Answer

Average of 14 platelets $\times 15 \times 10^9/L = 210 \times 10^9/L$. An acceptable range of the instrument count would be $168\text{--}252 \times 10^9/L$. Yes, this is within the acceptable reference range.

Checkpoint! 3

How many platelets per $1000\times$ field would you expect to observe on the peripheral smear of a patient with acute ITP?

Answer

You would expect to see an average of fewer than six platelets per field. It can be difficult to find platelets on the blood smear of some ITP patients.

Checkpoint! 4

A 6-year-old boy was brought to his pediatrician because the mother noticed small pinkish spots on the boy's legs. Upon examination he also had several bruises on his arms and legs. Laboratory tests were ordered. His platelet count was $20 \times 10^9/L$ and PT and APTT were within normal limits. The CBC was normal except for the low platelet count. There was no previous history of bleeding. The mother said she noted the spots after he was given the hepatitis vaccine. What is the most probable type of thrombocytopenia? Should other coagulation tests be performed at this time?

Answer

The most probable type of thrombocytopenia experienced by this patient is an immune type of increased destruction, which is reportedly

Question:

11. What additional testing would be considered?

Explanation:

DNA studies may be done in a research facility to determine the molecular abnormality or flow cytometry to demonstrate reduction of the GPIb/IX complex on the platelet membrane.

associated with viral infections in some children. Other coagulation tests are not necessary.

Checkpoint! 5

What is the pathophysiology of the thrombocytopenia in megaloblastic anemia?

Answer

Thrombocytopenia occurs in megaloblastic anemia because of ineffective production of all myeloid cell lines in the bone marrow.

Checkpoint! 6

Explain why primary thrombocytosis is often associated with abnormal platelet function while secondary thrombocytosis is not.

Answer

Primary thrombocytosis is associated with the myeloproliferative disorders, which are clonal disorders of the pluripotential stem cell. The abnormal clone grows autonomously and not in response to normal regulatory factors. It is likely that abnormalities in platelet function are acquired along with the ability to grow autonomously. In secondary thrombocytosis, the platelets are increased because of the normal regulatory routes in response to a need for more platelets.

Checkpoint! 7

Compare the results of platelet aggregation studies in platelet adhesion, aggregation, and secretion disorders.

Answer

Platelet adhesion to collagen requires that the von Willebrand factor attached to platelet GPIb/IX receptors bridge the platelet to the collagen fiber. Platelet aggregation studies are abnormal with ristocetin in these disorders because it takes the place of collagen in the test. Other routine agonists require the platelet GPIIb/IIIa receptor and fibrinogen as the bridge to attach one platelet to another platelet. Platelet aggregation disorders involve abnormalities in the GPIIb/IIIa receptor or in fibrinogen. Therefore, platelet aggregation studies will be abnormal with all agonists except ristocetin. In platelet secretion disorders, platelets are able to respond to agonists in the primary wave of aggregation but are unable to release their own ADP and manufacture their own thromboxane A_2 , so that the secondary wave of aggregation seen with ADP and epinephrine and the wave of aggregation with collagen are abnormal.

Checkpoint! 8

Why are the bleeding time test and the closure time abnormal for up to 7 days following ingestion of aspirin?

Answer

Aspirin inhibits the platelet enzyme cyclooxygenase, which is necessary for production of thromboxane A_2 . TXA_2 is necessary in the ac-

tivated platelet for secretion of granule contents and, therefore, the function of the platelets is impaired. The defective platelets continue to circulate for their normal life span, which is about 10 days. Because

they are circulating, the bone marrow is not stimulated to produce new platelets to replace the defective ones.

Disorders of Secondary Hemostasis

Shannon Carpenter, MD, MS
Beverly Kirby, EdD

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define *deficiency* as it relates to the proteins of secondary hemostasis.
2. Describe the expected results of laboratory screening tests that detect abnormalities of the proteins of secondary hemostasis.
3. Describe the expected laboratory results, pathophysiology, and clinical symptoms in patients with classic (type I) von Willebrand disease.
4. Identify hemostatic proteins that are deficient in hemophilias A and B.
5. Characterize deficiencies of factors VIII and IX by inheritance pattern, clinical symptoms, and laboratory findings.
6. Differentiate classic (type 1) von Willebrand disease and deficiencies of factors VIII and IX based on results of laboratory tests and clinical symptoms.
7. Identify clinical conditions associated with acquired disorders of the hemostatic proteins and describe the expected results in laboratory screening tests for hemostasis.
8. Characterize disseminated intravascular coagulation (DIC) by etiology, pathophysiology, and the results of laboratory testing.
9. Explain physiologic variations in the reference ranges of laboratory hemostatic screening tests in newborns.
10. Describe the expected general clinical consequences in a patient with an abnormality of the proteins of secondary hemostasis.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Explain the clinical symptoms characteristic of deficiencies of the fibrin-forming proteins, and contrast them with the symptoms associated with disorders of primary hemostasis.
2. Compare and contrast the results of laboratory tests for hemostasis in disorders of primary and secondary hemostasis.
3. Describe genetic mutations and diagram the inheritance pattern that results in deficiencies of the hemostatic proteins.
4. Differentiate von Willebrand disease subtypes, deficiencies of factors VIII and IX, and the inherited deficiencies of the remaining proteins of fibrin formation by inheritance pattern, pathophysiology, clinical symptoms, and laboratory findings.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Disorders of the proteins of fibrin formation
- ▶ Flow charts
- ▶ Hemostasis in the newborn
- ▶ Summary
- ▶ Review questions
- ▶ References

OBJECTIVES—LEVEL II (continued)

5. Select and interpret the results of laboratory tests, and identify clinical symptoms that differentiate von Willebrand disease subtypes, deficiencies of factors VIII and IX, Bernard-Soulier disease, and Glanzmann's thrombasthenia.
6. Describe the pathophysiology of the conditions that result in acquired abnormalities of the hemostatic system, and select confirmatory laboratory procedures.
7. Select and describe the laboratory screening methods for distinguishing between deficiencies and inhibitors of hemostatic proteins.
8. Describe the significance and clinical implications of the development of circulating anticoagulants, and select laboratory procedures that confirm and differentiate between specific and nonspecific factor inhibitors.
9. Choose laboratory methods that differentiate between excessive primary and secondary fibrinolysis, and support your selection.

KEY TERMS

Acquired inhibitor (circulating anticoagulant)
 Afibrinogenemia
 Consumption coagulopathy
 Cross-reacting material/positive (CRM+)
 Cross-reacting material/negative (CRM-)
 Disseminated intravascular coagulation (DIC)
 Dysfibrinogenemia
 Hemophilia A
 Hemophilia B
 Hemorrhagic disease of the newborn (HDN)
 Hypofibrinogenemia
 Lupus anticoagulant (LA)
 Platelet-type-pseudo-VWD
 Primary fibrinogenolysis
 Ristocetin-induced platelet agglutination (RIPA)
 VWF multimers
 von Willebrand disease (VWD)
 von Willebrand factor:ristocetin cofactor activity (VWF:RCo)
 von Willebrand factor antigen (VWF:Ag)

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Secondary hemostasis: Describe the formation of fibrin and the process of fibrinolysis.
- ▶ Laboratory testing in coagulation: Review coagulation screening tests.

Level II

- ▶ Molecular genetics: Summarize the principles and the use of molecular diagnostic tests.

CASE STUDY

We will address this case throughout the chapter.

Scott, a 2-year-old male, developed a severe bleed into a knee joint and was seen in the emergency room of his local hospital. Consider which of the three physiologic compartments involved in hemostasis could be responsible for his bleeding and how this diagnosis could be established.

OVERVIEW

This chapter discusses disorders of clotting factors that result in excess bleeding. Deficiencies of most of the fibrin-forming proteins are included in this category as are some proteins associated with the fibrinolytic system. The pathophysiologic basis and clinical manifestations for each defect are presented. A major emphasis is on the laboratory involvement in the diagnosis and treatment of the defects. Because the levels of coagulation proteins are different in neonates when compared with adults and testing presents a unique challenge, a section on newborn hemostasis also is included.

INTRODUCTION

The process of secondary hemostasis results in the formation of fibrin, which stabilizes the primary hemostatic plug. Production of an effective fibrin clot requires the interaction of several plasma proteins (procoagulant proteins) that become activated by the injured tissue in a cascade sequence. In addition, other proteins are required to inhibit or inactivate the procoagulant proteins so that clot formation is limited to the injured area. Fibrin subsequently is broken down, or lysed, as the wound heals.

If one or more of these proteins are defective, either quantitatively or qualitatively, the balance between clot formation and clot lysis is upset. Fibrin formation is impaired if the fibrin-forming proteins are faulty. If proteins of the fibrinolytic system malfunction, either too much fibrin is

formed or lysis of fibrin is inadequate or excessive. The results of such imbalances in the system are symptoms of either excessive bleeding or inappropriate and excessive clotting. This chapter discusses disorders of the plasma proteins that result in excess bleeding. Plasma protein disorders resulting in excessive clotting (thrombosis) are discussed.

▶ DISORDERS OF THE PROTEINS OF FIBRIN FORMATION

Disorders of the proteins of fibrin formation arise either by inheritance of a defective gene that directs the synthesis of a hemostatic protein or by acquisition of a deficiency secondary to another condition during the individual's lifetime. In the hereditary disorders, the genetic defect causes either the failure of synthesis of one of the proteins or the production of a malfunctioning molecule (Web Figure 1■). In both situations, the rate of fibrin formation is slowed and ineffective, and the patient can experience abnormal bleeding.

Early investigators of coagulation disorders assumed that if a patient bled excessively, a coagulation protein was absent or decreased in quantity and called the defect a deficiency. The word *deficiency* currently is applied to either hereditary or acquired disorders and is understood to relate either to the absence of a coagulation protein (quantitative disorder) or to a protein that is present in the plasma but that is functionally defective (qualitative disorder). The defect affects fibrin formation both *in vivo* and *in vitro* in laboratory screening tests such as the prothrombin time (PT) and the activated partial thromboplastin time (APTT).

Laboratory screening tests are based on the length of time that it takes a clot to form in plasma. They depend, therefore, on the presence of an adequate amount of the clot forming proteins (quantity) and how well the proteins function (quality). They do not differentiate qualitative from quantitative defects. A functionally defective coagulation factor prolongs the clotting screening test but can still be recognized by immunologically based procedures in the laboratory, which utilize antibodies to detect the presence of the protein. Individuals who have these functionally defective factors that can be detected immunologically are said to be positive for **cross-reacting material (CRM+)** (i.e., the protein is present although it is nonfunctional). Patients in whom the clotting factor is quantitatively decreased and thus have abnormal results in both functional and immunological assays are negative for **cross-reacting material (CRM-)** (Web Figure 1).

Clinical bleeding symptoms in patients with coagulation factor deficiencies differ from those seen in platelet defects (Table 1♣). These patients bleed from the rupture of small arterioles rather than from capillaries, and the sites of bleeds are into deep muscular tissues and joints rather than the superficial areas seen in platelet disorders. Hematomas

♣ TABLE 1

Bleeding Characteristics in Disorders of Secondary Hemostasis

Symptoms typical of secondary hemostatic disorders

- Delayed bleeding
- Deep muscular bleeding
- Spontaneous joint bleeding

Symptoms common to primary and secondary hemostatic disorders

- | | |
|-----------------------------|---|
| • Ecchymoses | • Gingival (gums) bleeding |
| • Gastrointestinal bleeding | • Increased bleeding after tooth extraction |
| • Hematuria | • Intracranial bleeding |
| • Hypermenorrhea | • Epistaxis |

are common and can be massive. Patients also experience delayed bleeding from cuts. Patients with coagulation factor defects usually have normal platelets; therefore, a typical primary hemostatic plug is formed after a superficial cut. This initially arrests the blood flow, and the bleeding stops. Delayed bleeding occurs because, in the absence of stabilization with fibrin formation, the plug dislodges and the wound begins to bleed again later. The subsequent bleed usually continues for a longer time with the loss of a larger amount of blood. Patients with disorders of secondary hemostasis do not bleed faster but for a prolonged period of time.

Patients with coagulation factor deficiencies can experience ecchymoses, excess bleeding from traumatic injuries, and bleeding from the body sites listed in Table 1. Some of these symptoms are also seen in patients with platelet disorders. Retroperitoneal bleeding and hematuria also are common, but petechiae are not usually seen in disorders of secondary hemostasis.

The physician's evaluation and laboratory investigation of a bleeding patient proceeds as described. The battery of screening tests in a factor deficiency usually show a normal platelet count, but the PT, the APTT, or both are usually prolonged (Table 2♣). In the case of von Willebrand disease (VWD), at times the only abnormal laboratory test is the bleeding time or PFA-100®, or the patient can have no abnormal lab results and only a strong family or personal history of bleeding (see discussion of VWD testing). The thrombin clotting time can be the only abnormal test in disorders of fibrinogen. Abnormalities of factor (F) XIII require specific testing. When the history and results of the screening tests indicate, additional testing is ordered to more specifically define the problem. Coagulation factor assays, fibrinogen levels, a D-dimer test, and/or antithrombin levels can be useful confirmatory procedures.

This chapter discusses the hereditary disorders of each of the coagulation factors on the basis of inheritance pattern. The most common types of VWD demonstrate an autosomal dominant pattern of inheritance; hemophilias A and B show

★ TABLE 2

Coagulation Screening Test Results in Congenital Deficiencies

Platelet Count	PT	APTT	PFA-100	TT	Suspected Congenital Deficiency
N	N	N	N	N	Factor XIII, mild deficiencies of any factor, α_2 -antiplasmin, Plasminogen Activator Inhibitor-1
N	A	N	N	N	Factor VII
N	N	A	N	N	Factors XII, XI, IX, VIII, prekallikrein, high molecular weight kininogen
N	A	A	N	N	Factors X, V, II (prothrombin)
N	A	A	N	A	Fibrinogen

N = normal; A = abnormal; PT = prothrombin time; APTT = activated partial thromboplastin time; TT = thrombin time

X-linked recessive inheritance. Deficiencies of the remaining clotting factors exhibit an autosomal recessive inheritance pattern. Acquired disorders of the clotting factors follow and are classified as consumption disorders, liver disease, vitamin K deficiencies, and acquired pathologic inhibitors.

The amino acid sequences of most of the hemostatic proteins and their inhibitors have been determined as has the nucleotide sequences of most of their genes. Research laboratories are involved in characterizing the molecular sites and types of mutations that lead to coagulation factor deficiencies. Specific molecular defects in many genes and their corresponding proteins have been established, and various mutations have been characterized. Point mutations, alterations of splice junctions, deletions, insertions, inversions, and mutations resulting in premature stop codons are a few of the known molecular defects. Researchers are gathering information in an attempt to correlate sites and types of mutations with the clinical symptoms seen in patients.

HEREDITARY DISORDERS OF SECONDARY HEMOSTASIS

Secondary hemostasis disorders can be inherited as autosomal dominant, X-linked recessive, and autosomal recessive disorders. Inherited coagulation factor disorders usually involve a single coagulation protein, and if bleeding occurs, it is generally from one site at a time.

Autosomal Dominant Inheritance

An autosomal dominant inheritance of a defective protein causes two coagulation disorders: von Willebrand disease (types 1, 2A, 2B, and 2M) and dysfibrinogenemia. Dysfibrinogenemia will be discussed with the other disorders of fibrinogen in the autosomal recessive category. von Willebrand disease is considered here.

von Willebrand Disease **von Willebrand disease (VWD)** is a quantitative or qualitative deficiency of von Willebrand factor (VWF) arising from mutations in the VWF gene. Inherited defects in VWF can result in defective protein processing or disruption of specific ligand-binding sites.

Based on the nature of the mutation and inheritance patterns, VWD is subdivided into three types with type 2 containing 4 subtypes. The results of laboratory tests in VWD can sometimes be confused with a deficiency of F-VIII. The similarities and differences between VWD and F-VIII deficiency will be addressed later.

VWF serves as a bridge between GPIb/IX receptors on activated platelets and subendothelial collagen exposed when the vessel is injured (primary hemostatic plug formation).¹ VWF also plays a role in secondary hemostasis, complexing with and stabilizing circulating coagulation F-VIII in the plasma. The function of VWF in both primary hemostasis and fibrin formation is altered in most patients with clinically symptomatic VWD.

The autosomal dominant pattern of inheritance is important in the clinical expression of type 1 VWD. Clinical symptoms occur when one gene is defective and the production of VWF is reduced by about one-half. Circulating levels of F-VIII generally are reduced in proportion to the reduction in VWF. The platelet-associated function of VWF is independent of the presence or absence of F-VIII. While the inheritance pattern of most patients with VWD is autosomal dominant, more severely affected patients (with types 2N and 3) demonstrate an autosomal recessive or compound heterozygous pattern. Symptomatic patients with these inheritance patterns have mutations in both the VWF genes (i.e., are homozygotes or double heterozygotes).

Nature of von Willebrand Factor. Figure 1 ■ depicts the synthesis of the F-VIII/VWF complex. The structure of the mature VWF molecule is a chain of identical subunits called *multimers*. Normally, the number of subunits in individual molecules varies so that the molecular weights range from 0.5 to more than 20 million Daltons (Da). Although VWF in plasma consists of a wide range of sizes, most VWF molecules bind only one F-VIII molecule; thus, the molar ratio of VWF:F-VIII is ~1:1. A detailed description of the synthesis of VWF, which occurs in endothelial cells and megakaryocytes, can be found on this text's Companion Website.

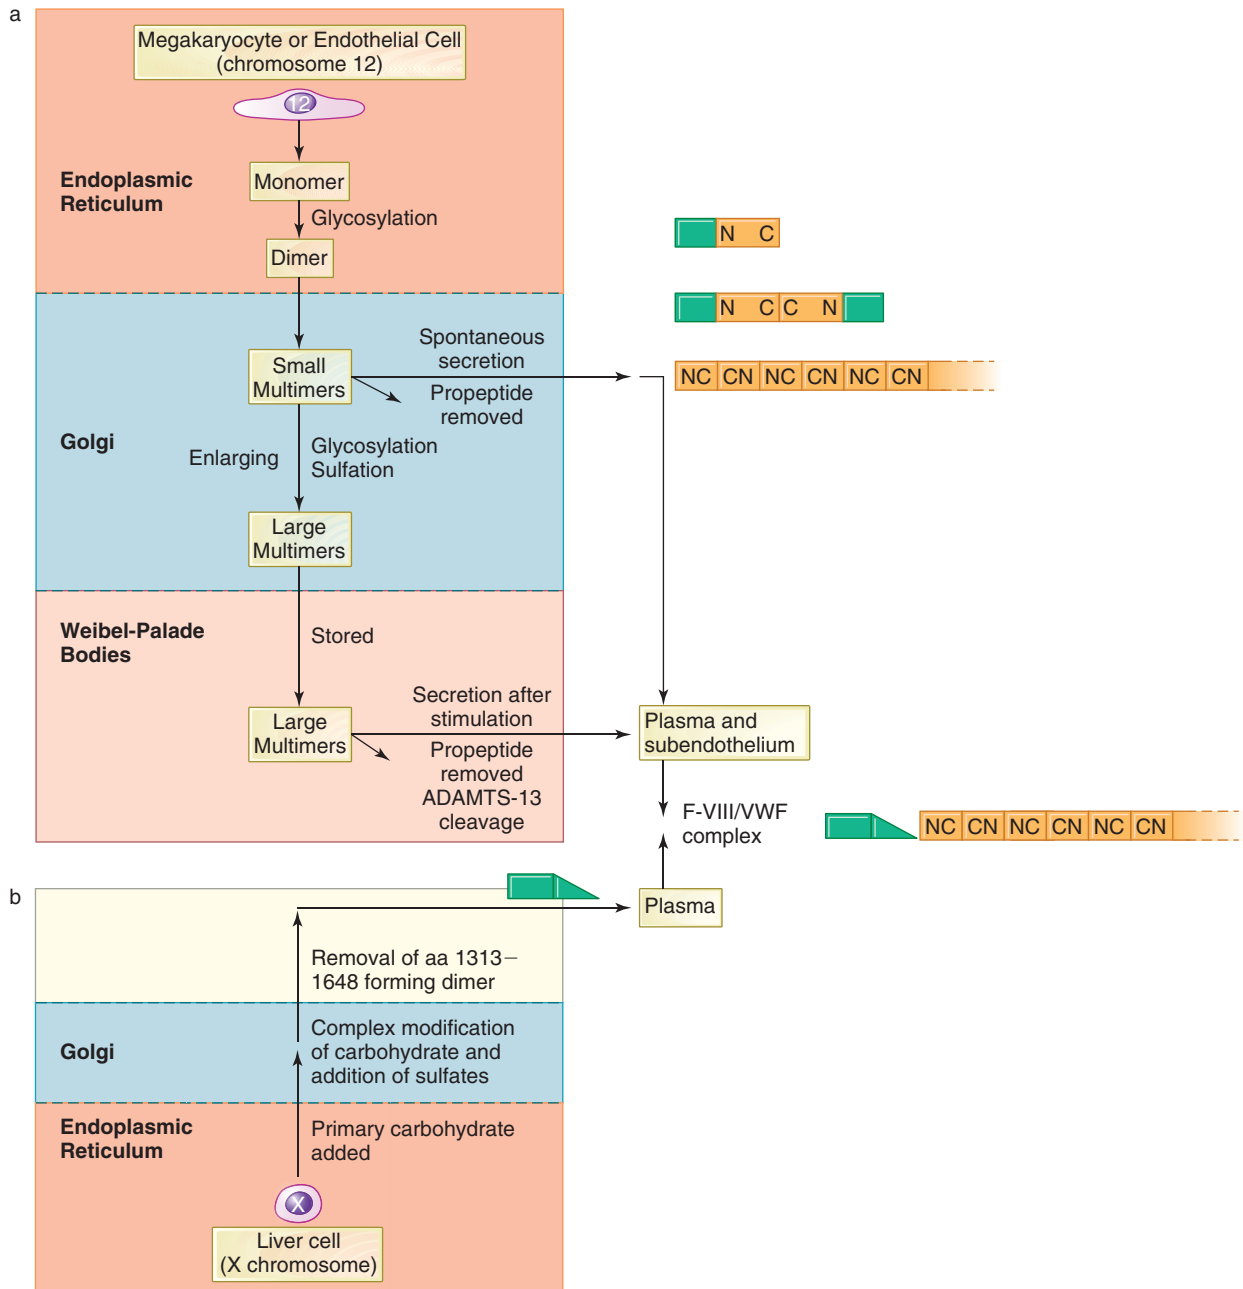

FIGURE 1 Synthesis and secretion of F-VIII/von Willebrand complex. **a.** Synthesis of von Willebrand factor. VWF transcripts are processed in the endoplasmic reticulum (ER) and then the Golgi. Subunits of VWF are synthesized in the ER as single-chain proprotein monomers. Dimers are formed by attachment of two monomers at the carboxyterminal (C) ends. Dimers move to the Golgi where the propeptide is removed and the dimers associate at the amino terminal (N) ends to form large multimers. **b.** Synthesis of F-VIII in the liver. Both VWF and F-VIII are secreted into the plasma where they bind together. = propeptide; = F-VIII

A schematic diagram of the structure of a VWF subunit is shown in Figure 2. It consists of four types of domains, A through D, which are repeated and numbered in the arrangement shown. Sites of interaction with F-VIII, GPIIb/IX, GPIIb/IIIa, collagen, and heparin have been identified.^{1,2}

Clinical Findings. Dr. von Willebrand first described the disease that carries his name after studying an extended family in the Åland Islands of Finland in 1926.³ The first patient studied died during her fourth menstrual period, and four sisters also had died from bleeding. At the time, available laboratory tests included the platelet count, coagulation

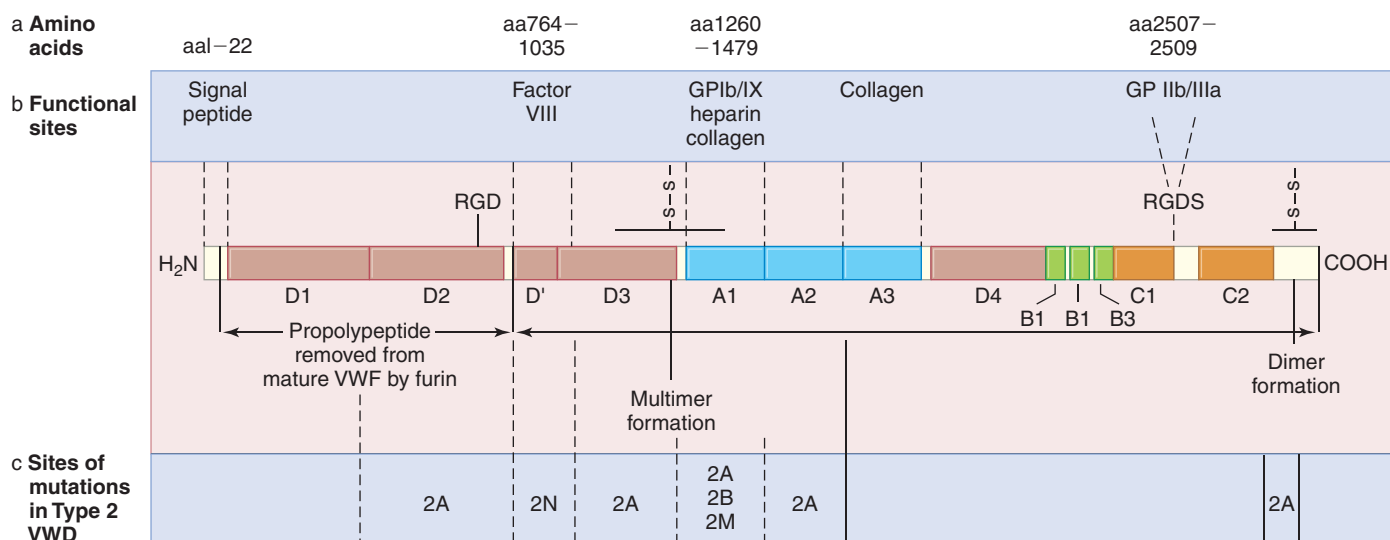

FIGURE 2 A diagrammatic depiction of the domain structure of a VWF monomer precursor protein. The precursor protein consists of 2813 amino acids. **a.** The amino acids (aa) involved in the functions at **b.** aa 1–22 is the signal peptide; domains D1 and D2 (aa 23–741) are the propeptide removed during processing; domain D' (aa 764–1035) plus part of domain D3 are the binding site for F-VIII; domain A1 (aa 1260–1479) contains binding sites for GP Ib, heparin and collagen; domain A3 contains the major binding site for collagen; domain C1 contains the binding site for GP IIb/IIIa; disulfide bridges at D3 and the C terminal end are the sites of attachment when forming multimers and dimers, respectively. The mature protein with the propeptide removed contains 2050 amino acids. **c.** Sites of mutations of the subtypes of type 2 VWD. R = arginine; G = glycine; D = aspartic acid; S = serine

time, and clot retraction, all of which were normal. With further studies, von Willebrand concluded that the disease was related to platelet dysfunction.

VWD is the most common inherited bleeding disorder. It is estimated that about 125 in 1 million persons have VWD with clinical (bleeding) symptoms and another 1% of the population is asymptomatic and thus not aware of having the disease.⁴

Bleeding symptoms, if present, are usually mild. Those patients who are homozygous or doubly heterozygous for VWD can exhibit severe symptoms and have the potential for life-threatening bleeding. The typical type of bleeding is hemorrhage in mucosal and cutaneous tissues. Approximately 60% of patients report epistaxis, and 50% report menorrhagia and bleeding after dental extraction. Thirty-five percent of patients report gingival bleeding and easy bruising.^{5,6} These clinical features resemble those seen in platelet disorders. Excessive bleeding at childbirth is comparatively rare because in pregnancy the activity of the entire F-VIII/VWF complex increases, but postpartum bleeding can occur in 21–59% of patients.⁷ In type 3 VWD (homozygous), the symptoms can include hemarthroses and spontaneous deep bleeding resembling coagulation factor deficiencies due to the concomitant decrease in F-VIII levels. An individual's ABO blood type affects VWF antigen levels (discussed later), which may affect the severity of bleeding symptoms although the impact is still somewhat controversial.^{8,9}

One hallmark of the disease is its variability. The severity of bleeding symptoms differs in individuals within the same

kindred, among kindreds, and, from time to time, within the same individual. Symptoms might not begin until the second decade of life in mild forms of the disease. In the severe forms, symptoms begin early in life and often decrease with age. Laboratory test results vary, often requiring repeated testing of the same individual.³ The severity of clinical symptoms does not necessarily correlate with the level of VWF activity. However, some VWD subtypes demonstrate unique symptoms related to the nature of the mutations.

Laboratory Evaluation of VWD. The common laboratory tests for fibrin formation do not directly evaluate VWF. The laboratory diagnosis of VWD is based on the results of a battery of tests after identification of a patient with a life-long clinical history of the typical bleeding symptoms and/or a history of similar symptoms in other family members. Screening tests include the platelet count, APTT, PT, the template bleeding time, and/or the PFA-100®. The recently developed platelet function analyzer (PFA-100), a device that uses a membrane coated with collagen and a platelet agonist to which platelets adhere, has replaced the bleeding time in many institutions. Typical results of these tests in VWD are shown in Table 3 and are compared with the results in the hemophilias (discussed in the next section).

The template bleeding time, a crude measure of platelet function, is abnormal not because the platelets are abnormal but because in the absence of VWF, the platelets are unable to adhere to collagen and initiate the formation of the pri-

mary hemostatic plug. The platelet function analyzer has been shown to be abnormal with collagen/ADP and collagen/epinephrine cartridges for similar reasons.^{9,10} The APTT is used as an indirect screening test for VWF because of the correlation of VWF and F-VIII levels. An abnormal APTT occurs only when the level of F-VIII is near or below the sensitivity of the APTT reagent (for most commercial reagents \leq 30% of normal). Therefore, bleeding time (BT), PFA, and APTT results may produce discordant normal/abnormal results. The PT, which does not depend on either F-VIII or VWF, is normal.

If the screening test results and the patient's clinical history suggest VWD, specific tests are required to establish the diagnosis and to determine the type or subtype of VWD. The specific tests quantitate VWF and F-VIII activity and determine various functional and structural aspects of the VWF protein.

Because VWF cannot be measured by clotting assays, immunologic tests are used to quantitate the amount of VWF protein in the plasma as **von Willebrand factor antigen (VWF:Ag)**. Various immunologic methodologies (e.g., ELISA) are available and use commercially prepared monoclonal antibodies to VWF. F-VIII activity is determined by a standard factor assay method. F-VIII levels usually correlate with the amount of VWF antigen. The patient's ABO blood type should also be determined because blood type signifi-

cantly affects the normal level of VWF protein. Type B plasma has up to twice the VWF antigen as type O plasma. Some laboratories have developed different reference ranges for each blood type. Also, because VWF is an acute phase reactant, levels of protein are increased during inflammatory states, stress, or pregnancy.

The ability of VWF to function in platelet adhesion is determined by the **von Willebrand factor:ristocetin cofactor activity (VWF:RCo)**. The VWF:RCo assay is performed on a platelet aggregometer and measures the ability of the patient's VWF to support agglutination of platelets by ristocetin.

The diagnosis of VWD is established by finding a decreased plasma level of VWF activity, VWF antigen, F-VIII levels (which usually correlate with the quantity of VWF), and/or a prolonged bleeding time or prolonged closure time. Classic (type 1) VWD results from a partial quantitative deficiency and typically leads to abnormal results in all of these tests. In some cases, however, one or more of the tests is normal, making diagnosis more difficult. The functional VWF:RCo activity might not correspond to the VWF antigen levels, depending on whether the patient has a quantitative or a qualitative defect as described later. Patients with qualitative defects usually have decreased concentrations of VWF antigen but more markedly abnormal functional tests than would be expected by the amount of VWF present.

When the diagnosis of VWD is established by decreased VWF:Ag and/or abnormal function of VWF, the final step in the laboratory diagnosis of VWD is to establish the subtype. The structure of **VWF multimers** is studied by electrophoresis using 1% agarose gels in the presence of sodium dodecyl sulfate (SDS). The multimers are separated by size and visualized as bands. These tests can be performed on platelet- or plasma-derived VWF. Other tests of VWF functional activity include ELISA tests designed to measure the ability of the patient's VWF to bind to either F-VIII or to collagen, described as VWF:CB (collagen binding) and VWF:VIII B (F-VIII binding) assays.^{11,12} The **ristocetin-induced platelet agglutination test (RIPA)** detects the ability of the patient's VWF to bind patient's platelet GPIb/IX. In patients with rare qualitative mutations, one or more of these abilities is decreased. Theoretically, DNA analysis to establish the specific gene mutation would be desirable but is difficult because the VWF gene is very complex and most molecular defects have not yet been identified. Databases for VWD mutations have been established.⁹ An online database is accessible at www.shef.ac.uk/vwf/index.html. In the future, with improvements in methodology, DNA analysis could become the test of choice for differentiating the qualitative types of VWD because the sites of mutations are more predictable than in the quantitative types of VWD.⁶

Classification. A classification system for VWD proposed in 1994 simplifies previous schemes and is based on the phenotype of the VWF protein determined using the laboratory tests described previously.¹³ This classification was updated in 2006 to include our improved understanding of the metabolism of VWF.¹⁴ This scheme has three major categories, types 1, 2, and 3, which depend on whether the patient has a quantitative or a qualitative defect and, in the case of quantitative defects, the extent of the quantitative defi-

ciency. Types 1 and 3 VWD are both quantitative deficiencies of VWF. Type 1, the most common type (the "classic" type), is a mild form of VWD in which patients have a partial quantitative deficiency of VWF. Type 3 patients have an absolute absence of VWF (a severe form of the disease). Type 2 patients have qualitatively abnormal VWF of various kinds; the type is further subdivided into four variants, Types 2A, 2B, 2M, and 2N.¹⁵ The structure of a VWF protein with sites of mutations is depicted in Figure 2. Some characteristics of the VWF types are shown in Table 4. Table 5 summarizes laboratory test results in all types and subtypes of VWD. Discriminating qualitatively normal and abnormal VWF by routine laboratory testing is difficult. A common approach used by many laboratories is to compare values obtained in functional assays (VWF:RCO, VWF:CB, VWF:FVIIB) with VWF:Ag. A ratio <0.6 ¹¹ or <0.7 ¹² the VWF:Ag value is considered to be abnormal (i.e., a dysfunctional protein).

✓ Checkpoint! 1

- Why do patients with type 1 VWD have 25–50% of VWF in their plasma?
- Why do they have a corresponding decrease in F-VIII in their plasma?

Two additional forms of VWD are **platelet-type-pseudo-VWD** and acquired von Willebrand syndrome. While clinical bleeding symptoms and laboratory test results are similar to those in VWD, they are not caused by mutations in the VWF gene.

Pseudo-VWD is a platelet disorder that results in increased affinity of the platelet GPIb/IX receptor for VWF.

★ TABLE 4

Description of von Willebrand Disease (VWD) Subtypes

Type	Description	% of VWD	Mutation Sites; Functional Abnormalities
1	Partial quantitative deficiency with normal structure and function of the multimers	70–80	Multiple
2	Qualitative disorder with functionally abnormal VWF		
2A	Decreased platelet adhesion because of absence of largest multimers	10–15	A2, A1, D2, D3 domains—either defective synthesis of largest multimers or increased proteolysis
2B	Increased affinity for platelet GPIb and absence of largest multimers	<5	A1 domain—spontaneous binding to platelets and removal from circulation
2M	Decreased platelet adhesion via GPIb/IX not due to absence of largest multimers	Rare	A1 domain—inactivation of specific binding sites for ligands on platelets or in connective tissue
2N	Decreased affinity for F-VIII (autosomal recessive)	Rare	D', part of D3 domains—platelet-dependent functions preserved, loss of function as carrier of F-VIII
3	Absence of VWF in platelets and plasma	0.5–5 per million	Varied; 64% characterized

WVF:Ag = von Willebrand factor:antigen; WVF:RCo = von Willebrand factor:ristocetin cofactor activity; RIPA = ristocetin-induced platelet aggregation

Pseudo-VWD is clinically similar to VWD type 2B, but its defect is in the platelet receptor for VWF, usually resulting in spontaneous binding of the larger multimers of plasma VWF to platelet GPIIb. This results in a decrease of large VWF multimers and F-VIII in the plasma. In addition, GPIIb/IIIa receptors are exposed and platelets aggregate, resulting in thrombocytopenia.

Acquired VW syndrome (AVWS) is called a *syndrome* rather than a *disease* because it is not caused by VWF mutations. AVWS is very rare and has been reported in fewer than 100 patients. It is associated primarily with lymphoproliferative diseases such as multiple myeloma, lymphoma, and chronic lymphocytic leukemia. The pathogenic mechanism of AVWS varies from patient to patient, although most are associated with loss of VWF due to neutralizing anti-VWF antibodies, proteolytic or mechanical degradation of the protein, or adsorption to cell surfaces. AVWS is diagnosed with the same laboratory tests used for inherited VWD: F-VIII coagulant activity, WVF:Ag, and WVF:RCo.¹⁶ Elevated levels of the VWF propeptide (WVFpp or WVF antigen II) can sometimes help distinguish between acquired and congenital disease (normal or elevated in AVWS, decreased in VWD), although this result is not completely specific for acquired VWS because some forms of congenital disease also result from increased clearance of VWF.¹⁷

Prenatal Diagnosis. Prenatal diagnosis of VWD is available but is usually reserved for patients with severe types of the disease. Type 2 is easily identified prenatally by PCR techniques, but diagnosis of type 3 is more difficult.⁴

VWD Therapy. Patients with mild VWD who are not experiencing clinical bleeding do not require therapy. For VWD patients who are actively bleeding, several preparations are available to raise the level of VWF in their plasma. The classic treatment for VWD was to inject cryoprecipitate preparations that contain all molecular forms of VWF including the large multimer forms, as well as F-VIII and fibrinogen. A drawback to using cryoprecipitate is that it cannot be treated to inactivate blood-borne viruses and, therefore, carries a risk of transmission of blood-borne disease.

The current preferred method of treatment is a modified antidiuretic hormone, desamino-D-vasopressin (DDAVP), which was found to induce endothelial cell release of VWF from the Weibel-Palade bodies. It temporarily increases the levels of VWF and F-VIII and is used in treating patients who are bleeding. Transmission of blood-borne disease is not a risk with DDAVP. About 20–25% of VWD patients, including all type 3 patients and about 10–15% of type 1 patients, do not respond to DDAVP. The response to DDAVP can be

variable in type 2 subtype patients. It should be used with caution to treat patients with type 2B VWD because it can cause a dangerous reduction in the platelet count. Patients with type 2A do not respond consistently.

The preferred form of therapy for those who do not respond to DDAVP is concentrated “intermediate purity” preparations of F-VIII that contain intermediate-size VWF molecules. High purity or monoclonal F-VIII preparations do not contain sufficient VWF to be useful in treating VWD. F-VIII concentrates are virus inactivated by a variety of methods. A potential complication of using products containing both F-VIII and VWF is the elevation of plasma F-VIII levels, sometimes to as high as 400 IU/mL. Excessively high levels of F-VIII can be associated with venous thrombosis. A highly purified VWF concentrate that contains little F-VIII has been used successfully in treating European patients with VWD but is not yet available in the United States.¹⁸

✓ Checkpoint! 2

If a patient with VWD has an equal decrease in F-VIII activity, VWF:RCo, and VWF:Ag assay, does this more likely indicate that there is a true decrease in the amount of VWF, or does it indicate that the patient has a type of VWD that is characterized by a functional abnormality of VWF? Support your answer.

What type of VWD is most likely in a patient with these laboratory results?

🌀 CASE STUDY (continued from earlier in this chapter)

Scott's mother was questioned about how the bleeding had begun in the joint and about other bleeding history. She answered that Scott had taken a slight tumble, but that it had not seemed to her enough to cause such severe bleeding. She also mentioned that when Scott had minor cuts, they seemed to stop bleeding quickly but often would bleed again in a day or two.

1. What term is used to describe the type of bleeding from minor cuts that Scott's mother is describing?
2. Does this history seem to be typical of a platelet disorder or of a coagulation factor disorder? Why?

X-Linked Recessive Disorders

The hemophilias are hereditary bleeding disorders resulting from congenital deficiencies of proteins involved in blood coagulation. The clinically most common deficiencies are associated with mutations in the genes for factors VIII and IX on the X chromosome. These proteins participate as a cofactor (F-VIII) and serine protease (F-IX) in the intrinsic pathway of fibrin formation. Deficiency of F-VIII is known as **hemophilia A**; deficiency of F-IX is called **hemophilia B** (also known as *Christmas disease*). Both deficiencies demonstrate X-linked recessive inheritance patterns.

X-linked recessive disorders are usually inherited by sons from their carrier (heterozygous) mothers who have an abnormal allele on one X chromosome and a normal allele on the other. Each son has a 50% chance of inheriting the affected gene. Males have only one X chromosome (hemizygous); thus, if they inherit an abnormal allele on that chromosome, they are affected with hemophilia. In the case of F-VIII or F-IX deficiency, males are able to synthesize little or none of the clotting factor, depending on the particular mutation inherited.

Hemophilia A is a deficiency of the F-VIII portion of the F-VIII/VWF complex as opposed to VWD in which the VWF portion of the complex is abnormal (discussed previously). Patients with hemophilia A have normal circulating levels and functionally normal VWF. Thus, their platelets adhere properly to collagen, and the formation of an effective primary hemostatic plug is not disrupted. Patients with hemophilia B have an intact F-VIII/VWF complex and likewise have normal primary hemostatic plug formation. The abnormal bleeding in both diseases is caused by delayed and inadequate fibrin formation with a secondary increase in fibrinolysis. These patients generate a normal tissue-factor driven *initiation* phase of coagulation but fail to generate the massive amounts of thrombin during the *propagation* phase of coagulation. As a result, in addition to inadequate thrombin and fibrin production, thrombin activation of TAFI fails to occur, resulting in excessive fibrinolysis compounding the bleeding associated with inadequate fibrin formation.

The clinical presentations in both deficiencies are identical. They can be distinguished only by laboratory testing. The common clinical and laboratory aspects of the hemophilias are discussed later after a discussion of the genetic mutations specific for F-VIII and F-IX.

Hemophilia has been known for several thousand years. It has contributed to world history by its presence in the royal families of Europe, particularly Great Britain, Russia, and Spain, through Queen Victoria, who was a carrier for hemophilia A. Originally, all patients with X-linked bleeding disorders were believed to have the same disease. This idea was challenged when, in 1947, Pavlovsky observed that prolonged recalcification times (the test available then) on two patients with hemophilia were corrected when the test was performed on mixtures of the two plasmas.¹⁹ In 1952, three groups of investigators reported patients who were missing a new clotting factor that became known as F-IX.

Hemophilia A accounts for 80–85% of all cases of hemophilia with a prevalence of approximately 1 in 5,000–10,000 male births. Most of the remaining 15–20% of hemophilia patients are deficient in F-IX (affecting ~1 in 30,000 males). Hemophilia A is second to VWD in the overall frequency of inherited bleeding disorders. Approximately 30% of the affected individuals have no positive family history of the disease, indicating that de novo genetic mutations occur often.

Factor VIII Nomenclature In 1985, the International Committee on Thrombosis and Hemostasis published rec-

TABLE 6

Nomenclature of the F-VIII/von Willebrand Factor Complex

von Willebrand factor—deficient in von Willebrand disease (VWD)

VWF	von Willebrand factor protein

VWF:RCo	Functional activity of the VWF molecule as measured by ristocetin cofactor activity

Factor VIII—deficient in hemophilia A

F-VIII	F-VIII protein
F-VIII:C	Functional activity of F-VIII as a procoagulant in fibrin formation (as measured by APTT)
F-VIII:Ag	Antigenic properties of F-VIII

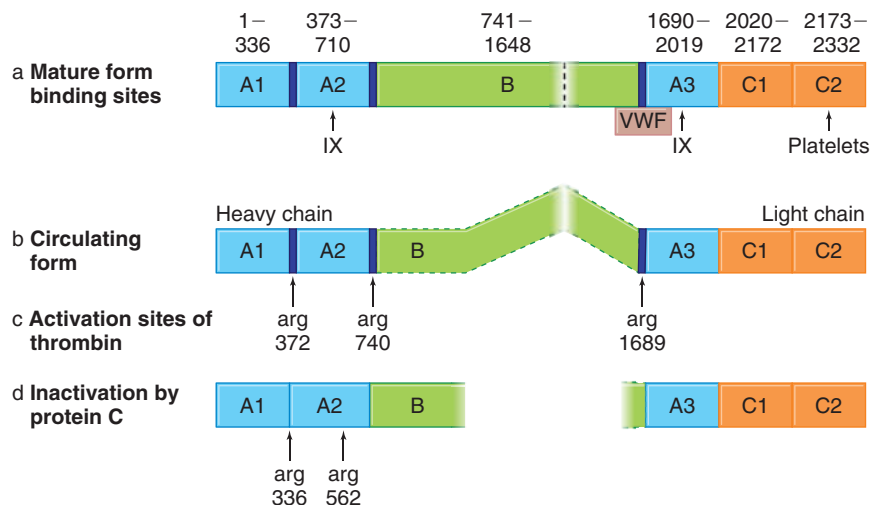

ommendations that defined nomenclature for the F-VIII/VWF complex.²⁰ Prior to these recommendations, the literature referring to F-VIII and VWF was quite confusing. By the mid-1980s, the genes for both F-VIII and VWF had been identified and cloned. The 1985 committee recommendations recognized that two distinct proteins were associated as the F-VIII/VWF complex, each having unique immunologic and functional properties. The currently accepted definitions and abbreviations for the F-VIII/VWF complex components are shown in Table 6.²⁰ The original name for F-VIII, *antihemophilic factor*, is still an acceptable synonym.

✓ Checkpoint! 3

What abbreviation is acceptable for:

- the antigenic properties of VWF?
- the functional activity of F-VIII?
- the complex of F-VIII and VWF?

F-VIII Mutations The molecular structure and key sites of functional activities of F-VIII are shown in Figure 3.²¹ Genetic defects in the F-VIII gene cause hemophilia A. Using restriction enzyme techniques, the polymerase-chain reaction, and other methods, the molecular defects have been determined in more than 4500 patients. The Hemophilia A Mutation Database (www.europium.csc.mrc.ac.uk/WebPages/Main/main.htm) lists >1200 different mutations.²² Genetic defects include point mutations (more than 50% of the identified defects), gross deletions, and regulatory defects spread throughout the gene.^{23,24} Mutations result in either quantitative or qualitative defects of the F-VIII protein. The majority of mutations result in a CRM- or CRM reduced phenotype (~95%). The clinical severity of the disease depends on the site of mutation within the gene and the molecular functions of the protein that are disrupted. One unique type of mutation involving intron 22, called the *F-VIII inversion mutation*, occurs in almost 50% of patients with a severe phenotype. The same mutation occurs in all members of a family, resulting in a similar clinical expression of disease in affected members of the family.

■ **FIGURE 3** Schematic diagram depicting F-VIII. **a.** The mature protein with domains A1, A2, B, A3, C1, and C2. **b.** The circulating form of F-VIII with variable portions of the B domain removed; attaches to VWF at the acidic region preceding domain A3. **c.** Sites of activation by thrombin at Arg residues 372, 740, and 1689. The heavy chain is cleaved, forming a 3-chain structure, and F-VIII is released from VWF. **d.** Sites of proteolytic inactivation of F-VIII by activated protein C (APC) at Arg 336 and Arg 562. Arg = arginine

Factor IX Mutations F-IX deficiency, or hemophilia B, is also known as *Christmas disease* (*Christmas* was the surname of the first reported affected family). Heterogeneous mutations in the F-IX gene or its regulatory components result in hemophilia B. A database of mutations, available at www.kcl.ac.uk/ip/petergreen/haemBdatabase.html, includes more than 1050 unique mutations in 2891 patients.^{25,26} Point mutations (mis-sense and nonsense), deletions of various portions of the gene, and insertions are the main types of molecular events. The clinical severity depends on the type of mutation and the region of the gene affected. Some F-IX deficient patients are CRM⁻, approximately one-third are CRM⁺, and some have reduced levels of antigen (CRM^R). CRM⁺ hemophilia B patients have a mutation in the structural gene resulting in production of an abnormal molecule. These patients have normal levels of F-IX antigen and variably reduced levels of F-IX activity. Patients who are CRM⁻ can have large deletions of the gene and are at risk for developing inhibitors and anaphylactic reactions to replacement therapy.

Clinical Aspects of the Hemophilias Clinical manifestations of hemophilia vary with the amount of factor present and are classified as severe, moderate, or mild disease (Table 7 ★). Generally individuals with >30% activity do not have hemophilia symptoms. The variation in clinical symptoms is largely the result of the type and site of the mutation (e.g., F-VIII deficient patients who have mutations at the thrombin-cleavage sites of F-VIII are unable to activate it, and patients with the inversion mutation have no F-VIII activity and severe bleeding symptoms).

Clinical symptoms in severe disease can begin at circumcision. Hemarthrosis is the most common feature of severe

hemophilia. Bleeding into a joint can be triggered by even minor trauma and is accompanied by intense pain. The joint fills with blood, some of which is not reabsorbed, causing chronic inflammation, pain, and eventually destruction of the joint. Joint bleeds, particularly into the knee and ankle, generally occur when the child starts to walk. Subcutaneous hematomas can begin with slight trauma and spread to involve a large mass of tissue, causing purple discoloration of the skin. Epistaxis is rare in hemophilia. Other manifestations include hematuria, deep muscle bleeding, excess bleeding from dental extractions, bleeding with intramuscular injections, and delayed bleeding after minor cuts. The most common cause of death (after exclusion of viral infections transmitted by the replacement product) is intracranial hemorrhage, which can occur spontaneously or after trauma.

Hemarthrosis and severe spontaneous crippling bleeding into muscles are usually found in patients with severe disease. These symptoms are not commonly seen in those with moderate or mildly severe disease. More characteristic of moderate hemophilia is excessive bleeding after traumatic injury. Mild deficiencies of F-VIII or F-IX can be asymptomatic and unsuspected until a surgical procedure or major traumatic injury results in severe bleeding. Although the site of bleeding varies from individual to individual, the clinical severity of deficiencies of both factors remains similar within families.

Laboratory Evaluation of the Hemophilias

Laboratory tests are required to screen for abnormalities of coagulation factors and then to confirm and quantitate the specific factor that is deficient. Screening tests (APTT) are expressed as time, usually in seconds. Confirmatory assays are expressed in units of activity with normal plasma considered to have 1 unit (U) activity per mL, or 100 U per dL. The reference range for both F-VIII and F-IX is ~50–150% of normal (0.5–1.5 U/mL).

See Table 2 for the results of screening tests in a variety of hemostatic disorders. The APTT is prolonged in both F-VIII and F-IX deficiencies; it is lengthened inversely to the level of factor present in the patient's plasma when the level is below the sensitivity of the testing methodology. Levels of ≤ 20 U/dL of F-IX and ≤ 30 U/dL of F-VIII consistently prolong the APTT.

Definitive diagnosis is made on the basis of the results of specific factor assays. These precautions should be used in interpreting results: (1) F-VIII levels are lower in persons with blood group O than other blood groups (corresponding to the level of VWF) so the blood type must be considered when diagnosing F-VIII deficiency. (2) F-VIII level varies as an acute phase reactant and increases with exercise, inflammation, and so on. Estrogen-containing contraceptives also increase F-VIII levels. (3) Screening test systems might not be sensitive enough to detect mild deficiencies at levels between 20 and 50 U/dL. In these cases, the physician can order a factor assay on the basis of the patient's history. (4) The newborn range for F-IX is lower than that in adults

★ TABLE 7

Clinical Findings in Deficiencies of Factors VIII and IX

Factor VIII or IX Level, Units/dL	Severity	Symptoms
<1	Severe	Frequent spontaneous hemarthrosis with crippling Frequent severe, spontaneous hemorrhage (intracranial, intramuscular)
1–5	Moderate	Bleeding at circumcision Infrequent spontaneous joint and tissue bleeds Excessive bleeding after surgery or trauma Serious bleeding from minor injuries
6–30	Mild	Rare spontaneous bleeds Excessive bleeding after surgery or trauma Might not be discovered until bleeding episode occurs

(20–50% of normal), so one must refer to age-appropriate ranges when making the diagnosis of hemophilia B.

The results of additional laboratory tests shown in Table 3 are compared with the results in type 1 VWD. All platelet testing results are normal in the hemophilias. The thrombin time and PT are normal because neither assay depends on F-VIII or F-IX. One abnormal molecular variant, F-IXBm, does cause prolongation of the PT when bovine brain thromboplastin is used instead of rabbit thromboplastin.²⁷ Tests for fibrinolysis also are normal.

Hemophilia A must be distinguished from deficiencies of F-IX or F-XI and from VWD types 2N and 3. Hemophilia A is distinguished from hemophilia B by factor assays and from F-XI deficiency by both factor assays and inheritance pattern. Mixing studies in which the patient's plasma is mixed with normal plasma (1:1 ratio) with subsequent APTT testing should also be performed to eliminate the possibility of an inhibitor rather than the genetic disorder prior to performing the factor assay. In the event of an inhibitor, the APTT remains prolonged whereas with a factor deficiency, mixing corrects the defect. Type 2N VWD is caused by abnormalities of the D' domain of VWF that prevent F-VIII from binding.³ Both hemophilia and type 2N VWD demonstrate low F-VIII levels and normal structure and functional tests for VWF:Ag, ristocetin cofactor activity, and VWF multimeric structure. Specialized testing is required to distinguish hemophilia A from VWD type 2N, and patients with type 2N VWD would not respond well clinically to F-VIII replacement therapy. Patients with type 2N VWD exhibit autosomal recessive inheritance. Type 3 VWD could be differentiated on the basis of an autosomal inheritance pattern and by a decrease of VWF:Ag in both platelets and plasma.

Checkpoint! 4

Referring to Table 3, explain why the platelet function tests are abnormal in VWD but not in F-VIII or F-IX deficiencies.

Carrier Detection and Prenatal Diagnosis

Daughters of hemophilic males are obligate carriers of the disease and generally do not require further testing. Daughters of obligate carriers may inherit either one of their mother's X chromosomes and thus can be either carriers or normal. Hemophiliac males can inherit the disorder from carrier mothers or represent a spontaneous mutation. Female carriers of X-linked disorders are usually asymptomatic because they have one functional allele. Inactivation of one of the X chromosomes occurs randomly in each somatic cell of a female. Theoretically, in a carrier of an X-linked disorder, random inactivation results in approximately 50% of the cells having a functional X chromosome active, while the remaining 50% would have the X chromosome bearing the mutant allele. A female carrier of F-VIII or F-IX deficiency is expected to have approximately 50% of the normal plasma

level of the factor in question. Detection of the carrier state cannot, however, be based merely on finding half of the normal activity in a factor assay because the normal reference range is 50–150%. Approximately 6% to 20% of women studied could be erroneously classified for two reasons. First, inactivation of the X chromosomes is not always randomly distributed. A carrier can have functional F-VIII- or F-IX-bearing X chromosomes in more than 50% of her hepatocytes, in which case her activity level would fall within the reference range. Conversely, if more than 50% of the hepatocytes have the normal X chromosomes inactivated, she could show clinical signs of mild hemophilia. Second, the F-VIII protein is an acute phase reactant and is physiologically increased in pregnancy, exercise, fever, and several other conditions, which can result in a transient rise of F-VIII to within the reference range. Both F-VIII and F-IX coagulant activity can rise with the use of oral contraceptives.

Detection of carriers is sometimes possible by analysis for both VWF antigen and F-VIII activity levels. VWF:Ag levels in carriers should be ~2 times the F-VIII:C.²⁸ The preferred method of detection of carriers is genetic testing when a proband is available to establish the genetic mutation. In families with a severe phenotype, DNA testing using the Southern blot technique is available for screening for the inversion mutation in intron 22, the most commonly encountered mutation in severe deficiencies. Potential carriers of F-IX deficiency can be detected by direct gene sequencing.^{29,30}

Prenatal diagnosis by genotypic analysis has certain advantages over phenotypic analysis. Results are not affected by X chromosome inactivation, ABO blood type, or VWF levels, and testing can be done earlier in gestation. Various methods are available for prenatal diagnosis; the method of choice varies with the type of mutation anticipated. A chorionic villus biopsy can be done at 11 weeks of gestation and tested with DNA studies such as restriction enzymes (restriction fragment length polymorphism [RFLP]) or PCR methods. Because of the enormous variety of different molecular defects and the considerable size of the F-VIII gene, direct DNA diagnosis (PCR) is not available for all families. Direct DNA analysis is also limited by the fact that as many as one-third of hemophilia cases arise from new mutations. If the precise genetic defect is not known, it is difficult to do direct molecular analysis, but indirect DNA analysis (RFLP) can still be informative.

Direct sampling of fetal blood from the umbilical vein is possible at many institutions, and a factor assay can be performed on the blood sample. Some mutations require the simultaneous analysis of both antigen and activity levels for identification. Ultrasound analysis for determining the gender of the fetus is also available. Patients often elect to undergo prenatal diagnosis (even when pregnancy termination is not being considered) so that physicians can take precautions at birth to prevent bleeding if the fetus is at risk for hemophilia.³¹ Intracranial hemorrhage during vaginal delivery is a potentially life-threatening complication.

Therapy for Hemophilia The goal of treatment for bleeding in hemophilia is replacement of the clotting factor to a level sufficient to achieve hemostasis. Typically, hemostasis for minor bleeding can be achieved at plasma factor levels of 25–30% of normal, whereas severe bleeding requires at least 50% of normal activity. Patients with severe trauma or surgery require plasma levels of 75–100% of normal. For patients who are actively bleeding, several preparations are available to raise the level of F-VIII or F-IX in the patient's plasma (Table 8 .

F-VIII deficiencies were originally treated with cryoprecipitate preparations or F-VIII concentrate. F-VIII concentrates are prepared from plasma by a lyophilization process that results in a slight reduction of the activity of F-VIII, and loss of the largest VWF multimers. In the past, major problems were encountered with the use of plasma-derived concentrates of F-VIII, because the plasma from up to 20,000 donors is pooled to prepare one lot of product. Most patients who received this therapy before 1984 were exposed to hepatitis B, hepatitis C, and the HIV viruses. Since 1984, heat or solvent-detergent treatments have been used to inactivate the viruses, and concentrates are now considered safe. However, for a time, 90% of patients with severe F-VIII deficiency had HIV antibodies and antibodies to hepatitis B surface antigen (indicating exposure to both viruses). Since 1987, no new cases of HIV have been attributed to the administration of clotting factor concentrates in North America, and transmission of hepatitis has been documented only rarely.

To prevent virus transmission, F-VIII products can be prepared using monoclonal antibodies or recombinant technologies. Recombinant F-VIII (rF-VIII), however, also has hazards. Human albumin was added to the “first generation” rF-VIII preparations to stabilize the protein, and this has been associated with transmission of the B19 parvovirus (although there have been no significant clinical sequelae from these transmissions). Full-length F-VIII products stabilized

by sucrose, not human albumin, are also available. Another form of F-VIII replacement therapy is a rF-VIII in which the B domain is deleted. This type of rF-VIII does not require albumin additive for stabilization. Concentrates can be used by hemophiliacs at home as prophylactic therapy to prevent extensive bleeding; they have markedly reduced the crippling hemarthropathy and improved the quality of life for patients with severe disease.

An alternative form of therapy in patients capable of producing some F-VIII (mildly affected hemophilia A) is the hormone, DDAVP, which stimulates storage cells to release F-VIII and VWF into the plasma.

F-IX deficiency can be treated with whole plasma or with concentrates that also contain factors II, VII, and X (prothrombin complex concentrates [PCC]). Another complication of therapy with intermediate purity products (PCC) in addition to viral infections is thrombosis because these concentrates contain variable amounts of activated factors VII, X, and prothrombin. Purified F-IX concentrate called Mononine is prepared from plasma using monoclonal antibodies. Purified F-IX concentrates are heat treated to inactivate the hepatitis and HIV viruses as described for F-VIII. Recombinant F-IX (Benefix[®]) is also available and is now the preferred form of therapy, avoiding complications of both viral transmission and hypercoagulability.

To achieve cure for both F-VIII and F-IX deficiencies, gene therapy is being researched. Because of the larger size of the F-VIII molecule (~200 kDa) compared to the F-IX protein (44 kDa), it has been more difficult to successfully express F-VIII using gene transfer protocols. The first clinical trials in F-IX deficiency were promising, but limited benefits and complications resulted in the trials' termination prematurely.³² Progress in the development of gene therapy for the hemophilias has been slow. The increases in clotting factor activity are transient, and problems have been associated with the viral vectors used in the early studies. However, most researchers in the field believe that the likelihood of eventual success is high.³³

Some hemophilia patients form neutralizing antibodies, also called *inhibitors*, to their deficient factor after factor-replacement therapies. In vivo antibody formation causes destruction of the infused factor, neutralizes the coagulant effects of therapy, and complicates treatment of the patient. An inhibitor to F-VIII or F-IX is clinically suspected when a bleeding episode fails to respond to an adequate dose of factor concentrate. Inhibitors develop primarily in severely affected patients. Approximately 5–20% of F-VIII-deficient patients and 1–3% of hemophilia B patients have inhibitors. There is no way to accurately predict which patients will form inhibitors. The prevalence of antibody formation is higher in patients with severe disease than those with moderate or mild disease. F-VIII inhibitors occur twice as commonly in African Americans than in Caucasians. Scandinavians are at higher risk than other populations to develop F-IX inhibitors. Severe gene lesions, resulting in CRM– or

 TABLE 8

Therapy for Hemophilia

Modes of therapy for F-VIII deficiency

- Recombinant F-VIII (rF-VIII)
- F-VIII concentrates
- Cryoprecipitate
- Desamino-D-vasopressin (DDAVP) (for some)
- Gene therapy (in research phase)

Modes of therapy for F-IX deficiency

- Recombinant F-IX (Benefix)
- Prothrombin complex concentrates (e.g., Konyne, Proplex)
- F-IX concentrates (e.g., Mononine)
- Gene therapy (in research phase)

reduced phenotypes are associated with a higher risk of developing inhibitors compared to CRM+ phenotypes. Patients with large F-VIII gene deletions (affecting >1 domain of the F-VIII molecule) have a threefold higher risk of developing an inhibitor compared with single domain deletions.³³

CASE STUDY (continued from earlier in this chapter)

Scott's mother was questioned regarding the family history. She stated that her father and his brother had had similar bleeding symptoms. Her father died from a brain hemorrhage, and his brother died from complications associated with HIV. These brothers had sisters, none of whom had bleeding problems.

3. What type of inheritance is most probably present in this family?
4. Is this history typical of that of a patient with von Willebrand disease? Why?
5. What could have caused the patient's great uncle to have acquired HIV infection?

Autosomal Recessive Disorders

Autosomal recessive traits are expressed only in those individuals homozygous for the defective gene who inherit an abnormal allele from each parent. Each parent is likely to be heterozygous for the trait. Individuals who are homozygous generally have bleeding symptoms; those who are heterozygous usually have normal hemostasis.

Hereditary deficiencies of the remainder of the coagulation factors are rare in most of the world's populations. In areas of the world where consanguinity (mating between relatives) is more common, the prevalence of autosomal recessively inherited factor deficiencies is higher and can approach that of hemophilia B.³⁴

The genetic mutations for all the proteins to be discussed are diverse between families but unique and constant within each family group. The mutation type and site within the molecule determines the severity of bleeding symptoms. Some mutations result in CRM+, and others result in CRM- phenotypes.

The clinical expression of the autosomally inherited deficiencies varies. Deficiencies of some factors result in severe bleeding symptoms while others are not associated with any bleeding abnormalities. Bleeding phenotype even among individuals with the same disorder can vary significantly. Deficiencies of some fibrinolytic inhibitors can also result in bleeding symptoms. The conditions are discussed under the appropriate categories.

Coagulation Factor Disorders with Bleeding Symptoms The diagnosis of the bleeding disorder is suspected from the results of the PT and APTT and confirmed with subsequent specific factor assays (Table 2). The degree of abnor-

malty suggested by both PT and APTT can be small in cases of mild deficiency. Tests for platelet number and function are normal as are tests for fibrin split products and the thrombin time with some exceptions. Before a hereditary disease is considered, though, all possible causes for acquired coagulation factor deficiencies must be ruled out.

The autosomal recessive bleeding disorders are discussed in numerical order beginning with fibrinogen (factor I) deficiencies. Rare hereditary deficiencies of hemostatic proteins other than those involved in fibrin formation are presented briefly. Additional information including clinical bleeding characteristics and therapy can be found on this text's Companion Website. Table 9  shows the results of laboratory tests in these disorders.

Fibrinogen (Factor I) Deficiency. Two forms of fibrinogen deficiency are inherited as autosomal recessive traits. First reported in 1999, **afibrinogenemia** is a homozygous form of the disease in which no chemically, antigenically, or functionally detectable fibrinogen is found. **Hypofibrinogenemia** is a heterozygous form in which plasma levels of fibrinogen are ~50% of normal (reference range: 200–400 mg/dL). Consanguinity is found in about half of the families with afibrinogenemia. The prevalence of afibrinogenemia is estimated to be 1 in 1,000,000. More than 30 novel mutations have been identified in patients with afibrinogenemia.³⁵ A database of mutations is available at www.geht.org/databaseang/fibrinogen/l.

Clinically, afibrinogenemia is the more severe disease with patients having a severe bleeding disorder. At birth, umbilical cord and mucosal bleeding are frequent symptoms and can lead to death, but in general, patients have a milder course than do severe hemophiliacs and can go long periods without bleeding episodes. Joint or uterine bleeding is seen in 50% of patients.³⁴ Fatal bleeds from intracranial hemorrhages in infants have been reported. Patients with hypofibrinogenemia have a milder bleeding course. They are often asymptomatic, but bleeding can follow invasive procedures. Both disorders are associated with recurrent pregnancy loss as well as antepartum and postpartum hemorrhage.³⁶

In afibrinogenemia, all laboratory tests based on production of a fibrin clot (PT, APTT, and thrombin time) are abnormal, and all are corrected in mixing studies with normal plasma. The bleeding time is prolonged in about half of the patients because fibrinogen is required for primary platelet aggregation. Platelet aggregation tests are also abnormal (Table 9). The diagnosis is confirmed using antigenic and functional assays for fibrinogen, which usually reveal <1mg/dL of the protein. The platelet count is also decreased in ~20% of patients. The erythrocyte sedimentation rate approaches zero because of the lack of fibrinogen in the plasma.

The presence of heparin, fibrin degradation products, or circulating anticoagulants in the plasma, which also prolong the hemostasis screening tests, must be considered in the differential diagnosis of afibrinogenemia. Mixing studies, the

patient's history, and tests for FDPs are helpful in distinguishing inherited afibrinogenemia from acquired conditions in which fibrinogen can be decreased.

Replacement therapy with cryoprecipitate or fresh frozen plasma is used when patients are actively bleeding or to prevent excessive hemorrhage during surgical procedures.

A third form of fibrinogen abnormality is **dysfibrinogenemia**, in which the patient has normal levels (mg/dL) of fibrinogen but has abnormal fibrinogen molecules in the plasma. Dysfibrinogenemia is a relatively rare disorder that most commonly occurs in a heterozygous state. More than 300 novel mutations have been associated with dysfibrinogenemia.³⁵ Mutations have been identified in all three genes encoding the fibrinogen peptide chains (α , β , or γ chains).^{36,37} Similar to abnormal hemoglobins, the fibrinogen abnormalities are often named for the city in which they were discovered. Some individuals have both reduced antigen levels and variant fibrinogen molecules and constitute a subcategory called *hypodysfibrinogenemias*.³⁵

Dysfibrinogenemia is inherited as an autosomal dominant trait. Clinically, ~50% of individuals with dysfibrinogenemia have no bleeding symptoms or other clinical manifestations and are discovered incidentally when laboratory tests are ordered for unrelated reasons and unexpected abnormal results are found. Approximately 25% of individuals have bleeding complications, and 25% have thrombosis. It is suspected that the number of identified patients with dysfibrinogenemia is a small percentage of the actual number present in the population. In those patients who do exhibit hemorrhagic symp-

oms, the bleeding is mild and generally occurs only after trauma. Dysfibrinogenemia has also been associated with hereditary renal amyloidosis.^{35,38} Clinical manifestations depend on the type and the location of the mutation in the protein.

The functions or properties of fibrinogen are also affected by the type and site of mutation. In general, these mutations impair either the conversion of fibrinogen to fibrin monomer (proteolysis step), the conversion of fibrin monomers to polymers (spontaneous polymerization step), or the cross-linking of the fibrin polymers. Some mutations affect either thrombin binding or fibrinopeptide cleavage and are associated with abnormal release of either fibrinopeptides A or B. Other mutations affect the polymerization sites within the N-terminus of the α or β chain or the C-terminal region of the γ or β chains.

Laboratory tests for hemostasis in patients with dysfibrinogenemia are usually normal with the exception of the thrombin time, clot-based quantitative fibrinogen assays, and reptilase time, which are prolonged in most patients. However, determinations of fibrinogen antigenically or by a biochemical technique of precipitation and quantitation of fibrinogen are normal. Bleeding times and other platelet tests also are normal.

Checkpoint! 5

Explain why the thrombin time is abnormal in patients with afibrinogenemia and dysfibrinogenemia.

Prothrombin (Factor II) Deficiency. Deficiencies of prothrombin occur at an estimated prevalence of 1 in 2,000,000, making it likely the rarest inherited bleeding disorder. Prothrombin deficiency is genetically heterogeneous with both quantitative (type 1) and qualitative (type 2) deficiencies identified (www.archive.uwcm.ac.uk/uwcm/mg/hgmd0.html). Combined defects have also been reported. Heterozygotes have prothrombin levels of ~50% of normal; complete absence of prothrombin appears to be incompatible with life.³⁹ Both the PT and APTT are typically prolonged while the thrombin time and bleeding time are normal (Tables 2 and 9). The degree to which the PT and APTT are prolonged varies from patient to patient, and results can occasionally be within the reference range. The diagnosis is established using a specific factor assay for functional prothrombin and immunologic tests for antigen levels.

Factor V Deficiency. The first reported case of F-V deficiency was presented by Owren in 1947.⁴⁰ The prevalence of F-V deficiency is 1:1,000,000, and both quantitative (type 1) and qualitative (type 2) disorders have been described (www.hgmd.org; in Search enter “119896” for keyword). The specific genetic defect in most patients has not been identified.³⁹ Like prothrombin and F-X, F-V functions in the common pathway, so the PT and APTT are both prolonged, but thrombin time (TT) is normal (Table 2). Abnormal bleeding times are reported in about one-third of patients and may be related to a deficiency of F-V in platelet alpha granules.³⁴ Other screening tests are normal (Table 9). Definitive diagnosis requires an F-V assay (functional and immunologic).

Factor VII Deficiency. F-VII deficiency is the only plasma coagulation factor deficiency in which the PT alone is prolonged (Tables 2 and 9). The incidence is estimated as 1 in 300,000 to 1 in 500,000. To date, more than 150 cases have been reported, and both quantitative (type 1) and qualitative (type 2) disorders have been described (<http://193.60.222.13/>). A quantitative F-VII determination by standard factor assay methods (functional and immunologic) provides a definitive diagnosis. Homozygous patients usually have less than 10 U/dL of the factor; heterozygous individuals (who are generally asymptomatic) have 40–60 U/dL. It is important to use age- and gestational-related reference ranges because F-VII is naturally low at birth.³⁶

Checkpoint! 6

Explain why the prothrombin time but not the APTT is prolonged in F-VII deficiency.

Factor X Deficiency. The incidence of F-X deficiency is 1 in 1,000,000 in the general population.³⁶ F-X deficiency is genetically heterogeneous, and both quantitative (type 1) and qualitative (type 2) disorders have been described (www.hgmd.org; in Search enter “119890” for keyword).^{41,42} Both the PT and APTT screening tests are usually prolonged

(Tables 2 and 9). However, in three mutations, the PT is prolonged, but the APTT is normal; the opposite is true in another variant.⁴³ The Russell’s viper venom (RVV) test, which directly activates F-X, is prolonged, although it too can be normal in some variants. A F-X assay (functional and immunologic) is the definitive test although it is important to exclude vitamin K deficiency before confirming the diagnosis.

Factor XI Deficiency. F-XI deficiency is the fourth most common inherited bleeding disorder³⁴ with an estimated frequency in the general population of 1 in 100,000.⁴⁴ F-XI deficiency has a high frequency in the Ashkenazi Jewish population; approximately 0.2% of these individuals are homozygous, and 11% are heterozygous for this disorder.⁴⁵

Laboratory screening tests reveal a prolonged APTT and normal PT, although the APTT can be normal in heterozygous patients with mild deficiency. Other tests are normal (Table 9). Deficiencies of factors XII, XI, VIII, and IX, prekallikrein (PK), and high molecular weight kininogen (HK) are considered when the APTT is the sole abnormal screening test. The clinical and family histories are useful in determining which factor assay to perform. The specific assay for F-XI is the definitive test for this deficiency. Homozygous individuals have from less than 1 U/dL up to 10 U/dL F-XI activity. Most patients have equivalent decreases in antigenic and functional activity, indicative of a type I (quantitative) disorder. A few F-XI mutations are associated with production of a dysfunctional protein.⁴⁶ More than 80 mutations in the F-XI gene have been associated with F-XI deficiency, although three different point mutations account for >90% of the affected patients (www.med.unc.edu/isth/mutations-databases/Factor_XI.htm).

Laboratory testing for F-XI activity requires precautions in collecting and handling the specimen. If the blood sample is collected in glass tubes, F-XI can become activated (glass preactivation of contact proteins) and can lead to false normal results and missed diagnosis of mild deficiencies. It is recommended that blood be drawn in plastic to minimize glass-contact activation. Multiple freezing and thawing of the specimen and/or a delay in running the assay (prolonged plasma storage) have been reported to cause preactivation of F-XI and can cause normalization of an abnormal APTT. However, a single quick freeze and quick thaw appear to have minimal effect on F-XI levels. The type of activator used by different manufacturers can also affect a test system’s ability to detect a deficiency. Patients with mild F-XI deficiencies may react variably with different activators. Abnormal results may be obtained with one reagent and normal results with another.

Factor XIII Deficiency. F-XIII deficiency is very rare with an estimated prevalence of 1 in 2,000,000. F-XIII deficiency is a highly heterogeneous disorder, and a wide variety of genetic mutations affecting either the A or B chain of

F-XIII have been reported. Patients generally lack both plasma and platelet F-XIII.⁴⁷ Platelet F-XIII contains only the A₂ form of F-XIII, which carries the active enzymatic site. However, inherited deficiencies of the B chain also result in low plasma F-XIII levels because the B chains are required for the stabilization and survival of F-XIII (A₂B₂) in plasma. Low plasma levels of F-XIII (<5% of normal) are sufficient to control bleeding. The hallmark of F-XIII deficiency is bleeding from the umbilical cord site, after circumcision, or spontaneous intracranial bleeding after delivery. Miscarriage is very common because stabilization of fibrin at the maternal-fetal interface is required to maintain pregnancy.⁴⁷

Because F-XIII functions after formation of fibrin, a deficiency does not affect the usual screening tests (PT, APTT, TT). However, *in vitro* clot formation is abnormal. One can observe excess red cells at the bottom of a whole blood clot tube after clot retraction. Laboratory diagnosis still relies on a screening test for F-XIII based on dissolution of the fibrin clot in 1% monochloroacetic acid or 5M urea. This clot solubility test is positive (i.e., the clot dissolves) when the F-XIII concentration is 0.5 U/dL or less. The clot is insoluble at levels as low as 1–2 U/dL. Because this screening test is not sensitive to mild deficiencies that can result in clinical sequelae, efforts have been made to develop more sensitive tests.⁴⁸ Specific assays are available, some that measure enzymatic activity and others that use immunologic techniques. One recently developed ELISA assay was used to establish the first reference range for F-XIII at 14–28 mg/L.⁴⁸

Combined Factor V and Factor VIII Deficiency. In this rare disorder (< 100 families identified), both F-V and F-VIII levels are reduced (5% to 30% of normal levels).⁴⁹ The antigen and clotting activity are usually concordant. This disorder is also called *familial multiple clotting factor deficiency type 1*. Bleeding is mild to moderate and similar to that observed in other coagulation disorders. Combined F-V/VIII deficiency is due to a mutation of either of two genes.³⁹ The first gene produces a protein of the endoplasmic reticulum-Golgi intermediate compartment (ERGIC 53), also called *LMAN1* (*L-mannose 1*), and mutations of this protein are found in ~70% of patients with this disorder. The second is the multiple coagulation factor deficiency 2 (*MCFD2*) gene, which accounts for the remaining 30% of patients. The *LMAN1-MCFD2* proteins form a complex, which functions to facilitate transport of F-V and F-VIII from the ER to the Golgi apparatus. The decrease in F-V and F-VIII results from defective intracellular transport and secretion in a pathway unique to these two coagulation factors.³⁹ The PT and APTT are prolonged in this disorder with the prolongation of APTT out of proportion to that of the PT.

Combined Deficiencies of Vitamin K-Dependent Clotting Factors. Vitamin K clotting factor deficiency (VKCFD) is caused by mutations of either the carboxylase enzyme responsible for the γ -carboxylation reaction (γ -glutamyl carboxylase, VKCFD1) or one of the enzymes of

the pathway for vitamin K metabolism (e.g., vitamin K epoxide reductase, VKCFD2).³⁹ VKCFD is characterized by deficient activity of all vitamin K-dependent clotting factors. γ -carboxylation is required for the production of functional forms of these clotting factors and enables them to interact with phospholipids in the formation of the prothrombinase and Xase complexes. In this disorder, the proteins are produced but are nonfunctional due to their lack of γ -carboxylation. Affected individuals resemble patients on coumadin therapy with drastically prolonged PT and APTT tests and normal TT.

Checkpoint! 7

Explain why the laboratory screening tests are normal in patients with F-XIII deficiency.

Factor Deficiencies without Clinical Bleeding The combination of a normal PT, a prolonged APTT, and a negative history of bleeding suggests deficiencies of either F-XII, PK, or HK. No bleeding symptoms are associated with deficiencies of these proteins even after severe trauma or during surgery. When an abnormal APTT is found in presurgical or screening testing, it must be resolved.⁴⁵ Although deficiencies of F-XII, PK, or HK display abnormal *in vitro* plasma coagulation, none is associated with *in vivo* bleeding. However, these deficiencies must be distinguished from those of F-VIII, F-IX, and F-XI, which are accompanied by defective hemostasis. The abnormal APTT is corrected by 1:1 mixing studies with normal plasma. All other hemostatic screening tests are normal (Table 9). The three deficiencies are differentiated by specific factor assays performed by the traditional modification of the APTT or by chromogenic substrate assays.

The specific factor assay can be preceded by a laboratory screening procedure (a modified APTT) to presumptively identify whether PK is the deficient factor and to choose assay procedures to perform. If the patient's plasma is incubated with a kaolin- or celite-containing APTT reagent for 10 minutes (rather than the usual 2 or 3 minutes), the prolonged APTT is corrected to normal in a PK deficiency.⁴⁵ The APTT remains prolonged in F-XII or HK deficiencies.

A deficiency of HK (also called *Fitzgerald*, *Williams*, or *Flaujac factor*) is one of a group of disorders involving not only HK but also variable deficiencies of low molecular weight kininogens (LK). LK does not affect the hemostatic system, so an isolated LK deficiency would not affect laboratory coagulation tests. Concurrent absence of the LK aids in classifying the disorders, however. “Williams” trait was characterized by a deficiency of both HK and LK; “Fitzgerald” and “Flaujac” traits were deficient in only HK.⁵⁰

Because there is no clinical bleeding, therapy is usually not needed for these conditions. However, F-XII deficiency

can be associated with defective fibrinolysis (due to decreased plasminogen activator activity) and an increased risk of thromboembolism.

Disorders of Fibrinolytic Protein Inhibitors with Bleeding Symptoms Congenital deficiencies of these disorders are rare.⁵¹ Deficiencies of α_2 -antiplasmin (AP) and plasminogen activator inhibitor-1 (PAI-1) result in impaired regulation of fibrinolysis with excess plasmin activity. This disturbs the balance between coagulation and fibrinolysis, resulting in a bleeding disorder. Initial hemostasis is typically normal, but delayed bleeding can occur because of premature lysis of hemostatic plugs. Further information is available on this text's Companion Website.

CASE STUDY (continued from earlier in this chapter)

Screening hemostasis tests were performed on Scott's blood in the hemostasis laboratory. The results follow (see reference ranges in table E on cover):

Platelet count	$250 \times 10^9/L$
Prothrombin time	12 sec
Activated partial thromboplastin time	95 sec

- Name the coagulation factor deficiencies that are possible with these laboratory results.
- What is the most likely factor deficiency? Why?

ACQUIRED DISORDERS OF HEMOSTASIS ASSOCIATED WITH BLEEDING

Acquired deficiencies of hemostatic proteins that result in bleeding symptoms can occur in individuals who were previously normal. Acquired deficiencies are far more common than the hereditary disorders of coagulation factors. Acquired coagulation disorders are also more complicated than the inherited conditions because multiple factors usually are defective, and bleeding is often simultaneous from more than one site. In addition to acquired deficiencies of the fibrin-forming proteins, there are also deficiencies of naturally occurring inhibitors.

Acquired disorders occur in response to another disease process and are produced by a variety of mechanisms. The conditions in which these disturbances occur are classified into the following categories: disseminated intravascular coagulation, primary fibrinolysis, liver disease, vitamin K deficiency, and acquired pathologic inhibitors.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a condition in which the normal balance of hemostasis is altered, allowing the uncontrolled and inappropriate formation and lysis of fibrin within the blood vessels. Activation of coagulation occurs systemically rather than locally at sites of vascular injury. Fibrin is deposited diffusely within the capil-

laries as well as in arterioles and venules. As fibrin is formed, several clotting proteins and naturally occurring inhibitors and platelets are consumed faster than they are synthesized (**consumption coagulopathy**). The result is an acquired deficiency of multiple hemostatic components. Fibrinolysis follows fibrin formation as a natural sequence of the hemostatic process, the same processes that occur in normal hemostasis except that they are happening at the wrong time and in the wrong place. As a result of consumption of coagulation factors and platelets and the formation of fibrin degradation products (FDP), the patient often bleeds at the same time that disseminated clotting is occurring.

Incidence DIC occurs in approximately 1 in 1000 hospitalized patients. About 20% of the cases are asymptomatic and suspected only on the basis of laboratory data. It can occur at any age, although it is more often seen in the very young and the elderly.

Etiology DIC is a syndrome, not a disease. It is a group of symptoms that is always triggered by a primary condition that does not necessarily involve coagulation. A number of diverse disease states can trigger the DIC syndrome; they often involve the introduction of tissue factor (TF) into the blood stream, resulting in the initiation of fibrin formation. TF can enter the blood from mechanical injury to tissues or from injury to the endothelial cells.

Conditions most often associated with triggering DIC are summarized in Table 10, the most common of which are infections, particularly those associated with septicemia. The trigger mechanism of infections is likely cytokines (IL-1, IL-6, and/or tumor necrosis factor TNF) released into the tissues by the inflammatory response, which activate endothelial cells. Resting endothelium does not express TF, but endothelial cells or monocytes activated by inflammatory cytokines or injured by endotoxin express TF activity. The full DIC response is seen in 30–50% of patients with Gram-negative or Gram-positive septicemia.⁵²

Complications of pregnancy likely cause DIC because amniotic fluid acts as a thromboplastin to activate fibrin formation pathways. With massive tissue or blood cell injury, it is thought that TF-like substances, such as fat and phospholipids, enter the circulation and activate coagulation. In one study, most patients with head trauma had laboratory evidence of DIC caused by procoagulants entering the circulation from the injured brain tissue.⁵³ The trigger mechanism of malignant cells is a variation of tissue injury. Some malignant cells express a TF-like substance, and others have been shown to produce a cysteine protease capable of directly activating F-X.^{52,54} Figure 4 summarizes the potential activation sites in the hemostatic system.

Pathophysiology After the initiating event has occurred, thrombin is formed within the circulation. Unlike the physiologic formation of the hemostatic plug in which thrombin generation remains limited and localized at the site of vessel injury, DIC results in generalized or systemic activation of

★ TABLE 10

Clinical Conditions Associated with the Development of Disseminated Intravascular Coagulation (DIC)

coagulation. The circulating thrombin acts on its substrates as they circulate in the same manner as it does after an injury-induced localized formation of fibrin. This unregulated generation of thrombin results in consumption of fibrinogen; factors V, VIII, and XIII (the natural substrates of thrombin); and depletion of prothrombin (the precursor zymogen). Thrombin is a potent agonist of platelets inducing platelet activation and aggregation. Thrombin also binds to receptors on endothelial cells, inducing endothelial release of tissue plasminogen activator (tPA), which in the presence of the newly formed fibrin activates plasminogen to plasmin and triggers an aggressive secondary fibrinolysis. As plasmin is generated, plasminogen becomes depleted. DIC results from a failure of the mechanisms that limit blood clotting and thrombin generation (the normal inhibitory pathways to prevent the systemic effects of thrombin).

The coagulation inhibitors antithrombin (AT), heparin cofactor II (HC II), and thrombomodulin (TM), normally effective in regulating the localized generation of thrombin, are overwhelmed in DIC. Deficiencies of AT, protein C (PC),

and protein S (PS) are induced because they are utilized in removing their activated substrates from the circulation. Also, IL-1 and TNF (elevated in sepsis) decrease TM expression on endothelium, resulting in decreased activation of the PC/PS inhibitory mechanism.

Plasma levels of fibrinopeptides A and B (FPA and FPB) and D-dimer are elevated because of the actions of thrombin on fibrinogen and of plasmin on fibrin. FDPs interfere with fibrin formation and platelet function, contributing to the bleeding tendency.

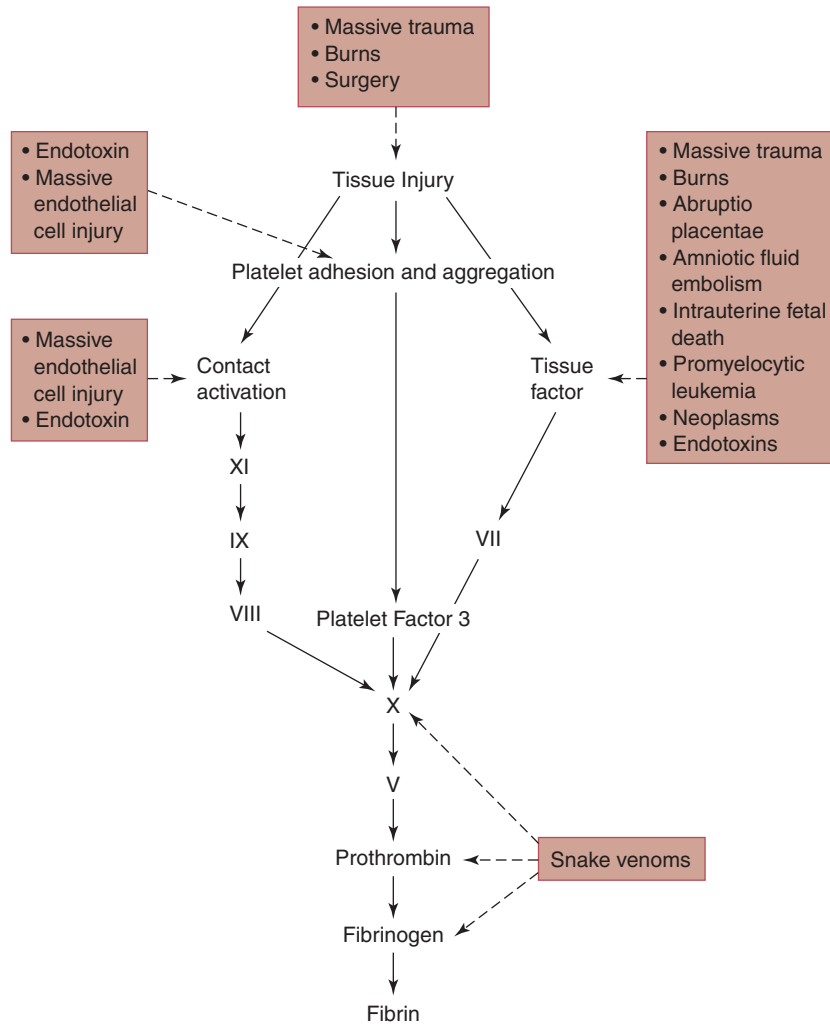

All of these events can result in bleeding as the clotting mechanism is activated and procoagulant components become depleted. The pathogenesis of DIC is summarized in Figure 5 ■.

Clinical Aspects of DIC The symptoms seen in patients with DIC result from the presence and activation of thrombin, plasmin, platelets, endothelium, and proteolytic inhibitors within the bloodstream and vary from patient to patient because of the complex interactions between these components. Because clotting factors and platelets are consumed, bleeding symptoms are favored in some patients. In other patients, thrombosis is the dominant process. In addition, the intensity and duration can result in either an acute or chronic clinical course. Patients with acute disease tend to manifest hemorrhagic symptoms whereas in those with chronic disease thrombosis is more likely to predominate.⁵⁴ The more commonly recognized acute form begins with sudden onset of severe bleeding and is seen in 80–90% of patients with DIC. In the chronic form (10–20% of patients), the stimulus that triggers clotting is weaker, and the natural homeostatic mechanisms are sufficient to replace depleted hemostatic components.

Hemorrhages and thrombosis occur predominantly in the microvasculature and are responsible for the clinical manifestations. In patients with acute DIC whose disease course is hemorrhagic, bleeding begins abruptly and generally occurs from three or more sites simultaneously.⁴⁵ Sites of bleeding tend to correspond to the tissues involved in the triggering event. Possible bleeding manifestations include hematuria; gastrointestinal and respiratory tract bleeding; intracranial bleeding; epistaxis; oozing from needle puncture sites, surgical drains, or sutures; and spontaneous bruising and petechiae. Bleeding can be profuse, leading to death.

At the same time, small strands of fibrin (microclots) form inside blood vessels and obstruct the microvasculature. Because blood vessels are occluded, tissue anoxia and microinfarcts in various organs can occur. Manifestations can include renal failure, coma, liver failure, respiratory failure, skin necrosis, gangrene, and venous thromboembolism.

Shock is a common feature and can be either a cause or an effect of DIC. The association of shock with DIC is complex and not well understood. Shock is likely induced because cytokine generation and products of the kinin and complement systems cause increased vascular permeability and hypotension. The mortality rate of DIC is 50–60%.

■ **FIGURE 4** Conditions that initiate DIC activate the hemostatic pathways in a variety of ways. Normal hemostasis is shown by solid arrows. Processes that trigger DIC are shown in the boxes, and broken arrows indicate proposed sites of activation. (Adapted with permission from: Grosset AMB, Rodgers GM. Acquired coagulation disorders. In: Lee GR, Foerster J, Lukens J, Paraskevas F, Greer JP, Rodgers GM, eds. *Wintrobe's Clinical Hematology*, 10th ed. Baltimore: Williams & Wilkins; 1999: 1733–80.)

Laboratory Evaluation of DIC The physician makes the diagnosis of DIC primarily based on the patient's clinical symptoms. No single laboratory test will establish a diagnosis of DIC, nor are any combination of tests specific for DIC. Laboratory tests are ordered to confirm a suspected clinical diagnosis. Screening tests that are usually ordered by the physician include a platelet count, blood smear, PT, APTT, fibrinogen level, and D-dimer test. Some laboratories include a test for AT. These tests demonstrate the generation of both thrombin and plasmin and can reflect the severity of the consumption of hemostatic components. Table 11  shows the typical laboratory results in patients with DIC.

The platelet count, the most useful parameter, can fall to levels of $40\text{--}75 \times 10^9/\text{L}$. It is decreased in 97% of patients.

Identifying a decrease in the platelet count can be difficult in patients whose usual platelet count is in the upper reference range, and serial platelet counts clearly demonstrating decreasing values are more useful than a single determination.

The PT and APTT can be prolonged because of the decrease in factors II, V, and VIII and fibrinogen, although their alterations are not as consistent as the platelet count. One or more of these tests are prolonged in 60–75% of patients with DIC.⁴⁵ Early in the disease process, these tests occasionally may be shorter than normal, perhaps due to the presence of factors that are already activated, and which would require less time for clot formation in vitro.⁴⁵

In severe disease, the fibrinogen level can drop to 10–50 mg/dL but is decreased in only 23–71% of patients.⁵² Fibrinogen

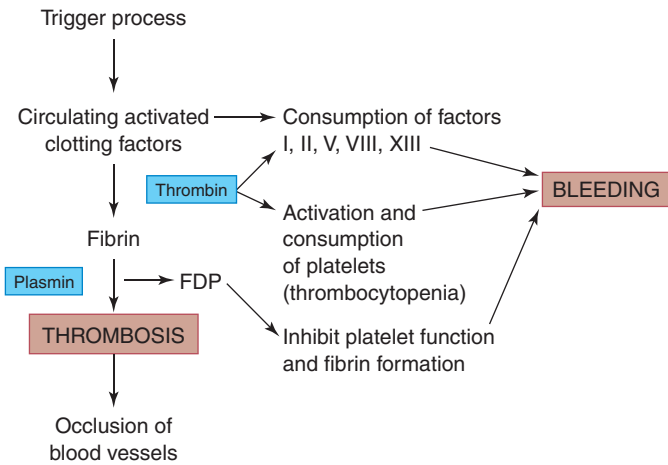

FIGURE 5 Pathogenesis of DIC. Activation of hemostasis by triggering processes leads to clotting and bleeding simultaneously. Intravascular fibrin formation results in occlusion of vessels. During clotting, several coagulation factors and platelets are consumed, leading to bleeding. (Adapted from: Grosset AMB, Rodgers GM. Acquired coagulation disorders. In: Lee GR, Foerster J, Lukens J, Paraskevas F, Greer JP, Rodgers GM, eds. *Wintrobe's Clinical Hematology*, 10th ed. Baltimore: Williams & Wilkins; 1999: 1733–80.)

is an acute phase reactant, and the protein increases in inflammatory conditions. Because many patients with DIC have underlying disease, their fibrinogen levels could have been initially elevated because of the acute phase response.

The D-dimer test to demonstrate the presence of fibrin-derived FDPs, and therefore generation of both thrombin and plasmin, is elevated in 93% of patients and provides good evidence supporting the diagnosis of DIC.⁴⁵ D-dimers, which are present only after F-XIII stabilization of fibrin, confirm that activation of coagulation has taken place, but they are not specific for DIC. The D-dimer test can be positive in several other clinical conditions such as after surgery and in patients with renal disease or pulmonary emboli. Most laboratories use the D-dimer test, which has replaced a similar latex test for fibrin degradation products that fails to distinguish between plasmin degradation products of fibrinogen and fibrin.

Some clinicians have recommended a test to demonstrate a decrease in AT. AT decreases in concentration early in the disease process as it combines with and inactivates thrombin and other serine proteases. It is decreased in 89% of patients. Examination of the blood smear reveals the presence of schistocytes in 50% of patients. Schistocytes are produced as

★ TABLE 11

Typical Laboratory Findings in Acquired Disorders of Hemostasis Associated with Bleeding

Test	DIC	Primary Fibrinogenolysis	Severe Liver Disease	Vitamin K Deficiency	Specific Factor Inhibitor	Lupus Anticoagulant*
Screening tests						
Platelet count	Dec	N	Dec	N	N	N
PT	Inc	Inc	Inc	Inc	N (inc with inhibitor against F-VII)	N (occasionally inc)
APTT	Inc	Inc	Inc	Inc	Inc (except if inhibitor against F-VII)	Inc
TT	Inc	Inc	Inc	N	N	N
Definitive tests						
Fibrinogen	Dec	Dec	Dec	N	N	N

*Not a hemostatic disorder associated with bleeding but necessary to consider in the differential diagnosis.

Inc = increased; Dec = decreased; N = normal; PT = prothrombin time; APTT = activated partial thromboplastin time; TT = thrombin time; FSP = fibrin split products.

blood cells are forced through the fibrin webs that clog the microvessels. However, fragmented red blood cells rarely constitute >10% of the red cells on the peripheral smear.

Other laboratory tests that could be abnormal in DIC but generally are not necessary for a diagnosis in most cases are the TT and serial specific factor assays for F-V, F-VIII, or prothrombin (to demonstrate decreased factor levels/increased consumption). The TT is increased because of the presence of FDPs and the decreased fibrinogen level and is abnormal in 58% of patients. Additional tests of thrombin generation include tests for fibrin monomers, FP-A and -B, thrombin-AT complexes (TAT), and prothrombin fragment 1.2. They are all potentially useful parameters but at present are mainly research tools.

Therapy for DIC The first step in the treatment for DIC is to eliminate the underlying cause, if possible. After that it is controversial. The acute form is often self-limited and disappears when the fibrin is completely lysed. Replacement therapy using platelets, red cells, cryoprecipitate, or fresh frozen plasma are used when indicated (patients with clear laboratory evidence of DIC and bleeding).⁵⁵ Low molecular weight heparins have been found helpful in those patients with strong clinical and laboratory evidence of DIC and predominant thromboembolic manifestations or in patients in whom replacement therapy fails to alleviate excessive bleeding and increase the level of clotting factors. Newer approaches to therapy are to replace the depleted physiologic inhibitors (AT, PC, and TFPI) with concentrates. Clinical trials are being conducted on some of these products. Under most circumstances, patients with DIC should not be treated with fibrinolytic inhibitors.

The chronic form of DIC is usually seen secondary to disseminated malignancy in which case elimination of the precipitating event can be difficult. Heparin therapy sometimes is helpful if thrombosis is life threatening because it will stop intravascular fibrin formation. It must be administered with caution, however, because fatal bleeding has occurred with its use.

Checkpoint! 8

- Why is thrombocytopenia usually present in a patient with DIC?
- Which hemostasis laboratory screening tests (PT and APTT), if any, will the following affect:
Decreased F-V
Decreased F-VIII
Decreased fibrinogen
Decreased antithrombin
- Which laboratory test results would distinguish DIC from hemophilia A?

Primary Fibrinogenolysis

This syndrome is sometimes referred to as *primary fibrinolysis*, but this is technically inaccurate because the proteolytic

action of plasmin is on fibrinogen, not fibrin. **Primary fibrinogenolysis** is a condition clinically similar to DIC, but it requires differentiation so that proper treatment can be instituted. In primary fibrinogenolysis, plasminogen becomes inappropriately activated to plasmin without concomitant thrombin generation. Plasmin then circulates and, if it overwhelms the antiplasmin inhibitors, degrades fibrinogen; factors V, VIII, and XIII; and other coagulation factors (and other proteins). An acquired deficiency of the proteins eventually develops and leads to bleeding symptoms that resemble DIC.

Similar pathologies can cause the two conditions, but liver disease is one of the most common triggers of primary fibrinogenolysis. Differentiating the two conditions with laboratory tests is sometimes difficult. Patients with primary fibrinogenolysis can have an abnormal PT, APTT, TT, fibrinogen assay, and increased fibrin(ogen) degradation products but normal D-dimer and fibrin monomer tests because stabilized fibrin is not formed. The level of fibrinopeptide A is normal in primary fibrinogenolysis but is elevated in DIC.⁵⁶ Table 11 compares laboratory test results in these two conditions with other acquired hemostatic disorders.

Therapy for primary fibrinogenolysis is epsilon aminocaproic acid (EACA), a specific inhibitor of plasmin. EACA is dangerous if administered to patients with DIC; therefore, the diagnosis of DIC needs to be excluded before the drug is given.⁵⁶

Liver Disease

Liver disease affects all hemostatic functions. Most hemostatic proteins (those involved in fibrin formation, fibrinolysis, as well as hemostatic inhibitors) are synthesized in the liver (Web Table 1 🌟). The liver macrophages play a major role in the removal of activated factors, products of activation such as the fibrinopeptides, fibrin degradation products, and plasminogen activators. A diseased liver diminishes these functions.⁵⁶

Laboratory test results on a patient with liver disease can resemble those obtained from a patient with DIC. Differentiating the two conditions may be a difficult task for the physician. Table 11 compares the results of laboratory testing. The decreased production of proteins involved in fibrin formation can prolong all screening coagulation tests including the PT, APTT, and TT. The fibrinogen concentration is usually normal but can stabilize in the low reference range. An abnormal fibrinogen molecule that has an increased content of sialic acid and can cause defective clot formation may be synthesized.

The platelet count can be decreased for several reasons including hypersplenism (backing up of the portal blood supply when it is unable to enter the liver), alcohol toxicity of the bone marrow, decreased thrombopoietin production, and consumption of the platelets if DIC is also present.

FDPs are increased because the liver cells are unable to remove them from the circulation. Incomplete removal of

plasminogen activators can result in systemic formation of plasmin and subsequent proteolysis of fibrinogen, contributing to the increase of FDPs. Excess fibrin or fibrinogen degradation products can impair blood coagulation and result in platelet dysfunction. The D-dimer test is usually normal and can be one way to differentiate DIC from liver disease.

Clinical bleeding is minimal except in severe liver disease when ecchymoses and epistaxis can occur. Bleeding from local lesions in the GI tract is common. Therapy involves the use of replacement products as needed.

Vitamin K Deficiency

Hepatic cells need vitamin K to complete the post-translational alteration of factors II, VII, IX, and X, PC, and PS. In the absence of vitamin K, the hepatic cells synthesize precursor proteins, but because γ -carboxyglutamic acid residues are absent, the calcium-binding sites are nonfunctional. Deficiency of vitamin K results in induced functional deficiencies of all of these proteins. If the level of functional proteins falls below 30 U/dL, bleeding symptoms can result, and the PT and/or the APTT is prolonged.

Sources of vitamin K are green, leafy vegetables and synthesis by bacteria in the GI tract. Symptomatic vitamin K deficiency in newborns called **hemorrhagic disease of the newborn (HDN)** is most often seen in the first days of life. Because their livers are still immature, synthesis of the vitamin K-dependent factors in newborns is 30–50% of adult levels. Almost all neonates are vitamin K deficient, presumably as a result of the mother's vitamin K deficiency and/or the lack of colonization of the colon by vitamin K-producing bacteria in the neonate.

HDN is broken into three subtypes: early, classic, and late. Early HDN occurs primarily in infants of mothers who have been on a vitamin K-blocking medication, such as anticonvulsants, and usually occurs within hours to the first week of life. Classic HDN occurs between the first week and first month of life and is largely prevented by prophylactic vitamin K administration at birth. Late HDN occurs from the first month to 3 months after birth.⁵⁷ This deficiency is more prevalent in breast-fed babies because human milk contains less vitamin K than cow's milk does. Infants with liver disease can also be susceptible to HDN.

Manifestations of hemorrhagic disease of the newborn are bleeding in the skin or from mucosal surfaces, circumcision, generalized ecchymoses, large intramuscular hemorrhages, and (rarely) intracranial bleeds. In the laboratory, the PT and possibly the APTT are more prolonged than expected at this age. Specific factor assays for factors II, VII, IX, and X are markedly decreased. The BT and the platelet count are within normal limits (Table 11).

Hemorrhagic disease of the newborn is prevented in the United States by encouraging administration of vitamin K to all newborns. Although most states have laws requiring its administration, some do not. In countries where this practice has recently been stopped, the disease occurs occasionally.

Causes of vitamin K deficiency in adults include malabsorptive syndromes such as sprue, obstruction of the biliary tract (because bile salts are necessary for absorption), ingestion of vitamin K inhibitors (such as warfarin), and prolonged broad-spectrum antibiotic therapy that abolishes normal flora of the intestine. Vitamin K administration corrects the deficiency within 24 hours.

Acquired Pathologic Inhibitors

Acquired inhibitors of blood coagulation, also called **circulating anticoagulants**, develop pathologically in patients with certain disease states and in some who have no apparent underlying condition. Almost all are immunoglobulins, either IgG or IgM, and can be either alloantibodies or autoantibodies. Two types of inhibitors are described: those directed toward a single coagulation factor and the lupus anticoagulant (LA).

Inhibitors of Single Factors Pathologic inhibitors against most coagulation factors have been reported. They are usually seen in patients with inherited factor deficiencies who have received replacement treatment for bleeding complications, but they are also associated with other conditions such as diseases or drugs and are sometimes seen in patients who are otherwise healthy. With the exception of antibodies to F-VIII and F-IX, they are extremely rare. These inhibitors are recognized because of their interference with or neutralization of clotting factor activity. The following discussion concentrates on the F-VIII and F-IX inhibitors.

Clinical Aspects. Inhibitors to F-VIII and F-IX are observed most often in association with the hemophilias. Approximately 15–20% of patients with severe hemophilia A and 1–3% of patients with severe hemophilia B develop alloantibodies to the respective deficient factor. Inhibitors are neutralizing alloantibodies that render the replacement factor inactive. Twenty-two percent of hemophilia A patients with the inversion mutation described earlier develop F-VIII inhibitors. Most patients with inhibitors have severe hemophilia with very low coagulant levels of the affected factor. All patients also have received replacement therapy for their factor deficiency, and most inhibitors develop within the first 50–100 exposure days to factor, although patients can develop an inhibitor at any time in their life. In hemophilia A patients, the antibody specificity is directed toward the coagulant antigen (VIII:Ag) only, not the VWF portion of the F-VIII/VWF complex. Although most inhibitors develop in severe or moderate forms of hemophilia, they also may be found in some patients with mild forms of hemophilia A.⁵⁸

F-VIII inhibitors (autoantibodies) can also be found in nonhemophilic patients (acquired hemophilia A). Occasionally they develop in otherwise healthy individuals who most often are older patients or females during or following a pregnancy. Disease states associated with F-VIII inhibitors include autoimmune and lymphoproliferative diseases as well

as multiple myeloma. Autoantibodies to other clotting factors can appear in similar circumstances as the F-VIII inhibitors.

The clinical course of patients with acquired inhibitors is variable but can resemble that of patients with severe hemophilia and result in fatal consequences in 10–20% of cases. In patients with congenital hemophilia who have not received therapy for 1 to 2 years, the antibody level often decreases, but an anamnestic response can be seen within 2 to 4 days after re-exposure. The antibody can also disappear spontaneously.

Laboratory Evaluation. Laboratory test results in patients with F-VIII or F-IX inhibitors resemble those in patients with severe factor deficiencies. The APTT is markedly prolonged and other screening tests are normal (Table 11). Mixing studies (1:1 patient plasma with normal plasma) can be performed as a screening procedure to distinguish between a true factor deficiency and an inhibitor. If an inhibitor is present, the test on the mixture will remain prolonged. Assays for specific inhibitors can then be performed.

Therapy for Factors VIII and IX Inhibitors. The type of therapy used for patients with F-VIII inhibitors depends on whether the patient is a low or high responder and on the inhibitor's titer. Low responders (25% of hemophiliacs with inhibitors) are patients with low titer antibodies that do not rise after further exposure to F-VIII. Patients with inhibitors that rise markedly with further exposure to F-VIII (anamnestic response) are known as high responders (~75% of hemophiliacs with inhibitors). For those who are low responders, large amounts of F-VIII that function by “overwhelming” the antibody can be administered successfully to treat or prevent clinical bleeding. If human F-VIII cannot be used because the inhibitor level is too high, F-IX complex products or porcine F-VIII can be used in an attempt to bypass the need for F-VIII. F-IX complex concentrates (PCC) contain prothrombin and factors VII, IX, and X. The mechanism of bypass activity of these concentrates remains unclear, but it has been suggested that their content of activated vitamin K-dependent factors (IIa, Xa, and trace amounts of VIIa and IXa) probably promote thrombin generation *in vivo*.³³ Recombinant F-VIIa is another bypass agent effective in the treatment of hemophilia patients with inhibitors.³³ Recombinant F-VIIa works by activating F-X and bypassing the need for F-VIII or F-IX in the formation of fibrin and thus is equally effective in both hemophilia A and B patients with inhibitors.

Lupus Anticoagulant The second type of inhibitor of major clinical importance is the **lupus anticoagulant (LA)**, so called because it was first discovered in patients with systemic lupus erythematosus (SLE). Approximately 6–16% of patients with SLE develop LA. The term *LA* is a misnomer because LA is more frequently encountered in patients without lupus and has been associated with a variety of other autoimmune diseases, neoplasias, certain infections,

and the administration of drugs such as chlorpromazine or procainamide as well as apparently normal individuals. However, many people still call it the lupus anticoagulant or lupuslike anticoagulant.

LAs are autoantibodies that interact with the phospholipid surfaces of the reagents used in the APTT test (and occasionally the PT), prolonging the test results. They are part of a family of antibodies called *antiphospholipid antibodies (APL)*. LAs are usually discovered by finding an unexpectedly prolonged APTT and sometimes PT while performing routine coagulation studies. However, the lupus anticoagulant is a laboratory phenomenon. Although laboratory testing suggests defective hemostasis, most patients do not in fact bleed but rather tend to be hypercoagulable. The pathophysiology, clinical aspects, and laboratory evaluation of LA/APL are discussed in with other disorders of hypercoagulability.

CASE STUDY (continued from earlier in this chapter)

A TT was performed on Scott, and the results were within the laboratory's reference range. Mixing studies were performed. Scott's plasma was mixed with normal plasma, and the APTT was repeated on the mixture. The result of the APTT on the mixture was 36 sec.

8. What do the results of the APTT on the mixture of Scott's plasma with normal plasma indicate?
9. What test should be performed next?
10. If a F-VIII assay was done with results of <1 U/dL, what molecular studies should be done?
11. What therapy is indicated for this patient?
12. What complications from the therapy are possible?

▶ FLOW CHARTS

A flow chart that outlines reflex testing procedures that the laboratory can follow to investigate abnormal hemostatic screening tests is included on this text's Companion Website (Web Figure 2■).

▶ HEMOSTASIS IN THE NEWBORN

Hemostasis is an evolving process and is age dependent (i.e., it develops or evolves during the process of fetal development and changes with gestational age).⁵⁹ Blood coagulation studies in the newborn present special challenges to the laboratory. At birth, hepatic synthesis of several of the clotting proteins is at a lower level than in normal adults, and this makes diagnosing some inherited and acquired hemostatic abnormalities difficult. Some proteins do not reach adult levels until 6–12 months of age. Laboratory screening tests are prolonged (relative to adult normal values) and depend on the child's age

and the presence of accompanying diseases. These factors influence the interpretation of the laboratory tests.

Obtaining an adequate blood sample is of utmost importance but technically extremely difficult. Even with maximum attention to quality control, spuriously altered results are possible. A venous sample is preferred to capillary or arterial blood. Obtaining the sample from an indwelling catheter should be avoided because of the danger of heparin contamination.

Adding anticoagulant to the syringe allows one to draw blood more slowly while minimizing the risk of clotting. The amount of anticoagulant must be reduced when the infant's hematocrit is above 55% because of the reduced plasma volume.

Because the total volume of blood in newborns is only 250–350 mL, efforts must be made to minimize the amount of sample drawn. Some suggestions for minimizing the amount of plasma needed for newborn testing are eliminating duplicate testing when performing the PT and APTT, or running several factor assays using diluted plasma rather than the screening tests.⁶⁰ Micro adaptations of several routine procedures, using 5–40 μL of plasma, have been developed.⁶¹

NORMAL HEMOSTASIS IN THE NEWBORN

Platelets and the proteins of the coagulation and fibrinolytic systems are first detected in fetuses at 10–11 weeks of gestation. Table 12[✪] shows expected values for various laboratory tests for preterm and term infants at birth compared with results in older children and adults as well as the ages when adult levels of the proteins are reached.

Platelet counts reach adult levels by 27 weeks of gestation and, therefore, should be in the normal adult range (and size—i.e., mean platelet volume [MPV]) at birth. As with adults, platelet counts of less than $100 \times 10^9/\text{L}$ should be

considered abnormal. Counts of $100\text{--}150 \times 10^9/\text{L}$ are considered borderline and should be repeated. Platelet structure viewed by electron microscopy appears normal, but the dense body content of serotonin and ADP is $<50\%$ of adult levels.⁵⁹ Decreased platelet aggregation (relative to adult “normal”) with low levels of ADP and with collagen, epinephrine, and thrombin are found at birth but normalize within several weeks. Platelet agglutination with ristocetin, on the other hand, is increased in newborns, which must be considered when diagnosing VWD. Plasma concentration of VWF and the proportion of high molecular weight multimers are increased in newborns (newborns have low levels of the VWF cleaving protease ADAMTS-13).⁵⁹ This likely explains the enhanced agglutination with ristocetin. Drugs that affect platelet function such as aspirin when taken by the mother also influence hemostasis in the fetus.

Concentrations of the coagulation proteins for term and preterm infants, older children, and adults are shown in Table 13[✪]. Multiple reference ranges are required because the hemostasis system is evolving. The fibrinogen group of factors is at normal adult levels at birth. The concentrations of the proteins of the prothrombin and contact factor groups are decreased at birth due to newborn liver immaturity. They reach adult levels at varying times (Table 13). The levels of these clotting factors usually are not low enough to affect hemostasis unless a stressful situation is present. VWF, on the other hand, is increased at birth and gradually decreases over the first 6 months of life.⁶²

Natural inhibitors that the liver synthesizes are also decreased in newborns (Table 13). Adults with levels of AT equivalent to that of infants are considered at risk for thrombosis. Infants do not have this problem because the procoagulant proteins that are inactivated by AT are also decreased. Levels of PC are very low at birth and remain decreased during the first 6 months of life. Total PS is also decreased, but functional activity is similar to that in adults because it is

✪ TABLE 12

Laboratory Tests in Preterm and Term Infants as Compared to those of Adults and Older Children

Test	Preterm Infant (28–31 Weeks) (Day 1)	Preterm Infant (32–36 Weeks) (Day 1)	Term Infant (37–41 Weeks) (Day 1)	Adults and Older Children	Age Adult Level Reached

completely present in the free (active) form due to the absence of C4BP.⁵⁹ Plasminogen levels in infants are decreased, and FDPs are similar to adult values.

The decrease in hemostatic factors in term and preterm infants affects coagulation tests (Table 12). The PT is prolonged ~3 seconds compared to that of adults because of the low levels of factors II, VII, and X. However, a PT of more than 17 seconds should be considered abnormal in the newborn.⁶³ Values in the normal adult range are usually achieved in 3–4 days.

The APTT is also prolonged ~2–3 seconds in term infants and can be significantly prolonged in preterm infants. This test depends on the factors of the intrinsic system and is particularly sensitive to the contact factors. Results of this test are also highly dependent on the reagent used.^{60,62} Adult levels can be reached in 4–6 months.⁶³ The thrombin clotting

time is abnormal although the fibrinogen level is normal due to the presence of a distinct fetal fibrinogen molecule with altered function. The thrombin time becomes normal within a few days after birth.

In general, hemostatic values in preterm infants differ from adults as discussed above. They also differ from term infants but erratically so; however, by 6 months of age, their values are comparable to those of term infants.⁶⁴

COMMON BLEEDING DISORDERS IN THE NEONATE

Although the coagulation systems of the “well” term and preterm infants show low levels of many procoagulant, anticoagulant, and fibrinolytic proteins, hemostasis is usually functionally balanced, and neither thromboses nor

hemorrhages occur. However, abnormalities of hemostasis are present in ~1% of newborns. The classification of the most common problems depends on whether the child is considered sick or well. Sick infants include those with prematurity, perinatal infection, respiratory distress syndrome, metabolic derangements, and/or birth asphyxia. Hemostatic abnormalities in babies considered sick are most commonly either DIC, isolated platelet consumption independent of a decrease in clotting factors, or liver failure.

In well babies, the most common abnormalities of hemostasis are immune thrombocytopenia, vitamin K deficiency, hemophilia, and bleeding from a localized vascular lesion. Diagnosing some hereditary bleeding disorders in the neonatal period is difficult, particularly mild or moderate deficiencies of F-IX and VWD. Severe forms of F-VIII or F-IX deficiencies are easier to diagnose. Early onset vitamin K-deficiency bleeding (within the first 24 hours of life) is usually due to placental transfer of maternal drugs that inhibit vitamin K activity in the baby, including Dilantin or other anti-convulsants, antibiotics, and oral anticoagulants.

Bleeding manifestations in babies with DIC are similar to those in other patients with the syndrome and include bleeding from puncture sites, the GI tract, and other locations. The PT and APTT are markedly prolonged, and thrombocytopenia is present in symptomatic babies.

One of the most common causes of death in premature infants is intracranial hemorrhage. Many of these are patients who have severe respiratory distress syndrome or a familial bleeding diathesis (hemophilia or other hereditary coagulation deficiency).

Thrombosis can also occur in infants, particularly those with indwelling catheters, those born to diabetic mothers, or those with predisposing medical conditions (e.g., asphyxia,

infection, respiratory distress syndrome). Neonatal hypercoagulability can also be seen in infants with a hereditary thrombophilia.

SUMMARY

This chapter discusses the conditions associated with abnormal secondary hemostasis encompassing those in which fibrin is formed too slowly or poorly or fibrinolysis proceeds too rapidly so that excessive bleeding results. It also discusses the unique hemostatic status of newborns.

Abnormal fibrin formation occurs in patients with mutations of the genes that code for the circulating procoagulant proteins and result either in decreased synthesis or abnormal function of the protein. The most widely known of these disorders are X-linked deficiencies of F-VIII and F-IX, called the *hemophilias*. von Willebrand factor is complexed with F-VIII in the circulation and when deficient can result in the most common bleeding disorder, von Willebrand disease. More unusual deficiencies of the remaining coagulation factors and of components of fibrinolysis can also result in excessive bleeding. However, in the case of F-XII, prekallikrein, and high molecular weight kininogen, no clinical bleeding symptoms are present in spite of abnormal in vitro laboratory test results. Some patients with deficiencies of these three components can have an increased risk for thrombosis, presumably secondary to impaired fibrinolysis. Laboratory screening tests and specific factor assays establish the diagnosis in disorders associated with coagulant protein deficiencies.

Newborns are at higher risk for bleeding and can have prolonged PTs and APTTs until the vitamin K-producing intestinal bacteria and liver production of the various coagulation factors are established.

REVIEW QUESTIONS

LEVEL I

1. A patient who has a deficiency of a clotting factor could have: (Objective 1)
 - a. inherited an abnormal gene from a parent
 - b. acquired the deficiency because of another disease present
 - c. decreased amount of the particular factor in the blood
 - d. all of the above
2. Why do patients who have deficiencies of clotting factors usually have abnormal bleeding? (Objectives 1, 2)
 - a. Fibrin formation is slower and less effective than normal.
 - b. Platelets do not aggregate normally.
 - c. Fibrin is formed too fast and in too large a quantity.
 - d. Fibrin is broken down as fast as it is formed.

LEVEL II

1. Referring to the case study for Level I questions 4–6, the results of the platelet aggregation studies indicate that the patient has a defect in which of the following? (Objective 4)
 - a. F-VIII
 - b. platelet adhesion
 - c. fibrinolysis
 - d. intrinsic system of fibrin formation
2. What is the usual inheritance pattern of von Willebrand disease? (Objective 3)
 - a. autosomal dominant
 - b. autosomal recessive
 - c. X-linked recessive
 - d. not inherited, usually acquired

REVIEW QUESTIONS (continued)

LEVEL I

3. What clotting factor is deficient in a patient with hemophilia A? (Objective 4)
- F-VII
 - F-VIII
 - F-IX
 - F-XIII

Use the following case study to answer questions 4–6.

An 18-year-old female bled profusely following extraction of a tooth. She had a history of sporadically increased menstrual bleeding and nosebleeds. She had had an appendectomy at age 10 with no unusual bleeding. A workup in the coagulation laboratory showed the following:

Laboratory Test	Patient Results	Laboratory Reference Range
Platelet count	$312 \times 10^9/L$	$150\text{--}440 \times 10^9/L$
Bleeding time	9.5 minutes	2–9 minutes
Closure time	Increased	
Prothrombin time	11.5 sec	10–12 sec
Activated partial thromboplastin time	38.0 sec	23–36 sec
F-VIII assay	20 U/dL	50–150 U/dL
F-IX assay	102 U/dL	50–150 U/dL
Platelet aggregation studies	Normal: ADP, collagen, epinephrine Abnormal: ristocetin	

4. Which laboratory tests are outside their reference range? (Objective 2)
- all tests shown
 - platelet aggregation with ristocetin, activated partial thromboplastin time, F-VIII assay
 - platelet count, prothrombin time, F-IX assay
 - prothrombin time, activated partial thromboplastin time, F-IX assay
5. The most probable cause of this patient's bleeding is: (Objectives 3, 10)
- vascular disorder
 - F-IX deficiency
 - von Willebrand disease
 - disseminated intravascular coagulation
6. What laboratory test that is abnormal in this patient is different from that of a patient with hemophilia A? (Objectives 5, 6)
- F-VIII assay
 - F-IX assay
 - platelet aggregation studies with ADP
 - platelet aggregation studies with ristocetin

LEVEL II

3. Which of the following is characteristic of Type I von Willebrand disease? (Objective 4)
- decreased amounts of large multimers of VWF
 - increased amounts of large multimers of VWF
 - decreased amounts of all VWF multimers
 - decreased amounts of small VWF multimers only
4. Which laboratory procedure analyzes VWF qualitatively for abnormalities of the molecular structure? (Objective 4)
- ristocetin-induced platelet aggregation
 - F-VIII assay
 - SDS-page gel electrophoresis
 - activated partial thromboplastin time
5. What is the cause of von Willebrand disease? (Objective 3)
- genetic mutations in the F-VIII gene
 - genetic mutations in the VWF gene
 - genetic mutations in the glycoprotein Ib gene
 - exposure to dyes and chemicals
6. In which of the following conditions would the presence of delayed bleeding and deep muscular hematomas be most likely? (Objectives 1, 5)
- a patient with F-VIII deficiency
 - a patient with F-XII deficiency
 - a patient who is heterozygous for F-V deficiency
 - a patient with dysfibrinogenemia
7. In which of the following diseases would you most likely find an abnormal prothrombin time? (Objectives 4, 6)
- F-VIII deficiency
 - F-IX deficiency
 - disseminated intravascular coagulation
 - prekallikrein deficiency
8. Which of the following is true concerning acquired circulating pathologic inhibitors to single coagulation factors? (Objective 9)
- They do not cause bleeding symptoms.
 - They cause the same symptoms in the patient as an inherited deficiency of the same factor.
 - They are often found in patients with von Willebrand disease.
 - They are antibodies to the phospholipid in the coagulation reagents.
9. Which of the following is true in the condition known as *disseminated intravascular coagulation (DIC)*? (Objective 7)
- F-V and F-VIII become increased in activity.
 - Fibrinolytic activity is absent.
 - The patient has a single coagulation factor deficiency.
 - Fibrinogen and platelets become depleted.

REVIEW QUESTIONS (continued)

LEVEL I

7. What result of the platelet count would you expect in a patient with hemophilia A? (Objective 5)
 - a. normal
 - b. increased
 - c. decreased
 - d. unpredictable
8. Which is (are) characteristic(s) of a patient with DIC? (Objective 8)
 - a. a prolonged PT
 - b. a prolonged APTT
 - c. a decreased platelet count
 - d. all of the above
9. What is the cause of disseminated intravascular coagulation (DIC)? (Objective 8)
 - a. an inherited deficiency of F-X
 - b. a reaction to another disease that causes the hemostatic system to become activated
 - c. a deficiency of vitamin K
 - d. an antibody to F-VIII
10. Which result would be expected in a newborn infant? (Objective 9)
 - a. a shorter APTT test than that in an adult
 - b. a longer APTT test than that in an adult
 - c. the lower platelet count than that in an adult
 - d. the higher platelet count than that in an adult

LEVEL II

10. What laboratory test is helpful in differentiating primary and secondary fibrin(ogeno)lysis? (Objective 9)
 - a. thrombin time
 - b. D-dimer test
 - c. plasmin-antiplasmin complexes
 - d. platelet count

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Scott was seen in the ER for severe bleeding in the knee after a slight fall. There is a family history of similar bleeding in males on the maternal side of the family. A prothrombin time and thrombin time on Scott were normal, but the APTT was prolonged. The APTT was corrected when patient's plasma was mixed with normal plasma, suggesting a factor deficiency. An F-VIII assay showed a severe decrease. Scott was diagnosed with hemophilia A.

Question:

1. What term is used to describe the type of bleeding from minor cuts that the mother is describing?

Explanation:

The type of bleeding in this patient indicates delayed bleeding and joint bleeding (hemarthrosis).

Question:

2. Does this history seem to be typical of a platelet disorder or of a coagulation factor disorder? Why?

Explanation:

These bleeding symptoms are characteristic of coagulation factor disorders (disorders of secondary hemostasis) rather than platelet disorders (disorders of primary hemostasis).

Question:

3. What type of inheritance is most probably present in this family?

Explanation:

X-linked inheritance is most probable in this family.

Question:

4. Is this history typical of that of a patient with von Willebrand disease? Why?

Explanation:

No, the inheritance pattern seems to be X-linked. The inheritance of vWD is usually autosomal dominant, although inheritance of the severe form of vWD is described as autosomal recessive.

Question:

5. What could have caused the patient's great uncle to have acquired HIV infection?

Explanation:

The uncle's HIV infection could have been acquired prior to 1984 from preparations of F-VIII concentrate that he received to control bleeding (prior to current protocols that include a viral-inactivation step in the production of the concentrate).

Question:

6. Name the coagulation factor deficiencies that are possible with these laboratory results.

Explanation:

When the APTT is abnormal and the PT is normal, the possible deficiencies are F-VIII, F-IX, F-XI, F-XII, prekallikrein, and high molecular weight kininogen.

Question:

7. What is the most likely factor deficiency? Why?

Explanation:

The most likely factor deficiency is F-VIII because it is the most common.

Question:

8. What do the results of the APTT on the mixture of Scott's plasma with normal plasma indicate?

Explanation:

The results of the mixing studies indicate that normal plasma corrected the patient's result. This indicates a factor deficiency rather than an inhibitor.

Question:

9. What test should be performed next?

Explanation:

An F-VIII assay should be performed next.

Question:

10. If an F-VIII assay was done with results of <1 U/dL, what molecular studies should be done?

Explanation:

Molecular studies for the inversion mutation in intron 22 should be done for all patients with severe F-VIII deficiency.

Question:

11. What therapy is indicated for this patient?

Explanation:

Therapy for F-VIII deficiency includes heat-inactivated F-VIII concentrates and recombinant F-VIII.

Question:

12. What complications from the therapy are possible?

Explanation:

A complication of therapy that occurs in patients with hemophilia A, particularly those with the inversion mutation in intron 22, is the development of an inhibitor.

ANSWERS TO CHECKPOINTS**Checkpoint! 1**

a. Why do patients with type 1 VWD have 25–50% of VWF in their plasma?
b. Why do they have a corresponding decrease in F-VIII in their plasma?

Answer

a. Type 1 VWD is inherited as an autosomal dominant characteristic. Patients have symptoms with abnormalities of only one gene. The second gene is still functional. Theoretically, 50% of VWF would be present but other variations such as the blood type O may result in less than 50% in some patients.
b. Patients with type 1 VWD have a corresponding decrease in F-VIII in their plasma because F-VIII requires the presence of VWF to be present in the plasma.

Checkpoint! 2

a. If a patient with VWD has an equal decrease in F-VIII assay, VWF:RCO, and VWF:Ag assay, does this more likely indicate that there is a true decrease in the amount of or does it indicate that the patient has a type of VWD that is characterized a functional abnormality of F-VIII. Support your answer.
b. What type of VWD is most likely in a patient with these laboratory test results?

Answer

a. A true quantitative decrease in the amount of F-VIII occurs because the tests for function and immunologic activity are both decreased.
b. These results are characteristic of VWD, type 1.

Checkpoint! 3

What abbreviation is acceptable for:
a. the antigenic properties of VWF?
b. the functional activity of F-VIII?
c. the complex of F-VIII and VWF?

Answer

a. VWF:Ag

b. F-VIII:C
c. F-VIII/VWF complex

Checkpoint! 4

Referring to Table 3, explain the reason why the platelet function tests are abnormal in VWD and not in F-VIII or F-IX deficiencies.

Answer

Platelet function tests are abnormal in VWD because VWF is necessary for platelets to adhere to collagen. This affects the closure time, the bleeding time, and platelet aggregation studies with ristocetin. Ristocetin takes the place of collagen in the platelet aggregation test system. In the absence of VWF, platelets do not adhere and do not aggregate. VWF is not needed for platelets to aggregate with other agonists. F-VIII and F-IX deficiencies have a decrease in these coagulation proteins that affects fibrin formation, but platelets are normal and VWF is present.

Checkpoint! 5

Explain why the thrombin time will be abnormal in patients with afibrinogenemia and dysfibrinogenemia.

Answer

The thrombin time depends on the adequate conversion of soluble fibrinogen to fibrin. Patients with afibrinogenemia have no fibrinogen to convert to fibrin, and patients with dysfibrinogenemia have fibrinogen with an abnormal ability to convert to fibrin.

Checkpoint! 6

Explain why the prothrombin time but not the APTT is prolonged in F-VII deficiency.

Answer

F-VII is activated by tissue thromboplastin, which is the first step in fibrin formation via the “extrinsic pathway.” The reagent for the prothrombin time is tissue thromboplastin; therefore, when the F-VII is deficient, fibrin formation is delayed. In the APTT, tissue thromboplastin is not present in the test system. Instead, fibrin is formed by activating the contact factor system and F-VII is bypassed.

Checkpoint! 7

Explain why the laboratory screening tests are normal in patients with F-XIII deficiency.

Answer

All laboratory screening tests depend on fibrin formation in the test container and are not influenced by whether or not the fibrin was covalently cross-linked. F-XIII functions after fibrin formation to stabilize the fibrin in vivo. It is not necessary to produce the end-point (fibrin formation) in the in vitro assays.

Checkpoint! 8

- a. Why is thrombocytopenia usually present in a patient with DIC?
 b. Which hemostasis laboratory screening tests (PT and APTT), if any, will the following affect?
 Decreased F-V?
 Decreased F-VIII?
 Decreased fibrinogen?

- Decreased antithrombin?
 c. Which laboratory test results would distinguish DIC from hemophilia A?

Answer

- a. Thrombocytopenia is usually present because platelets are consumed in DIC. They are activated by thrombin and are incorporated into the fibrin clots within the circulation.
 b. Decreased F-V—PT and APTT
 Decreased F-VIII—APTT
 Decreased fibrinogen—PT and APTT
 Decreased antithrombin—neither
 c. The APTT is abnormally prolonged and the F-VIII assay is decreased in hemophilia A. All other tests are normal. In DIC, all factors and inhibitors that are consumed as blood clots are abnormal, and fibrinolytic products are increased because blood is clotting and lysing in DIC. This affects all of the hemostasis tests that are routinely performed as well as the platelet count.

Thrombophilia

Lynne Williams, Ph.D.

OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define *hypercoagulability*, *thrombophilia*, *thrombus*, and *thrombosis*.
2. Describe the physiological processes involved in hypercoagulability.
3. Explain how a thrombus becomes a thromboembolus.
4. Contrast a white thrombus and a red thrombus, and list the risk factors predisposing to the formation of each.
5. Define *deep vein thrombosis* (DVT); explain how it is diagnosed and what clinical conditions can result.
6. Describe the role of heparin in the neutralization of activated coagulation factors by antithrombin.
7. Diagram the relationship of protein C (PC) and protein S (PS) to the coagulation pathway and explain why a deficiency of either might lead to a thrombotic tendency.
8. Explain why both molecular (antigenic) and functional assays should be performed for diagnosing antithrombin, protein C (PC), or protein S (PS) abnormalities in a patient.
9. Describe activated protein C (APC) resistance (APCR), and explain its contribution to thrombophilia.
10. List two side effects of heparin therapy and what hematology procedures should be monitored to prevent or limit these complications.
11. Contrast unfractionated heparin (UFH) and low molecular weight heparin (LMWH) including anticoagulant mechanisms and monitoring.
12. Discuss how oral anticoagulants such as coumadin decrease a person's risk for thrombosis, and describe the best way to monitor oral anticoagulation.

OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Evaluate the utility of laboratory tests in the differential diagnosis of arterial and venous thrombotic disease.
2. List four clinical manifestations suggestive of an inherited thrombophilia, and explain why many patients are not diagnosed.
3. Explain the differences between type I and type II deficiencies of protein C (PC), protein S (PS), and antithrombin; given values for antithrombin or protein C and S assays, determine the type of deficiency in a patient.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Thrombus formation
- ▶ Thrombophilia
- ▶ Laboratory testing in patients with suspected thrombosis
- ▶ Anticoagulant therapy
- ▶ Summary
- ▶ Review questions
- ▶ References

■ OBJECTIVES—LEVEL II (*continued*)

4. List two deficiencies that can cause warfarin- (coumadin-) induced skin necrosis and give potential treatment options.
5. Justify performing both a clotting and molecular assay for diagnosis of activated protein C resistance (APCR).
6. Describe the two most common mutations leading to hyperhomocysteinemia.
7. Explain how increased levels of prothrombin or fibrinogen might predispose to thrombosis.
8. Describe how deficiencies of plasminogen or plasminogen activator or increased levels of plasminogen activator inhibitor could lead to thrombosis.
9. Identify secondary disorders leading to thrombosis.
10. Describe and explain the treatment of a thrombotic episode.
11. Explain how the INR has standardized prothrombin times.
12. Evaluate the use and monitoring of thrombolytic therapy in treatment of thrombosis.
13. Given a patient history and appropriate laboratory results, interpret the data to determine a probable diagnosis.

KEY TERMS

Activated protein C resistance (APCR)
 Antiphospholipid antibody syndrome (APLS)
 Deep vein thrombosis (DVT)
 Disseminated intravascular coagulation (DIC)
 Dysfibrinogenemia
 Embolus
 Factor-V Leiden (FVL)
 Hemolytic uremic syndrome (HUS)
 Heparin-induced thrombocytopenia (HIT)
 Hypercoagulable
 Hyperhomocysteinemia
 Low molecular weight heparin (LMWH)
 Pulmonary embolism (PE)
 Red thrombi
 Thromboembolism (TE)
 Thrombolytic therapy
 Thrombophilia
 Thrombophlebitis
 Thrombosis
 Thrombotic thrombocytopenic purpura (TTP)
 Thrombus
 Unfractionated heparin (UFH)
 White thrombi

BACKGROUND BASICS

Information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Describe the mechanisms of platelet activation and the functions of platelets in both primary and secondary hemostasis.
- ▶ Outline the coagulation cascade and the components contributing to fibrin formation.
- ▶ List the components and the function of the fibrinolytic system and the products produced by fibrinolytic action (FDPs).
- ▶ List the mechanisms that maintain normal physiologic control of hemostasis, particularly the inhibitors of both coagulation and fibrinolysis.

Level II

- ▶ Describe the mechanism of activation of serine proteases (complex formation on a phospholipid surface).
- ▶ Summarize the physiologic controls that limit activation of coagulation and fibrinolysis to the sites of vessel injury.
- ▶ Describe the method of activation and physiologic function of the inhibitors of coagulation and fibrinolysis.

CASE STUDY

We will address this case study throughout the chapter. Andrea is a 37-year-old woman recently diagnosed with deep vein thrombosis (DVT) of the right leg. She is dehydrated and on oral contraceptives. She is also on coumadin. Consider possible factors contributing to the thrombosis in this patient and the laboratory tests that might be used to differentiate and diagnose the cause.

OVERVIEW

This chapter describes imbalances between procoagulant and anticoagulant processes in the hemostatic system that result in an increased tendency to form thrombi (thrombophilia). The chapter begins with a summary of the factors that influence thrombus formation in the arterial and venous blood vessels and the nature of the resulting thrombi that form in each side of the circulatory system. The chapter defines *thrombophilia* and describes the hereditary and acquired factors that contribute to thrombophilia. It discusses the pathophysiologic basis, clinical manifestations, and laboratory diagnosis for each thrombophilic factor. Emphasis is on the concept of thrombophilia as a multifactorial disease process. The chapter ends with a brief discussion of the available therapies for the thrombophilic patient.

INTRODUCTION

The human hemostatic system represents a balance between procoagulant or thrombogenic factors and anticoagulant and/or fibrinolytic activity. In a normal healthy individual, the two systems are balanced so that neither excessive bleeding nor clotting occurs. When the balance is tipped so that there is more procoagulant or clotting activity (or less anticoagulant activity), the person is said to be **hypercoagulable**. **Thrombosis** is the formation of a platelet and/or fibrin mass within a vessel, known as a **thrombus** (plural, thrombi). Many conditions can cause hypercoagulability and lead to thrombosis.

The three physiologic components responsible for hemostasis are also the sources of thrombogenic influences: the vascular endothelial cell, platelets, and coagulation proteins (Table 1). The normal intact endothelium is antithrombogenic and does not activate platelets or blood coagulation factors. Damage to vascular endothelial cells can cause the release of prothrombotic substances (e.g., tissue factor, thromboxane [TXA₂], and plasminogen activator inhibitor [PAI-1]) or loss of normally protective antithrombotic functions (e.g., thrombomodulin/protein C activation; heparan sulfate/antithrombin activation; nitric oxide and prostacy-

TABLE 1

Physiologic Alterations Contributing to Thrombosis

Thrombogenic alterations

- Damage/activation of endothelial cells
- Exposure of subendothelium (loss of endothelial cells)
- Activation of platelets (circulating agonists, interaction with subendothelium)
- Activation of plasma coagulation proteins
- Inhibition of fibrinolysis
- Stasis

Protective mechanisms lost

- Antithrombotic properties of factors released from intact endothelium (prostacyclin, nitric oxide)
- Neutralization of activated coagulation factors by endothelial cell-bound components (thrombomodulin, heparan sulfate)
- Inhibition of activated coagulation factors by naturally occurring plasma protease inhibitors (antithrombin [AT], tissue factor pathway inhibitor [TFPI], heparin cofactor II [HCII])
- Degradation of coagulation factors by inhibiting proteases (activated protein C [APC])
- Dilution of activated clotting factors and disruption of platelet aggregates by unimpeded blood flow
- Breakdown of fibrin thrombi by the fibrinolytic system

(Hirsch J, Colman RW, Marder VJ, George JN, Clowes AW. Overview of thrombosis and its treatment. Hirsch J, Colman RW, Marder VJ, Clowes AW, George JN, eds. In: *Hemostasis and Thrombosis: Basic Principles and Clinical Practice*, 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2000:1071–84.)

clin) (Figure 3). Circulating agonists or interaction with exposed subendothelium can activate platelets. Tissue factor (TF) or collagen, resulting from damaged vessels can activate procoagulant plasma proteins. Inadequate control of plasma coagulation can result from decreased activity of protective protease inhibitors or inadequate fibrinolysis. Additionally, stasis, or impaired blood flow, is thrombogenic. Normal unimpeded blood flow dilutes or removes activated clotting factors from their site of activation.

Thrombi can form in any part of the cardiovascular system, including the arteries, veins, heart, and microcirculation. Thrombi are composed of fibrin, platelets, and entrapped cells; the relative proportion of each component is influenced by hemodynamic factors and differs in arterial and venous thrombi. The thrombus is often incorrectly referred to as a *clot*; however, a clot is a mass that forms extravascularly (either in vitro or from blood shed into the tissues or body cavities). Thrombus formation can lead to two major pathologic events. The thrombus can enlarge, causing local obstruction of the blood vessel (ischemia) and resulting in the death of the tissue supplied by that vessel (necrosis). A piece of thrombotic material (an **embolus**) can break off from the thrombus and travel through the circulatory

system, lodging at a distant site and obstructing blood flow in that tissue, causing ischemia and necrosis. This obstruction is termed an *embolism*. If the blockage originates from a thrombus, it is referred to as a **thromboembolism (TE)**.

► THROMBUS FORMATION

ARTERIAL THROMBI

Thrombi formed in arteries where blood flow is rapid are termed **white thrombi**. They are composed primarily of platelets and fibrin with relatively few leukocytes and erythrocytes. Arterial thrombi usually form in regions of disturbed flow, at sites of damage to the endothelium, often in areas of atherosclerotic plaques. Plaques are composed of extracellular lipids, fibrous connective tissue, and foam cells (lipid-filled macrophages and smooth muscle cells). Thrombosis is generally initiated by rupture of the plaque, exposing thrombogenic material in the subendothelium to the blood. Platelet activation and activation of plasma coagulation factors occur, resulting in the formation of fibrin. The activated platelets and fibrin interact to form a thrombus that can extend into the lumen of the vessel, eventually obstructing the artery and inducing ischemia. An embolus often breaks off and lodges in the small vessels of the heart or brain, causing myocardial or cerebral infarction (and tissue death). In addition to endothelial cell loss, more subtle endothelial injury (e.g., exposure to endotoxin, hypoxia, cytokines such as IL-1 or TNF [tumor necrosis factor]) can also promote coagulation. Treatment for arterial thrombi usually involves platelet-inhibiting drugs (e.g., aspirin, clopidogrel, or ticlopidine) or thrombolytic therapy.

Traditional risk factors associated with an increased predisposition to atherosclerosis and the formation of arterial thrombi include hypercholesterolemia, hypertension, smoking, physical inactivity, obesity, and diabetes. Historically, up to one-half of all patients who developed a coronary thrombosis did not have any of these conventional risk factors. Consequently, there was interest in identifying additional laboratory tests that could predict an impending arterial thrombotic event. Standard laboratory tests (prothrombin time [PT], activated partial thromboplastin time [APTT], and thrombin time [TT]) are neither specific nor sensitive for predicting arterial thrombi, and novel risk factors or laboratory tests have thus been sought. While the clinical data for some of these new tests are inconsistent, some do show promise as indicators of an increased thrombotic tendency.¹ These new approaches include tests for hyperhomocysteinemia; elevated lipoprotein (a); fibrinogen; D-dimer; PAI-1; C-reactive protein (CRP); and decreased tPA. None of these tests is specific for arterial thrombosis. Tests suggesting an increase in procoagulant activity (elevated fibrinogen, hyperhomocysteinemia) or decreased fibrinolytic activity (elevated PAI-1) can reflect a thrombotic tendency but not specifically arterial thrombosis.

It was recently recognized that inflammatory processes play a role in the initiation and progression of atherosclerosis (see website, for further information). Thus, inflammation can be linked to cardiovascular risk, and markers of inflammation can be useful as predictors of preclinical atherosclerosis.² CRP is a typical acute phase reactant with elevated serum levels occurring in response to acute injury, infection, or other inflammatory stimuli. The high sensitivity assays for CRP (hs-CRP) are being used to evaluate its role as a sign of chronic vascular inflammation. Clinical data for CRP, fibrinogen, and serum amyloid A (two other acute phase reactant proteins) strongly support a role for inflammation in atherogenesis. Evidence of inflammation can be detected many years in advance of acute thrombosis in apparently healthy men and women, indicating that inflammatory processes occur early and precede vascular occlusion.³

VENOUS THROMBI

Thrombi formed in the veins where blood flow is slower are termed **red thrombi**. They are primarily composed of red blood cells trapped in the fibrin mesh with relatively fewer platelets and leukocytes. Such thrombi usually form in regions of slow or disturbed blood flow, often in venous segments that have been exposed to direct trauma.

Although venous thrombi can occur in any vein in the body, they most commonly occur in the lower limbs. Thrombosis of the superficial veins of the legs is usually benign and self-limiting (**thrombophlebitis**). In contrast, involvement of the deep veins of the leg (**deep vein thrombosis [DVT]**) is more serious. Generally, distal thrombi localized to the deep veins of the calf are less serious (and often undergo spontaneous lysis) than those involving the proximal veins (popliteal, femoral, or iliac veins). DVT involving the calf are also less commonly associated with long-term disability or **pulmonary embolism (PE)**. The symptoms of venous thrombosis can include localized pain, warmth, redness, and swelling. Embolization of a (deep vein) thrombus to the pulmonary circulation is a serious and potentially life-threatening complication of DVT. A strong association exists between PE and the presence of venous thrombosis in the lower limbs; PE is detected by perfusion lung scanning in ~50% of patients with documented proximal DVT.⁴ It has been suggested that DVT and PE are different stages and clinical presentations of the same pathologic process, termed *venous thromboembolism (VTE)*.⁵

Like arterial thrombosis, venous thrombosis occurs when activation of blood coagulation exceeds the ability of the natural protective mechanisms (anticoagulants or inhibitors and the fibrinolytic system) to prevent fibrin formation (Table 1). Venous thrombosis is associated with the activation of plasma coagulation proteins initiated by vascular trauma or inflammation, the consequences of which are amplified by stasis. Venous stasis predisposes to local thrombosis by impairing the clearing of activated coagulation factors.

VTE can occur spontaneously or be provoked by recognizable clinical risk factors. Clinical risk factors that predispose to venous thrombosis include:

1. *Venous stasis.* Venous return from the legs is enhanced by contraction of calf muscles, which act as a pump to propel blood from the legs toward the heart. Immobility (loss of the pumping action of the contracting muscles), venous obstruction, venous dilation, and increased blood viscosity (polycythemia, dysproteinemia, elevated fibrinogen) all predispose to venous thrombosis.
2. *Vessel wall damage.* The vascular endothelium can be damaged by direct trauma (surgery, severe burns, severe trauma) and by exposure to endotoxin, inflammatory cytokines (IL-1, TNF), thrombin, or hypoxia. Damaged endothelial cells synthesize tissue factor and PAI-1 and internalize thrombomodulin—changes that promote thrombogenesis⁶ (Figure 3).
3. *Factor V Leiden (FVL) and activated protein C resistance.* Discussed later.
4. *Deficiency of circulating protease inhibitors.* Antithrombin, protein C [PC], protein S [PS], heparin cofactor II (HCII), discussed later.
5. *Elevated prothrombin levels.* Prothrombin 20210, discussed later.
6. *Antiphospholipid antibodies.* Discussed later.
7. *Hyperhomocysteinemia.* Discussed later.
8. *Decreased fibrinolytic activity.* Discussed later. Fibrinolytic activity has been found to be lower in leg veins than in arm veins, which could partly explain the greater tendency for venous thrombosis to occur in the lower extremities.⁷
9. *Malignancy.* The association between venous thrombosis and cancer has been attributed to procoagulant material released from the tumor cells or to complications of chemotherapy.
10. *Miscellaneous.* Other factors associated with increased risk of thrombosis include advanced age, obesity, pregnancy, use of oral contraceptives (OC) and hormone replacement therapy, smoking, hypertension, hyperlipidemia, and a clinical history of previous venous thromboembolism. Blood groups other than Group O (e.g., A, B, AB) have been shown in some studies to have an increased risk of thrombosis^{8–13} perhaps the result of higher levels of von Willebrand factor (VWF) in blood groups A, B, and AB.¹⁴

The diagnosis of DVT can be difficult because similar clinical features and laboratory test results are found in other conditions. It is generally accepted that clinical/laboratory diagnosis of venous thrombosis is unreliable and objective tests are needed to confirm the diagnosis.¹⁵ Objective tests using radiologic procedures to visualize the thrombus can help to identify thrombi.¹⁶ Venography, venous compression ultrasonography (CUS), and spiral computerized tomography (s-CT)

can be used to confirm a diagnosis of DVT; pulmonary angiography and ventilation-perfusion lung scanning can be used to confirm PE. Blood tests for biologic markers of thrombin generation and fibrinolysis are often elevated in patients with DVT.⁷ Laboratory tests analyzed for their diagnostic utility include prothrombin fragment 1.2, fibrinopeptide A (FPA), thrombin-antithrombin (TAT) complex, soluble fibrin monomer, D-dimer, tPA, and PAI-1. However, these tests are nonspecific and can be abnormal in a number of clinical conditions associated with excessive coagulation and/or fibrinolysis and thus have low specificity for DVT. An appropriately validated quantitative D-dimer assay (different assays have variable sensitivity and specificity) appears to have both high sensitivity and a negative predictive value; thus, a negative result can be used to rule out DVT.^{17,18}

 **Checkpoint! 1**
Why would defects of fibrinolysis result in hypercoagulability?

 **THROMBOPHILIA**

The most common cause of death in the United States is thrombosis; more than 2 million people die from arterial or venous thrombosis every year¹⁹ (Table 2 ). Thrombotic episodes can be caused by a congenital abnormality and/or an acquired alteration. The proper treatment or prevention of thrombosis depends on careful clinical assessment and extensive testing procedures.

The term **thrombophilia** is used to describe any disorder either inherited or acquired associated with an increased tendency to thrombosis. Although thrombosis at a young age is probably the most important feature of inherited thrombophilia, many patients have their first episode later in life. Women with certain inherited thrombophilic abnormalities have an increased risk of pregnancy loss,

 **TABLE 2**

Incidence of Thrombosis		
Thrombotic Incident	Incidence per 100,000	U.S. Cases per Year
Deep vein thrombosis (DVT)	159	450,000
Pulmonary embolus (PE)	139	355,000
Fatal pulmonary embolus	94	240,000
Myocardial infarction (MI)	600	1,500,000
Fatal myocardial infarction	300	750,000
Cerebrovascular thrombosis (CVT)	600	1,500,000
Fatal cerebrovascular thrombosis	396	990,000

preeclampsia, and hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome whereas some acquired thrombophilic conditions are also associated with recurrent pregnancy loss.²⁰ Carriers of some inherited thrombophilic defects are prone to other thrombotic complications, such as vitamin K antagonist (warfarin)-induced skin necrosis or heparin resistance. The thrombotic risk of a given hereditary predisposition or an acquired condition varies from low to modest to high risk of VTE (Table 3).

An inherited thrombophilic defect places an individual at risk for but does not inevitably lead to thrombosis. Not all persons with thrombophilia experience a thrombotic event; many will not develop thrombosis unless some other (acquired) risk factor is present. Surgery, pregnancy, immobilization, estrogen therapy, obesity, trauma, and infection can initiate thrombotic events. These conditions can lead to thromboses even in people without an inherited thrombotic tendency, so when a thrombotic episode occurs, it must be decided whether it represents an isolated event or the patient has an underlying genetic predisposition. A thorough personal and family history can help in determining the likelihood of a genetic component. However, other affected family members can be asymptomatic, their condition discovered only after another family member is diagnosed. More than one hemostatic defect or abnormality increases the risk for thrombosis.

HEREDITARY THROMBOPHILIA

Inherited thrombophilia refers to individuals with predisposing genetic defects resulting in a tendency to thrombosis.

Specific inherited alterations associated with TE have been identified (Table 4). Most of these changes involve an increase in procoagulant potential (e.g., activation of the coagulation cascade) or a defect or decrease in natural inhibitors of clotting. Likewise, abnormalities of fibrinolysis or platelet activation can contribute to the thrombotic tendency. An acquired predisposition to thrombosis, such as prolonged immobility or pregnancy, can interact with an underlying hereditary predisposition to precipitate an acute thrombotic event. A combination of more than one hereditary predisposition strongly accelerates and exaggerates the thrombotic process. Thus, thrombosis can occur in susceptible patients having one or more genetic mutations when they are exposed to exogenous prothrombotic stimuli.²¹ Their “thrombotic potential” is higher than normal, and generally an additional prothrombotic exposure must occur to push them into an acute thrombotic episode (Figure 1). Inherited thrombotic disorders are usually associated with venous thrombosis.

Patients diagnosed with inherited thrombophilia usually present with one or more of the following clinical manifestations:²⁰

1. venous thromboembolism at a young age (prior to age 45)
2. recurrent venous thromboembolism
3. family history of venous thromboembolism
4. thrombosis in an unusual site (cervical or visceral veins)

The five most clearly delineated hereditary abnormalities associated with thrombophilia (Factor V Leiden; decreased

or defective protein C, protein S, or antithrombin; and prothrombin 20210 mutation) combined account for ~30% of the initial cases of DVT and are the apparent hereditary defects in 75% of thrombophilic families²² (Table 5). In contrast to heterozygous female carriers of a hemophilia gene in whom 50% of normal levels of the clotting factor are sufficient to protect against bleeding, half-normal levels of anticoagulant proteins (AT, PC, PS) are associated with an increased risk of thrombosis.

■ **FIGURE 1** Interaction of acquired thrombotic triggers with individual baseline hypercoagulability. Individuals with hereditary mutations resulting in thrombophilia have a higher baseline level of hypercoagulability (red line) compared to normal individuals (blue line). As a result, the introduction of an identical acquired prothrombotic stimulus will more easily push the thrombophilia individual into an overt acute thrombotic event (dotted line), compared to a normal individual.

CASE STUDY (continued from earlier in this chapter)

Andrea's mother had had eight children and had experienced no thrombotic events, although two paternal uncles died suddenly of pulmonary embolism. Two of the mother's cousins also had pulmonary emboli: one died suddenly, but the other recovered.

1. What risk factors, if any, are revealed in the patient's history?

Antithrombin Deficiency

Antithrombin (AT) is the major inhibitor of the serine proteases involved in coagulation. AT's relatively weak natural inhibitory function is augmented 1000-fold in the presence of heparin. In vivo, endothelial cell glycosaminoglycans (e.g., heparan sulfate) are the natural catalyst for the inhibitor. Reduction of AT levels to ~50% of normal predisposes to venous thrombosis, because of a decrease in the normal inhibition of the coagulation pathway.

Pathophysiology AT deficiency was the first identified cause of inherited thrombophilia. Described by Egeberg in 1965,²³ AT deficiency is inherited as an autosomal dominant trait. More than 200 different mutations of the AT gene have been identified (www.archive.uwcm.ac.uk/uwcm/mg/hgmd/search.html). Two major types of inherited deficiencies have been described (Table 6). Type I deficiency is the result of reduced synthesis of a biologically normal protein (i.e., a quantitative deficiency). In this case, the antigenic and functional activities of AT are reduced in parallel. The second type of AT deficiency is produced by a specific molecular defect within the inhibitor (type II, or qualitative deficiency). Functionally, type II mutations involve either the heparin-binding site or the reactive (protease-binding) site of the AT molecule. In this case, the plasma levels of AT functional activity are reduced while AT immunologic activity is essentially normal.

Clinical Findings The prevalence of AT deficiency in the general population is about 0.02% and in patients with VTE is ~1–2%.²² Heterozygous individuals generally have AT functional activity of 30–60% (reference range 80–120%, or ~140 $\mu\text{g}/\text{mL}$). Homozygous type I deficiency is not compatible with fetal survival. Homozygous type II deficiency is usually associated with severe, life-threatening thrombotic problems in the perinatal period. Affected heterozygous individuals rarely develop thrombotic episodes before puberty, and the risk of thrombosis increases with advancing age. The infrequency of thrombotic events prior to puberty is thought due to the protective effect of α_2 -macroglobulin, which is found at higher levels during the first two decades of life than in adults. About 55% of affected patients with familial AT deficiency experience thrombotic episodes (lifetime risk), most commonly involving DVT of the leg and mesenteric veins. About 60% of these individuals develop recurrent thrombotic episodes, and ~40% show clinical signs of PE.²⁴ Individuals with heparin-binding site defects

★ TABLE 5

Inherited Thrombophilia: Characteristics of the Five Most Studied Defects

	Factor V Leiden	Prothrombin 20210	Protein C Deficiency	Protein S Deficiency	Antithrombin Deficiency
Occurrence					
General population	4–10%	2–4%	0.2–0.4%	0.07–2.3%	0.02%
First DVT	20%	7%	3%	2–3%	1–2%
Thrombophilic families	40%	18%	6%	4%	4%
Physiologic effect					
	F-Va resistant to cleavage by APC	↑ Prothrombin	↓ Inactivation of F-Va, F-VIIIa	↓ Cofactor for APC	↓ Inhibition of F-Xa, thrombin
		↑ Thrombin formation	Unregulated coagulation	↓ APC function	Unregulated coagulation
Clinical presentation					
Homozygous	↑↑ Risk VTE (80×)	↑ Risk VTE Possible ↑ arterial TE	Purpura fulminans	Purpura fulminans	Lethal in utero
Heterozygous	↑ Risk VTE (7×)	↑ Risk VTE (3×)	↑ Risk VTE (7×)	↑ Risk VTE (6×)	↑ Risk VTE (10–20×)

DVT = deep vein thrombosis; VTE = venous thromboembolism; APC = activated protein C; ↑ = slightly–moderately increased; ↑↑ = highly increased; ↓ = decreased.

Adapted from Marder VJ, Matei DE. Hereditary and acquired thrombophilic syndromes. In: Colman RW, Hirsh J, Marder VJ, Clowes AW, George JN, eds. *Hemostasis and Thrombosis: Basic Principles and Clinical Practice*, 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2000:1243–75.

generally have significantly less frequent and less severe thrombotic episodes than individuals with defects involving the thrombin-binding site.²⁵ Among the inherited thrombophilias, AT deficiency, although rare, is generally associated with the most severe clinical manifestations.²⁶

Acquired deficiencies of AT occur as well. Healthy newborns have about half the normal adult concentration and gradually reach the adult level by six months of age.²⁵ A variety of clinical conditions can reduce the concentration of AT in the blood including decreased production of AT (severe hepatic disease), increased consumption of AT (acute throm-

bosis, DIC), and increased clearance or loss (urinary excretion in the nephrotic syndrome, increased clearance with heparin administration).²⁷ AT levels are affected by estrogen; premenopausal women have lower levels than men. Also, AT levels are decreased with high-dose (but not low-dose) estrogen OC and in late pregnancy. The low doses of estrogen used in hormone replacement therapy generally do not affect the AT level.²²

Laboratory Evaluation The two major subtypes of type II AT deficiency are differentiated by two different functional

★ TABLE 6

Laboratory Classification of Congenital Antithrombin Deficiency

	Concentration	Functional Activity	
		Heparin Cofactor	Progressive AT
Type I	Decreased	Decreased	Decreased
Type II			
Active site defect	Normal	Decreased	Decreased
Heparin-binding site defect	Normal	Decreased	Normal

AT assays. The progressive AT assay quantifies the capacity of AT to neutralize the enzyme activity of a serine protease (e.g., thrombin, or F-Xa) in the absence of heparin, and the heparin cofactor assay measures heparin's ability to catalyze the neutralization of the protease by AT. These two assays combined have identified AT-deficient patients with reductions in heparin cofactor activity without a loss of progressive AT activity (i.e., defects at the heparin-binding site in AT). Other patients exhibit reductions in both functional assays, reflecting mutations near the thrombin-binding site. Immunologic assays (antigen measurements) help distinguish type I and type II defects.

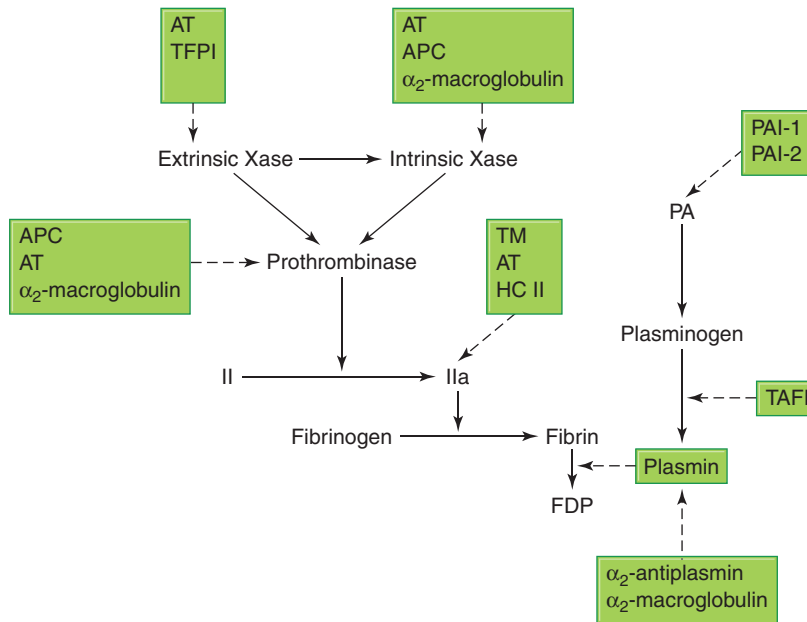

Therapy Patients with AT deficiency can usually be treated successfully with heparin for an acute thrombotic episode, although occasionally higher than usual doses of the drug are required to achieve adequate anticoagulation. If difficulty is encountered in achieving adequate heparinization or recurrent thrombosis is observed despite adequate anticoagulation, AT concentrates are available. Asymptomatic AT-deficient individuals from a thrombophilic kindred are not generally anticoagulated prophylactically unless they

are exposed to situations that predispose them to developing thrombosis.²² Patients with recurrent thrombotic disease may require lifelong antithrombotic treatment with oral anticoagulants (warfarin or coumadin).

Protein C Deficiency

PC is a vitamin K-dependent inhibitor of coagulation. PC is converted to an activated form (activated protein C [APC]) by thrombin bound to endothelial cell thrombomodulin²⁸ (Figure 18). APC degrades F-Va and F-VIIIa in the presence of its cofactor, PS, and Ca²⁺ (Figure 2■). PC in adults is present in plasma at concentrations of about 3–5 μg/mL (70–140%).²⁹ Term newborns have PC levels of ~25–45% of adult levels, which slowly rise to adult levels during adolescence.³⁰

Pathophysiology Reduction of PC levels to ~50% of normal predisposes to venous thrombosis. The diminished capacity to destroy F-Va and F-VIIIa results in an increased production of thrombin, which generates fibrin (a procoagulant effect).

■ **FIGURE 2** Physiologic control of the hemostatic process. The extrinsic Xase and intrinsic Xase activate F-X, which forms the prothrombinase complex with F-Va, Ca⁺⁺, and phospholipid. The prothrombinase complex cleaves prothrombin (II) to form thrombin (IIa). Thrombin cleaves fibrinogen to form fibrin. Plasmin cleaves fibrin and forms fibrin degradation products (FDP). The inhibitors of each of these pathways are depicted in boxes with broken arrows to show the site of inhibition. If there is a defect or deficiency in any of the inhibitors, the hemostatic control mechanism is tipped in favor of thrombosis. AT = antithrombin; TFPI = tissue factor pathway inhibitor; APC = activated protein C; TM = thrombomodulin; HC II = heparin cofactor II; TAFI = thrombin-activatable fibrinolytic inhibitor; PAI = plasminogen activator inhibitor; PA = plasminogen activator

PC deficiency is inherited in an autosomal dominant fashion. Griffin first described the hereditary deficiency of PC in 1981.³¹ Similar to AT deficiency, there are two major types of congenital PC deficiency. Type I (the more common form) is characterized by a decrease of both antigen (immunologic) and functional activity to levels of 40–60% of normal (reference range 70–140%). In type II deficiency, there are normal PC antigen levels by immunologic assay but reduced functional levels (a qualitative abnormality of the protein) (Table 7). More than 180 different mutations have been identified for the protein C gene²⁵ (www.itb.cnr.it/procmd/).

Clinical Findings Heterozygous PC deficiency is found in ~0.2% of the general population and accounts for about 6% of families with thrombophilia.²² PC-deficient individuals who develop thrombosis typically present with DVT of the legs and mesenteric veins, often before age 40. About 63% of affected patients develop recurrent venous thrombosis and ~40% exhibit signs of PE.²⁵ However, many PC-deficient individuals never experience a thrombotic episode unless presented with an additional thrombotic risk factor (either inherited or acquired). Homozygous PC deficiency presents with aggressive thrombotic complications at birth manifest by purpura fulminans (large bruises that become necrotic, histologically similar to warfarin-induced skin necrosis; see below), massive venous thrombosis, and intravascular coagulation.²⁹ These individuals require replacement of PC and lifetime antithrombotic treatment, usually with oral anticoagulants (warfarin). Liver transplantation has been reported to produce a definitive cure.³² Acquired PC deficiency is seen in liver disease, severe infection and septic shock, DIC, adult respiratory distress syndrome, and the postoperative state. Oral anticoagulation and vitamin K deficiency also lead to reduced functional PC levels.²⁵

Some heterozygous individuals with PC deficiency can experience skin necrosis when treated with warfarin anticoagulants, usually in the first few days of treatment.³³ This warfarin-induced skin necrosis is due to a transient hypercoagulable state, resulting in the formation of fibrin thrombi in the cutaneous vasculature, hemorrhage, and necrosis. With warfarin administration, all vitamin K-dependent clotting factors decrease at a rate that depends on the half-life of the individual factor. PC and F-VII (with the shortest half-lives) decrease within one day with levels of F-II, -IX, and -X falling more slowly over 2–3 days. Individuals with heterozygous PC deficiency who start with PC levels at ~50% quickly

develop a transient hypercoagulable state as their levels of PC fall precipitously. The decrease of anticoagulant PC, occurring more rapidly than decreases of most of the procoagulant factors, initially disrupts the delicate hemostatic balance and precipitates a thrombotic event in microvasculature of skin with purpura fulminans symptoms. If this occurs, oral anticoagulation should be stopped immediately, and PC replacement therapy initiated.

Laboratory Evaluation Various immunologic and functional techniques have been developed to measure PC levels in plasma samples. Some patients with type II deficiency have normal antigen levels and reduced functional levels in a clotting assay but normal or nearly normal amidolytic activity in chromogenic assays. Therefore, clotting assays are better functional assays for screening for PC deficiency.³⁴ Testing should not be done while the patient is on oral anticoagulant (coumadin) therapy.

Therapy Initial treatment for thrombosis associated with PC deficiency is the same as that for most other thrombotic events: heparin followed by oral anticoagulation. Because many heterozygous PC deficient individuals never experience a thrombotic episode, oral anticoagulation may not be needed unless a secondary risk factor is present.²⁹ PC concentrates are available but usually are used only to treat purpura fulminans in newborns.

Protein S Deficiency

PS is a vitamin K-dependent protein that functions as a cofactor for APC inactivation of F-Va and F-VIIIa. The plasma concentration in normal adults is 65–140% (~23 µg/mL).

Pathophysiology PS circulates in two forms: an inactive form bound to C4b-binding protein (C4b-BP) (~60% of total) and an unbound or free form (~40% of total). Only free PS has PC cofactor activity. The absolute and relative amounts of PS that are free are influenced by the plasma concentration of C4b-BP. C4b-BP is an acute phase reactant; thus, conditions that increase its production decrease the amount of free PS available to complex with APC. Decreases of free PS contribute to a prothrombotic tendency due to inadequate APC inactivation of F-Va and F-VIIIa. In addition, the direct anticoagulant effect of PS due to its binding to and inhibition of F-Va, F-VIIIa, and F-Xa is decreased in PS deficiency.

First described and linked to a thrombotic tendency in 1984,³⁵ PS deficiency is inherited in an autosomal dominant manner. The three types of congenital PS deficiency are defined on the basis of total and free PS antigen and APC cofactor activity (Table 8). Type I PS deficiency is characterized by low total antigen and functional activity. Type II deficiency is characterized by normal concentration of both total and free antigen but decreased functional activity (dysfunctional molecule). Type III deficiency is characterized by normal total PS but a decreased free and functional PS concentration (reflecting either a high C4b-BP concentration in plasma or an abnormal bind-

ing of PS to this carrier protein).²² More than 150 mutations causing PS deficiency have been described (www.archive.uwcm.ac.uk/uwcm/mg/hgmd/search.html).

Clinical Findings The prevalence of PS deficiency in the general population is ~0.7–2.3%, and it accounts for ~6% of cases of familial thrombophilia.³⁴ The clinical presentation of heterozygous PS deficiency is similar to that of PC deficiency, although PS deficiency has been implicated in some cases of arterial thrombosis.²² Like PC, PS has been linked with warfarin-induced skin necrosis and in neonatal purpura fulminans when levels approach 0%. Total PS antigen level in healthy full-term newborns is 15–30% of normal adults; however, C4b-BP is also markedly reduced (<20% of adult levels); thus, free PS/functional levels are only slightly reduced compared to those of adults.³⁶ Acquired PS deficiencies are seen during pregnancy, in association with the use of OC and hormone replacement therapy, in acute TE disease and DIC, in liver disease, in cases of acute bacterial or viral disease (inflammatory states), in vitamin K deficiency, and during oral anticoagulant therapy.²² Any condition that increases the acute phase reactant C4b-BP decreases free PS and increases the risk of thrombosis.

Laboratory Evaluation Laboratory evaluation of PS should include assays of both total and free PS (generally immunologic assays) and a functional assay based on the ability of PS to serve as a cofactor for the anticoagulant effect of APC. Plasma level of PS in normal adults is ~23 µg/mL. There is considerable overlap of heterozygous PS deficiency patients and the low normal range; thus, diagnosis can require the performance of multiple assays to establish the diagnosis of PS deficiency.³⁷ APCR (see below) was reported to cause false positive test results when screening for PS deficiency if clotting (functional) assays are used. However, newer assays using F-V deficient plasma as the substrate have improved the specificity of PS assays.³⁸

Therapy Treatment for PS deficiency is similar to that for PC deficiency. PS concentrates have not yet been developed for clinical use. Coumadin-induced skin necrosis is a rare complication of oral anticoagulation in PS deficiency.

Activated Protein C Resistance

Thrombin activates protein C to APC, which in turn inhibits coagulation by degrading F-Va and F-VIIIa. A novel mecha-

nism for familial thrombophilia was recognized in 1993 with the description of a syndrome characterized by inherited resistance to APC, **activated protein C resistance (APCR)**.³⁹

Pathophysiology APCR is characterized by APC's inability to prolong clotting tests when it is added to the test system. The addition of APC to plasma normally results in a prolongation of the clotting time due to the destruction of F-Va and F-VIIIa. Individuals with APCR exhibit the diminished ability of APC to destroy F-Va. In vivo, inadequate F-Va inactivation can lead to increased production of thrombin and possibly thrombosis. About 90% of cases of APCR are due to a single point mutation of the F-V gene, involving replacement of Arg 506 with Gln (FV^{R506Q}, also called **F-V Leiden [FVL]**). This mutation makes the mutant F-Va molecule resistant to APC inactivation by altering an APC cleavage site.⁴⁰

Studies are currently being conducted in the 10% of individuals with APCR who do not have the FV^{R506Q} mutation.⁴¹ Mutations at Arg 306 (a second APC cleavage site in F-Va) have recently been reported.^{42,43} The HR2 F-V haplotype is a recently described polymorphism that also demonstrates low APC sensitivity. However, neither appears to be linked to a thrombotic tendency.^{41,43} So far, no genetic abnormalities in the F-VIII gene have been identified as causing APC resistance in humans.²⁵

Clinical Findings The prevalence of heterozygous FVL mutation in Caucasians ranges from 1.0 to 8.5%, depending on the geographic population studied. The mutation is rare in Africans, Asians, Australians, and Native Americans.⁴⁴ FVL is seen in as many as 10–30% of patients with venous thrombosis and accounts for about 40% of the cases of familial thrombophilia.²² Homozygotes are at higher thrombotic risk than heterozygotes as are patients with heterozygous APCR combined with mutations in the genes for PC, PS, or AT.²⁵ Heterozygotes with FVL are unlikely to develop thromboses unless other acquired risk factors are present (OC, pregnancy, trauma).

Laboratory Evaluation Laboratory tests for APCR are either clot-based functional tests or molecular techniques. The confirmatory test for FVL is a PCR-based molecular assay. Polymerase chain reaction (PCR) based confirmatory tests for APCR due to mutations other than FVL are available

in research laboratories only. Routine clinical diagnosis requires both clotting (screening) tests for APCR and molecular (PCR) tests for FVL because 10% of individuals with APCR do not have the FVL mutation.

Therapy The management of acute thrombosis in patients with APCR is the same as in other thrombotic patients. Individuals with heterozygous APCR are usually given prophylactic antithrombotic treatment only if they are in a situation of increased thrombotic risk.

Prothrombin Gene Mutation 20210

Prothrombin is cleaved by the activated F-Xa–F-Va complex to form thrombin.

Pathophysiology In 1996, it was reported that a G → A substitution in the 3' untranslated region of the prothrombin gene (nucleotide 20210) is associated with a mild elevation of plasma prothrombin levels (115–130% of normal) and an increased risk of venous thrombosis.⁴⁵ The prothrombin mutation is the most recent of the hereditary thrombophilias to have a clear-cut genetic mutation defined. The elevated plasma prothrombin level can directly contribute to an increased thrombotic risk by causing increased thrombin generation. Additionally, decreased fibrinolytic activity can occur because of enhanced activation of TAFI.

Clinical Findings The prevalence of this autosomal dominant gene is ~1–2% among Caucasians, and like FVL, it is infrequent among persons of African, Asian, and Native American origin. It is estimated that ~6% of thrombotic patients are heterozygous for this mutation and that it accounts for about 18% of cases of familial thrombophilia (making it the second most common cause after FVL mutation).²² A substantial percentage of symptomatic individuals with the prothrombin mutation also had the FVL mutation or another genetic risk factor for thrombosis,⁴⁶ supporting the concept that thrombophilia is a multirisk factor disease. Individuals homozygous for the prothrombin mutation have a significantly higher risk of VTE and can have an increased risk of arterial thrombosis.

Laboratory Evaluation Screening for this mutation using coagulation testing is unreliable because prothrombin levels in these patients overlap with values in the normal population. Molecular testing (PCR) for the single-point mutation at position 20210 in the prothrombin gene is confirmatory.

Therapy Patients with this disorder are treated the same way other thrombotic patients are. Prophylactic treatment can be given in high-risk situations.

Heparin Cofactor II Deficiency

HC II is a second thrombin inhibitor, and like AT, its action is accelerated by heparin and by dermatan sulfate. In contrast to AT, which inhibits most of the procoagulant serine proteases, HC II inhibits primarily thrombin. HC II defi-

ciency is inherited as an autosomal dominant disorder. Many individuals with this defect are asymptomatic, and it is likely that a partial deficiency (heterozygous state) is a thrombotic risk factor only if it is combined with another thrombophilic risk factor (inherited or acquired).^{47,48} Acquired HC II deficiency can be seen in patients with liver disease and in DIC. Several assays are available for measuring HC II, but none is currently FDA approved and thus not available in routine coagulation laboratories. Because both HC II and AT inhibit thrombin, it is recommended that functional assays for AT be based on F-Xa inhibition rather than thrombin inhibition to improve assay specificity for AT.

Tissue Factor Pathway Inhibitor Variant

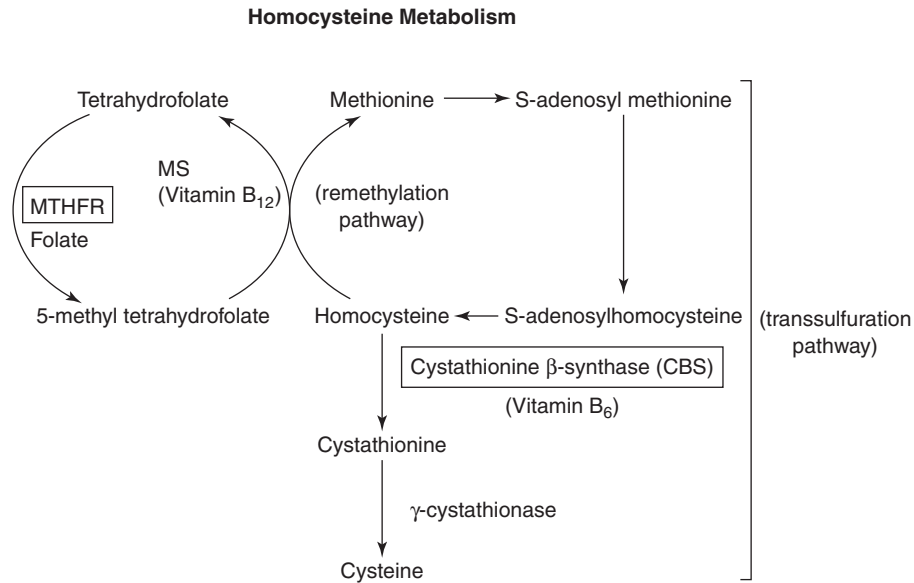

Tissue factor pathway inhibitor (TFPI) is a natural inhibitor of coagulation that directly neutralizes F-Xa and, in complex with F-Xa, neutralizes the tissue factor:VIIa complex.^{49,50} TFPI exists in vivo primarily bound to endothelial cells, and thus measurement of plasma levels (representing ~10–15% of total TFPI) may be uninformative in identifying a deficiency state that could predispose to thrombophilia.⁵¹ A candidate mutation in the TFPI gene resulting in a proline to leucine alteration at position 151 of TFPI has been reported to have an increased risk of VTE.⁵²

Hyperhomocysteinemia (HC)

Homocysteine is an amino acid that is metabolized either by transsulfuration to cystathionine or by remethylation to methionine (Figure 3 ■). The two main enzymes involved in HC metabolism are cystathionine beta synthase (CBS) and methylene tetrahydrofolate reductase (MTHFR). Normal plasma levels of HC are ~5–15 μmol/L, and HC levels increase with age.

Pathophysiology Hyperhomocysteinemia (plasma homocysteine level above the normal range) results when homocysteine metabolism is impaired. Severe hyperhomocysteinemia (plasma HC >100 μmol/L) is associated with homocysteinuria and is seen in a group of rare inborn errors of metabolism. The most common causes for homocysteinuria are homozygous mutations in the CBS gene; less commonly mutations occur in the MTHFR gene. Homocysteinuria is associated with premature atherosclerosis (cardiovascular disease and stroke) and venous and arterial thrombosis.⁵³ More recently, less severe elevations of blood homocysteine levels have also been implicated in VTE.⁵⁴

The mechanisms that link homocysteine to thrombosis are not fully understood, but the major effect is on the vessel wall. Proposed mechanisms include endothelial cell loss, smooth muscle cell proliferation, induction of TF, inhibition of heparan sulfate expression (loss of AT binding), inhibition of nitric oxide (NO) and prostacyclin release, inhibition of tPA binding, and inhibition of thrombomodulin-dependent protein C activation.²⁵ Mild to moderate homocysteinemia is now recognized to be an independent risk factor for both arterial and venous thrombotic disease. Up to 40% of pa-

■ **FIGURE 3** Homocysteine metabolism. Mutations of MTHFR and CBS are associated with hyperhomocysteinemia. Deficiencies of vitamin B₁₂, vitamin B₆, and folate are associated with acquired hyperhomocysteinemia. Hyperhomocysteinemia can lead to increased risk for thrombosis. MTHFR = methylene tetrahydrofolate reductase; MS = methionine synthetase

tients with atherosclerotic coronary or cerebrovascular disease have elevated plasma homocysteine as do 13–18% of patients with an initial episode of VTE prior to age 45.²⁵

Clinical Findings Both inherited and acquired conditions can cause increased HC levels. Multiple genetic mutations of CBS and MTHFR have been identified. Although homozygous CBS deficiency is the most common cause of homocysteinuria, the most common genetic causes of mild homocysteinemia involve mutations of the MTHFR gene. A MTHFR gene polymorphism, nucleotide C677T, which replaces Ala222 by Val, results in a thermolabile molecule with reduced specific activity. This polymorphism appears in homozygous form in 10–20% of the Caucasian population,⁵⁵ with 30–40% of the population estimated to be heterozygous for this mutation.⁵⁴ This MTHFR mutation is believed to be responsible for the majority of cases of a hereditary predisposition to mild hyperhomocysteinemia.⁵⁶ Most heterozygotes do not experience hyperhomocysteinemia or increased risk for vascular disease unless they have other thrombotic risk factors. The most common causes of acquired hyperhomocysteinemia are deficiencies of vitamin B₁₂, folate, or vitamin B₆ (which are cofactors in HC metabolism), smoking, some medications, aging, hypothyroidism, diabetes, and renal disease.⁵⁴

Laboratory Evaluation HC can be measured by gas chromatography, ion exchange chromatography, and high-performance liquid chromatography. The C677T MTHFR mutation can be identified using molecular assays. MTHFR

heterozygotes or individuals with inadequate vitamin B₆ levels can have normal or only slightly elevated levels of HC. There are significant age and gender differences in HC levels.

Therapy Treatment of hyperhomocysteinemia usually involves dietary manipulation or vitamin therapy. Administration of vitamin B₆, vitamin B₁₂, or folate often results in normalization of homocysteine levels in these patients, but no clinical efficacy of this approach has been demonstrated in controlled clinical trials.⁵⁴

Fibrinogen Disorders

Fibrinogen is cleaved by thrombin to form fibrin. Fibrinogen can be qualitatively or quantitatively abnormal. Qualitative abnormalities of fibrinogen usually show autosomal dominant inheritance patterns.

Pathophysiology The **dysfibrinogenemias** are a heterogeneous group of disorders that result in a structurally altered fibrinogen molecule that can lead to altered fibrinogen function. More than 400 different mutations have been identified as causing dysfibrinogenemias.⁵⁷ Dysfibrinogenemias can present with no clinical symptoms (~55% of cases), a bleeding diathesis (~25% of cases), or a history of recurrent venous or arterial thromboembolism (~20% of cases).⁵¹ Alterations of fibrinogen predisposing to bleeding include impaired release of fibrinopeptides, defective fibrin polymerization, and abnormal cross-linking by F-XIIIa.⁵⁸ Two types of thrombotic dysfibrinogenemias appear to be associated with decreased fibrinolytic activity in vivo (thus

predisposing to thrombosis): one is abnormally resistant to lysis by plasmin (mutations of plasmin cleavage sites in fibrin), and the other is associated with reduced plasminogen activation (mutations of binding sites for plasminogen or plasminogen activators).²⁵

Clinical Findings Patients with thrombotic dysfibrinogenemias are reported to have problems related to pregnancy (spontaneous abortions and postpartum thromboembolism).⁵⁹

Laboratory Evaluation Both quantitative (immunologic assays) and functional tests (thrombin times, reptilase times) for fibrinogen should be performed when dysfibrinogenemia is suspected. Functional fibrinogen measurements are usually significantly lower than antigenic measurements in the plasmas of individuals with dysfibrinogenemia.

Elevated Factor VIII

Individuals with increased plasma levels of F-VIII (>150% of normal) have an increased risk of thrombotic disease possibly due to enhanced thrombin formation⁶⁰ or diminished anticoagulant effect of APC.⁶¹ A dose–response relationship appears to exist between F-VIII level and VTE risk.⁶² F-VIII levels increase with aging, pregnancy, surgery, chronic inflammation, liver disease, and exercise. Although elevated F-VIII appears to have a hereditary component in some families, a specific molecular basis for the elevated F-VIII levels has not been identified.⁶³

Elevated Levels of Other Coagulation Factors

The Northwick Park Heart Study evaluated eight hemostatic measurements as possible thrombogenic risk factors.⁶⁴ This study showed a strong positive association between thrombosis and increased levels of F-VII_a and fibrinogen. Elevated fibrinogen can contribute to thrombosis by increasing blood viscosity or thrombin substrate availability. Fibrinogen is an acute phase reactant, and plasma levels of fibrinogen increase in inflammation. Both F-VII_a and fibrinogen levels increase with age. The relative risk for cardiovascular disease is nearly 3 times higher for individuals in the highest quintile of fibrinogen concentration compared to those in the lowest. Increased levels of other factors have been reported to be linked with an increased risk for venous thrombosis.⁶⁵ These include F-IX (>129% of normal),⁶⁶ and F-XI (>121% of normal).⁶⁷

Factor XII Deficiency

Patients with F-XII deficiency have a prolonged APTT but no clinical bleeding tendency. A number of cases of VTE, myocardial infarction, and stroke have occurred in F-XII-deficient patients.⁶⁸ This thrombophilic tendency has been postulated to be related to the role of F-XII in activating fibrinolysis. A number of studies have shown that heterozygous F-XII deficiency does not constitute a major thrombotic risk factor although severe deficiency could be associated with increased thrombotic risk.^{22, 23}

Fibrinolytic System Disorders

Hereditary disorders of fibrinolysis are less frequently associated with thrombotic disease than are hereditary anomalies of procoagulants or coagulation inhibitors.⁶⁹ Possible causes of abnormalities of fibrinolysis include the structure of fibrin (see dysfibrinogenemias earlier), the amount and function of plasminogen, and the physiology of plasminogen activation (impaired plasminogen activator synthesis or release, increased plasminogen activator inhibitor, or increased levels of TAFI).⁷⁰

Plasminogen Deficiency Plasminogen abnormalities have been classified as either type I (decrease of both protein concentration and functional activity) or type II (normal antigen levels but reduced functional activity [dysplasminogenemia]). Both types have been reported in patients with venous thrombosis.^{71,72} However, the association of hypo/dysplasminogenemia as a predisposing factor in VTE is not firmly established. Laboratory tests are available to measure protein levels (immunologic) and functional activity (clot-lysis or chromogenic substrate) of plasminogen.

Tissue Plasminogen Activator (tPA) and Plasminogen Activator Inhibitor (PAI) Inadequate stores or release of tPA or an inappropriate/excess release of PAI could theoretically result in thrombotic events. (Figure 1). Several reports have linked defective fibrinolysis associated with decreased release of tPA and/or elevated PAI-1 with familial thrombosis.^{73–75} However, two of these families subsequently were shown to have hereditary PS deficiency, the more likely cause of clinical disease in these families.^{76,77} It is thought that tPA and PAI-1 likely play a greater role in acquired thrombophilia than in hereditary thrombophilia. Functional (chromogenic assays) and quantitative (ELISA) assays for tPA and PAI-1 are available.

Checkpoint! 2

Why is thrombotic disease associated with hereditary thrombophilia considered a multigene (or multirisk factor) disease?

CASE STUDY (continued from earlier in this chapter)

Andrea was initially tested while she had deep vein thrombosis and again six months later after being taken off coumadin. The tests included AT, PC, and PS, fibrinogen, D-dimer, and plasminogen. All test results were in the reference range on both occasions.

2. What other possibilities could explain the thrombotic event in this patient?

ACQUIRED THROMBOPHILIA

The acquired or secondary thrombophilic states include a heterogeneous group of disorders in which an increased risk

appears to exist for developing thromboembolic complications. The pathophysiologic basis for the thrombophilic state in most of these situations is complex. Various clinical conditions are associated with a high risk of thrombotic complications (Table 9). As with the hereditary thrombophilias, acquired disorders vary widely in their tendency to cause venous and arterial thrombotic disease (Table 3). Acquired defects leading to thrombosis are at least as common as inherited deficiencies and often precipitate the acute thrombotic episode in the patient with an inherited thrombophilia.²

Acquired Fibrinolytic Defects

Early studies of fibrinolytic function in patients with thromboembolic disease consistently demonstrated that 30–40% of these patients had an impaired fibrinolytic function.⁷⁸ Decreased fibrinolysis has been linked to many acquired conditions including postsurgery, coronary disease, taking OCs, the last trimester of pregnancy, certain infections, aging, ra-

diation therapy, some drugs, and malignancy.⁷⁹ Increased plasma PAI-1 level is the most common reason for an impaired fibrinolytic function although this increase is often combined with a decreased capacity to release tPA.⁷⁸ Many patients with DVT have a history of a long-lasting inflammatory response, which contributes to an impaired fibrinolytic function by elevating the PAI-1 levels (an acute phase reactant). An increased PAI-1 level in plasma can predict the development of a new thrombotic event (postoperatively, in myocardial infarction, and idiopathic DVT).⁷⁸

**Antiphospholipid (aPL) Antibodies/
Antiphospholipid Antibody Syndrome**

Antiphospholipid antibody syndrome (aPLS) has multiple clinical manifestations and is the most common cause of acquired thrombophilia.²⁰ aPL include a broad group of autoantibodies that includes the lupus anticoagulant (LA), anticardiolipin antibodies (ACLA), and several subgroups (antibodies that recognize other phospholipids and phospholipid-binding proteins).⁸⁰ These antibodies prolong phospholipid-dependent clotting assays in vitro.²³

Phospholipid-reactive antibodies (aPL) were first described in patients with biologic false-positive serologic tests for syphilis and were shown to recognize cardiolipin within the test reagent (i.e., ACLA).⁸¹ The same year, aPL were identified in patients with systemic lupus erythematosus (SLE), subsequently named LA.⁸² Other antibodies that reacted with anionic phospholipids other than cardiolipin (e.g., antiphosphatidylserine) were later identified. Before 1990, it was thought that aPL antibodies recognized epitopes within the anionic phospholipids, but it was subsequently demonstrated that many of them recognize proteins (cofactors or antigenic targets) in complex with the phospholipids.⁸⁰ These include antibodies recognizing β_2 -glycoprotein-1 (β_2 GP1), prothrombin, PC, PS, and F-VII. These aPL antibodies can be produced after certain infections (mycobacteria, malaria, and other parasitic organisms), after exposure to certain medications (neuroleptics, chlorpromazine, quinidine, procainamide), and by patients with autoimmune disorders (SLE, Sjögren syndrome, rheumatoid arthritis, immune thrombocytopenic purpura ITP).

Pathophysiology Paradoxically, although these antibodies prolong in vitro coagulation assays (suggestive of defective hemostasis), individuals with aPL antibodies do not suffer from a bleeding diathesis unless other hemostatic defects are present (e.g., thrombocytopenia, hypoprothrombinemia). Rather, the presence of aPL increases the apparent risk of both arterial and venous TE with approximately one-third of patients with such inhibitors having thrombotic events.²⁵

The most commonly identified antiphospholipid antibodies, LA and ACLA, behave similarly, and 73% of patients with LA also have ACLA.⁸³ Immunologically, both LA and ACLA are usually IgG but can be IgM or a mixture of the two. The antibody combines with the phospholipid surfaces

TABLE 9

Secondary Disorders and Other Factors Contributing to Acquired Thrombosis

Secondary disorders

- Fibrinolytic system defects
- Antiphospholipid antibody syndrome
- Malignancy
- Hip, knee surgery
- Hematologic disorders
 - Polycythemia vera/myeloproliferative disorders
 - Hemolytic anemia
 - Sickle cell anemia
 - Paroxysmal nocturnal hemoglobinuria
 - Acute promyelocytic leukemia
- Chronic inflammatory disease
- Congestive heart failure
- Atrial fibrillation
- Nephrotic syndrome
- Atherosclerosis
- Hyperlipidemia, hypercholesterolemia, increased lipoprotein (a)

Other factors

- >50 years of age
- Obesity
- Diet with inadequate folate, vitamin B₆ or vitamin B₁₂; chronic intake of fatty food
- Smoking
- Pregnancy, use of OCs, hormone replacement therapy
- Stasis/immobilization (prolonged car or air travel; bed rest)
- Trauma/postoperative state

of test reagents used in the APTT (and occasionally the PT), prolonging the clotting times. Both LA and ACLA were originally thought to react only with phospholipid. Further studies of antibody specificity revealed, however, that ACLA requires β_2 -GPI to be associated with the phospholipid on the surface of the cells to which they bind,⁸³ and LA were directed against epitopes on prothrombin.

Various mechanisms have been proposed to explain the increased risk of thrombosis with aPL: inhibition of endothelial cell anticoagulant processes and causing cells in the blood (or in contact with the blood) to acquire a procoagulant phenotype.⁸⁰ Specific aPL-induced changes include interference with protein C activation or activity (decrease in thrombomodulin expression, decrease in free PS), inhibition of heparin sulfate interaction with AT, inhibition of endothelial cell production or release of prostacyclin, alterations in fibrinolytic mechanisms (decreased tPA and/or increased PAI-1). In addition, aPL can stimulate platelet aggregation and promote tissue factor synthesis by leukocytes.⁸⁴

Clinical Findings The clinical manifestations that are most frequent in these patients include systemic vascular thrombosis (DVT, PE), thrombosis at unusual sites, increased risk of arterial thrombosis (stroke and other neurological complications), and increased risk of adverse pregnancy outcomes (recurrent miscarriages). It is estimated that 5–15% of patients with VTE are positive for LA (aPL) in comparison to 0–2% of the general population.⁸⁴ *Secondary aPL syndrome* is a term used to describe when aPL and thrombosis occur in conjunction with an autoimmune condition such as SLE. When aPL occurs as an independent autoimmune disorder, it is referred to as *primary aPL syndrome*.

Laboratory Evaluation No single test identifies every LA/aPL; instead, a combination of tests must be performed. Two types of assays are used to detect aPL antibodies: “LA” are detected by their ability to prolong phospholipid-dependent coagulation reactions, and specific immunoassays, usually ELISA, are used to detect antibodies reactive with cardiolipin, phosphatidylserine, β_2 GP1, prothrombin, or F-VII. The sensitivity of the APTT reagent for LA detection varies with different commercial reagents used for the test. Some commercial APTT reagents have been created to be very sensitive to the presence of LA.

The Subcommittee on Lupus Anticoagulant/Antiphospholipid Antibodies of the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis has proposed criteria to standardize the diagnosis of LA. Diagnosis requires a four-step approach:

1. prolongation of a phospholipid-dependent coagulation assay (usually the APTT)

2. evidence of inhibitor activity in the patient plasma
3. evidence of the phospholipid-dependence of the inhibitor effect
4. absence of a specific inhibitor against a coagulation factor.

A sequence of suggested tests for evaluating a patient’s plasma for the presence of LA is outlined in Table 10.⁸⁵

The first step in identifying LA is that at least one laboratory test that uses phospholipid in the reagent (e.g., the APTT) must be prolonged. This prolonged test must then be repeated on a 1:1 mixture of patient’s plasma and normal plasma (NP) to distinguish between an inhibitor and a single-factor deficiency (see mixing studies). In the presence of an LA inhibitor, no correction will be noted (the LA usually prolongs the clotting time of the NP immediately after mixing in contrast to inhibitors specific for coagulation factors, which usually require incubation). A specific factor deficiency can also be ruled out by factor assays, if needed.

The possibility that the presence of heparin causes the prolonged APTT must also be eliminated. Heparin can be identified by observing a prolonged thrombin time and a normal reptilase time. At least one additional abnormal screening test for the LA must be demonstrated.

A confirmatory test is then performed to establish that the antibody/inhibitor is phospholipid dependent. Confirmatory tests are modifications of the screening tests (that were originally abnormal) that alter the amount of phospholipid in the test system. The modifications usually involve ei-

TABLE 10

Recommended Approach for Identifying the Lupus Anticoagulant (LA)⁸⁵

Screening procedures—two or more using single concentration of phospholipid

1. Demonstrate at least one prolonged phospholipid-based clotting test (e.g., APTT).
2. Demonstrate at least one additional prolonged LA screening test (e.g., dilute Russell’s viper venom time [dRVVT], plasma clot time [PCT], kaolin clotting time [KCT])

Confirmatory procedures—modify abnormal screening procedure by altering phospholipid content of the test procedure, which demonstrates that the LA depends on phospholipid

1. Reducing phospholipid concentration in test reagent to accentuate prolonged test (e.g., diluting the test reagent)
2. Neutralizing the effect of the LA by increasing the phospholipid in the test system (e.g., frozen-thawed platelets [platelet neutralization procedure]; platelet vesicles hexagonal phase phospholipid)

Additional requirements for documenting LA

1. Mixing studies with normal platelet free plasma not corrected
2. Exclusion of presence of heparin in the sample (e.g., normal thrombin time/reptilase time)
3. Proof that another coagulopathy is not present or concurrent; specific factor assays to rule out a factor deficiency; detailed clinical history

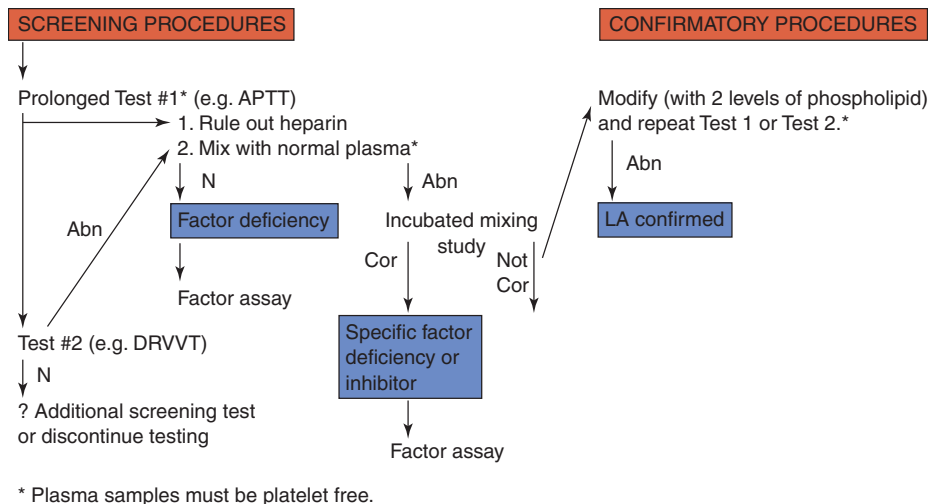

ther reducing the amount of phospholipid in the reagent or adding an excess of phospholipid to the test system. The most sensitive tests for detecting the inhibitor contain only limited amounts of procoagulant phospholipids (dRVVT, dilute PTT, or perform PT with very dilute tissue factor—the tissue thromboplastin inhibition [TTI] test). When excess phospholipid is added to the test system, there is an overabundance of phospholipid, the antibody is overwhelmed, and the original prolonged test time is shortened to the normal range. The *platelet neutralization procedure* is a popular confirmatory test. This test adds washed, frozen, and thawed platelets, an abundant source of phospholipid, to the patient's plasma; the prolonged screening test is corrected. A better confirmatory test is the *hexagonal phase phospholipid test* (Stacot LA by Diagnostica Stago). The LA can recognize phosphatidylethanolamine in the hexagonal phase array configuration (hexagonal H₁₁) but not in the lamellar phase. Adding H₁₁ phase phosphatidyl ethanolamine to an LA patient specimen will correct the prolonged APTT by absorbing the LA antibodies. Unlike the platelet neutralization procedure, the hexagonal phospholipid test does not give false positives with heparin. Figure 4 ■ outlines a flow chart for an approach to the laboratory testing for LA.

Therapy Management of acute VTE in patients with aPLS is similar to that of other individuals with thrombosis. However, the APTT cannot reliably be used to monitor unfractionated heparin dosage without modifications (e.g., the use

of an insensitive APTT reagent or the activated coagulation time/ACT test).²⁵ Low-dose heparin circumvents this problem because it does not require laboratory monitoring (see later section). Patients who develop transient LA/aPL in association with infections do not usually sustain TE episodes. The presence of a persistent LA and/or a high-titer antibody in an asymptomatic patient with no prior thrombotic history is not an indication for anticoagulant therapy unless there are coexisting clinical circumstances (surgery, prolonged immobilization). Corticosteroids can normalize clotting times or reduce aPL antibody titers but might not prevent recurrent thrombosis.¹⁸

Heparin-Induced Thrombocytopenia (HIT)

Heparin is used to prevent or treat thrombosis. However, its use can cause thrombocytopenia in some patients, generally associated with platelet activation. *Heparin associated thrombocytopenia* (HAT) in which the thrombocytopenia results from a direct, nonimmune mediated platelet activation, is not associated with an increased risk of thrombosis. **Heparin induced thrombocytopenia (HIT)**, is due to an autoantibody directed against heparin complexed with platelet factor 4 (PF4).⁸⁶ PF4 is released from platelet α-granules during platelet activation, nonspecifically binds to heparin in the circulation, and antibodies are produced to the heparin/PF-4 complex. The antibody/heparin/PF-4

■ **FIGURE 4** A flow chart for an approach to the diagnosis of the lupus anticoagulant (LA). At least two screening phospholipid-based screening tests (tests using one concentration of phospholipid) must be prolonged. Mixing studies must be uncorrected with normal plasma. The presence of heparin must be ruled out. Confirmatory tests are performed by modifying the abnormal screening tests with two levels of phospholipid. (Adapted from: Brandt JT, Triplett DA, Alving B, Scharrer I. Criteria for the diagnosis of lupus anticoagulants: An update. *Thromb Haemost.* 1995;74:1185–90.) (Cor = corrected; N = normal; Abn = abnormal; LA = lupus anticoagulant; APTT = activated partial thromboplastin time; dRVVT = dilute Russell’s viper venom time)

complex then attaches to the platelet surface via the platelet FcγIIa receptors, resulting in increased platelet clearance and thrombocytopenia. The antibody heparin-PF4 complexes occasionally induce platelet activation and aggregation.

The most serious complication of HIT is activation of the clotting system and thrombosis, which can be life threatening. Isolated HIT refers to the patient with thrombocytopenia without thrombosis, whereas HITT is used to refer to patients with HIT and thrombotic complications. It is thought that a number of events contribute to the thrombotic complications including in vivo platelet activation, generation of procoagulant platelet-derived microparticles, and activation of endothelium via HIT antibody recognition of PF4/endothelial heparan sulfate complexes.⁸⁶ Thrombocytopenia develops in approximately 3% of patients who receive **unfractionated heparin (UFH)**, and thrombosis occurs in one-third of those.⁸⁷ The most common venous thrombotic complications are DVT and PE, and arterial thrombosis most commonly affects the lower limb (acute limb ischemia) or cerebral vessels (thrombotic stroke). Low molecular weight (LMW) heparin can trigger HIT but much less frequently than UFH.⁸⁸

HIT is suspected when a patient receiving heparin demonstrates a thrombocytopenia of $<150 \times 10^9/L$, or a 50% drop in platelet count from baseline. Typically, the onset is 5–14 days after starting any dose, any type, or any route of heparin exposure.⁸⁹ A more rapid fall (within hours) in platelet count occasionally occurs if the patient has been treated with heparin within the previous 100 days. Because heparin is generally used in patients who have experienced an acute thrombotic episode or who are at risk of one, other causes of thrombocytopenia must be excluded.

Two types of assays are available to diagnose HIT: functional and antigen assays.⁸⁶ Functional assays based on the ability of HIT-IgG to activate platelets are most commonly used. Either ¹⁴C-serotonin release or platelet aggregation are used as endpoints in these assays. ELISA assays for HIT-IgG have been developed using the heparin-PF4 target antigen. Most routine hospital laboratories do not offer assays for HIT, but they may be available through reference labs. The HIT antibodies usually remain detectable for only 4–6 weeks. Routine screening for HIT antibodies in patients who are receiving heparin is not recommended because many patients can form HIT antibodies without developing thrombocytopenia or experiencing other adverse events.⁸⁶

Patients receiving UFH should have their platelet counts monitored periodically during therapy, beginning on day 5 of heparin use. If the platelet count falls, heparin should be discontinued and another form of anticoagulant therapy begun (e.g., the heparinoid danaparoid or a direct thrombin inhibitor such as hirudin or argatroban). Although LMWH is a less frequent inducer of HIT, once the antibodies are formed, LMWH cannot be used because it also binds PF4 and the HIT antibody. Oral anticoagulants should not be started until adequate anticoagulation with these alternative agents

has been achieved and the platelet count has returned to the normal range.

Thrombohemorrhagic Disorders

Thrombotic microangiopathies (TMA) The term *thrombotic microangiopathies* has been used to describe clinical disorders characterized by the presence of a microangiopathic hemolytic anemia, thrombocytopenia and microvascular thrombotic lesions. **Disseminated intravascular coagulation (DIC)**, **thrombotic thrombocytopenic purpura (TTP)**, and **hemolytic uremic syndrome (HUS)** are TMA disorders. For a number of years, TTP and HUS were considered similar, perhaps overlapping, clinical conditions and were often included in a combined clinical classification of “TTP/HUS.” Both conditions are associated with primarily activation of platelets without activation of the coagulation cascade. Platelet aggregates form in the microvasculature and result in a thrombocytopenia. Typically, coagulation assays (PT, APTT, TT) are normal. It has recently been shown that the two disorders are distinct entities with different pathophysiologic causes, laboratory diagnostic approaches, and therapies (Table 11 .

Disseminated Intravascular Coagulation DIC is a syndrome associated with systemic rather than localized activation of coagulation. It is a condition in which the normal balance of hemostasis is altered, resulting in the uncontrolled and inappropriate formation and lysis of fibrin within the blood vessels. It can be triggered by numerous events and can manifest as either a thrombotic or a hemor-

rhetic hemostatic state. for the full discussion of the pathophysiology and laboratory evaluation of patients with DIC.

Thrombotic Thrombocytopenic Purpura Moschowitz first described TTP in his 1924 report of a 16-year-old female who presented with microangiopathic hemolytic anemia, petechiae, renal failure, and hemiparesis. At autopsy, she was found to have disseminated microvascular thrombi in the terminal arterioles and capillaries of the heart and kidney.⁹⁰ For years, TTP was defined by the “classic pentad” of (1) microangiopathic hemolytic anemia, (2) thrombocytopenia, (3) neurologic symptoms, (4) fever, and (5) renal dysfunction.⁹¹ Systemic platelet agglutination produces microvascular thrombosis with variable tissue ischemia and infarction. The thrombi are composed predominantly of platelets with little or no fibrin. The most commonly affected organs are the brain, heart, pancreas, and adrenals; although renal involvement occurs, it rarely progresses to acute renal insufficiency or renal failure.

TTP is now known to be triggered by the presence of ultralarge VWF multimers (ULVWF) in the plasma.^{92,93} VWF is secreted from the Weibel-Palade bodies of activated endothelial cells as ultralarge multimers, larger than the typical large VWF forms that normally circulate. These ultra-large multimers are cleaved by a VWF cleaving protease known as *ADAMTS-13* (a **d**isintegrinlike **a**nd **m**etalloprotease domain with **t**hrombospondin) type motifs. ADAMTS-13 binds to the surface of endothelial cells and cleaves ULVWF multimers as they are synthesized and released^{94,95} (Figure 5 ■). When ADAMTS-13 is significantly reduced or absent, the resulting ULVWF multimers adhere to platelets and induce platelet agglutination, resulting in disseminated platelet thrombi.⁹⁶

Familial or inherited TTP is known as the *Upshaw-Shulman Syndrome*.⁹³ It is a rare autosomal recessive disorder character-

ized by repeated episodes of TMA during childhood (chronic, relapsing TTP). It is due to a mutation of the ADAMTS-13 gene (9q34), resulting in a deficiency/dysfunction of the enzyme.⁹⁷ As a result, these patients have ULVWF in their plasma and a predisposition to forming platelet-rich microvascular thrombi. Treatment is plasma infusion to replace the missing enzyme as needed. Heterozygotes are clinically asymptomatic.

Acquired TTP is an acquired autoimmune deficiency of ADAMTS-13.⁹³ Also called *idiopathic TTP*, the disorder is more common in females than males (3:2 ratio). Other risk factors for idiopathic TTP are African ancestry and obesity. Of patients, 10–45% have a history of upper respiratory or flulike symptoms within weeks preceding diagnosis. Acquired TTP has also been associated with pregnancy, certain drugs, cancer/chemotherapy, and tissue transplantation. The autoantibodies against ADAMTS-13 block the activity of the VWF cleaving enzyme, producing TTP.⁹⁸ Mortality is >90% without treatment. Recommended treatment is plasma exchange (to remove the autoantibody and replacement with functional ADAMTS-13). Most patients (65%) have a single episode of TTP; ~35% have recurrent disease.

Laboratory testing for ADAMTS-13 can be done to confirm the suspected diagnosis, but plasma exchange treatment should begin immediately without waiting for results. Most hospitals rely on reference laboratories for ADAMTS-13 assays. Antibody or inhibitor activity against the protease is measured by a Bethesda-type methodology similar to that used to measure antibodies to F-VIII.

Hemolytic Uremic Syndrome HUS occurs in two forms, “typical” and “atypical.”⁹³ Typical HUS is associated with bloody diarrhea, fever, and infection by verotoxin-producing *E. coli* (VTEC). Also called *D+* *AMS* (diarrhea positive),

■ **FIGURE 5** VWF Processing by ADAMTS-13. **a.** Normal ADAMTS-13 proteolytically cleaves ultralarge von Willebrand factor (ULVWF) multimers into smaller subunits. **b.** In the absence of ADAMTS-13 activity, ULVWF multimers persist, inducing platelet agglutination and the formation of platelet thrombi. (Reprinted with permission from the American Society for Clinical Laboratory Science (ASCLS), Schneider M, Thrombotic Microangiopathy (TTP and HUS): Advances in Differentiation and Diagnosis, *Clin Lab Sci.* 2007;20(4):216.)

it accounts for 95% of all cases in children. *E. coli* O157:H7 accounts for most of the cases (80%), but other toxin-bearing *E. coli* serotypes, and *Shigella dysenteriae* type 1 have also been linked with HUS.⁹⁹

Thrombocytopenia and neurologic manifestations are less common and less severe in HUS than in TTP. However, renal involvement is more severe than in TTP. Of patients, 60% require renal dialysis, and 40–50% of patients develop chronic renal insufficiency. The pathogenesis of VTEC-HUS is thought to be toxin-induced endothelial damage, primarily in the renal glomeruli, resulting in microvascular thrombi consisting of platelets and fibrin.

Familial (inherited) HUS is a chronic, relapsing clinical condition characterized as a D- or atypical form of HUS.⁹³ It is usually associated with an inherited abnormality of the complement regulatory system with persistently low levels of complement. Identified abnormalities include homozygous deficiency of complement factor H, membrane cofactor protein (MCP) or factor I.^{99,100} However, 50% of the cases of familiar HUS remain unexplained at the molecular level.

Malignancy

The association between thrombosis and malignancy has been recognized for more than 100 years and for a variety of different cancers.²² TE disease affects 3–25% of cancer patients and is the second most common cause of death.¹⁰¹ The causes of thrombosis in cancer patients are complex. The three components that play a significant role in thrombogenesis (stasis, activation of blood coagulation, and vascular injury) are present in patients with malignant disease. Patients with cancer are often immobile and bedridden. Tumor cells release coagulation-activating factors including TF and cancer procoagulant protein (a cysteine-containing protease that directly activates F-X). Often malignancies are accompanied by a reduction of natural anticoagulants (AT and PC).²² Vascular injury can be triggered by surgery, chemotherapy drugs, and vascular access catheters. Chemotherapy appears to augment the risk for thrombosis. Patients with malignancy also have a higher rate of postoperative thrombotic complications than the general population.²⁵ In some instances, thrombosis manifests itself prior to the diagnosis of an underlying malignancy and predates the diagnosis by several years.²⁵

Pregnancy and Oral Contraceptives (OC)

Pregnancy is associated with an increased risk of VTE, and the puerperium (the 6-week period following delivery) is associated with a higher rate of thrombosis than pregnancy itself.²⁵ Risk factors for thrombosis in pregnancy include advanced maternal age, Cesarean delivery, prolonged immobilization, obesity, prior TE, and one of the inherited thrombophilias. Thrombosis during pregnancy and the puerperium is due to pregnancy-induced alterations in hemostasis as well as venous stasis in the lower extremities. The levels of most coagulation proteins increase during preg-

nancy (particularly fibrinogen and F-VIII), and there is a significant decline in AT, free and total PS, and fibrinolytic system activity (decreased tPA and increased PAI-1).²⁵ The net effect of these changes is to promote blood coagulation and may represent a mechanism to control bleeding at the time of placental separation.

Estrogen therapy and high-dose OC have been associated with increased venous and arterial thrombosis related to the estrogen dose.²⁵ The mechanisms by which OC induce a prothrombotic state are unclear. Its use is associated with changes in the levels of many coagulation proteins including increases of fibrinogen, F-VII, and F-VIII and decreases of AT and PS. Any individual with an inherited thrombophilia or increased thrombotic risk factors should be carefully evaluated before estrogen therapy is begun.

Postoperative State and Trauma

DVT and PE occur with increased frequency in postoperative patients, although the thrombotic risk varies depending on the type of surgery performed. Risk factors associated with increased rates of thrombosis include age (advanced), previous VTE, coexistence of malignancy, inherited thrombophilia, and extended surgical and immobilization times.²⁵ DVT and PE are also commonly encountered after major trauma. Proposed mechanisms for the activation of the coagulation system include exposure of tissue factor from injured tissue, elevated levels of fibrinogen and VWF, and decreased levels of AT and PC (associated with an acute inflammatory response).

Hematologic Disorders

Several hematologic disorders are associated with thrombosis. Patients with myeloproliferative disorders often experience a predisposition to thrombotic and hemorrhagic complications. Idiopathic myelofibrosis, essential thrombocythemia, and polycythemia vera all are associated with venous and arterial thrombotic events. The mechanisms involved are complex and include the association of vascular occlusive episodes with a high hematocrit and hyperviscosity as well as elevated platelet counts and platelet hyperactivity. Sick cell anemia can lead to thrombosis because of hyperviscosity secondary to sickled erythrocytes. Acute promyelocytic leukemia (APL) is often complicated by a profound coagulopathy due to enhanced procoagulant activity associated with the release of TF from the leukemic cells. Either diffuse or localized thrombosis can result. Interestingly, with the adoption of all-transretinoic acid as the treatment of choice for APL, patients appear to be more at risk of vascular occlusive disease (thrombosis) than diffuse coagulopathies (DIC).²⁵ In paroxysmal nocturnal hemoglobinuria (PNH), the chronic intravascular hemolysis is often associated with thrombotic crises. Membrane vesicles produced by complement-induced hemolysis of the erythrocytes pos-

sess prothrombinase-promoting activity and can induce thrombotic events at various vascular sites.²⁴

► **LABORATORY TESTING IN PATIENTS WITH SUSPECTED THROMBOSIS**

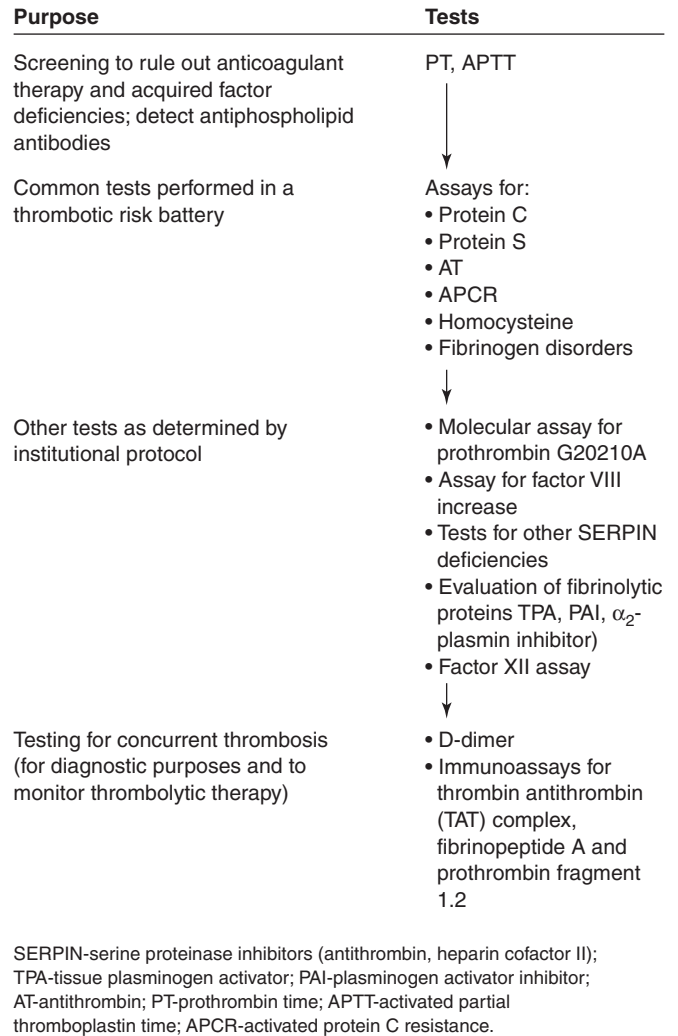

When patients are suspected of having an acute thrombotic process or a thrombotic diathesis, it is helpful to ascertain whether they are likely to have an inherited (primary) or an acquired (secondary) thrombophilia. Patients with hereditary defects are at lifelong risk of developing thrombosis, and clinical circumstances (e.g., pregnancy, estrogen use, surgery) can trigger thrombotic episodes in ~50% of such individuals.²⁵ Taking a complete history is essential including age of onset, location of prior thromboses, circumstances that could have precipitated the event, and particularly a family history of other affected individuals (suggesting a hereditary defect).

Samples for laboratory analysis should not be drawn during a thrombotic episode because the episode itself can affect many laboratory assays. Acute thrombosis is often associated with acquired deficiencies of AT, PC, or PS because these proteins are consumed during thrombosis. Any anticoagulant therapy should be noted because it can affect coagulation tests. Heparin therapy may be associated with up to a 30% decline in AT levels, and warfarin produces a marked drop in the functional activity of PC and PS and a decline to a lesser extent in immunologic levels. Warfarin has also been shown to (rarely) elevate AT levels significantly, sometimes into the normal range in patients with a hereditary deficiency.²⁵

Clinical guidelines for thrombotic risk assessment should be based on outcomes assessment. Many institutions have or are preparing testing protocols for effective diagnosis in patients with thrombophilia. The protocol described here varies depending on the patient population, laboratory resources, and other factors (Figure 6 ■).

Thrombosis risk testing should begin with screening tests (PT, APTT) to rule out anticoagulant therapy and acquired factor deficiencies and to detect antiphospholipid antibodies that interfere with interpretation of clot-based PS and APCR tests. Additional testing typically includes functional and antigenic (or molecular) measurements of the most common inherited defects: APCR/FVL, prothrombin 20210, MTHFR mutations, PC, PS, and AT. Additional testing for other deficiencies or defects can be performed even if the patient tests positive for one of these initial tests because patients with thrombophilia can have multiple defects.

The best screening tests for deficiencies of AT, PC, and PS are functional assays that detect both quantitative and qualitative defects. Immunologic (antigenic) assays detect only quantitative deficiencies of these proteins. To obtain a definitive diagnosis (differentiate type I and type II deficiencies), thrombotic

■ **FIGURE 6** Protocol for thrombotic risk testing. Testing begins with coagulation screening tests and proceeds according to the protocol established by the institution.

patients need to have both a functional and an antigenic test performed on the hemostatic component in question.

Many thrombotic disorders are difficult to diagnose because individuals can present with borderline laboratory values of a hemostatic component that is not clearly normal or abnormal; multiple testing may be needed. In addition to assays for particular hemostatic proteins associated with hereditary or acquired thrombophilias, assays are available to measure the extent of coagulation enzyme activation in the blood in vivo (e.g., fibrinopeptide A, prothrombin fragment 1.2, thrombin-AT complex, plasmin-antiplasmin complex). Although these assays do not give information regarding the specific *type* of hypercoagulable state that is present, they can provide information supporting the presence of increased activation of the coagulation system. Determining an episode's etiology is important because it suggests specific

and appropriate therapy. All risk factors or possible deficiencies need to be ascertained because they can interact and, in some cases, significantly increase the risk of thrombosis.¹⁰² Table 12★ lists some tests that may be useful in diagnosing thrombotic disorders.

✓ **Checkpoint! 3**

Why are both immunologic and functional assays recommended when screening a patient suspected of having a familial thrombophilic defect?

CASE STUDY (continued from earlier in this chapter)

Initial screening tests left the physician with no clear explanation for the thrombotic events. Several years later, when new tests became available, Andrea, her mother, and two sisters were tested for the factor V Leiden mutation and prothrombin mutation 20210. Results follow:

	Mother	Andrea	Sister 1	Sister 2
FVL mutation	N	Heterozygous	N	N
20210 mutation	Heterozygous	Heterozygous	Heterozygous	Heterozygous

3. Why is Andrea at greater risk for a thrombotic event than her mother or her two sisters?

▶ **ANTICOAGULANT THERAPY**

The main objective of anticoagulant therapy is to treat or prevent thrombosis. Arterial thrombosis is often caused by the interaction of platelets and vessel wall atherosclerotic plaques and can be treated with antiplatelet drugs. **Thrombolytic therapy** can be useful in treating an acute arterial thrombosis because rapid clot lysis and restoration of blood flow minimize permanent tissue damage. The role of anticoagulant therapy in the treatment of arterial thrombosis is controversial.

Venous thrombosis is often associated with abnormalities in the plasma coagulation system. An acute DVT has historically been treated with heparin for several days followed by oral anticoagulant therapy for 3–6 months. Recently, **low molecular weight heparin (LMWH)** has been found to produce the best results with the lowest risks of adverse complications for many patients with thrombosis.¹⁰²

HEPARIN

Heparin is a heterogeneous group of molecules of sulfated glycosaminoglycans that bind to AT, resulting in rapid inhibition of serine proteases of the coagulation pathway. When administered parenterally, intravenously, or subcutaneously (heparin is not absorbed by the gastrointestinal tract), it produces a potent anticoagulant effect. Heparin does not have a direct effect on blood coagulation but facilitates AT's ability to neutralize serine proteases.

Mechanism of Action

Heparin for therapeutic use is usually extracted from porcine intestinal mucosa or bovine lung. The standard (unfractionated) heparin preparations (UFH) are heterogeneous mixtures of molecules with a mean molecular weight of 12,000 Da (range 5,000–30,000 Da). LMWH preparations (mean molecular weight of 4,500–5,000 Da) are prepared from standard heparin by chemical or enzymatic depolymerization of UFH.

Whereas UFH catalyzes AT inhibition of thrombin, F-Xa and F-IXa, LMWH's major anticoagulant effect is to catalyze the interaction between AT and F-Xa. By inactivating thrombin, heparin prevents fibrin formation, inhibits thrombin-catalyzed activation of F-V and F-VIII, and inhibits thrombin activation of platelets.

The actions of two coagulation inhibitors are accelerated by heparin: AT and HC II. At therapeutic doses of heparin (0.2–0.4 U/mL), F-IXa, F-Xa, and thrombin are inhibited almost exclusively by AT (which has a greater affinity for heparin than does HC II). In the presence of higher concentrations of heparin (or in the presence of dermatan sulfate), thrombin is inhibited primarily by HC II.¹⁰³

Dosage Considerations

The dose of heparin required to produce a therapeutic effect varies from patient to patient because of differences in the plasma concentrations of various heparin-binding proteins (platelet factor 4, histidine-rich glycoprotein, fibronectin, VWF). These proteins bind to and neutralize heparin in the circulation. In some patients, larger doses than normal of heparin are required to achieve a therapeutic effect. The majority of these heparin-resistant patients have high levels of F-VIII and heparin-binding proteins (which are acute phase reactants) in their plasma. Patients with inherited AT deficiency (with AT levels of 40–60% of normal) respond normally to heparin therapy. However, individuals with acquired or inherited AT levels of <25% of normal can be resistant to the anticoagulant effects of heparin.

LMWH is being used with increasing frequency because of its convenience and more reliable pharmacokinetics.¹⁰³ The pharmacokinetic profile of UFH varies widely among individuals as a result of binding of heparin to plasma proteins. LMWH does not bind "heparin-binding proteins" in the plasma and thus has a more predictable dose-response profile, nor does it require routine laboratory monitoring. LMWH has a longer half-life and a more predictable anticoagulant effect and is less likely to cause heparin-induced thrombocytopenia and osteoporosis.

Laboratory Monitoring

Several different laboratory tests can be used to determine proper heparin dosage. Individuals' response to heparin varies, so there is no standard dose that provides protection from clotting while preventing adverse side effects. Therapy with standard heparin is usually monitored with a global test of coagulation, such as the activated clotting time (ACT) or the APTT. The PT is not sensitive to heparin and thus is not useful. Usually the heparin dose is adjusted so the APTT is 1.5–2.5 times the patient's baseline value before treatment.¹⁰⁴ Because the sensitivities of APTT reagents and instruments vary widely, each clinical laboratory should determine its own heparin therapeutic range.

LMWH does not produce a predictable prolongation of the APTT at therapeutic doses, so if laboratory monitoring is

required, an anti-Xa-based assay using an LMWH standard should be performed.

Complications

Heparin is an effective agent for treating and preventing VTE, but it can have adverse side effects. Excessive bleeding is the most common toxic effect of (high-dose) heparin therapy and has been reported in up to 30% of patients (although fatal bleeding occurred in <0.5% of patients).¹⁰³ HIT is suspected when the platelet count falls to $<150 \times 10^9/L$ (or platelet count decreases by 50% in patients with preexisting thrombocytopenia). HIT occurs in ~3 % of patients receiving standard heparin but occurs less frequently in patients receiving LMWH (see previous discussion of HIT). Osteoporosis, or bone loss, is sometimes seen with long-term (one month or more) standard heparin therapy. In contrast to warfarin, heparin does not cross the placenta and has not been associated with fetal malformations. Therefore, it is the anticoagulant of choice for prophylaxis and treatment of VTE during pregnancy. In cases of heparin overdose resulting in excessive anticoagulation or bleeding, protamine sulfate can be given to neutralize and reverse the anticoagulant effect of heparin.

In the event that a patient develops HIT or is resistant to heparin, alternate anticoagulants can be used. These include direct anti-Xa inhibitors (fondaparinux and idraparinux) and direct thrombin inhibitors not requiring heparin (argatroban, hirudin, and bivalirudin).¹⁰⁵

ORAL ANTICOAGULANTS

Oral anticoagulants have been used to treat acute DVT and PE since the 1940s. The coumadin drugs (either sodium warfarin or dicoumarol) are vitamin K antagonists that inhibit coagulation by interfering with vitamin K's action in the liver. Coumadin inhibits hepatic carboxylation of the vitamin K-dependent proteins, resulting in the release of non-functional (incompletely γ -carboxylated) molecules to the plasma. These proteins have reduced functional activity relative to their antigenic levels.

Mechanism of Action

Coumadin blocks the epoxide reductase enzyme that converts vitamin K epoxide back to the reduced form of vitamin K, which is the form required as a cofactor for the carboxylation reaction (Figure 3). The anticoagulant effect of coumadin depends on the reduced synthesis of biologically active vitamin K-dependent proteins and the normal clearance from the circulation of fully active proteins synthesized before the introduction of the drug. Coumadin inhibits γ -carboxylation of newly synthesized proteins but does not affect the plasma half-life of already circulating proteins. The anticoagulant effect of coumadin (the decrease in plasma activity of the vitamin K-dependent proteins) lags behind the point at which optimal plasma coumadin concentration is

reached. The disappearance of biologically active, fully γ -carboxylated factors is determined by the half-life of each. F-VII activity disappears most rapidly ($T_{1/2} \sim 6$ hours), F-X and F-IX follow ($T_{1/2} \sim 24$ hours), and prothrombin disappears at the slowest rate because of its longer half-life ($T_{1/2} \sim 72$ hours).¹⁰⁴ Thus, coumadin does not produce instantaneous anticoagulation but must be administered for 4–5 days before therapeutic anticoagulation is achieved. Coumadin is administered orally, is nearly completely absorbed, and circulates in the blood bound to albumin (97%). Only free coumadin is biologically active. Its plasma half-life is ~ 44 hours.

Dosage Considerations

Patients who have had a thrombotic incident are normally treated with heparin during the initial phase of anticoagulation because it produces an immediate anticoagulant effect. Because coumadin's full anticoagulant action is achieved only after 4–5 days, coumadin and heparin are given simultaneously during this time. Subsequently, when oral anticoagulation has been achieved, heparin can be discontinued. Coumadin is usually the therapy of choice for chronic anticoagulation to prevent the recurrence of thromboembolic disease. After the treatment of acute TE (DVT or PE), patients are routinely maintained on coumadin for 3–6 months.

Genetic factors can influence coumadin's anticoagulant effect.¹⁰⁵ Coumadin is a racemic mixture of two isomers, the R and S forms that are found in approximately equal proportions. However the S form is five times more potent, and the two forms are cleared by different pathways in the liver. Cytochrome P-450 is the hepatic enzyme responsible for the oxidative metabolism of the S-isomer of coumadin. Mutations of *CYP2C9*, the gene coding for cytochrome P-450, have been associated with hereditary resistance to coumadin resulting from enhanced affinity of the receptor for the drug and accelerated clearance.¹⁰⁵ Patients with genetic coumadin resistance require doses 5- to 20-fold higher than average to achieve an anticoagulant effect. Molecular testing can identify hereditary coumadin resistance.

Laboratory Monitoring

The PT is routinely used to monitor oral anticoagulation. The therapeutic coumadin dosage varies among individuals, and monitoring the anticoagulant effect can be difficult. A major problem has been a variation in the potency of thromboplastins used by different manufacturers. The patient's PT was usually reported as the clotting time in seconds and was compared with the PT of a normal plasma sample. The introduction of a reference standard for thromboplastins by the World Health Organization (ISI—International Sensitivity Index) and the use of the International Normalized Ratio (INR) have reduced the interlaboratory and interhospital variability in monitoring oral anticoagulants.

Complications

Bleeding complications are observed in 10–20% of patients treated with coumadin; about 50% of these complications occur when the therapeutic range of the PT has been exceeded, but 50% occur despite a PT within the therapeutic range. Although bleeding is usually mild, severe and life-threatening bleeding can occur. Thus, patients receiving oral anticoagulation must be carefully monitored. During the initiation of therapy, PT measurements can be required 2 or 3 times a week; once stabilized, patients generally require a PT every 3 or 4 weeks.¹⁰⁴ The antidote for coumadin overdose is administration of vitamin K. Coumadin crosses the placenta and has been associated with fetal abnormalities; therefore, its use is contraindicated during pregnancy.

THROMBOLYTIC THERAPY

Thrombolytic therapy is a clinical approach to TE disease with the goal of re-establishing vascular perfusion. All currently used thrombolytic agents are plasminogen activators (PA) used to lyse thrombi in vivo. Clinical trials assessing efficacy have been conducted for DVT, PE, peripheral arterial occlusion, acute myocardial infarction (MI), and acute ischemic stroke. The potential clinical benefit of thrombolytic treatment for acute thrombosis is in part determined by the time frame in which treatment should be initiated.¹⁰⁶ For MI or cerebral thromboses, treatment should be started within 4 and 3 hours, respectively, whereas treatment should be initiated for PE within 48 hours. Thrombolytic therapy for DVT maintains efficacy if treatment is initiated within 7 days.

Mechanism of Action

All of the PAs are capable of inducing plasmin lysis of fibrin within a thrombus and are accompanied by a variable degree of plasma fibrinogenolysis (the lytic state). Under normal physiologic conditions, plasminogen and PAs interact when bound to fibrin in the thrombus. Fibrin facilitates the conversion of plasminogen to plasmin because PAI-1 and α_2 -antiplasmin (AP) do not efficiently inhibit fibrin-bound PA and plasmin, respectively. Under physiologic conditions, systemic lysis of fibrinogen does not occur because tPA and plasmin are efficiently inhibited by PAI-1 and AP in the circulation. With administration of therapeutic dosages of PA, virtually all of the plasma plasminogen is converted to plasmin, overwhelming the neutralizing capacity of AP and leading to some degree of fibrinogenolysis.

Dosage Considerations

The Food and Drug Administration has approved six plasminogen activators: streptokinase/SK, urokinase/UK, alteplase/tPA, anistreplase, reteplase, and tenecteplase.¹⁰⁶ UK currently is not available in the United States, and anistreplase is rarely used. The major distinctions among the agents relate to their antigenicity, half-life, potential for inducing a lytic state, and hemorrhagic potential. Those PAs derived

from a human protein (UK, tPA, alteplase, tenecteplase, and reteplase) are essentially nonantigenic whereas those from a bacterial species can induce antibody formation. The agents' half-life varies from 5 minutes for tPA to 20 minutes for SK to 70 minutes for anistreplase. Several new PAs are in various stages of development or clinical trials. The continued search for new PA variants seeks to develop new agents with greater activity, a longer half-life, or a reduced lytic state.

Laboratory Monitoring

The *lytic state* is due to the systemic conversion of plasminogen to plasmin by circulating PA and the effects of plasmin on components of the circulating blood. Although a number of plasma proteins are involved, the identification of the lytic state is usually a demonstration of a decrease in plasma fibrinogen.¹⁰⁶ This increased degradation of fibrinogen is detected by a prolonged thrombin time test and increased fibrinogen degradation products (FDPs). Other plasma proteins including F-V and F-VIII are also degraded by plasmin. Other potential laboratory tests to monitor the lytic state include a shortened euglobulin lysis time, a quantitative decrease in circulating plasminogen and α_2 -antiplasmin, and the generation of plasmin-antiplasmin complexes (P-AP). Free circulating plasmin can be demonstrated using chromogenic assays. Free plasmin also affects platelet function by decreasing aggregation induced by various platelet agonists and by cleaving the platelet membrane receptor for VWF. The lytic state induces a hypocoagulable state due to a combination of decreased clottable fibrinogen and other procoagulant proteins, the generation of FDPs (which inhibit coagulability), and platelet hyporeactivity.¹⁰⁶

PA dosage regimens are standardized; thus, monitoring thrombolytic therapy is necessary only to document that a lytic state has indeed been achieved.¹⁰⁶ The thrombin time (TT) is sometimes used to monitor fibrinolytic therapy. A baseline TT should be determined and another performed at 3–4 hours after starting therapy. If a lytic state is induced, the TT should become prolonged due to the increased fibrin(ogen) degradation products and decreased fibrinogen level. FDP or D-dimer assays can be used to determine whether the thrombus is lysing.

Complications

The degradation of fibrin produces the beneficial effect of reducing the size of the thrombus (thrombolysis). However, a potential complicating effect can be the lysis of hemostatic plugs and resultant bleeding. Blood hypocoagulability can compound the bleeding tendency due to fibrinogenolysis and platelet dysfunction caused by the increased lytic state. The patient's response to PA therapy is inadequate if the thrombosed vessel does not manifest full reperfusion or if re-occlusion quickly follows initial success. Thus, adjunctive treatment with antithrombin and antiplatelet agents is often added to thrombolytic therapy to minimize early reocclusive events.

ANTIPLATELET THERAPY

Various antiplatelet agents are available to reduce or block platelet responsiveness and activation. As with anticoagulant therapy, antiplatelet therapy includes the use of both oral and intravenous agents. Laboratory monitoring generally is not necessary with antiplatelet agents except for the need to monitor platelet counts with some of the drugs that cause thrombocytopenia in a small number of patients.

Aspirin is probably the most common drug used as an antithrombotic/antiplatelet agent in managing arterial thrombosis. Although it has been used for more than a century as an analgesic and antipyretic, it has been used as an antithrombotic only since the 1950s.¹⁰⁰ Aspirin blocks prostaglandin synthesis (TXA₂) in platelets by permanently and irreversibly inhibiting cyclooxygenase (COX-1 enzyme) in them. Aspirin accomplishes this by acetylating serine 520 in human platelet COX-1, blocking the enzyme's ability to interact with its substrate arachidonic acid. As little as a single "baby aspirin" (~30 mg) per day is used as prophylaxis for stroke (far below the dosage used for pain and fever).¹⁰¹ The unique sensitivity of platelets to aspirin's therapeutic effect is due to the fact that platelets are cytoplasmic fragments from megakaryocytes and lack a nucleus. As a result, the platelet cannot replace its aspirin-acetylated, permanently inhibited COX-1 by synthesis of new proteins and continues to circulate for the rest of its life span in an inactive/inactivatable state (~9–10 days). In spite of the fact that aspirin also inhibits COX-1 in endothelial cells, blocking PGI₂ (platelet inhibitor) production, it has a net antithrombotic effect because these nucleated cells simply synthesize new COX-1 to replace the aspirin-inhibited enzyme. Patients taking aspirin do not have a severe bleeding diathesis, and aspirin exerts only a modest effect on platelet function and bleeding times. The PG-TXA₂ pathway augments platelet aggregation to weak agonists but is not needed for platelet responsiveness to strong agonists such as ADP or thrombin.¹⁰⁷

The nonsteroidal anti-inflammatory drugs (NSAIDs) excluding aspirin are competitive inhibitors of COX-1 (and COX-2) rather than irreversible inhibitors. Because their actions block enzyme function transiently, they are not generally used as antithrombotic agents alone but sometimes in conjunction with aspirin. NSAIDs include ibuprofen, fluriprofen, and sulfinpyrazone. However, because they do have an antiplatelet effect although transient, surgeons recommend that patients not take these drugs for 7–10 days prior to surgery (as with aspirin). Acetaminophen does not affect platelet function.

ADP receptor antagonists—ticlopidine and clopidogrel—are drugs that block a different platelet activation pathway than do aspirin and other NSAIDs. They modify the ADP receptor, blocking platelet P2Y₁₂ receptor activity.¹⁰⁷ Both drugs have been linked to causing TTP in a small number of patients. Ticlopidine is also associated with neutropenia and marrow suppression in a small number of patients (1–2%),

which clopidogrel does not. Clopidogrel also has a lower incidence of TTP and thus is generally the ADP receptor-antagonist drug of choice for most patients.

Dipyridamole inhibits phosphodiesterase, resulting in increased cAMP levels and inhibition of platelet activation. It has been used in patients for decades but has limited antithrombotic effectiveness when used alone. It is often combined with aspirin to improve effectiveness.

Intravenous antiplatelet agents include inhibitors of GP IIb/IIIa. The GPIIb/IIIa platelet membrane receptor interacts with fibrinogen and VWF during platelet activation and aggregation. In contrast to the previously discussed drugs, which block only one of multiple platelet activation pathways, the blockade of GPIIb/IIIa almost completely eliminates platelet function if given in sufficient dosages. *Abciximab (ReoPro)* has been used for a number of years although its use requires the platelet count to be monitored because it causes thrombocytopenia in 1–2% of treated patients. *Eptifibatide (Integrilin)* has also been used and is generally not associated with thrombocytopenia.

✓ Checkpoint! 4

Why should heparin therapy overlap initiation of oral anticoagulant therapy when treating a patient with an acute thrombosis?

SUMMARY

The human hemostatic system normally maintains a balance between procoagulant or thrombogenic factors and anticoagulant or fibrinolytic activity. If this delicate balance is disturbed, the result can be excessive bleeding or unwanted clotting. Arterial and/or venous thrombosis occurs when activation of blood coagulation exceeds the ability of the natural protective mechanisms (anticoagulants/inhibitors and the fibrinolytic system) to prevent or minimize fibrin formation. Clinical risk factors that predispose an individual to either arterial or venous thrombosis have been identified. *Thrombo-*

philia refers to any disorder (inherited or acquired) with an increased tendency to venous thromboembolism. Familial thrombophilia generally results from three broad categories of hemostatic abnormalities: (1) accelerated fibrin formation (increased procoagulant activity or diminished natural inhibitor activity), (2) defective fibrinolysis (reduced profibrinolytic factors or increased fibrinolytic inhibitors), or (3) abnormal fibrin (dysfibrinogenemias). An inherited thrombophilic defect places an individual at risk for but does not inevitably lead to thrombosis. Thrombosis occurs in susceptible patients who have one or more genetic mutations when they are exposed to exogenous prothrombotic stimuli. The five most common and most clearly delineated hereditary abnormalities associated with thrombophilia are Factor V Leiden, prothrombin 20210, and decreased or defective antithrombin, PC, and PS.

Patients with a documented thrombotic event need to be carefully evaluated including a complete personal and family history. Any additional risk factors for thrombosis present at the time of the incident (e.g., surgery, pregnancy, stasis) should be assessed. If a positive family history exists, the thrombosis was spontaneous, or multiple thrombotic incidences occurred, a full diagnostic workup should be undertaken to ascertain, if possible, the etiology of the thrombotic event. The evaluation of many of the components that regulate hemostasis (procoagulant proteins, inhibitory proteins, and fibrinolytic regulators) requires both functional (activity) and quantitative (immunologic) assays because both qualitative and quantitative defects of these proteins occur. Definitive diagnosis of some inherited thrombophilic disorders requires molecular analysis of the inherited gene product. The presence of multiple inherited or acquired thrombophilic factors significantly increases the risk for thrombosis. Patients experiencing an acute thrombotic event can be treated with a thrombolytic agent (plasminogen activators), heparin or LMW heparin, or oral anticoagulants. Long-term anticoagulation usually utilizes oral anticoagulants. Antiplatelet therapy can be used to manage arterial thrombosis. These agents block platelet responsiveness and activation. The most common antiplatelet prophylaxis is aspirin. Individuals with inherited thrombophilia usually do not require prophylactic therapy unless an additional prothrombotic clinical risk factor exists (prolonged immobility, surgery, pregnancy, etc.).

REVIEW QUESTIONS

LEVEL I

1. A platelet fibrin mass that forms within a vessel is known as a(n): (Objective 1)
 - a. thrombus
 - b. embolism
 - c. platelet plug
 - d. clot
2. Rupture of plaque in an artery may result in: (Objective 4)
 - a. formation of a white thrombi
 - b. formation of a red thrombi
 - c. hyperhomocysteinemia
 - d. decreased fibrinolysis

LEVEL II

1. Which of the following clinical manifestations is more likely to be found in a person with an inherited thrombophilia than in a person with an acquired thrombophilia? (Objectives 2, 9)
 - a. venous embolism at a young age
 - b. absence of a family history of thrombosis
 - c. presence of a pulmonary embolism
 - d. myocardial infarction in a 50-year-old

REVIEW QUESTIONS (continued)

LEVEL I

3. A patient is diagnosed with DVT. Four days later, a thrombus is found in his lung. This is an example of: (Objectives 3, 5)
 - a. a white thrombi
 - b. local thrombosis
 - c. a thromboembolus
 - d. DIC
4. What type of laboratory test results for AT will a patient with a type I deficiency of AT have? (Objective 8)
 - a. decreased antigenic and normal functional activity
 - b. normal antigenic and normal functional activity
 - c. normal antigenic and decreased functional activity
 - d. decreased antigenic and decreased functional activity
5. An inherited abnormality in the factor V molecule that renders it resistant to inactivation by protein C is known as: (Objective 9)
 - a. AT deficiency
 - b. APCR
 - c. DIC
 - d. prothrombin G20210A
6. A deficiency or defect in protein C can lead to thrombosis due to: (Objective 7)
 - a. inability to inactivate protein S
 - b. increased platelet activation
 - c. inability to neutralize thrombin
 - d. inability to inactivate factors Va and VIIIa
7. Patients who receive unfractionated heparin as treatment for a thrombus should be monitored periodically for the complication of HIT. What laboratory test should be used to monitor the patient? (Objective 10)
 - a. APTT
 - b. PT
 - c. thrombin time
 - d. platelet count
8. Therapy with low molecular weight heparin is best monitored using what laboratory test? (Objectives 10, 11)
 - a. PT
 - b. APTT
 - c. factor Xa assay
 - d. platelet count
9. The best test to monitor coumadin therapy is the: (Objective 12)
 - a. PT
 - b. APTT
 - c. factor Xa assay
 - d. platelet count

LEVEL II

2. A patient with thrombophilia has a decreased functional and antigenic activity of protein C. What is the diagnosis? (Objective 3)
 - a. APCR
 - b. protein S deficiency
 - c. type I PC deficiency
 - d. type II PC deficiency
3. Why is following up an abnormal clotting assay for APCR with a molecular test recommended? (Objective 5)
 - a. the clotting test is not sensitive or specific for APCR
 - b. 10% of individuals with APCR do not have the FVL mutation
 - c. the clotting test cannot be used for 6 months after a thrombotic episode
 - d. the molecular test is inexpensive and more accurate
4. Why does a patient with a thrombotic incident receive both heparin and coumadin for 4–5 days after the incident? (Objective 10)
 - a. Heparin is not effective as an anticoagulant without coumadin present.
 - b. Coumadin requires heparin for its full anticoagulant effect.
 - c. This gives the patient an initial bolus dose of anticoagulant.
 - d. Coumadin takes this long to produce its full anticoagulant action.
5. The value of using the INR to report the PT is: (Objective 11)
 - a. It reduces interlaboratory variability in monitoring oral anticoagulants.
 - b. It can be used to monitor both heparin and coumadin therapy.
 - c. Patients on coumadin therapy do not need to be tested as often.
 - d. Patients' coumadin dosage does not need to be adjusted as frequently.
6. A patient with a myocardial infarction is admitted to the ER. The physician starts the patient on streptokinase. She calls the laboratory and wants you to suggest a test to ensure that a lytic state is induced by the therapy. What test will you suggest? (Objective 12)
 - a. a baseline TT and TT after 3–4 hours of therapy
 - b. fibrinogen, plasminogen, and plasmin assays
 - c. a PT, APTT, and platelet count
 - d. none because no available tests give this information

REVIEW QUESTIONS (continued)

LEVEL I

10. What physiologic protein's anticoagulant effect is accelerated by heparin? (Objective 6)
- AT
 - protein C
 - protein S
 - lupus anticoagulant

LEVEL II

7. A patient has hyperhomocysteinemia. What laboratory test(s) can be helpful in establishing the etiology of his disease? (Objective 6)
- APCR clotting assay
 - AT and PS antigenic assays
 - molecular tests for MTHFR and CBS
 - molecular test for prothrombin G20210
8. Which of the following conditions is *not* associated with an increased tendency for thrombosis? (Objective 9)
- antiphospholipid antibody syndrome
 - pregnancy
 - malignancy
 - factor VIII deficiency
9. A 30-year-old patient is diagnosed with DVT. This is his third episode of DVTs. He is currently hospitalized and receiving heparin therapy. The physician orders a thrombotic risk battery of tests. What is the most appropriate action that the laboratory should take? (Objective 1)
- call the physician and explain that testing will not be accurate during anticoagulant therapy and during the thrombotic episode
 - perform the battery of tests in the thrombotic risk profile but note that results are not reliable
 - perform a PT and an APTT and, if prolonged, refuse to do the testing
 - call the physician and explain that this patient is not a candidate for thrombotic risk testing
10. A patient is on coumadin for treatment of DVT. He returns to the doctor with skin necrosis. What protein deficiency should be tested for after coumadin therapy is finished? (Objective 4)
- AT
 - PC
 - HC-II
 - TPAI

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Andrea is a 37-year-old female who was diagnosed with deep vein thrombosis of the leg. She is dehydrated. She is on oral contraceptives and coumadin. Her family history revealed that paternal uncles and maternal cousins had thrombotic episodes. Testing for AT, PC, PS, fibrinogen, D-dimer, and plasminogen was done during the DVT episode and again 6 months after she was off coumadin. All tests were within the reference range. Several years later, she was tested and found to be heterozygous for both F-V_{Leiden} and prothrombin G20210.

Question:

1. What risk factors, if any, are revealed in the patient's history?

Explanation:

This patient had several risk factors for thrombosis including dehydration and oral contraceptives. There is also a strong family history of thrombosis, suggesting a hereditary component in the etiology of her acute thrombotic event.

Question:

2. What other possibilities could explain the thrombotic event in this patient?

Explanation:

She was initially tested twice because testing during an acute thrombotic episode or while on coumadin is not as informative as testing after the episode has resolved or when the patient is no longer taking anticoagulants. Unfortunately, based on the available tests, neither set of tests helped establish a diagnosis. Additional causes of hereditary thrombophilia could include activated protein C resistance; prothrombin mutation 20210; hyperhomocysteine; deficiencies of heparin cofactor II, TFPI, t-PA, or F-XII; and elevated fibrinogen, F-VIII, or PAI-1.

Question:

3. Why is Andrea at higher risk for a thrombotic event than her mother or her two sisters?

Explanation:

Specific molecular assays of the family were subsequently done, and they revealed both the V_{Leiden} and prothrombin 20210 mutations. The fact that both these mutations were found in the same family probably accounts for the strong family history. The patient had inherited two different genetic mutations, both of which carry an increased risk of

thrombosis. In addition, she had several other clinical risk factors, probably contributing to her thrombotic event. Because the mother and sisters had a single genetic mutation, their risk of thrombosis was probably less than that of Andrea. The patient was taken off oral contraceptives and put back on coumadin.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Why would defects of fibrinolysis result in hypercoagulability?

Answer

Under normal conditions, hemostasis depends on a delicate balance between clot-promoting factors (procoagulant influences) and clot-inhibiting factors (anticoagulants and fibrinolysis). Defects in fibrinolysis result in hypercoagulability because the delicate balance has been disturbed, and the clot-promoting factors dominate the clinical picture.

Checkpoint! 2

Why is thrombotic disease associated with hereditary thrombophilia considered a multigene (or multirisk factor) disease?

Answer

Individuals who have inherited a thrombophilia gene generally do not experience thrombotic episodes unless they have a second genetic or acquired predisposing factor. Thus, many individuals who carry thrombophilia genes do not have acute thrombotic events and may be diagnosed only when family screening is done for another family member who has had a thrombosis.

Checkpoint! 3

Why are both immunologic and functional assays recommended when screening a patient suspected of having a familial thrombophilic defect?

Answer

Inherited defects of the hemostatic proteins involved in familial thrombophilia can be either quantitative or qualitative. Immunologic

assays for total protein will fail to diagnose qualitative defects (dysfunctional proteins), which typically give normal antigen levels but reduced functional levels. Functional assays are generally considered the better screening assay if a familial thrombophilia is suspected.

Checkpoint! 4

Why should heparin therapy overlap initiation of oral anticoagulant therapy when treating a patient with an acute thrombosis?

Answer

Oral anticoagulants (vitamin-K antagonists) decrease functional levels of procoagulant proteins F-II, F-VII, F-IX, and F-X, as well as the anticoagulant proteins PC and PS. However, this action is not immediate (as is the anticoagulant effect of heparin), and the decrease in activity of each of these proteins varies, depending on the half-life of each in the circulation. Because PC has a relatively short half-life, clearance of biologically active molecules (presynthesized before oral anticoagulants were begun) occurs more quickly for PC than for the procoagulant protein factors F-II, F-IX, and F-X. Thus, for the first few days after initiating coumadin therapy, there is an imbalance between clot-inhibiting influences (PC) and clot-promoting influences (F-II, F-VII, and F-X). The net effect is a period of hypercoagulability before the full anticoagulant effect of coumadin is realized. For a patient who already has a hemostatic system that is presumably not in balance, this could further aggravate it. Thus, heparin anticoagulant therapy should be continued through the first 4–5 days of oral anticoagulant therapy until the full effect of coumadin is achieved.

Hematology Procedures

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Overview
- ▶ Sample collection: Phlebotomy
- ▶ Microscopy: The microscope

Part I Routine Hematology Procedures

- ▶ Peripheral blood smear preparation
- ▶ Peripheral blood smear staining
- ▶ Peripheral blood smear examination
- ▶ Cell enumeration by hemacytometer
- ▶ Hemoglobin concentration
- ▶ Hematocrit
- ▶ Erythrocyte indices
- ▶ Erythrocyte sedimentation rate
- ▶ Reticulocyte count
- ▶ Solubility test for hemoglobin S

Part II Reflex Hematology Procedures

- ▶ Hemoglobin electrophoresis using cellulose acetate
- ▶ Quantitation of hemoglobin A₂
- ▶ Acid elution for hemoglobin F
- ▶ Quantitation of hemoglobin F
- ▶ Heat denaturation test for unstable hemoglobin
- ▶ Heinz body stain
- ▶ Osmotic fragility test
- ▶ Sugar-water screening test
- ▶ Donath-Landsteiner test for PCH
- ▶ Erythropoietin
- ▶ Soluble transferrin receptor
- ▶ Cytochemical stains
- ▶ Summary
- ▶ Review questions
- ▶ References

Hematology Procedures

Cheryl Burns, M.S.
Aamir Ehsan, M.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Identify the three anticoagulants used in the hematology laboratory and give examples of laboratory tests that should be performed on blood anticoagulated with each.
2. Explain the mechanism of preventing coagulation for each anticoagulant.
3. Identify equipment and supplies required for phlebotomy.
4. Describe Occupational Safety and Health Administration (OSHA) standards related to phlebotomy.
5. List factors affecting the collection of a blood sample.
6. Determine sequence of draw of phlebotomy collection tubes and correlate the collection technique of a blood sample with potential problems in sample analysis.
7. Describe proper disposal of contaminated equipment and supplies.
8. Identify the component parts of a microscope and explain their functions.
9. Discuss the microscope's preventative maintenance procedures.
10. Describe the peripheral blood smear preparation methods.
11. Identify the characteristics of an optimally prepared peripheral blood smear.
12. Describe the Romanowsky-staining technique.
13. Recognize characteristics of a properly stained peripheral blood smear.
14. Discuss potential causes of improperly stained peripheral blood smears.
15. List the components included in a complete peripheral blood smear examination.
16. Correlate erythrocyte indices, leukocyte count, and platelet count with peripheral blood smear observations.
17. Determine the corrected leukocyte count based on the presence of nucleated erythrocytes.
18. State the principle of each test: cell enumeration by hemacytometer, hemoglobin concentration, hematocrit, erythrocyte sedimentation rate, reticulocyte count, solubility test for hemoglobin S, hemoglobin electrophoresis, acid elution for hemoglobin F, osmotic fragility.
19. For each test listed in Objective 18, describe the procedure, identify potential sources of error, determine appropriateness of use including reflex testing, calculate and interpret results, and explain the clinical significance of the test.
20. Calculate the erythrocyte indices.
21. Correlate erythrocyte indices with CBC data and peripheral blood smear examination.
22. Calculate the reticulocyte count.
23. Identify reference ranges for each test in terms of gender and age.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Describe factors that influence brightfield microscopy.
2. Explain the principle of phase contrast microscopy.
3. Choose corrective actions for an improperly prepared or stained peripheral blood smear.
4. Detect abnormalities on peripheral blood smear examination, assess how they can alter cell count results (i.e., presence of nucleated erythrocytes or platelet satellitism), and recommend corrective action to ensure valid results.
5. State the principle of each of the following tests: quantitation of hemoglobin F and hemoglobin A₂, heat denaturation test for unstable hemoglobin, Heinz body stain, sugar-water screening test, Donath-Landsteiner test for PCH, erythropoietin assay, soluble transferrin receptor, and cytochemical stains (e.g., myeloperoxidase).
6. For each test listed in Objective 5, describe the procedure, identify potential sources of error, determine appropriateness of use including reflex testing, interpret results, and explain the clinical significance of the test.
7. For each test discussed in this chapter, correlate abnormal values with clinical conditions.
8. Select the cytochemical stain appropriate for confirming cell lineage and diagnosis in hematopoietic neoplasms.

KEY TERMS

- | | |
|---|--|
| Acute phase reactant | Multiple myeloma |
| Anticoagulant | Optimal counting area |
| Anemia | Platelet clump |
| Beer-Lambert's law | Platelet satellitism |
| Biphasic antibody | Polycythemia |
| Cold agglutinin disease | Reference interval |
| Column chromatography | Refractive index |
| Coverglass smear | Romanowsky-type stain |
| Densitometer | Rouleaux |
| Edematous | Rule of three |
| Hemoconcentration | Smudge cell |
| Isoelectric focusing | Supernatant |
| Isopropanol precipitation | Supravital stain |
| Leukocyte alkaline phosphatase (LAP) | Tartrate-resistant acid phosphatase (TRAP) |
| Mean cell hemoglobin (MCH) | Unique identification number |
| Mean cell hemoglobin concentration (MCHC) | Wedge smear |
| Mean cell volume (MCV) | |

BACKGROUND BASICS

The information in this chapter builds on concepts learned in other chapters. To maximize your learning experience, you should review and thoroughly understand these concepts before starting this unit of study.

Level I

- ▶ Describe normal leukopoiesis.
- ▶ Describe normal erythropoiesis.
- ▶ Summarize the basics of hemoglobin synthesis and structure.
- ▶ Outline the classification systems for the anemias.

Level II

- ▶ Describe potential causes for changes in leukocyte concentrations.
- ▶ Describe potential causes for decreased erythrocyte concentrations.
- ▶ Recognize the erythrocytic morphologic changes associated with size, shape, inclusions, and patterns of distribution.
- ▶ Recognize neutrophil and monocyte morphology and the reactive changes associated with lymphocytes.
- ▶ Recognize and describe the morphologic characteristics of the developing erythrocytes and leukocytes.
- ▶ Recognize and describe normal bone marrow architecture.
- ▶ Describe the hemoglobinopathies including hemoglobin S and hemoglobin C.
- ▶ Compare and contrast alpha thalassemia, beta thalassemia, and hereditary persistence of fetal hemoglobin.
- ▶ Describe anemias characterized by membrane defects: including the pathophysiology of hereditary spherocytosis.
- ▶ Describe immune hemolytic anemias including hemolytic disease of the newborn, transfusion-induced hemolytic anemia, cold hemagglutinin disease, and paroxysmal nocturnal hemoglobinuria.
- ▶ Describe the anemias of disordered iron metabolism and heme synthesis including iron-deficiency anemia and anemia of chronic disease.
- ▶ Describe the etiology, pathophysiology, and classification of:
 - ▶ Myeloproliferative disorders
 - ▶ Acute myelogenous leukemia
 - ▶ Acute lymphoblastic leukemia
 - ▶ Lymphoid malignancies

▶ OVERVIEW

Hematology tests are some of the most frequently ordered laboratory tests. The results obtained from these laboratory procedures are utilized in the diagnosis of a variety of disor-

ders including anemias, leukemias, infections, and inherited leukocyte disorders. The clinical laboratory professional must be able to perform these tests, verify results, solve problems related to erroneous results, correlate abnormalities with disease states, and suggest reflex tests when appropriate.

The two levels of testing in the hematology laboratory are routine and reflex. *Routine tests* such as the CBC, differential, and reticulocyte count are used as screening tests to determine the presence of a primary disease in the hematopoietic system or to identify hematologic changes that provide clues to the presence of nonhematologic diseases. Analysis of the results of these screening tests with the patient's clinical signs and symptoms help to determine whether further testing is necessary. Algorithms or critical pathways assist in the choice of follow-up testing (reflex testing) to abnormal screening test results. These reflex tests are used to definitively diagnose the patient's disease state. With a definitive diagnosis, the appropriate treatment plan can be implemented and monitored with additional laboratory procedures such as the reticulocyte count. The chapter begins with a discussion of the collection of the sample and care and use of the microscope. Next routine hematology tests are discussed, and the chapter concludes with a discussion of the laboratory procedures used in reflex testing. The principles, procedures, and results of the tests for specific clinical conditions are summarized. Detailed procedures for selected tests are provided on the Companion Website.

▶ SAMPLE COLLECTION: PHLEBOTOMY

The phlebotomy procedure is important to all laboratory testing. The sample's quality dictates the accuracy of its final result. All clinical laboratory professionals should have a thorough understanding of each sample collection technique. This section reviews the various aspects of phlebotomy or sample collection.

ANTICOAGULANTS

Most tests performed in the hematology laboratory involve anticoagulated blood. Once the blood has left the body, a series of reactions occurs causing blood to clot within minutes. To prevent coagulation from occurring, a substance called an **anticoagulant** is mixed with the blood. Three anticoagulants are used in the hematology laboratory: (1) ethylenediaminetetraacetic acid (EDTA), (2) sodium citrate, (3) heparin.¹ Sample collection tubes are color coded by stopper to indicate the type of anticoagulant present in the tube (Table 1 ★).

EDTA is the most commonly used anticoagulant in the routine hematology laboratory. Sample collection tubes can contain one of three different salt forms of EDTA: disodium, dipotassium, or tripotassium. The sample collection tube's stopper is color coded in lavender to indicate the presence of EDTA. EDTA prevents coagulation by chelating calcium, a

 **TABLE 1**
Sample Collection Tubes, Their Anticoagulant, and Typical Laboratory Use

Color Code	Anticoagulant	Typical Laboratory Procedure
Red	No anticoagulant	Antibody detection
Light blue	Sodium citrate	PT and APTT
Mottled red	No anticoagulant but contains clot activator and gel to facilitate separation of serum from cells	Cholesterol
Green	Heparin	Osmotic fragility
Purple or lavender	EDTA, K ₃ (liquid), or K ₂ (spray-coated)	CBC (K ₂ EDTA can also be used for routine blood bank procedures; see below)
Pink	EDTA, K ₂ (spray coated)	Blood bank procedures and whole blood hematology procedures (different colored stopper for easy distinction of blood bank vs. hematology samples)
Gray	Potassium oxalate and sodium fluoride	Glucose

PT = prothrombin time; APTT = activated partial thromboplastin time

necessary component of the coagulation cascade. Its removal inhibits the coagulation process. The optimal concentration is 1.5 mg of EDTA per mL blood.

Tests using EDTA samples include complete blood count (CBC), hematocrit, peripheral blood smear examination, platelet count, reticulocyte count, and flow cytometry. Ideally, the sample should be used within 6 hours of collection for the majority of these tests. The sample's stability can be extended to 24 hours with storage at 4°C for certain tests such as the CBC and platelet count. If peripheral blood smears are to be prepared, they should be made within 3 hours of collection. After 3 hours at room temperature, degenerative changes can be observed by examining a Wright-stained blood smear. These changes include leukocytes with vacuoles, irregular cytoplasmic borders, and irregularly shaped nuclei. Also, platelets increase in size. Excess anticoagulant causes erythrocyte shrinkage. Concentrations of more than 2 mg of EDTA per mL blood cause false decreases in the microhematocrit and erythrocyte sedimentation rate (ESR).

Sodium citrate is the recommended anticoagulant for coagulation studies. The Clinical and Laboratory Standards Institute (CLSI) recommends the use of 3.2% sodium citrate.² The sample collection tube's stopper is color coded in light blue to indicate the presence of sodium citrate. Sodium citrate prevents coagulation by binding calcium in a soluble complex. The appropriate ratio of anticoagulant: blood is 1:9.

Lithium heparin is the CLSI recommended salt of heparin to be used for laboratory testing.¹ The sample collection tube's stopper is color coded in green to indicate the presence of heparin. Heparin's interaction with antithrombin prevents coagulation. The interaction leads to the inhibition of thrombin. The recommended concentration for sample collection tubes is 15–30 units heparin/mL blood.

Lithium heparin is specifically recommended for the following laboratory tests: ammonia, carboxyhemoglobin,

blood gases, zinc, and potassium. In hematology, lithium heparin is the appropriate anticoagulant for the osmotic fragility test. The use of heparin for routine hematology procedures is not appropriate. Heparin can affect the platelets and leukocytes, causing them to clump. In addition, heparin causes morphologic distortion of platelets and leukocytes and tends to cause a bluish discoloration of the background of blood films stained with a Romanowsky stain such as Wright stain.

 **Checkpoint! 1**

Contrast the mechanisms of anticoagulation for EDTA and heparin.

EQUIPMENT

The equipment needed for blood collection by venipuncture includes sample collection tubes, needles, tube holders or syringes, and a tourniquet. Lancets are used for capillary puncture. Other miscellaneous supplies are described in this section.

Sample Collection Tubes

Evacuated sample collection tubes are sterile and color coded to indicate the type of anticoagulant present or the lack of anticoagulant (Web Figure 1■, Table 1). The Occupational Safety and Health Administration (OSHA) recommends the use of plastic sample collection tubes whenever possible. Collection tubes are manufactured in a variety of sizes to collect different volumes of sample (1 mL, 3 mL, 5 mL, etc.). The variety of volumes available minimizes the removal of excess amounts of blood. Today's hematology and chemistry instruments require only small amounts of sample for analysis. The interior of the sample collection tube is a vacuum. When the stopper is pierced by a needle, the required amount of blood is drawn from the vein into the tube by the vacuum.¹ The tube

might not fill properly if the vein collapses or if the needle is displaced from the lumen of the vein.

For capillary punctures, microcollection tubes are available with the same anticoagulants and color coded in the same manner as the evacuated collection tubes, but they do not contain a vacuum. The microcollection tubes contain special features that facilitate the collection of capillary blood into the tubes, such as capillary pipet tips (see Web Figure 2 ■ for examples of microcollection tubes). These adaptations help to decrease the time that it takes to collect the capillary sample and decrease errors related to sample collection (e.g., presence of micro clots or hemolysis).

Needles

Sample collection needles are sterile hollow shafts of stainless steel with a beveled tip. The most common needles used for blood collection are 20- or 21-gauge. The gauge of a needle relates to the diameter of its bore. A small gauge needle has a large diameter. For example, an 18-gauge needle is used to collect donor blood for transfusions because its larger bore diameter permits a more rapid collection of blood and decreases the chance of hemolysis. Special needles are required for sample collection using the evacuated collection tube system. For this system, the needle must be double ended. The needle is screwed into a tube holder. The long end of the needle is inserted into the vein and the short end punctures the collection tube stopper (inside the tube holder) and releases the vacuum allowing for blood collection into the tube.

Tube Holders

The evacuated sample collection tube system requires a tube holder or adapter with a shape similar to a syringe. The needle is threaded into its position in the holder, and sample collection tubes are rested in the holder, semiattached by the shorter needle end (Figure 1 ■). The tube holder also facilitates the insertion of the needle into the vein.

Syringe

The syringe was once the principal method of obtaining a blood sample, but it is now used only for difficult phle-

■ **FIGURE 1** Assembled evacuated collection tube system.

The double-ended needle is threaded into the tube holder and the purple top collection tube is secured in the holder by the shorter end of the needle that has partially pierced the stopper. Blood replaces the vacuum in the collection tube when the vein is entered and the stopper is completely pierced.

botomies or the collection of an arterial blood sample. Sterile plastic syringes are available in a variety of sizes (e.g., 1 mL, 5 mL, or 10 mL).

Tourniquet

Various tourniquets including rubber straps, blood pressure cuffs, and rubber tubing are available. Placement of the tourniquet on the patient's upper arm increases the resistance in venous blood flow, resulting in the distension of veins below the tourniquet. The phlebotomist is then able to visualize and/or palpate the veins to identify the "good" vein. The tourniquet should never be left in place longer than 1 minute prior to phlebotomy because this will result in discomfort to the patient and **hemoconcentration** of the blood sample.

Lancets

Various sterile disposable lancets are available for performing capillary puncture. The design of these devices has been improved to minimize the discomfort and maximize the quality of the sample. Disposable lancets provide a controlled incision depth. The selection of a lancet depends on the individual's age. For example, a lancet with an incision depth of 1.8 mm is typically used for neonatal collection to minimize trauma; a device with an incision depth of 2.4 mm is appropriate for older children and adults.

Other Equipment

Other equipment required to perform a phlebotomy includes gloves, safety goggles, alcohol pads, gauze, adhesive bandages, and biohazard sharps containers. Gloves and safety goggles have become important protective equipment for the phlebotomist to prevent exposure to blood-borne pathogens. Alcohol pads are commonly used to cleanse and prepare the phlebotomy site. Gauze with applied pressure is used to stop bleeding after the needle has been removed. Adhesive bandages are used to protect the venipuncture or capillary puncture site. The biohazard sharps container is used for properly disposing of lancets and needles to minimize potential puncture wounds.

VENIPUNCTURE

The venipuncture phlebotomy technique removes blood from a vein for laboratory testing using a sterile needle and an evacuated sample collection tube system.³ Prior to performing the venipuncture, the phlebotomist must identify the patient. The 2008 National Patient Safety Goals implemented by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) requires that two patient identifiers be used when collecting blood samples.⁴ For example, proper identification can be achieved by comparing the patient's name and **unique identification number** from his or her wrist band to the information written on the requisition form.

Next, the phlebotomist assembles the appropriate equipment for performing the venipuncture. The vein is selected by placing the tourniquet on the patient's upper arm and inspecting the forearm for a prominent vein (see Web Table 1  for considerations in selection of venipuncture site). The median cubital vein is typically used, but the cephalic vein is also appropriate. The vein is cleansed with an alcohol pad and allowed to air dry. The venipuncture is accomplished by inserting the needle into the vein at a 15° angle to the forearm (Web Figure 3 ). A slight release in resistance can be detected when the vein is entered. Blood is collected into the appropriate evacuated collection tubes by pushing the tube until the stopper is punctured with the short end of the needle (see Web Table 2  for the correct collection sequence of evacuated tubes). The vacuum is released as blood enters the collection tube. When blood has been collected in each tube, the tourniquet is released, the needle is withdrawn, and pressure with gauze is applied to the venipuncture site. The needle is immediately discarded into the biohazard sharps container. Collection tubes containing anticoagulant should be thoroughly but gently mixed to prevent clotting of the sample. Each collection tube should be properly labeled with patient's name, unique identification number, and date. Finally, the patient should be checked one last time to verify that bleeding has ceased and an adhesive bandage is applied to the venipuncture site.

CAPILLARY PUNCTURE

The capillary puncture technique allows a small but adequate amount of blood to be obtained for laboratory testing.⁵ This is especially important in the pediatric patient (i.e., infant) who has a lower total blood volume. Venipuncture in this patient population can result in anemia. The phlebotomist should properly identify the patient before proceeding with the capillary puncture technique. Selection of the capillary puncture site depends on the individual's age. The side of the heel is used for newborns, and a location slightly to the side of center and perpendicular to the fingerprint of the last segment of the third or fourth finger is chosen for an older child or adult. The puncture site should be warm and not **edematous**. Accumulated interstitial fluid in the edematous area will contaminate the blood sample. Warming the site prior to the capillary puncture increases blood flow through the site, primarily arterial blood flow. With the site identified, appropriate equipment is assembled, and the site is cleansed with an alcohol pad and allowed to air dry. The capillary puncture is made, and the lancet is immediately discarded into a biohazard sharps container. The first drop of blood is wiped away because it likely contains excess interstitial fluid that could result in a diluted blood sample. Subsequent drops of blood are collected into the appropriate microcollection tubes. When sufficient blood has been collected, gauze is placed on the puncture site and slight pressure applied. The microcollection tubes containing anti-

coagulant should be properly mixed to ensure adequate anticoagulation to prevent clot formation. Each microcollection tube should be properly labeled with the patient's name, unique identification number, date, and time of collection. An adhesive bandage is applied to the puncture site.

PHLEBOTOMY SAFETY

OSHA mandates safety guidelines for phlebotomy. The 1992 Occupational Exposure to Bloodborne Pathogens Standard and its 1999 revised directive address this issue thoroughly.^{6,7} These standards promote safety through education, good work practices, use of personal protective equipment (PPE), and use of medical devices that minimize exposure risk. Each laboratory should develop an exposure control plan to address these issues. Clinical laboratory professionals should receive instruction as to the potential for exposure to, the methods of preventing exposure to, and the postexposure treatment of blood-borne pathogens such as hepatitis B (HBV), hepatitis C (HCV), and human immunodeficiency virus (HIV).

For the phlebotomist, the educational program should include practical experience using PPE and the new collection systems available to minimize risk of needlesticks. At a minimum, the phlebotomist's PPE should include gloves and goggles to decrease risk of exposure through cuts or abrasions on the skin and exposure through mucous membranes of the eyes. The revised directives require the evaluation and implementation of needlestick systems designed to reduce the risk of needlestick injury (Web Figure 4 ). Disposable lancet devices that retract the lancet into a protective guard after the capillary puncture has been made minimizes risk of a sharps injury due to a lancet. Biohazard sharps containers should be readily available for disposal of lancets and needles.

An additional measure to reduce exposure to blood-borne pathogens is the use of plastic splashguards on the stoppers of sample collection tubes. The splashguards reduce the formation of aerosols that are created when the stopper is removed.

The entire exposure control plan for phlebotomy should be reviewed annually and changed as new devices become available to reduce risk of sharps injury and as new treatments for blood-borne pathogens become available.

Checkpoint! 2

What are three steps a phlebotomist should take to minimize the risk of exposure to blood-borne pathogens when performing a venipuncture?

▶ MICROSCOPY: THE MICROSCOPE

The compound microscope is an essential instrument in the routine hematology laboratory. Its proper use and regular preventative maintenance are critical to the reliability of the results obtained from its use. Therefore, individuals utilizing

the microscope need to be knowledgeable in its basic principles, its operation, and its preventative maintenance.

BRIGHT-FIELD MICROSCOPY

Bright-field microscopy is used extensively to examine stained blood and bone marrow samples. This section describes the components of bright-field microscopy and aberrations that affect the quality of the sample examination.

Principles of the Compound Microscope

Any discussion of the principles of the compound microscope must begin with a review of its components. The components include eyepieces, binocular eyepiece tube, objectives located on the revolving nosepiece, microscope stage, condenser, condenser diaphragm, field diaphragm, and light source (Figure 2 ■). The condenser functions to direct the beam of light from the light source onto the sample. As the light rays illuminate the sample, they are altered and light is diffracted. The sample image is produced by a combination of the diffracted light and background light from the light source.^{8,9,10}

The magnifying system of the compound microscope uses two sets of lenses to form an enlarged image.^{9,10} The first lens system is the objective, which projects a primary image plane to a location approximately 1 cm from the top of the microscope's body. The distance from the back focal plane of the objective to the eyepiece is termed the *optical tube length* (160 mm). The second lens system is the eyepiece located above the primary image plane. The total magnification is the product of the magnification of the first and second lens systems (objective magnification times eyepiece magnification).

■ **FIGURE 2** Basic components of the compound microscope. (Courtesy of Nikon, Inc., Garden City, NY)

✓ Checkpoint! 3

What is the total magnification when a 10× objective is combined with a 10× eyepiece?

The resolving power (resolution) of a lens is its ability to distinguish two separate objects located close to one another and reveal the fine detail in a specimen.^{9,10} It is a function of the numerical aperture (NA) of the lens and the wavelength (λ) of the illuminating light. The numerical aperture is a designation of the amount of light entering the objective from the microscope field. The NA of the substage condenser should be equal to or greater than the NA of an objective; otherwise, interference effects will occur. Because the illuminating light remains constant in light microscopy, the numerical aperture determines the resolving power. That is to say, the higher an objective's NA, the greater the resolving power.

Lens Aberrations

An *aberration* is an optical defect that degrades the quality of an image.^{9,10} Three important types of aberrations are associated with the objectives:

1. *Chromatic aberrations* give rise to color fringes and poor image definition. These aberrations are due to the inability of the lens to bring the different wavelengths of light into focus at a single focal point. For example, blue light is brought to a focal point closer to the lens as compared to red light.
2. *Spherical aberrations* give rise to poor image definition and loss of contrast. In spherical aberrations, the light is refracted by the lens depending on the area (thickness) of the lens it passes through. For example, the light passing through the periphery of the lens is refracted more than light passing through the center. Therefore, the refracted light from the periphery is brought to a shorter focal point than the light passing through the center. This aberration becomes worse as the lens becomes thicker.
3. *Field curvature aberrations* result in the periphery of the field being slightly out of focus when the center is in focus. These aberrations are the result of the image in the focal plane being slightly curved by the objective.

In order to compensate for these aberrations, specialized lenses are employed. The achromat lens will compensate for chromatic aberrations at two colors and spherical aberrations at one color. The apochromat lens will compensate for chromatic aberrations at three colors and spherical aberrations at two colors. The field curvature aberrations may be eliminated with the use of a flat-field (plan) objective lens. A plan apochromat lens is the highest grade, giving exceptional definition, superior color reproducibility, and prominent image flatness. This lens is most useful in the examination of morphologic detail.

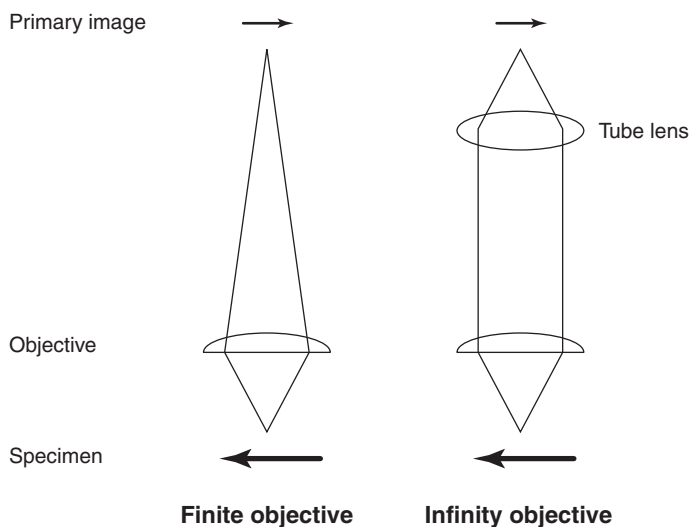

Infinity Optical System

Newer microscope models have an infinity optical system. In the infinity optical system, light that passes through the objective becomes a flux of parallel light rays.^{11,12} These light rays do not converge to form the primary image until they pass through the tube lens (Figure 3 ■). In other words, the infinity objective sends the primary image to “infinity.” For comparison, the finite objective projects light rays that converge within the tube length of the microscope to create the primary image (Figure 3). Two major advantages of the infinity optical system are the increased sharpness and clarity of the images and the increased flexibility of the microscope system. The increased sharpness and clarity result from higher numerical apertures and longer working distances (i.e., distance from the objective to the surface of the coverslip when the sample is sharply focused).

The infinity space associated with these systems allows for the addition of intermediate attachments without loss of optical performance such as an epi-fluorescence attachment for the evaluation of fluorescent stains.

PHASE-CONTRAST MICROSCOPY

With bright-field microscopy, unstained cells are difficult to examine due to the lack of absorption differences between cellular structures and undetectable variations in the **refractive index**. Examination of unstained cells can be accomplished using phase-contrast microscopy, which is

■ **FIGURE 3** Finite objective vs. infinity objective. In the finite objective, light rays projected from the objective converge to form the primary image within the optical tube. For the infinity objective, light is projected as parallel rays from the objective. These rays converge to form the primary image only after they pass through the tube lens. The infinity space as defined by the distance between the objective and the tube lens can vary from 160 mm to 200 mm.

based on the premise that transparent objects (e.g., unstained cells) cause a change in the phase of transmitted light (i.e., phase shift) due to scattering and deflection of light.^{10,12} When the transmitted light is shifted by one-quarter wavelength, these changes can be visualized as differences in light intensity. The two important components of a phase microscope are the annular diaphragm, or annular ring, located in the condenser, and the phase-shifting element, or phase ring, located in the objective. The annular ring directs light through its open circular area creating a hollow cone of light with a dark center that illuminates the sample (Figure 4 ■). The phase ring within the objective retards the wavelength of the deflected light by one-quarter wavelength and absorbs the nondiffracted light. This phase shifting occurs in the shaded area (Figure 4). As a result, light waves become out of phase. Maximum contrast between the cell and its surroundings is achieved when light waves are out of phase by one-quarter of a wavelength. With phase-contrast microscopy, cellular components that possess a higher refractive index than the surrounding environment appear dark while components that possess a lower refractive index than the surrounding environment appear bright.

For proper operation, the annular ring must be centered to the phase ring.

■ **FIGURE 4** Phase contrast light pathway. The annular ring within the condenser diaphragm creates a hollow cone of light that illuminates the sample. Transmitted light is shifted one-quarter wavelength by the phase-shifting element in the objective, creating maximum contrast between a cell and its surroundings. (Reprinted, with permission, from Molecular Expressions' World Wide Web pages.)

KOEHLER ILLUMINATION

Koehler illumination utilizes a double diaphragm illumination. The two diaphragms are the field diaphragm and the condenser diaphragm. The condenser diaphragm determines the resolution, contrast, and depth of field. Closing the condenser diaphragm increases the contrast and depth of field but decreases the resolution. The field diaphragm determines the illuminated area on the sample surface in relation to the microscope's field of view. In Koehler illumination, the two diaphragms are adjusted to give uniform illumination of the field of view and optimum contrast and resolution of a sample by focusing and centering the light path.^{8,9}

The procedure for Koehler illumination varies slightly depending on the microscope manufacturer (see Web Table 3  for this procedure). This procedure should be performed daily before using the microscope, and it should be repeated for each objective, since each objective will have a different light requirement (higher NA objectives require correspondingly higher NA settings on the condenser).

PREVENTATIVE MAINTENANCE

Each laboratory should establish a regular preventative maintenance program. The microscope manufacturer's instruction manual provides a preventative maintenance checklist. Any preventative maintenance program should include the following: (1) clean the oil immersion lens daily with lens tissue and cleaner, (2) dust optical surfaces (eyepieces, condenser, field lens, and filters) using bursts of air or a soft camel's hair brush, (3) clean external surfaces using a mild liquid soap—avoid the use of any organic solvents such as ether, alcohol, or xylene, and (4) periodically inspect objectives for stubborn smudges or scratches.^{9,10}

Checkpoint! 4

How does the examination of a sample by phase-contrast microscopy differ from bright-field microscopy?

PART I

ROUTINE HEMATOLOGY PROCEDURES

▶ PERIPHERAL BLOOD SMEAR PREPARATION

The morphologic evaluation of hematopoietic cells by light microscopy requires the preparation of a well-stained blood smear.¹³⁻¹⁶ The accuracy of the morphologic evaluation depends in part on the quality of the blood smear.

MANUAL METHOD

The two manual methods for preparing blood smears are: the **coverglass smear** and the **wedge smear**. The coverglass smear method provides a smear with even distribution of the leukocytes. The disadvantages of this method are the difficulty in mastering the technique, the fragility of the coverglass, and the difficulty in staining the coverglass. The wedge smear is the method most commonly used in routine laboratory practice but it is subject to poor leukocyte distribution with monocytes and neutrophils being drawn out of the **optimal counting area** to the feather edge. Although the leukocyte distribution is poor, the technique is easily mastered and the smears are less fragile and can be stored for extended periods of time. An advantage of the leukocyte distribution in a wedge smear is that it allows for the identification of abnormal cells that tend to locate on the edges of the smear.

Either EDTA-anticoagulated venous blood or capillary blood is acceptable for the preparation of a blood smear (see Web Table 4  for this procedure). An optimal blood smear has the characteristics listed in Table 2  (see Web Figure 5  for examples of properly and improperly prepared blood smears). A common problem associated with blood smears is the failure to dry the blood smear in a timely manner. This results in contraction artifacts of the cells, especially with increased humidity. In certain physiological conditions including **anemia**, **polycythemia**, **multiple myeloma**, and **cold agglutinin disease**, making good blood smears is difficult due to the abnormal composition of the blood (Table 3 ). The thickness or thinness of the blood smear is regulated by:

- Adjusting the amount of blood used to make the drop
- Altering the speed with which the drop is smeared
- Altering the angle at which the spreader slide is used

Automated Method

Automated methods for preparing blood smears have been developed for nearly all major hematology instruments on the market. These methods are based on the wedge smear technique. Automated methods that are a component of a hematology instrument combine blood smear preparation and staining. Advantages of these methods include minimal exposure to biohazardous material because many are closed tube systems, increased consistency between blood smears, and increased optimal counting area.

 TABLE 2

Optimal Blood Smear Characteristics

- Minimum length 2.5 cm
- Gradual transition in thickness from thick to thin
- Straight feather edge
- Margins narrower than slide
- No streaks, waves, or troughs

★ TABLE 3

Resolution of Problems in Preparation of a Blood Smear

Problem	Resolution
Presence of crenated erythrocytes	Dry smear quickly and thoroughly
Thin smear due to anemia	Increase spreader slide angle and increase push speed
Thick smear due to polycythemia	Decrease spreader slide angle and decrease push speed
Presence of agglutinated erythrocytes associated with cold agglutinin disease	Warm blood @ 37°C for 15 minutes prior to preparing smear
Increased viscosity associated with multiple myeloma	Decrease spreader slide angle and decrease push speed

Also available is a portable semiautomated instrument that is not specific for any given hematology instrument. With the semiautomated instrument, the instrument controls the speed and angle of the spreader blade, but the clinical laboratory professional controls the size of the blood drop. Overall advantages and disadvantages of the automated methods are similar to the manual wedge smear method.

✓ **Checkpoint! 5**

A clinical laboratory professional consistently prepares thin blood smears resulting in minimal counting area. What would you suggest this individual do to improve the quality of these blood smears?

▶ **PERIPHERAL BLOOD SMEAR STAINING**

For more than 100 years, **Romanowsky-type stains** have been used in the morphologic classification of hematopoietic cells.^{17,18} A Romanowsky-type stained blood smear is extremely important in the hematology laboratory because a wealth of information can be obtained from the evaluation of a well-stained peripheral blood smear.

The combined action of methylene blue and its oxidation products and eosin Y or eosin B produce the Romanowsky staining effect. This yields a purple color to the nuclei of leukocytes and neutrophilic granules and reddish orange color to the erythrocytes. The principal components responsible for this effect are azure B (a methylene blue oxidation product) and eosin Y. The wide variation in purple and red shades seen with Romanowsky staining allows for subtle distinctions in cellular characteristics.

The staining properties of Romanowsky stains depend on the binding of dyes to chemical structures and the interactions between azure B and eosin Y. Acidic groupings of nucleic acids, the proteins of the cell nuclei, and immature or reactive cytoplasm binds azure B, the purplish basic dye. Eosin Y, the reddish acidic dye, binds to the basic groupings of the hemoglobin molecules and the basic proteins within certain granules.

Examples of Romanowsky stains include Wright, Wright-Giemsa, Leishman, May-Grunwald, and Jenner stains. The most commonly used are Wright and Wright-Giemsa stains.

✓ **Checkpoint! 6**

Which component of Wright stain is responsible for staining hemoglobin within erythrocytes?

The staining process begins with the methanol fixation step, which results in the adherence of cellular proteins to the glass microscope slide preventing the cells from being washed away during subsequent steps (see Web Table 5 ★ for this procedure). Additional fixation takes place when the blood smear is flooded with Wright's stain. The actual staining begins with the addition of buffer to the Wright's stain resulting in the ionization of the dyes. A properly stained blood smear meets the criteria outlined in Table 4 ★. Potential causes of an improperly stained blood smear are given in Table 5 ★.

★ TABLE 4

Characteristics of a Properly Stained Blood Smear by Macroscopic and Microscopic Evaluation

Type of Evaluation	Characteristics
Macroscopic	Smear is pinkish purple in color.
Microscopic	Blood cells are evenly distributed. Areas between cells are clear. Erythrocytes are orange red. Neutrophilic granules are pale purple. Eosinophilic granules are red orange. Basophilic granules are purplish black. Lymphocyte's cytoplasm is blue. Leukocyte's nuclei are purple. Within nucleus, chromatin and parachromatin are distinct. Precipitated stain is minimal or absent.

★ TABLE 5

Potential Causes of Improperly Stained Blood Smear

Problem	Potential Causes
Excessively blue or dark stain	Prolonged staining
	Inadequate washing
	Use of a stain and/or buffer with an alkalinity that is too high
Excessively pink or light stain	Thick blood smear
	Insufficient staining
	Prolonged washing
Presence of precipitate	Use of a stain and/or buffer with an acidity that is too low
	Unclean slides
	Drying during staining process
	Inadequate filtration of stain

■ FIGURE 5 Platelet satellitism. (Peripheral blood, Wright-Giemsa stain; 1000× original magnification)

✓ Checkpoint! 7

If the erythrocytes appear bluish gray and leukocyte nuclei are black, how would you correct this problem?

▶ PERIPHERAL BLOOD SMEAR EXAMINATION

The examination of a well-stained peripheral blood smear is one of the most frequently performed tests in the hematology laboratory.^{13,19–21} The thorough examination of a peripheral blood smear may be used (1) as a screening tool to identify illness, (2) for making the definitive diagnosis of certain hematologic and nonhematologic conditions, and (3) to monitor the patient's response to therapy. The peripheral blood smear evaluation includes an estimation of leukocyte and platelet count, detection of abnormal cells and abnormal erythrocyte distribution, review of erythrocyte and platelet morphology, and counting a 100-cell leukocyte differential.

On 100× magnification (10× objective), the peripheral blood smear is scanned to ensure even distribution of leukocytes and observe for immature or abnormal cells, **smudge cells**, **platelet clumps**, **platelet satellitism**, and abnormal erythrocyte distribution patterns such as **rouleaux** or agglutination (Figure 5 ■, Table 6 ★). The leukocyte estimate is obtained by counting the number of leukocytes in each of five fields of view and applying the calculation formula (Figure 6 ■). The leukocyte estimate should correlate with the leukocyte count $\pm 25\%$.

On 1000× magnification (100× objective), platelet morphology is observed, and a platelet estimate is obtained by counting the number of platelets in each of five fields of view and applying a calculation formula similar to that used for the leukocyte estimate (Figure 7 ■). The platelet estimate should correlate with the platelet count $\pm 25\%$. Erythrocyte morphology is evaluated by carefully examining erythrocyte size, shape, color, and observation for the presence of inclu-

★ TABLE 6

Abnormalities Detected on Peripheral Blood Smear, Their Effect on Cell Counts, and Corrective Procedures to Take

Abnormality	Effect on Cell Counts	Corrective Action
Smudge cells	No effect on cell counts	Add 1 drop of 22% bovine albumin to 5 drops of blood, mix, and prepare blood smear.
Nucleated erythrocytes	Falsely elevated leukocyte count	Correct leukocyte count for presence of nucleated erythrocytes.
Platelet clumps	Falsely decreased platelet count	If collected in EDTA, recollect using citrate tube. Platelet count should be multiplied by 1.1 to correct for dilutional effect of liquid citrate.
Platelet satellitism	Falsely decreased platelet count	Use correction for platelet clumps.
Erythrocyte agglutination	Falsely decreased erythrocyte count	Warm blood @ 37°C for 15 minutes and retest.
Rouleaux	No effect on cell counts	No correction is available

$$\frac{\text{Total number of leukocytes counted}^*}{5} \times 0.2 \times 10^9/\text{L}^{**} = \text{leukocytes} \times 10^9/\text{L}$$

* Total number of leukocytes counted in 5 fields at 100x (10x objective) magnification

** 1 leukocyte = $0.2 \times 10^9/\text{L}$

Example: If total number of leukocytes counted = 150

$$150/5 \times 0.2 \times 10^9/\text{L} = 6.0 \times 10^9/\text{L}$$

■ **FIGURE 6** Calculation of leukocyte estimate. This formula is based on performing the estimate at 100× magnification. The estimation factor varies depending on the total magnification used as defined by the ocular and objective magnifications. Thus, each laboratory should determine or validate this factor based on its microscope.

sions. Normal erythrocytes are described as normocytic and normochromic, and this appearance correlates with normal erythrocyte indices. Any change beyond normal variation should be noted because certain variations in the erythrocytes are characteristic of specific hematologic disorders.

The leukocyte differential is performed by counting 100 cells per slide using the battlement track method for examination (Figure 8 ■). Each leukocyte encountered must be identified and placed in the appropriate category; distorted cells are included only if they are clearly identifiable. Nucleated erythrocytes are not included within the differential but are tabulated separately. The results of the differential are reported in percentage of each type of leukocyte counted. The nucleated erythrocytes are expressed as number per 100 leukocytes. If 5 or more nucleated erythrocytes are observed, the leukocyte count must be corrected for their presence because they are included in the leukocyte count (Figure 9 ■). Finally, leukocytes are observed for changes in morphology (i.e., Döhle bodies, hypersegmented neutrophils). These changes can be

$$\frac{\text{Total number of platelets counted}^*}{5} \times 15 \times 10^9/\text{L}^{**} = \text{Platelets} \times 10^9/\text{L}$$

* Total number of platelets counted in 5 fields at 1000x (100x objective) magnification

** If EDTA-anticoagulated blood, 1 platelet = $15 \times 10^9/\text{L}$
If capillary blood, 1 platelet = $20 \times 10^9/\text{L}$

Example: If total number of platelets counted = 100

$$100/5 \times 15 \times 10^9/\text{L} = 300 \times 10^9/\text{L}$$

■ **FIGURE 7** Calculation of platelet estimate. This formula is based on performing the estimate at 1000× magnification. Refer to Figure 6 for a discussion of estimation factor.

■ **FIGURE 8** Pathway for the leukocyte differential. The differential is performed within the optimal counting area where the erythrocytes can be touching but not overlapping. As you approach the opposite side of the smear, the objective is moved into the body of the smear by one field of view. This pattern is followed until 100 leukocytes have been identified.

the result of an underlying hematologic disorder, the presence of excess anticoagulant, or the failure to prepare the blood smears within 3 hours of collection. Typical anticoagulant changes include cytoplasmic vacuolization, degranulation, karyorrhexis, karyolysis, and changes in nuclear shape.

The leukocyte differential reference values for children as well as adult males and females can be found in Table B inside the front cover.

✓ **Checkpoint! 8**

In a platelet estimate, 76 platelets were observed in five fields. Calculate the platelet estimate. If the platelet count was $189 \times 10^9/\text{L}$, would these results correlate? Assume the sample was collected with EDTA.

$$\frac{\text{Leukocyte count} \times 100}{100 + \text{number of nucleated erythrocytes}^*} = \text{Corrected leukocyte count}$$

*Number of nucleated erythrocytes counted per 100 leukocytes at 1000x (100x objective) magnification

Example: Leukocyte count = $20.0 \times 10^9/\text{L}$
Nucleated erythrocytes/100 leukocytes = 10

$$\frac{20.0 \times 10^9/\text{L} \times 100}{100 + 10} = 18.2 \times 10^9/\text{L}$$

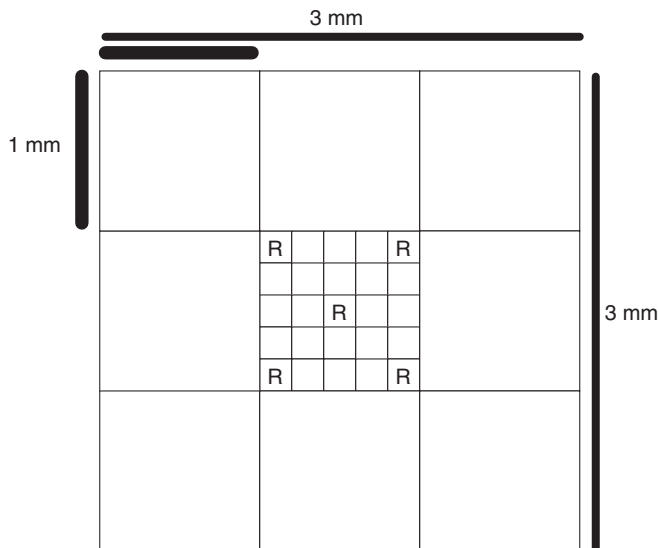

■ **FIGURE 9** Leukocyte count correction for presence of nucleated erythrocytes.

▶ CELL ENUMERATION BY HEMACYTOMETER

Cell counts are performed manually by diluting blood with a diluent, loading a small amount of the diluted sample on a ruled device (hemacytometer), and counting the cells microscopically. The hemacytometer consists of two side-by-side identically ruled glass platforms mounted in a glass holder. Each platform contains a ruled square measuring 3×3 mm (9 mm^2) and is subdivided according to the improved Neubauer ruling (Figure 10 ■). This ruling subdivides the ruled square into 9 large squares, each measuring 1×1 mm (1 mm^2). All 9 squares are used for leukocyte counts. The large center square (1 mm^2) is used for platelet and erythrocyte counts. This center square is divided into 25 smaller squares, each with an area of 0.04 mm^2 . The 5 squares labeled *R* are used in performing the erythrocyte count whereas the entire center square is used in performing the platelet count.

On either side of the two ruled glass platforms is a raised ridge. The coverglass is placed on top of the ridge. The distance between the coverglass and the surface of the ruled area (depth) is exactly 0.1 mm. Thus, the ruled area on each side of the hemacytometer holds a volume of 0.9 mm^3 ($3 \times 3 \times 0.1$).

The unopette system is a fast and accurate method for collecting and diluting blood for cell counts. For each labo-

■ **FIGURE 10** Neubauer hemacytometer counting area. The entire counting area is 9 mm^2 ($3 \text{ mm} \times 3 \text{ mm}$) and is divided into 9 squares. Each square is 1 mm^2 ($1 \text{ mm} \times 1 \text{ mm}$) in area. Using the $10\times$ objective, 1 square of the counting area (1 mm^2) can be viewed. For the manual leukocyte count, all 9 squares are counted. The center square is further divided and the *R* squares are used for erythrocyte counts, while the entire center square is used for platelet counts.

ratory determination performed, the unopette consists of the following elements: the reservoir, the pipet, and the pipet shield (Figure 11 ■). The reservoir contains a premeasured volume of diluting fluid that is specific for the cell count to be performed.

MANUAL LEUKOCYTE COUNT

Whole blood is diluted with a 1% ammonium oxalate solution, which hemolyzes mature erythrocytes and facilitates leukocyte (white blood cell [WBC]) counting.²² The standard dilution for leukocyte counts is 1:100. With proper light adjustment, the leukocytes should appear as dark dots. The number of leukocytes in all nine squares are counted using the $10\times$ objective.

The number of leukocytes is calculated per μL ($\times 10^9/\text{L}$) of blood. To make this determination, the total number of cells counted must be corrected for the initial dilution of blood and the volume of blood used for counting (Figure 12 ■). Because the dilution of blood for a leukocyte count is 1:100, the reciprocal of the dilution is 100. The volume of blood used is based on the number of squares counted, the area of each square, and the depth of the solution. For the leukocyte count, all nine squares are counted, each square's area is 1 mm^2 , and the depth of the solution is 0.1 mm; therefore the volume is 0.9 mm^3 . Thus, the number of leukocytes counted in the nine squares is multiplied by 111 ($100/0.9$) and reported as number of leukocytes per mm^3 .

Reference intervals for leukocyte counts in adults and children can be found in Table B on the inside cover. Conditions commonly associated with increased or decreased leukocyte counts are shown in Table 7 🌟.

■ **FIGURE 11** Unopette system (from left to right): pipet shield, pipet, and reservoir.

$$\frac{\text{Total number of cells counted} \times \text{Reciprocal of the dilution}}{\text{Number of squares counted} \times \text{Area of each square} \times \text{Depth of the solution}} = \text{Cells/mm}^3$$

Example:	Total number of cells (one side of hemacytometer)	90
	Dilution	1:100
	Number of squares counted	9
	Area of each square	1 mm ²
	Depth of solution	0.1 mm

$$\frac{90 \times 100}{9 \times 1 \text{ mm}^2 \times 0.1 \text{ mm}} = 10,000/\text{mm}^3 (\mu\text{L}) \text{ or } 10.0 \times 10^9/\text{L}$$

■ **FIGURE 12** Calculation formula for hemacytometer cell counts.

MANUAL ERYTHROCYTE COUNT

Manual erythrocyte counts are occasionally performed on certain body fluids; therefore they are included in this chapter. Whole blood is diluted with a 0.85% saline solution, which prevents erythrocyte (red blood cell) lysis and facili-

tates erythrocyte counting.²³ The standard dilution for erythrocyte counts is 1:200. For the manual erythrocyte count, erythrocytes are counted in five of the smaller squares within the large center square (*R*, Figure 10) using the high dry objective (40×). Potential sources of error are listed in Web Table 7.

The number of erythrocytes is calculated per μL ($\times 10^{12}/\text{L}$) of blood using the calculation formula for hemacytometer cell counts (Figure 12). The variations are in the reciprocal of the dilution and the volume. For erythrocyte counts, the reciprocal of the dilution is 200, and the volume is 0.04 mm^3 (10 squares counted, each square's area = 0.04 mm^2 ; depth = 0.1 mm) when the diluted sample from a single unopette reservoir is placed on both ruled areas of the hemacytometer.

The reference intervals for erythrocyte counts in adult males and adult females and children can be found in Table A on the inside cover. The reference intervals vary with age as shown. Conditions commonly associated with increased or decreased erythrocyte counts are shown in Table 7.

MANUAL PLATELET COUNT

Whole blood is diluted with a 1% ammonium oxalate solution (this unopette system is used for manual leukocyte and manual platelet counts).²² The isotonic balance of the diluent is such that all erythrocytes are lysed while the leukocytes, platelets, and reticulocytes remain intact. The standard dilution for platelet counts is 1:100. The detailed procedure is provided on the Website. Platelets are counted in the large center square (1 mm^2) using high dry objective (40×). With phase contrast microscopy, the platelets appear as round or oval bodies.

The number of platelets is calculated per μL ($\times 10^9/\text{L}$) of blood using the calculation formula for hemacytometer cell counts (Figure 12). The variations are in the reciprocal of the dilution factor and the volume. For platelet counts, the reciprocal of the dilution is 100 and the volume is 0.2 mm^3 (2 squares counted; each square's area = 1 mm^2 ; depth = 0.1 mm) when the diluted sample from a single unopette reservoir is placed on both ruled areas of the hemacytometer.

The reference interval for platelet counts is $150 - 440 \times 10^9/\text{L}$. Conditions commonly associated with increased or decreased platelet counts are shown in Table 7.

EOSINOPHIL COUNT

The eosinophil count is performed by diluting whole blood with a staining solution that contains phyloxine B, which stains the eosinophils red; all other leukocytes are preserved

★ **TABLE 7**

Conditions Commonly Associated with Changes in Erythrocyte, Leukocyte, and Platelet Concentrations

	Increased Concentration	Decreased Concentration
Erythrocyte	Polycythemia Myeloproliferative disorders Dehydration	Anemia Acute leukemia Myelodysplastic syndromes Hemorrhage Hemolysis
Leukocyte	Bacterial infections Inflammation Metabolic intoxication Hemolysis Hemorrhage Tissue necrosis Strenuous exercise Anxiety or stress Acute leukemia Myeloproliferative disorders	Viral infections Aplastic anemia Megaloblastic anemia Drug-induced leukopenia Myelodysplastic syndromes
Platelet	Splenectomy Hemorrhage Iron deficiency anemia Myeloproliferative disorders	Immune thrombocytopenic purpura Aplastic anemia Megaloblastic anemia Myelodysplastic syndromes Acute leukemia

but not stained.²⁴ Using the low power objective (10×), the eosinophils are counted in the entire ruled area of both counting chambers. Eosinophils appear bright orange-red and are clearly distinguishable from other leukocytes.

The number of eosinophils is calculated per μL ($\times 10^9/\text{L}$) of blood using the calculation formula for hemacytometer cell counts (Figure 12). The variations will be in the reciprocal of the dilution and the volume. For eosinophil counts, the reciprocal of the dilution for the Unopette system is 32. The volume factor will vary depending on the total area needed to count 100 eosinophils and the depth of the hemacytometer (e.g., Fuchs-Rosenthal hemacytometer = 0.2 mm depth).

The reference interval for adults is $0\text{--}0.45 \times 10^9/\text{L}$.

✓ Checkpoint! 9

- A manual platelet count was performed on an EDTA-anticoagulated blood sample. With the first unopette, 125 platelets were counted. The number of platelets counted from the second unopette was 131. What is this patient's platelet count?
- What are two possible physiologic causes or mechanisms that could lead to a decrease in this patient's platelet count?

▶ HEMOGLOBIN CONCENTRATION

This procedure dilutes whole blood in cyanmethemoglobin reagent. The diluting fluid hemolyzes the erythrocytes, releasing hemoglobin into the solution. The ferrous ions (Fe^{2+}) of the hemoglobin molecules are oxidized by potassium ferricyanide to ferric ions (Fe^{3+}). This oxidation results in the formation of methemoglobin, which combines with the cyanide ions (CN^-) to form cyanmethemoglobin, a stable compound that can be quantitated using spectrophotometry.^{25,26} All hemoglobin derivatives except sulfhemoglobin are converted to cyanmethemoglobin.

When measured spectrophotometrically at 540 nm, the absorbance of cyanmethemoglobin follows **Beer-Lambert's law** and is directly proportional to the concentration of hemoglobin in the blood. A reference (standard) curve is prepared using cyanmethemoglobin standard solutions of known hemoglobin concentrations (Figure 13■). The hemoglobin concentration (patient or control) is read from the reference (standard) curve. The reference intervals for hemoglobin vary with age and sex as shown in Table A on the inside cover. Conditions associated with changes in hemoglobin concentration are broadly divided into those associated with decreased levels, the anemias, and those associated with increased levels, the polycythemias.

Several physiologic conditions lead to turbidity in the cyanmethemoglobin reagent-patient sample mixture (Table 8★).

■ **FIGURE 13** Hemoglobin standard calibration curve. When using this standard curve, if the absorbance for a patient's hemoglobin determination is 0.250, the hemoglobin result is 10.0 g/dL.

Any turbidity in the mixture results in falsely elevated values. It is important to recognize the falsely elevated result and take the appropriate corrective action to obtain the true hemoglobin value. A falsely elevated hemoglobin result can be indicated by poor correlation between the patient's hemoglobin and hematocrit result (i.e., $\text{hemoglobin} \times 3 = \text{hematocrit}$) as will be discussed.

▶ HEMATOCRIT

The hematocrit of a blood sample is the packed cell volume (PCV) denoting the percentage of erythrocytes in a known volume of whole blood.^{27,28} It is one of the simplest and most reproducible laboratory tests. The hematocrit is useful in detecting anemia and polycythemia.

In the microhematocrit method, a capillary tube is filled with anticoagulated whole blood and centrifuged in a microhematocrit centrifuge at 10,000–15,000 g for 5 minutes. The volume occupied by the erythrocytes is expressed as a percentage of the total volume (packed cell volume). The reference values vary with age and sex as shown in Table A on the inside cover.

To ensure the accuracy of the hemoglobin and hematocrit a quick mathematical check of $\text{hemoglobin} \times 3 = \text{hematocrit}$ is done. This is called the **rule of three** and works only with normocytic, normochromic erythrocytes. If the calculated hematocrit does not agree within $\pm 3\%$ of the measured

★ TABLE 8

Physiologic Conditions Leading to Error in Hemoglobin Determination and Corrective Actions to Take

Physiologic Condition	Corrective Action
Extremely high leukocyte count ($>50.0 \times 10^9/L$)	Centrifuge hemoglobin mixture and use supernatant to determine hemoglobin concentration.
Presence of hemoglobin S or hemoglobin C	Use a 1:2 dilution of the hemoglobin mixture with distilled water to determine hemoglobin concentration (multiply hemoglobin by 2).
Presence of lipemia	Use a patient blank or replace patient's plasma with isotonic saline to determine hemoglobin concentration.
Presence of abnormal globulins (e.g., those found in multiple myeloma or Waldenstrom's macroglobulinemia)	Increase the alkalinity of the cyanmethemoglobin reagent by adding potassium carbonate, and then repeat hemoglobin determination.

hematocrit, a measurement error or instrument malfunction could have occurred, or the patient could have a pathology that requires investigation.

► **ERYTHROCYTE INDICES**

Wintrobe introduced the erythrocyte indices, **mean cell volume (MCV)**, **mean cell hemoglobin (MCH)**, and **mean cell hemoglobin concentration (MCHC)** in 1929. These indices are calculated from the erythrocyte count, hemoglobin concentration, and hematocrit (Table 9 ★). With the advent of automation in hematology, the erythrocyte indices are measured and/or calculated from data collected by erythrocyte analysis. The electrical impedance counters measure the MCV by averaging the heights of the voltage pulses. The MCH, MCHC, and hematocrit are calculated from the measured values, MCV, hemoglobin, and erythrocyte count. The automated MCV eliminates the problem of a falsely elevated MCV due to trapped plasma in the centrifuged hematocrit sample. Likewise, the MCHC can also be affected in cases of increased trapped plasma (e.g., sickle cell anemia). The manually calculated MCHC is lower than that

obtained from the automated instrument. When the hematocrit is corrected for trapped plasma, the erythrocyte indices calculated from the centrifuged hematocrit agree with those obtained from automated instruments. The erythrocyte indices are used in the morphologic classification of anemias, defining normocytic, microcytic, and macrocytic anemias with the MCV.

✓ **Checkpoint! 10**

Given the following erythrocyte data, what is the expected erythrocyte morphology? hemoglobin = 6.2 g/dL; hematocrit = 0.28 L/L; erythrocyte count = $4.10 \times 10^{12}/L$

► **ERYTHROCYTE SEDIMENTATION RATE**

The ESR is a measurement of the rate at which the erythrocytes settle from the plasma. The sedimentation process consists of three phases. Phase 1 occurs within the first 5 to 10

★ TABLE 9

Erythrocyte Indices

Calculation	Example	Reference Interval (Conventional)
$MCV^* = \frac{Hct (\%)}{RBC (\times 10^{12}/L)} \times 10$	$\frac{42.6}{4.88} \times 10 = 87 \text{ fL}$	80–100 fL
$MCH^\dagger = \frac{Hb (g/dL)}{RBC (\times 10^{12}/L)} \times 10$	$\frac{14.2}{4.88} \times 10 = 29 \text{ pg}$	28–34 pg
$MCHC^\ddagger = \frac{Hb (g/dL)}{Hct (\%)} \times 100$	$\frac{14.2}{42.6} \times 100 = 33 \text{ g/dL}$	32–36 g/dL

* If Hct is expressed in L/L, multiply by 1000 instead of 10.

† If Hb is expressed in g/L, do not multiply by 10.

‡ If Hct is expressed in L/L, do not multiply by 100; if Hct is expressed in L/L and Hb in g/L, divide results by 10 and do not multiply by 100.

minutes and represents the aggregation phase when erythrocytes form rouleaux. The second phase is the sedimentation phase when erythrocytes aggregate and the aggregates fall out of solution. The third phase is the packing phase in which the erythrocyte aggregates pack closely together at the bottom of the tube. The rate of erythrocyte settling depends on (1) the protein composition of the plasma, (2) the size and shape of the erythrocytes, and (3) the erythrocyte concentration.^{29,30} Increasing levels of plasma proteins (primarily **acute phase reactants** such as C-reactive protein, fibrinogen, alpha globulins, or gamma globulins) result in a decrease of the zeta potential surrounding the erythrocytes. With a lower zeta potential, the erythrocytes are able to join together in rouleaux formation and settle from the plasma at a faster rate. Likewise, the erythrocytes' size and shape affect the rate of fall. Macrocytes settle faster than normal erythrocytes, and microcytes settle slower. Due to their irregular shape, poikilocytes are unable to form rouleaux and settle at a slower rate. The erythrocyte concentration directly affects the ESR (i.e., the higher the erythrocyte concentration, the lower the ESR). An anemic individual will appear to have an increased ESR.

The ESR is used to demonstrate the presence of inflammation and/or tissue destruction. It is a nonspecific test indicating tissue destruction/inflammation but not specifying the cause (i.e., disease state responsible). Table 10  lists a number of conditions associated with an elevated ESR.^{31,32}

The CLSI's recommended method is the Westergren method in which EDTA-anticoagulated whole blood is diluted with 0.85% NaCl. The diluted blood is aspirated into a calibrated Westergren pipet, and the cells are allowed to settle for a period of exactly 1 hour at the end of which the distance in millimeters between the meniscus of the plasma and the top of the sedimented erythrocyte column is read.

The reference interval for ESR varies with age and sex. For adult males and children, the reference interval is 0–10 mm/hr. The reference interval for adult females is 0–20 mm/hr.

Automated methods for determining ESR have been available since the 1990s. The principle of measurement for each instrument is an adaptation of the manual Westergren ESR method that allows determination of ESR in a shorter time period, typically 20 to 30 minutes. The automated methods convert the observed result to “mm/hr” so that reported results are in the conventional unit of measurement for the Westergren ESR. These methods have been verified to provide results comparable to those of the manual Westergren method.³³ The advantage of automated instruments is that they allow standardization of the procedure, increasing accuracy and reproducibility of the results.

One example of an automated ESR instrument is the MINI-VES™ instrument (Diesse Diagnostica Senese, Milan, Italy). It is a compact instrument that simultaneously determines the ESR on 4 samples.³⁴ The sample is collected in a special vacuum collection tube containing 0.25 mL of 0.105 mol/L sodium citrate. The collection tubes are thoroughly mixed on a laboratory rocker and then placed in the instrument. Within the instrument, the collection tubes are held at an angle of 18°. A photoelectric cell passes up the collection tube and records the height of the erythrocyte column based on the point at which the light transmission is detected, the “initial” reading. After 20 minutes, the process is repeated to obtain the “final” reading. The decrease in height of the erythrocyte column is determined and used to mathematically derive the ESR in mm/hr.

The ESR-Auto Plus™ instrument (Streck, Inc., Omaha, NE) is a random access instrument with 10 ESR tube positions (Figure 14 ).³⁵ The instrument uses a special vacuum tube containing 3.2% sodium citrate. It is a narrow bore and

 TABLE 10

Conditions Associated with an Elevated ESR

- Acute and chronic infections
- Acute coronary syndrome
- Multiple myeloma
- Osteomyelitis
- Pelvic inflammatory disease
- Polymyalgia rheumatica
- Pregnancy
- Pulmonary tuberculosis
- Rheumatic fever
- Rheumatoid arthritis
- Systemic lupus erythematosus
- Subacute bacterial endocarditis
- Waldenstrom's macroglobulinemia

100 mm tube, and when filled properly blood is drawn to the 60 mm mark \pm 9 mm. Alternatively, an EDTA-anticoagulated sample can be used. In this case, the proper amount of blood is transferred from the EDTA sample to the ESR vacuum tube. The vacuum tubes are thoroughly mixed prior to placing them in the instrument. The vacuum tubes are held in a vertical position at ambient temperature. The instrument scans the tube to determine the height of the packed erythrocyte column at 30 minutes. The observed result is converted to "mm/hr" using a mathematical formula. Using this method, the measurement can be taken at 30 minutes because the majority of samples reach the "packing" phase of the erythrocyte sedimentation process by this time.

C-reactive protein (CRP) determinations by immunologic techniques such as nephelometry or enzyme-linked immunoassays have been introduced as a quantitative replacement for the ESR. CRP is an acute phase reactant that becomes elevated in the same conditions as the ESR. In fact, studies have demonstrated a rise in CRP levels prior to an elevation in the ESR.³⁶ Normal individuals have low levels of CRP, less than 5 mg/dL. In cases of inflammation, CRP levels can rise to 20–500 mg/dL within 8 hours of the acute inflammatory event.³⁷ CRP levels provide a quantitative measurement that can be used to monitor individuals with rheumatoid arthritis for better therapeutic management of the disease.³⁸ However, these assays are not sensitive enough for risk assessment for myocardial infarction or atherosclerosis. The high-sensitivity CRP assay is required if CRP levels are to be used as markers or predictors for those conditions.^{39,40}

► RETICULOCYTE COUNT

Reticulocytes are immature nonnucleated erythrocytes containing residual RNA (i.e., polychromatophilic erythrocytes). In the erythrocyte maturation sequence, the reticulocyte spends about 2 days in the bone marrow and 1 day in the peripheral blood. As the reticulocyte matures, the amount of RNA decreases. The quantitation of reticulocytes present in the peripheral blood provides a method of evaluating the bone marrow's erythropoietic activity. This evaluation is utilized in the differential diagnosis of anemias and in monitoring a patient's erythropoietic response to therapy.^{41–44}

Using a **supravital stain** (new methylene blue), residual ribosomal RNA is precipitated within the reticulocytes.⁴⁵ A blood smear is prepared from the mixture of anticoagulated whole blood and supravital stain. The smear is examined microscopically using the oil immersion lens (1000 \times magnification) fitted with a field-restricted ocular (Figure 15■). An erythrocyte containing two or more particles of blue-stained material is a reticulocyte (Figure 16■). The number of reticulocytes is expressed as a percentage of the total number of erythrocytes counted.

■ **FIGURE 15** Miller disk. Reticulocyte counting area = A; erythrocyte counting area = B. The B square is one-ninth the area of the A square.

Other erythrocyte inclusions (Pappenheimer bodies, Howell-Jolly bodies, and Heinz bodies) can also be stained with new methylene blue and must be distinguished from reticulocytes. Howell-Jolly bodies and Heinz bodies are distinguished from precipitated reticulum by their shape and staining characteristics. Heinz bodies appear as light blue-green inclusions located at the periphery of the erythrocyte. Howell-Jolly bodies are usually one or two round, deep-purple staining inclusions and are visible on Romanowsky stains. Pappenheimer bodies are indistinguishable from reticulum of reticulocytes. If Pappenheimer bodies are suspected, a Prussian-blue iron stain should be performed to verify their presence. Reticulum does not stain with the Prussian-blue iron stain.

Misinterpretations can occur when only the percentage of reticulocytes present in the peripheral blood is reported because the reticulocyte percentage is a relative number and depends on the total number of erythrocytes present in the peripheral blood. If the total erythrocyte count is decreased,

■ **FIGURE 16** Reticulocytes identified by new methylene blue stain. The reticulocytes are the cells containing bluish purple particulate inclusions. (1000 \times original magnification)

the reticulocyte percentage does not accurately reflect the bone marrow's production of new erythrocytes. The absolute reticulocyte count, corrected reticulocyte count, and the reticulocyte production index can be used to avoid these interpretation errors.

Automation is becoming a more popular method for the determination of the reticulocyte count. The new generation of automated hematology instruments is capable of performing absolute reticulocyte counts and other useful parameters.

✓ Checkpoint! 11

Morphologic evaluation of a Wright-stained peripheral blood smear reveals the presence of Pappenheimer bodies. How does this affect a reticulocyte count to be performed on the same blood sample? How would you confirm the presence of Pappenheimer bodies?

▶ SOLUBILITY TEST FOR HEMOGLOBIN S

The solubility test is the most commonly used screening test for the presence of hemoglobin S. It is based on the relative insolubility of hemoglobin S when combined with a reducing agent (sodium dithionite).⁴⁶ Anticoagulated whole blood is mixed with a lysing agent (saponin) and reducing agent. This solution releases the hemoglobin from the erythrocytes and reduces it. If HbS is present, it forms crystals and gives a turbid appearance to the solution (Figure 17 ■). A transparent solution is seen with other hemoglobins that are more soluble in the reducing agent.

■ **FIGURE 17** Sodium dithionite tube test. Negative results are indicated by the clear solution, where the black lines on the reader scale are visible through the test solution (right). Positive results are shown as a turbid solution, where the reader scale is not visible through the test solution (left).

The solubility test does not differentiate hemoglobin S disease from hemoglobin S trait. A hemoglobin electrophoresis procedure should be performed to differentiate these two states. In addition, several abnormal hemoglobin variants can cause sickling and give a positive solubility test. These variants include HbC Harlem, HbS Travis, and HbC Ziguinchor. High-pressure liquid chromatography or **isoelectric focusing** is used to differentiate these variants from HbS.

PART II

REFLEX HEMATOLOGY PROCEDURES

▶ HEMOGLOBIN ELECTROPHORESIS USING CELLULOSE ACETATE

Electrophoresis is the movement of charged molecules in an electric field. Use of this procedure⁴⁷ can detect and preliminarily identify hemoglobinopathies and thalassemias. In hemoglobin electrophoresis, hemoglobin A (adult hemoglobin) takes on a net negative charge at an alkaline pH and moves the farthest toward the anode (positive electrode). Many abnormal hemoglobin variants have altered charges due to single amino acid substitutions within their globin chains. This change in the degree of the negative charge allows for the separation of the majority of abnormal hemoglobin variants from hemoglobin A at an alkaline pH.^{48,49} The electrophoretic patterns and hemoglobin percentages of the unknown (patient) samples are compared to those of the control sample containing HbA, -F, -S, and -C, and those of a known adult sample.

In the hemoglobin electrophoresis procedure, EDTA-anticoagulated whole blood is centrifuged to obtain packed erythrocytes. The erythrocytes are washed, and a hemolysate is obtained by lysing them with a hemolysate reagent (e.g., 0.005 M EDTA). The hemolysate (i.e., patient, control, or known adult sample) is applied to a cellulose acetate plate, which is then placed in the electrophoresis chamber. An alkaline buffer, pH 8.6, permits the flow of electrons from the cathode to the anode within the chamber, alters the charge of the hemoglobin molecules based on their amino acid composition, and allows for the migration and separation of the hemoglobin molecules based on the strength of their negative charge. The hemoglobin molecules are allowed to electrophorese (migrate) for 25 minutes. Following the electrophoresis, the cellulose acetate plate is stained with Ponceau S, a protein dye-binding stain. The stained plate is cleared to remove the cellulose acetate and create a transparent plate with the stained hemoglobin bands representing the hemoglobin electrophoretic pattern for each sample. This plate can then be evaluated visually or with a **densitometer** using 525 nm filter to determine the percentage of hemoglobin present in each band or region.

Cellulose acetate electrophoresis allows for the separation of HbA, -F, -S, and -C into distinct bands (Figure 18■). However, other abnormal hemoglobin variants have the same electrophoretic mobility as HbS and HbC. HbD and HbG have the same mobility as HbS whereas HbE and HbO_{Arab} have the same mobility as HbC. Thus, additional tests must be used to confirm the presence of these abnormal hemoglobin variants. The solubility test can be used to confirm HbS, and citrate agar electrophoresis can be used to confirm the presence of HbS and HbC.

Citrate agar electrophoresis at pH 6.2 separates HbA, -F, -S, -C into distinct bands (Figure 19■). Because no other hemoglobin variants travel with HbS and HbC on citrate agar, it is used to confirm their presence.⁵⁰ It is also useful in differentiating other hemoglobin variants that travel with HbS and HbC on cellulose acetate electrophoresis; these hemoglobin variants (HbD, HbG, HbE, and HbO_{Arab}) have the same mobility as HbA on citrate agar. Rare abnormal hemoglobin variants can be positively identified with DNA analysis of the globin genes.

✓ Checkpoint! 12

What is the basis for hemoglobin separation in the hemoglobin electrophoresis procedures?

▶ QUANTITATION OF HEMOGLOBIN A₂

HbA₂ is a normal adult hemoglobin present in small amounts (up to 3.5%). Increased amounts of HbA₂ are characteristic of beta thalassemia minor. Therefore, the quantita-

■ **FIGURE 18** Electrophoretic mobilities of hemoglobins on cellulose acetate at pH 8.6. (Key: A, A₂, D, G, S, F, C, E = hemoglobin variants) (Courtesy of Helena Laboratories, Beaumont, TX)

■ **FIGURE 19** Electrophoretic mobilities of hemoglobins on citrate agar at pH 6.2, showing separation of hemoglobins S and C from other hemoglobins. (Key: A, A₂, S, F, C, D, E, G = hemoglobin variants)

tion of HbA₂ is useful in its presumptive diagnosis. Slight increases in HbA₂ concentration also have been noted in persons with either HbS trait, HbS disease, unstable hemoglobin variants, or megaloblastic anemia. Decreased HbA₂ concentrations can be seen in iron-deficiency anemia or alpha thalassemia.

Hemoglobin A₂ can be quantitated with anion exchange **column chromatography**. The anion exchange resin is a preparation of cellulose covalently coupled to small positively charged molecules. Thus, the anion exchange resin attracts negatively charged molecules. Hemoglobins, like other proteins, contain positive and negative charges due to the ionizing properties of their component amino acids. In the anion exchange chromatography of hemoglobin A₂, the ionic strength of the buffer and the pH levels are controlled to cause different hemoglobins to possess different net negative charges.⁵¹ These negatively charged proteins are attracted to the positively charged cellulose and bind accordingly. Following binding, the hemoglobins are removed selectively from the resin by altering the pH or ionic strength of the elution buffer. Due to the solubility of hemoglobin A₂ in the elution buffer, hemoglobin A₂ is eluted from the resin as the elution buffer moves through the column. The resin retains the other normal, and most abnormal, hemoglobins. The percentage of hemoglobin A₂ is determined by comparing the absorbance of the hemoglobin A₂ fraction to the absorbance of the total hemoglobin fraction at 415 nm using a spectrophotometer. The CDC National Hemoglobinopathy Laboratory reference interval for HbA₂ is 1.8–3.5%.

Values between 3.5% and 8% are considered indicative of beta thalassemia trait. Values above 8% indicate the pres-

ence of additional hemoglobin variants such as S, C, E, O, D, and S-G hybrid, which elute with HbA₂. HbA₂ cannot be differentiated from several abnormal hemoglobin variants such as hemoglobins C, E, and O, which have a net electrical charge similar to HbA₂ at pH 8.6. If abnormal hemoglobin variants are suspected, other hemoglobin electrophoretic techniques or DNA analysis of globin chains should be performed to confirm their presence. HbA₂ levels can be normal when iron-deficiency anemia coexists with beta thalassemia minor. In this situation, HbA₂ levels must be considered with family history, laboratory data including serum ferritin, serum iron, total iron-binding capacity, red cell morphology, Hb, Hct, and MCV.

Other techniques can be used to quantitate hemoglobin A₂ including high-pressure liquid chromatography and enzyme-linked immunoassay. The enzyme-linked immunoassay utilizes a monoclonal antibody that is directed against the delta-chain, making the assay specific for Hb A₂.⁵²

The Bio-Rad VARIANT™ II hemoglobin instrument measures Hb A_{1c} levels for glycemic control in diabetic patients and can be used to quantitate Hb A₂, HbF, and certain hemoglobin variants.⁵³⁻⁵⁶ For the quantitation of these hemoglobins, this fully automated instrument requires a separate cation-exchange column, specific sodium phosphate buffers and elution program (i.e. Beta-Thal Short program). Within the instrument, a portion of EDTA-anticoagulated blood sample is hemolyzed and diluted and then injected into the cation exchange column. The hemoglobins are separated using a gradient of sodium phosphate buffers of increasing ionic strength for a 6.5 minute elution. The eluted hemoglobins pass through a flow cell where the absorbance is measured at 415 nm with correction at 690 nm. The eluted hemoglobin is identified by its retention time. For example, Hb A₂'s retention time is between 3.3 and 3.9 minutes. The concentration of the eluted hemoglobin is determined from its absorbance measurement.

► ACID ELUTION FOR HEMOGLOBIN F

The acid elution test for fetal hemoglobin (HbF) can be used in the differentiation of hereditary persistence of fetal hemoglobin (HPFH) from other conditions associated with high levels of HbF. HPFH is characterized by an even or uniform distribution of HbF within the erythrocytes whereas other conditions with high HbF levels are characterized by an uneven or nonuniform distribution of HbF within the erythrocytes. Conditions such as beta thalassemia minor, beta thalassemia major, sickle cell anemia, hereditary spherocytosis, and aplastic anemia are associated with high levels of HbF but nonuniform distribution. This stain can also be used to detect the presence of fetal cells in the maternal circulation (fetal-maternal bleed) during problem pregnancies.

In an acid solution, all hemoglobins are eluted from the erythrocytes except hemoglobin F (fetal hemoglobin).⁵⁷

Blood smears are fixed in 80% ethanol and then incubated in the elution buffer, citrate-phosphate (pH 3.3). The slide is stained with acid hematoxylin and counterstained with eosin. The slide is observed microscopically using the oil immersion lens to determine the distribution of HbF within the erythrocytes and the percentage of HbF-containing erythrocytes. Erythrocytes containing fetal hemoglobin stain bright pink or red with the eosin B stain (Figure 20■). The rest of the erythrocytes appear as pale ghosts. Intermediate erythrocytes (pink colored, but not intense) are sometimes seen. The acid hematoxylin stains the leukocyte's nuclei a faint gray purple.

► QUANTITATION OF HEMOGLOBIN F

ALKALI DENATURATION

HbF is resistant to denaturation by strong alkali solutions, but other hemoglobins are not resistant. The addition of a strong alkali solution (1.27 M NaOH) to a hemolysate containing a known concentration of hemoglobin results in hemoglobin denaturation.⁵⁸ Adding a saturated solution of ammonium sulfate stops the denaturation process. Ammonium sulfate lowers the pH of the reaction mixture and precipitates all denatured hemoglobins. After filtration, the concentration of the remaining alkali-resistant hemoglobin is determined. The alkali-resistant hemoglobin is expressed as a percentage of the total hemoglobin concentration. The cyanmethemoglobin method determines the hemoglobin concentrations (alkali-resistant and total). The general reference interval for an adult is less than 2%.

■ **FIGURE 20** Acid elution test for determination of hemoglobin F. Erythrocytes containing hemoglobin F appear as bright pink staining cells. The light staining cells are erythrocytes that contain adult hemoglobins.

OTHER METHODS

In the clinical laboratory, HbF is typically determined by high-pressure liquid chromatography as discussed previously with HbA₂ quantitation or by flow cytometry. In flow cytometry, the cells are permeabilized to allow entry of the fluorescent-conjugated monoclonal antibody directed against HbF into the cell for recognition of HbF. The advantage of flow cytometry is that an increased number of cells (~10,000) are evaluated, thus improving the accuracy of the result. In addition, flow cytometry allows the determination of HbF concentration within individual cells and with the addition of thiazole orange, the differentiation of cells containing HbF such as mature erythrocytes, polychromatophilic erythrocytes or reticulocytes, and nucleated erythrocytes, which can be useful in evaluating certain hematologic diseases (e.g., β -thalassemia).⁵⁹

Checkpoint! 13

What are the advantages of using flow cytometry to quantitate HbF?

▶ HEAT DENATURATION TEST FOR UNSTABLE HEMOGLOBIN

Unstable hemoglobins are hemoglobin variants that result from a variety of amino acid substitutions or deletions affecting the intramolecular interactions of the hemoglobin molecule. These hemoglobin variants are susceptible to spontaneous denaturation resulting in Heinz body formation and erythrocyte hemolysis. In the laboratory, blood samples can be manipulated so that unstable hemoglobins become insoluble and form flocculent precipitate at higher temperatures (50°C) whereas normal hemoglobin remains soluble.^{60,61} The hemoglobin concentrations for heated and unheated fractions are determined by the cyanmethemoglobin method. The concentration of unstable hemoglobin is expressed as a percentage of the total hemoglobin concentration (unheated fraction). Low concentrations of unstable hemoglobin result in false negative results.

Unstable hemoglobins can cause congenital nonspherocytic hemolytic anemias. Examples of unstable hemoglobins are hemoglobin Köln, hemoglobin Hammersmith, hemoglobin Zurich, hemoglobin Seattle, and hemoglobin Bristol. A positive heat denaturation test should be confirmed by other test methods that identify unstable hemoglobins, such as tests for erythrocyte inclusions and the **isopropanol precipitation** test. The specific unstable hemoglobin is identified by DNA sequence analysis to determine the hemoglobin mutation followed by HPLC and tandem mass spectrometry analysis to confirm the specific amino acid substitution.

▶ HEINZ BODY STAIN

Heinz bodies represent denatured hemoglobin inclusions that are usually round or oval, appear refractile, and tend to locate adjacent to the erythrocyte membrane. Heinz bodies are visible only on supravital stained smears and are not visible on Wright-stained smears. Heinz bodies can be present in glucose-6-phosphate dehydrogenase deficiency and related enzyme disorders when the individual is exposed to oxidizing agents such as primaquine or sulfanilamide. In addition, they can be found in individuals with unstable hemoglobins or thalassemias. Heinz bodies are occasionally found in senescent erythrocytes of normal individuals.

A specific dye for Heinz bodies is brilliant green.⁶² To visualize Heinz bodies, EDTA-anticoagulated whole blood is first mixed with 0.5% neutral red. The mixture is counterstained with 0.5% brilliant green. Several thick smears are prepared from the final mixture. The smears are observed microscopically for the presence of Heinz bodies. Heinz bodies stain green, reticulocytes and Howell-Jolly bodies stain a deep red, and erythrocytes stain light red. The percentage of erythrocytes containing Heinz bodies can be determined by counting the number of erythrocytes containing Heinz bodies within 500 erythrocytes.

The specificity of the brilliant green dye for Heinz bodies eliminates problems that arise with the use of other supravital stains such as methyl violet or crystal violet. With these other supravital stains, Howell-Jolly bodies, basophilic stippling, and reticulum stain the same as Heinz bodies, often leading to difficulties in interpreting the stain.

▶ OSMOTIC FRAGILITY TEST

In the osmotic fragility test heparin-anticoagulated whole blood is added to increasingly hypotonic solutions of buffered sodium chloride (0.85% to 0.00%) and the solutions incubate for 20 minutes at room temperature.⁶³ The amount of hemolysis at each concentration is determined by measuring the absorbance of the **supernatants** spectrophotometrically. An osmotic fragility graph is prepared by plotting the percentage of hemolysis for each solution against its concentration, and the results are compared to a normal control. In normal individuals, an almost symmetrical sigmoid shaped curve is obtained (Figure 21■). Normal erythrocytes begin to hemolyze around 0.50% sodium chloride (NaCl) concentration, and hemolysis is complete at 0.30% NaCl. The normal values for osmotic fragility with each sodium concentration are given in Table J in the inside book cover.

In the osmotic fragility test, spherocytes with a decreased surface-area-to-volume ratio have a limited ability to expand in hypotonic solutions. They lyse at higher concentrations of sodium chloride than normal biconcave erythrocytes and

FIGURE 21 Normal osmotic fragility curve. The osmotic fragility curve of a normal individual would fall within the area defined by the two sigmoid curves. A curve to the left of normal indicates increased fragility and a curve to the right decreased fragility.

are said to have an increased osmotic fragility. Target cells or sickle cells have a large surface-area-to-volume ratio. This increased surface-area-to-volume ratio translates into an increased ability to expand in hypotonic solutions. These cells lyse at lower concentrations of sodium chloride than normal cells and are said to have a decreased osmotic fragility.

An increased osmotic fragility is associated with hemolytic anemias in which spherocytes, particularly hereditary spherocytosis, are present. Conditions associated with a decreased osmotic fragility include thalassemia, sickle cell anemia, and those conditions in which target cells are observed. Figure 22 depicts the increased osmotic lysis of spherocytes in a hypotonic medium.

An incubated osmotic fragility test is performed to identify patients with mild hereditary spherocytosis in which the standard osmotic fragility test is normal. In the incubated osmotic fragility test, a patient's blood and control blood are incubated for 24 hours at 37°C under sterile conditions. A significantly increased osmotic fragility after incubation is characteristic of hereditary spherocytosis.

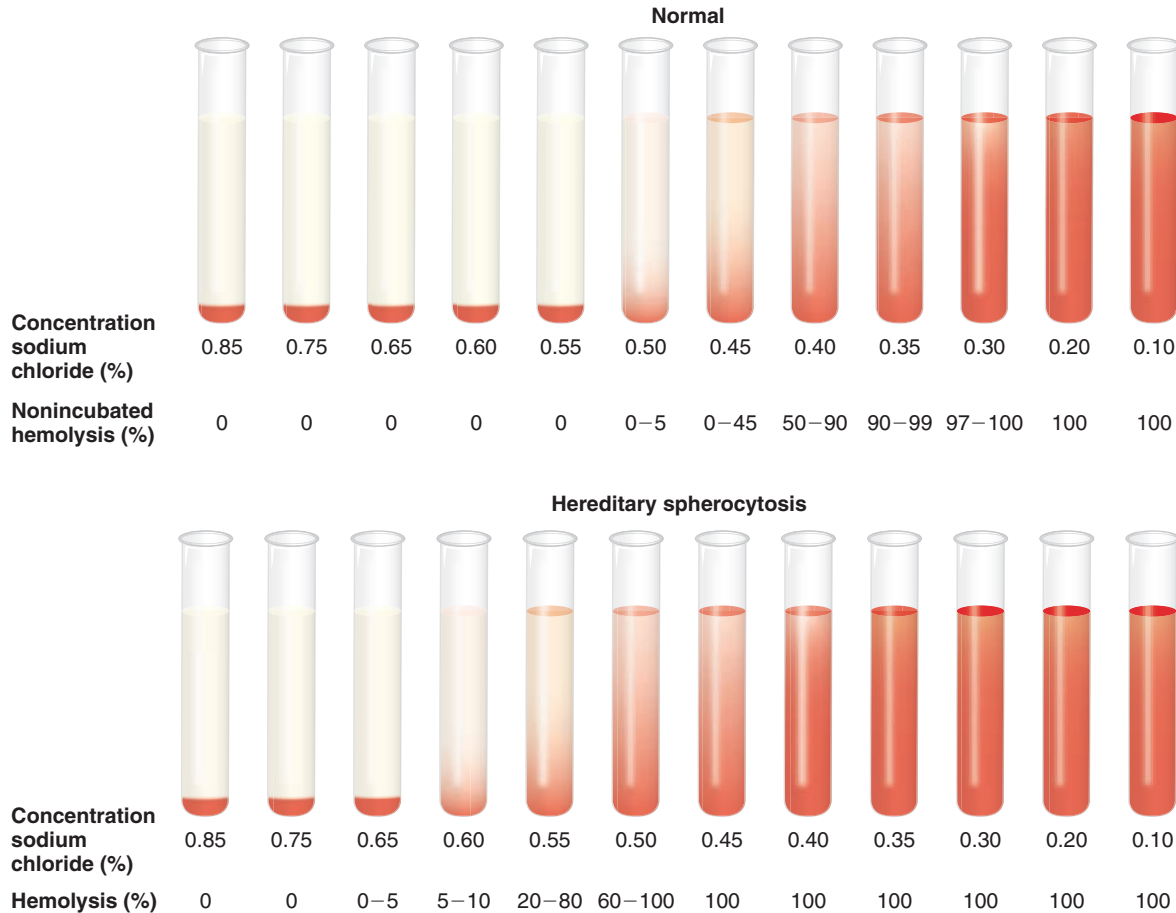

FIGURE 22 The osmotic fragility test demonstrates the increased osmotic lysis of spherocytes in a hypotonic medium compared with normal erythrocytes. (Key: clear supernatant = no hemolysis; pinkish supernatant = partial hemolysis; red supernatant = complete hemolysis)

✓ Checkpoint! 14

A patient's osmotic fragility test shows beginning hemolysis at 0.60% NaCl and complete hemolysis at 0.50% NaCl. How should these results be interpreted?

▶ SUGAR-WATER SCREENING TEST

A sugar-water solution (10%) provides a low-ionic-strength solution that promotes the attachment of complement to susceptible paroxysmal nocturnal hemoglobinuria erythrocytes.⁶⁴ Upon attachment of complement, the erythrocytes hemolyze. Normal erythrocytes do not hemolyze under these conditions. A positive sugar-water test (sucrose hemolysis test) is presumptive evidence for paroxysmal nocturnal hemoglobinuria (PNH). In the past, the acidified serum test was used to confirm PNH. However, flow cytometry is now the preferred method because it detects the absence of glycosyl phosphatidylinositol-anchored complement regulatory proteins, CD55 (decay accelerating factor), and CD59 (membrane inhibitor of reactive lysis), which are diagnostic for PNH.⁶⁵

▶ DONATH-LANDSTEINER TEST FOR PCH

The Donath-Landsteiner test is a screening test for paroxysmal cold hemoglobinuria (PCH),⁶⁶ which is characterized by the presence of the Donath-Landsteiner antibody, a **biphasic antibody** with anti-P specificity. This IgG antibody is capable of activating complement resulting in hemolysis. The Donath-Landsteiner test should be performed when an individual presents with hemoglobinuria and a positive direct antiglobulin test due to C3 only with no evidence of

autoantibody activity in the serum. In this procedure, a series of test tubes is set up to detect the biphasic nature of complement activation (Table 11). Normal serum serves as a source of complement because individuals with PCH can express low levels of complement. The 50% suspension of group O erythrocytes with P antigen serves as the antibody receptor. Following the appropriate incubation schedule, the tubes are centrifuged and observed for hemolysis. If anti-P is present in the patient's serum, it will bind to the erythrocyte's P antigen during the incubation time in the melting ice bath. During the second incubation time at 37°C, the antibody dissociates from the erythrocytes, and complement is activated leading to hemolysis. Therefore, the test is considered positive for PCH if tubes A1 and/or A2 demonstrate hemolysis and the remaining tubes have no hemolysis. Proper sample collection and processing are essential to this test's outcome. Patient's blood should be allowed to clot at 37°C and the serum separated at this temperature to avoid cold autoabsorption and loss of antibody prior to testing.

▶ ERYTHROPOIETIN

Erythropoietin (EPO) levels are determined by enzyme-linked immunosorbent assay (ELISA). In this procedure, microtiter plate wells are coated with a monoclonal mouse antihuman antibody directed against EPO.⁶⁷ This antibody represents the capture antibody because it will bind EPO from the serum, either patient, control, or standard. Following a washing step, the wells are incubated with a polyclonal rabbit anti-EPO that is enzyme-labeled with horseradish peroxidase. This second antibody will bind to the initial antigen-antibody complex. Hence, EPO is sandwiched between two specific antibodies (Web Figure 8). A substrate specific for the enzyme label (i.e., tetramethylbenzidine) is added to the microtiter plate wells, and a colorimetric reaction occurs.

TABLE 11

Schematic Outline of Donath-Landsteiner Test Procedure for Detecting PCH

Incubation Set	Tube 1	Tube 2	Tube 3	Incubation Protocol
A	Patient's serum — 50% group O cells	Patient's serum Normal serum 50% group O cells	— Normal serum 50% group O cells	→ 30 minutes in melting ice bath followed by 60 minutes @ 37°C
B	Patient's serum — 50% group O cells	Patient's serum Normal serum 50% group O cells	— Normal serum 50% group O cells	→ 90 minutes in melting ice bath
C	Patient's serum — 50% group O cells	Patient's serum Normal serum 50% group O cells	— Normal serum 50% group O cells	→ 90 minutes @ 37°C

PCH is indicated if hemolysis occurs in tubes A1 and/or A2 and remaining tubes have no hemolysis. Tubes A3, B3, and C3 represent controls for normal serum complement source and should not demonstrate hemolysis. Tubes B1 and B2 represent controls for the presence of cold-reacting antibodies, and tubes C1 and C2 represent controls for the presence of warm-reacting antibodies. Including these controls to eliminate possible false positive interpretations is important.

The absorbance of each microtiter well is determined using a microtiter plate reader, an adaptation of a spectrophotometer. The amount of absorbance measured in a given microtiter well is directly proportional to the concentration of EPO in the sample. The control and patient results are determined from a reference (standard) curve that is prepared using known concentrations of EPO. The general reference interval for serum EPO is 3.3–16.6 mIU/mL.

Measurement of EPO levels is useful in diagnosing certain anemias and polycythemia. For example, secondary polycythemias such as chronic obstructive pulmonary disease or cyanotic heart disease are associated with elevated levels of EPO while the myeloproliferative disorder polycythemia vera is associated with normal to low EPO levels. Decreased levels of EPO are observed in anemia of renal failure, anemia of chronic disease, and anemia of hypothyroidism.

▶ SOLUBLE TRANSFERRIN RECEPTOR

Soluble transferrin receptor (sTfR) represents a truncated form of the membrane transferrin receptor that is normally found on the surface of cells that require iron. sTfR levels are determined by ELISA. In this procedure microtiter plate wells are coated with a monoclonal antihuman antibody directed against sTfR.⁶⁸ This antibody represents the capture antibody because it will bind sTfR from the serum from either patient, control, or standard. Following a washing step, the wells are incubated with a second monoclonal anti-sTfR that is enzyme labeled with horseradish peroxidase. This second antibody will bind to the initial antigen–antibody complex. Hence, sTfR is sandwiched between two specific antibodies (Web Figure 8 for comparison). A substrate specific for the enzyme label is added to the microtiter plate wells, and a colorimetric reaction occurs. The absorbance of each microtiter well is determined using a microtiter plate reader. The amount of absorbance measured in a given microtiter well is directly proportional to the concentration of sTfR in the sample. The control and patient results are determined from a reference (standard) curve that is prepared using known concentrations of sTfR. The general reference interval for serum sTfR is 8.7–28.1 nmol/L.

Measurement of sTfR levels is useful in the differential diagnosis of iron-deficiency anemia from anemia of chronic disease because sTfR levels are elevated in iron-deficiency anemia but are normal in anemia of chronic disease.

✓ Checkpoint! 15

A patient was recently diagnosed with a hypochromic, microcytic anemia. Additional laboratory testing revealed EPO 1.5 mIU/mL and sTfR 15.8 nmol/L. Which anemia is consistent with these results?

▶ CYTOCHEMICAL STAINS

Cytochemical stains are useful in differentiating the cell lineage of malignant cells in the bone marrow. The first stains done usually are the myeloperoxidase and/or Sudan black B to differentiate myeloid cells from lymphoid cells. Additional stains can be required for further differentiation such as differentiating myelocytic from monocytic cells.

MYELOPEROXIDASE

Myeloperoxidase (MPO) is an enzyme capable of catalyzing the oxidation of substances by hydrogen peroxide. The methods using 3,3-diaminobenzidine as the color reagent with Giemsa counterstain or using 3-amino-9-ethylcarbazole provide satisfactory results.⁶⁹ This enzyme is present in primary granules of neutrophils, eosinophils, and monocytes. An insoluble dark brown reaction product identifies the sites of MPO activity (Figure 23■). MPO is the most sensitive and specific stain for granulocytes, which stain intensely. Monocytes stain less intensely than neutrophils. Lymphocytes do not exhibit MPO activity. The MPO is, therefore, useful in the differentiation of acute myelogenous leukemia (AML) from acute lymphocytic leukemia (ALL) and subgrouping of the AMLs (Table 12✚). A positive reaction is seen in myeloblasts. Weak staining rarely is seen in monoblasts. Leukemic blasts that are negative for MPO can represent lymphoblasts, AML (minimally differentiated), monoblasts, erythroblasts, and megakaryoblasts or undifferentiated leukemia.⁷⁰ The presence of many mature neutrophils with negative MPO staining can indicate a deficiency of MPO.

SUDAN BLACK B

Sudan black B (SBB) is a diazo dye that stains phospholipids, neutral fats, and sterols.⁷¹ Cellular components containing

■ **FIGURE 23** Blasts of AML showing a positive myeloperoxidase stain (brown-black color in cytoplasm). (Bone marrow; MPO stain; 500× magnification)

TABLE 12

Cytochemical Features of Acute Myelogenous Leukemia (AML) Subgroups

Subgroup	Myeloperoxidase or Sudan Black B	Chloroacetate (specific) Esterase	Nonspecific Esterase
AML-minimally differentiated	Negative	Negative	Negative
AML-without maturation	Positive	Positive	Negative
AML-with maturation	Positive	Positive	Negative
Acute promyelocytic leukemia	Positive	Positive	Negative
AML-myelomonocytic	Positive	Positive	Positive*
AML-monoblastic/monocytic	Negative	Negative	Positive*
Acute erythroid leukemia	Positive [†]	Negative	Positive or negative
AML-megakaryoblastic	Negative	Negative	Strongly positive when acetate is used as a substrate

*Monocytic component is positive, and the staining can be inhibited by sodium fluoride incubation. About 20% of AML-monoblastic can be negative for nonspecific esterase

[†]Myeloblasts in AML-erythroid are positive.

lipids stain brown black (Figure 24 ■). SBB stains phospholipids in membranes of primary and secondary granules of the granulocytic series. Auer rods have a rich phospholipid membrane that is identified by the SBB stain. The SBB stain results parallel those seen with the MPO stain in myeloblasts and monoblasts (Table 12). Lymphoblasts do not stain with SBB (rare cases are weakly positive). This stain is useful when fresh samples are not available and in unusual cases when myeloblasts have an acquired deficiency of MPO. Therefore, it is useful in the differentiation of AML from ALL. Because of its fat solubility, SBB also can stain marrow fat and some cytoplasmic vacuoles of Burkitt lymphoma cells.⁷²

■ FIGURE 24 Blasts of AML showing a positive Sudan black B stain (brown-black color in cytoplasm). (Bone marrow; SBB stain; 500× magnification)

CHLOROACETATE ESTERASE

Several cytochemical methods are available for specific esterase on smears. Chloroacetate esterase (also called *specific esterase*) activity is detected by incubating the sample in naphthol AS-D chloroacetate at an acid pH.⁷³ As a result of the esterase activity, enzymatic hydrolysis of ester linkages occurs, and free naphthol compounds are liberated. The liberated naphthol immediately couples with a diazonium salt (e.g., fast red violet) forming an insoluble, visible pigment at the site of enzyme activity (Figure 25 ■). Naphthol AS-D chloroacetate is considered specific for the granulocytic series and is present in mast cells. The sites of enzyme activity

■ FIGURE 25 Blasts of AML showing a positive specific esterase stain (red-magenta color in cytoplasm). (Bone marrow; specific esterase stain; 500× magnification)

show bright red granulation when fast red violet is used. Enzyme activity is weak or absent in monocytes and lymphocytes. Neoplastic eosinophils of acute myelomonoblastic leukemia rarely are positive for chloroacetate esterase. The naphthol AS-D chloroacetate is less sensitive than MPO and SBB, but positive results parallel those seen with the MPO and SBB stains. Therefore, it is useful in the differentiation of AML from ALL (Table 12). A combination of chloroacetate esterase and cyanide-resistant peroxidase stains is also helpful in diagnosing acute eosinophilic leukemia, which is characteristically negative for chloroacetate esterase and positive for cyanide-resistant peroxidase.⁷⁰

ALPHA-NAPHTHYL ESTERASE (NONSPECIFIC ESTERASE)

Alpha-naphthyl esterase activity is found primarily in monocytes and macrophages using either α -naphthyl acetate or α -naphthyl butyrate as substrate. Alpha-naphthyl acetate esterase (ANAE) activity is also present in plasma cells, megakaryocytes, hairy cells, and T lymphocytes (dot-like pattern). Similarly, alpha-naphthyl butyrate esterase activity is also present in megakaryocytes (less intense than ANAE) and helper T lymphocytes. The sites of enzyme activity show black granulation and are detected by incubating the sample in α -naphthyl acetate/or butyrate at an alkaline pH (Figure 26 ■). As a result of the esterase activity, enzymatic hydrolysis of ester linkages occurs, and free naphthol compounds are liberated. The liberated naphthol immediately couples with a diazonium salt (e.g., fast blue RR), forming an insoluble, visible pigment at the site of enzyme activity.⁷³

Granulocytes are usually negative but can show occasional activity. In addition, enzyme activity can be detected

■ **FIGURE 26** Blasts of acute monoblastic leukemia showing a positive nonspecific esterase (NES) stain (black granulation). (Bone marrow; NSE stain; 500 \times magnification)

in the erythroblasts of erythroleukemia and focally in lymphoblasts of ALL. Alpha-naphthyl butyrate exhibits strong activity in the monocytic cells but very weak or absent activity in granulocytes, megakaryocytes, and lymphocytes. The combined method for α -naphthyl butyrate esterase and chloroacetate esterase provides an objective means for demonstrating monocytes and granulocytes simultaneously in cytologic preparations and, thus, is useful for differentiating myeloblasts from monoblasts.^{74,75}

Alpha-naphthyl esterase is useful in diagnosing acute myelomonocytic and acute monocytic leukemias (Table 12).⁷⁶ To differentiate monocytes from other cells that occasionally show positivity, sodium fluoride can be added to the incubation mixture. Sodium fluoride inactivates the monocytic enzyme. This is referred to as the *fluoride inhibition test* in which two incubation mixtures are prepared, one without fluoride and the other with fluoride. Slides are incubated in the incubation mixtures, and the staining patterns of the two slides are compared. The slide stained in the incubation mixture containing fluoride shows an inhibition of staining in monocytes but not in other cell lines.

PERIODIC ACID-SCHIFF (PAS)

Periodic acid oxidizes 1,2-glycol groups to dialdehydes. These aldehyde groups combine with Schiff's reagent to produce a magenta product (Figure 27 ■). The stainable compound in the blood cells is primarily glycogen. Cellular components containing polysaccharides, mucopolysaccharides, and glycoproteins possess the 1,2-glycol groups and will be stained.⁷⁷ Mature granulocytes (the intensity of staining increases with maturity), platelets, megakaryocytes, and monocytes are stained with PAS. However, the early myeloid cells, the erythroid cells, and many of the lymphoid cells are negative with PAS. Therefore, PAS positivity in these cells can indicate abnormal glycogen metabolism and can be diagnostically important.

■ **FIGURE 27** PAS stain showing positive reaction (red-purple cytoplasm) of erythroblasts in acute erythroid leukemia. (Bone marrow; PAS stain; 400 \times magnification)

LEUKOCYTE ALKALINE PHOSPHATASE

The determination of **leukocyte alkaline phosphatase (LAP)** activity can be used to differentiate chronic myelogenous leukemia from leukemoid reaction/reactive neutrophilia.^{78,79} In this procedure, freshly prepared peripheral blood smears obtained from finger-stick capillary blood or samples anticoagulated with heparin are dried for at least 1 hour prior to fixation in 60% citrate buffered acetone.⁷⁸ Fixed slides can be stored overnight in the freezer. The smears are incubated in naphthol AS-MX phosphate at an alkaline pH. The liberated naphthol immediately couples with a diazonium salt (e.g., fast blue RR) forming brown to black particles in the cytoplasm of the cells at the enzyme sites (Figure 28 ■). After counterstaining, the smears are evaluated microscopically. Because this enzyme is found within the secondary granules of maturing granulocytes, 100 segmented neutrophils/bands are counted, and each cell is graded using a scale of 0 to 4+ according to the appearance and intensity of the precipitated dye (Table 13 ☆). The number of cells counted in each grade is multiplied by that grade, and the products are summed to obtain a total LAP score (Table 14 ☆). Improperly stored smears and those prepared from blood anticoagulated with EDTA can give falsely low LAP scores. The range of normal scores is 13–130, although this could vary slightly in each laboratory. The range of possible values is 0–400. A score higher than 160 is generally considered increased and lower than 13 is considered decreased. The LAP scores can be increased in leukemoid reaction (infection, inflammation), polycythemia vera, pregnancy, newborns, stress, oral contraceptives, and medications (steroids, estrogen, lithium, growth factors). In secondary erythrocytosis, idiopathic myelofibrosis and essential thrombocytosis, the enzyme activity is usually normal. LAP scores can be decreased in chronic myelocytic

■ **FIGURE 28** LAP stain showing neutrophil with a score of 3+. Note strong dark colored granulation. (Peripheral blood; LAP stain; 500× magnification)

☆ **TABLE 13**

Leukocyte Alkaline Phosphatase: Cell Rating and Staining Characteristics

Cell Rating	Amount	Intensity of Staining
0	None	None
1+	<50%	Faint
2+	50–75%	Moderate
3+	75–100%	Strong
4+	100%	Intense

leukemia (CML), paroxysmal nocturnal hemoglobinuria, idiopathic thrombocytopenic purpura, and sometimes in myelodysplasia. The LAP score for CML patients in blast crisis or with concurrent infections can be increased.

✓ **Checkpoint! 16**

A pathology resident is evaluating the peripheral blood smear of a 40-year-old female. The resident suspects CML. To confirm this suspicion, a LAP score is ordered. Do you think that the LAP score will be helpful in making the correct diagnosis?

ACID PHOSPHATASE AND TARTRATE-RESISTANT ACID PHOSPHATASE (TRAP)

Acid phosphatase activity is detected by incubating the sample in naphthol AS-BI phosphoric acid.^{80,81,82} Enzyme activity liberates naphthol AS-BI. The liberated naphthol immediately couples with a diazonium salt (e.g., fast garnet) forming an insoluble, visible pigment at the site of enzyme activity. Acid phosphatase activity is present in most normal leukocytes appearing as purplish, dark-red intracellular granules. The acid phosphatase activity in T cell ALL is characteristic, which exhibits focal polarized acid phosphatase activity.

Seven acid phosphatase isoenzymes (0, 1, 2, 3, 3b, 4, and 5) are present in leukocytes. These isoenzymes are cell specific with neutrophils containing isoenzymes 2 and 4, lymphocytes and platelets isoenzyme 3, blasts isoenzyme 3b, and hairy cells isoenzyme 5. All but isoenzyme 5 are sensitive

☆ **TABLE 14**

Example of a LAP Score Calculation

Cell Rating	Number of Cells Counted	LAP Score
0	45	0
1+	30	30
2+	15	30
3+	5	15
4+	5	20
		Total LAP score 95

to tartrate inhibition. The hairy cells of hairy cell leukemia exhibit acid phosphatase activity but can be differentiated from other leukocytes using tartrate inhibition.^{83,84} Tartrate inhibits the acid phosphatase activity within normal leukocytes, while enzyme activity within hairy cells is resistant to tartrate inhibition (Figure 29■). Therefore, hairy cell leukemia is said to be strongly **tartrate-resistant acid phosphatase (TRAP)** positive. Weak to moderate TRAP positivity occurs in activated lymphocytes and Sézary cells, a few cases of chronic lymphocytic leukemia, and prolymphocytic leukemia. Mast cells are also TRAP positive, and the morphology of abnormal mast cells on tissue sections is similar to hairy cell leukemia. Toluidine blue stain is helpful in distinguishing mast cells (positive) from hairy cells (negative).

✓ Checkpoint! 17

A 30-year-old male presented to the emergency room complaining of fatigue, weakness, and gum bleeding. The CBC showed anemia, thrombocytopenia, and a WBC of $30 \times 10^9/L$. The peripheral blood smear revealed numerous intermediate to large blasts with fine nuclear chromatin and abundant cytoplasm. The bone marrow biopsy contained 60% blasts. No Auer rods were seen after careful inspection. Several cytochemical stains were then performed. The blasts failed to stain with myeloperoxidase, Sudan black B, and specific esterase; however, the majority of blasts reacted intensely with α -naphthyl esterase. Incubation with sodium fluoride inhibited the staining seen with α -naphthyl esterase. What type of leukemia do you think this patient has?

TERMINAL DEOXYNUCLEOTIDYL TRANSFERASE

Terminal deoxynucleotidyl transferase (TdT) is an intranuclear DNA polymerase responsible for the template-independent addition of deoxyribonucleotides to the 3'-hydroxyl

■ **FIGURE 29** TRAP stain showing a positive reaction of hairy cell with acid phosphatase that is resistant to tartrate inhibition (reddish granulation). (Peripheral blood; TRAP stain; 500 \times magnification)

terminus of oligonucleotide primers during immunoglobulin and T cell receptor gene rearrangements. It is normally present in thymus lymphocytes, in pre-B lymphocytes (hematogones), and in 1–3% of normal bone marrow cells (blasts). It is not normally present in peripheral blood lymphocytes or lymph node lymphocytes. Because Tdt is primarily found in lymphoid precursors, its detection is useful in distinguishing ALL from malignant lymphoma.^{85,86} However, a positive Tdt result in an acute leukemia should be interpreted with caution because Tdt has been observed in up to 20% of AMLs and specifically in more than 90% of AML-minimally differentiated cases.

In the indirect immunofluorescence technique for detection of Tdt, rabbit anticalf Tdt is applied to the sample (e.g., bone marrow aspirate smear).⁸⁷ If the cells' nuclei contain Tdt, this antibody binds to it creating an antibody–antigen complex. Excess anticalf Tdt is washed away. A secondary antibody, fluorescein isothiocyanate-conjugated goat anti-rabbit IgG antiserum, is used to identify the antibody–antigen complex. The nucleus of cells containing Tdt will fluoresce. Tdt can also be detected by biochemical assays, enzyme immunoassays, and indirect immunoperoxidase or direct immunofluorescence using monoclonal antibodies.

✓ Checkpoint! 18

A pathologist is reviewing the slides from the pleural fluid of a 50-year-old male who has hepatosplenomegaly and minimal lymphadenopathy. It is not clear whether the mononuclear cells are mature lymphoma cells or leukemic blasts. There is not enough material for flow cytometry to do immunophenotyping, but there is enough to make a few extra cytospin smears. Which stain do you think can be useful in this case?

TOLUIDINE BLUE

Toluidine blue is a basic dye that reacts with acid mucopolysaccharides to form red to purple metachromatic granules. Bone marrow trephine sections are stained with 0.1% toluidine blue in ethanol and examined microscopically. A positive reaction is specific for basophils and mast cells. This stain is useful in diagnosing mast cell disease and rare cases of AML with basophilic differentiation.^{75,88,89} Because acid mucopolysaccharides can be decreased or absent in neoplastic disorders, a negative reaction does not rule out a neoplasm of these cells.

RETICULIN STAIN AND MASSON'S TRICHROME STAIN

The reticulin and trichrome stains are used to evaluate the presence and extent of fibrosis within the bone marrow. In the Gomori methenamine silver staining method, deparaffinized bone marrow trephine sections are incubated in the following solutions: 0.5% periodic acid, methenamine silver working solution (contains methenamine, silver nitrate, and sodium borate), 0.2% gold chloride, and 3% sodium thiosul-

■ **FIGURE 30** Bone marrow biopsy stained with reticulin stain showing fibrosis (black fibers) in a patient with myelofibrosis. (Bone marrow; paraffin section, reticulin stain; 200× magnification)

fate. The section is counterstained with nuclear fast red and examined microscopically. The reticulin fibers appear black. The silver staining method is used to examine reticulin fibers that form the framework of the bone marrow. In a hypercellular marrow, the reticulin becomes more prominent, but its structural framework is preserved. In myelofibrosis, reticulin is markedly increased and the structural framework is distorted (Figure 30 ■).

In the Masson's trichrome stain, deparaffinized bone marrow trephine sections or frozen trephine sections are stained with Weigert's iron hematoxylin working solution and then incubated in the following solutions: Biebrich scarlet-acid fuchsin, phosphomolybdic acid, and aniline blue. The slides are examined microscopically; collagen fibers appear blue, nuclei black, and the background red. The trichrome stain is used to evaluate collagenous fibrosis within the bone marrow. Normally, collagenous fibrosis is focal and perivascular. Increased staining can be observed in myelofibrosis and indicates significant fibrosis (Figure 31 ■).

■ **FIGURE 31** Bone marrow biopsy stained with Masson's trichrome stain showing collagenous fibrosis (fibers are stained light blue) in a patient with myelofibrosis. (Bone marrow; paraffin section, Masson's Trichrome stain; 400× magnification)

SUMMARY

This chapter reviewed the routine and reflex tests performed within the hematology laboratory. The accuracy and reliability of the results depend on the clinical laboratory professional's knowledge of the test procedure. A thorough understanding of each procedure is necessary to understand the appropriate use, troubleshoot potential sources of error, identify other problems in performing the test, and understand the meaning of test results. Although the majority of the routine hematology tests are performed by automated instrumentation, the basic principles, applications, and potential sources of error hold true for the automated adaptation of each procedure. The results obtained from the routine and reflex test procedures are utilized in diagnosing, prognosing, and therapeutic monitoring a variety of disorders including anemias, leukemias, infections, and inherited leukocyte disorders.

REVIEW QUESTIONS

LEVEL I

1. What is the appropriate sequence to fill sample collection tubes according to top color? (Objective 6)
 - a. red, lavender, blue, green
 - b. lavender, blue, red, green
 - c. blue, red, green, lavender
 - d. red, blue, lavender, green
2. The function of a microscope's condenser is to: (Objective 8)
 - a. magnify the light beam prior to it striking the sample
 - b. collect the diffracted light from the sample
 - c. direct the light beam onto the sample
 - d. project diffracted light to the objective

LEVEL II

1. In performing a manual platelet count using phase contrast microscopy, identification of the platelets is very difficult. What should be done to improve the identification of the platelets? (Objective 2)
 - a. lower the condenser to increase the depth of field
 - b. align the annulus with the phase-shifting element
 - c. perform Koehler illumination with the 100× objective
 - d. decrease the brightness dial to increase resolution

REVIEW QUESTIONS (continued)

LEVEL I

- A manual leukocyte count was performed on an EDTA-anti-coagulated sample. The sample was diluted 1:100, and a total of 75 leukocytes were counted in all 9 squares of the hemacytometer. What is the leukocyte count? (Objective 19)
 - $1.3 \times 10^9/L$
 - $3.3 \times 10^9/L$
 - $4.1 \times 10^9/L$
 - $8.3 \times 10^9/L$
- Any turbidity in a peripheral blood sample results in a falsely elevated hemoglobin determination. Which of the following is a potential source of turbidity? (Objective 19)
 - lipemia
 - leukocyte count = $18.0 \times 10^9/L$
 - increased levels of carboxyhemoglobin
 - presence of hemoglobin F
- Which of the following is *not* a condition associated with an elevated ESR? (Objective 19)
 - rheumatoid arthritis
 - polycythemia vera
 - multiple myeloma
 - osteomyelitis
- Which of the following is observed if a purple top collection tube is underfilled? (Objective 6)
 - falsely elevated erythrocyte count
 - falsely decreased microhematocrit
 - falsely elevated platelet count
 - falsely decreased hemoglobin
- In performing a reticulocyte count, the clinical laboratory professional observes suspicious light bluish-green bodies at the periphery of some erythrocytes. What is the appropriate course of action? (Objective 19)
 - These bodies are aggregated reticulum, and erythrocytes containing them should be tabulated as reticulocytes.
 - These bodies are iron-containing bodies and should be confirmed using the Prussian-blue stain.
 - These bodies are aggregated DNA, and erythrocytes containing them should not be tabulated as reticulocytes.
 - These bodies are denatured hemoglobin, and erythrocytes containing them should not be tabulated as reticulocytes.
- The laboratory is experiencing problems with the air conditioning system and it is unusually warm. What effect will this temperature change have on the ESRs performed during this time period? (Objective 19)
 - ESRs will be falsely elevated because higher temperature promotes sedimentation.
 - ESRs will be falsely decreased because erythrocytes have a higher zeta potential.
 - ESRs will be unaffected because erythrocyte sedimentation does not depend on temperature.
 - ESRs will be falsely elevated because erythrocytes will become swollen.

LEVEL II

- A manual platelet count was performed using the unopette system. A total of 526 platelets were counted on one side of the hemacytometer. Which of the following clinical conditions is associated with this result? (Objective 7)
 - immune thrombocytopenic purpura
 - megaloblastic anemia
 - acute leukemia
 - iron-deficiency anemia
- If the solubility test for hemoglobin S is positive, the appropriate reflex test is: (Objective 6)
 - hemoglobin electrophoresis using cellulose acetate
 - hemoglobin A₂ by column chromatography
 - isoelectric focusing with SDS gel
 - hemoglobin F determination by acid elution
- While evaluating the erythrocyte morphology on a Wright-stained peripheral blood smear, the clinical laboratory professional observed many crenated erythrocytes. What corrective action will minimize the presence of these cells? (Objective 4)
 - Allow the sample to stabilize for at least 4 hours and then prepare the blood smear.
 - Dry the blood smear quickly after its preparation.
 - Increase the spreader speed to prepare the blood smear.
 - No corrective action is available.
- A clinical laboratory professional noted that a patient's platelet count was significantly decreased. In examining the patient's blood smear, platelets appeared to adhere to the neutrophils. How would you obtain an accurate platelet count? (Objective 4)
 - Recollect sample in citrate and reanalyze platelet count.
 - Allow sample to set at 25°C for 5 hours and reanalyze platelet count.
 - Warm sample at 37°C for 15 minutes and reanalyze platelet count.
 - No corrective action is available.
- Which screening test can be used if a diagnosis of PNH is suspected? (Objective 6)
 - hemoglobin electrophoresis
 - sugar-water test
 - Donath-Landsteiner test
 - acid elution test

REVIEW QUESTIONS (continued)

LEVEL I

9. When examining an acid elution test for hemoglobin F, the clinical laboratory professional observed uniformly stained erythrocytes on the control slide (mixture of adult erythrocytes and cord cells) and on the patient's slide. What is the source of this error? (Objective 19)
- fixative
 - stain
 - elution buffer
 - counterstain
10. Electrophoresis using cellulose acetate reveals a band of hemoglobin with HbC mobility. Citrate agar electrophoresis does *not* show a HbC band. The most likely explanation is that the: (Objective 19)
- abnormal hemoglobin can be HbE or HbO_{Arab}
 - citrate agar electrophoresis result is erroneous
 - abnormal hemoglobin can be HbG or HbD
 - cellulose acetate electrophoresis is not reliable

LEVEL II

7. A patient had the following results:
- | | | | |
|------------|-------------------------|------|---------|
| RBC | $2.90 \times 10^{12}/L$ | MCV | 76 fL |
| Hb | 6.2 g/dL | MCH | 21 pg |
| Hct | 22.0% | MCHC | 28 g/dL |
| Serum iron | 45 μ g/dL | | |
| sTfR | 28.5 nmol/L | | |
- With what type of anemia are these results associated? (Objective 7)
- iron-deficiency anemia
 - beta thalassemia minor
 - anemia of chronic disease
 - sideroblastic anemia
8. In performing a reticulocyte count, the clinical laboratory professional observes erythrocyte inclusions suggesting denatured hemoglobin. What is the best stain to confirm the identity of these inclusions? (Objective 6)
- crystal violet stain
 - Wright's stain
 - brilliant green stain
 - methyl violet stain
9. You are performing several cytochemical stains on a bone marrow sample from a patient recently diagnosed with acute leukemia. You are examining the MPO slide, and the blasts are negative. However, the reagent is nearing its expiration date, and you are not sure whether the stain worked properly. Which cells found in the bone marrow normally express myeloperoxidase and could be used to assess the stain's integrity? (Objective 6)
- neutrophils
 - red cell precursors
 - megakaryocytes
 - lymphocytes
10. Based on a patient's CBC and peripheral blood smear examination, a diagnosis of CML is suspected. The physician orders an LAP score to be performed on the current hematology sample (lavender top tube). What should the clinical laboratory professional tell the physician? (Objective 6)
- The current hematology sample is acceptable, and the procedure will be completed today.
 - The current hematology sample is unacceptable because it would result in a falsely decreased LAP score. A new sample must be collected using heparin.
 - The current hematology sample is unacceptable because it would result in a falsely elevated LAP score. A blood smear should be obtained by capillary puncture.
 - The current hematology sample is acceptable; however, the LAP score needs to be corrected for the dilutional effect of the anticoagulant.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Contrast the mechanisms of anticoagulation for EDTA and heparin.

Answer

EDTA prevents blood coagulation by chelating calcium. Because calcium is an important component of several enzymatic reactions in the coagulation cascade, its removal blocks fibrin formation. Heparin prevents blood coagulation by enhancing antithrombin activity. Antithrombin, in turn, inhibits thrombin and blocks fibrin formation.

Checkpoint! 2

What are three steps a phlebotomist should take to minimize the risk of exposure to blood-borne pathogens when performing a venipuncture?

Answer

Steps to minimize exposure to blood-borne pathogens include (1) wearing gloves, (2) using goggles, (3) performing venipuncture with a safe needle tube holder, (4) disposing of the needle in a biohazard sharps container, and (5) washing the hands following the removal of gloves.

Checkpoint! 3

What is the total magnification when a 10× objective is combined with a 10× eyepiece?

Answer

The total magnification is $(10\times) \times (10\times) = 100\times$.

Checkpoint! 4

How does the examination of a sample by phase-contrast microscopy differ from bright-field microscopy?

Answer

(1) Bright-field microscopy requires a stained sample to examine cellular details; phase-contrast microscopy allows examination of unstained cells. (2) Phase-contrast microscopy requires a condenser with an annular ring and objective with phase ring. These components must be matched. Bright-field microscopy uses a standard condenser and objectives.

Checkpoint! 5

A clinical laboratory professional consistently prepares thin blood smears resulting in minimal counting area. What would you suggest this individual do to improve the quality of these blood smears?

Answer

Because the blood smears are consistently too thin, the clinical laboratory professional should try increasing the angle of the spreader slide and increasing the speed. This will achieve a thicker blood smear.

Checkpoint! 6

Which component of Wright stain is responsible for staining hemoglobin within erythrocytes?

Answer

Eosin, the acidic dye, binds to basic groups on the hemoglobin molecule.

Checkpoint! 7

If the erythrocytes appear bluish gray and leukocyte nuclei are black on a stain, how would you correct this problem?

Answer

Two common causes for excessive blue appearance are prolonged staining and use of a buffer or stain with too alkaline pH. Therefore, try decreasing the staining time to see if the problem resolves or check the pH of the buffer and stain to verify whether one or both are too alkaline. If the pH is the problem, make the appropriate adjustments to lower the pH or try a new bottle of reagent.

Checkpoint! 8

In performing the platelet estimate, 76 platelets were observed in five fields. Calculate the platelet estimate. If the platelet count was $189 \times 10^9/L$, would these results correlate? Assume the sample was collected with EDTA.

Answer

The platelet estimate is $228 \times 10^9/L$. Yes, the estimate is within 25% of the platelet count ($189 \times 10^9/L \times 0.25 = 47 \times 10^9/L$).

Checkpoint! 9

a. A manual platelet count was performed on an EDTA-anticoagulated blood sample. With the first unopette, 125 platelets were counted. The number of platelets counted from the second unopette was 131. What is this patient's count?

b. What are two possible physiologic causes or mechanisms that could lead to a decreased in this patient's platelet count?

Answer

a. The first unopette is $125 \times 100 \times 1/0.2 = 62.5 \times 10^9/L$; the second unopette is $131 \times 100 \times 1/0.2 = 65.5 \times 10^9/L$. The patient's platelet count equals $(62.5 \times 10^9/L + 65.5 \times 10^9/L)/2$, or $64 \times 10^9/L$. Note: Each unopette was used to charge both ruled areas of the hemacytometer so that the area counted was 0.2 mm^2 . b. This patient's decreased platelet count may be the result of decreased production of platelets in the bone marrow (e.g., aplastic anemia) or increased destruction of the platelets (e.g., immune thrombocytopenic purpura).

Checkpoint! 10

Given the following erythrocyte data, what is the expected erythrocyte morphology? hemoglobin = 6.2 g/dL; hematocrit = 0.28 L/L; erythrocyte count = $4.10 \times 10^{12}/L$

Answer

Based on the erythrocyte data, the erythrocyte indices are MCHC = 22 g/dL; MCV = 68 fL; MCH = 15 pg. These indices are lower than their respective reference intervals. Therefore, the expected erythrocyte morphology would be the presence of hypochromic microcytic erythrocytes.

Checkpoint! 11

Morphologic evaluation of a Wright-stained peripheral blood smear reveals the presence of Pappenheimer bodies. How will this affect a reticulocyte count to be performed on the same blood sample? How would you confirm the presence of Pappenheimer bodies?

Answer

The presence of Pappenheimer bodies could falsely elevate the reticulocyte count because both Pappenheimer bodies and reticulum will stain with new methylene blue. Prussian blue stain is used to confirm the presence of Pappenheimer bodies: It stains iron but not reticulum.

Checkpoint! 12

What is the basis for hemoglobin separation in the hemoglobin electrophoresis procedures?

Answer

The net charge of hemoglobin molecules can be altered by the pH of the buffer. When placed in an electric field, the hemoglobin molecules will be separated based on their net charge. For example, at pH 8.6, hemoglobin molecules have a net negative charge with hemoglobin A possessing the strongest net negative charge and traveling the fastest.

Checkpoint! 13

What are the advantages of using flow cytometry to quantitate HbF?

Answer

Flow cytometry allows the evaluation of large numbers of erythrocytes, thus increasing the significance of the HbF result. In addition, the HbF concentration within individual erythrocytes is observed to demonstrate the distribution of HbF within the patient's erythrocyte population. Flow cytometry can also be used to demonstrate HbF concentration in polychromatophilic erythrocytes (i.e., reticulocytes) and nucleated erythrocytes. These findings may be useful in diagnosing certain erythrocyte disorders such as beta-thalassemia major because it is characterized by an uneven distribution of HbF within its erythrocyte population.

Checkpoint! 14

A patient's osmotic fragility test shows beginning hemolysis at 0.60% NaCl and complete hemolysis at 0.50% NaCl. How should these results be interpreted?

Answer

These results indicate increased osmotic fragility that is associated with hereditary spherocytosis.

Checkpoint! 15

A patient was recently diagnosed with a hypochromic, microcytic anemia. Additional laboratory testing revealed EPO 1.5 mIU/mL and sTfR 15.8 nmol/L. Which anemia is consistent with these results?

Answer

These results are consistent with anemia of chronic disease. A normal sTfR level but decreased EPO are characteristic findings in this anemia.

Checkpoint! 16

A pathology resident is evaluating the peripheral blood smear of a 40-year-old female. The resident suspects CML. To confirm this suspicion, a LAP score is ordered. Do you think that the LAP score will be helpful in making the correct diagnosis?

Answer

Yes, the LAP score can be used to differentiate CML from a leukemoid reaction because the LAP score in patients with CML is usually decreased. However, patients with CML in blast crisis with high numbers of circulating blasts can have an increased score. Therefore, LAP scores should always be interpreted in conjunction with the morphologic examination of the sample.

Checkpoint! 17

A 30-year-old male presented to the emergency room complaining of fatigue, weakness, and gum bleeding. The CBC showed anemia, thrombocytopenia, and a WBC of $30 \times 10^9/L$. The peripheral blood smear revealed numerous intermediate to large blasts with fine nuclear chromatin and abundant cytoplasm. The bone marrow biopsy contained 60% blasts. No Auer rods were seen after careful inspection. Several cytochemical stains were then performed. The blasts failed to stain with myeloperoxidase, Sudan Black B, and specific esterase; however, the majority of blasts reacted intensely with the α -naphthyl esterase. Incubation with sodium fluoride inhibited the staining seen with α -naphthyl esterase. What type of leukemia do you think this patient has?

Answer

Alpha-naphthyl esterase stains primarily monocytes and its precursors; therefore, it is useful in the diagnosis of acute leukemias with a monocytic component such as acute monocytic and myelomonocytic leukemias. However, other bone marrow elements can also show staining with α -naphthyl esterase. Therefore, the fluoride inhibition test is recommended. In this test, sodium fluoride is added to the α -naphthyl esterase incubation mix. Sodium fluoride inhibits the monocytic enzyme. In our patient, the blasts failed to stain in the mix containing the fluoride, confirming the monocytic differentiation. The predominance of staining with α -naphthyl esterase and the absence of staining with myeloperoxidase, Sudan black B, and specific esterase indicate that this patient most likely has acute monocytic leukemia (AML).

Checkpoint! 18

A pathologist is reviewing the slides from the pleural fluid of a 50-year-old male who has hepatosplenomegaly and minimal lymphadenopathy. It is not clear if the mononuclear cells are mature lymphoma cells or leukemic blasts. There is not enough material for flow cytometry to do immunophenotyping, but there is enough to make a few extra cytospin smears. Which stain do you think can be useful in this case?

Answer

A TdT stain will be very useful. TdT is a DNA polymerase found in the nuclei of immature lymphocytes and is present in the majority of ALL cases. TdT is a primitive cell marker and is of value in distinguishing ALL from malignant lymphoma. It is also helpful in defining leukemic cells in body fluids.

Bone Marrow Examination

Aamir Ehsan, M.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Identify the sites for obtaining bone marrow samples.
2. List indications for the need to perform bone marrow studies.
3. Explain the difference between core biopsy and bone marrow aspirate and the use of each.
4. Describe how to perform a bone marrow differential count.
5. Define the *M:E ratio*, and explain what can cause an increase or decrease in it.
6. Describe how to estimate bone marrow cellularity and iron stores and interpret results.
7. Explain the role of the hematology laboratory in bone marrow evaluation.
8. List the reasons that special stains are used on bone marrow specimens.

■ OBJECTIVES—LEVEL II

Upon completion of this unit of study, the student should be able to:

1. Differentiate benign lymphoid aggregates from malignant lymphoma.
2. Evaluate the bone marrow specimen and select the appropriate specimens for ancillary studies.
3. Perform a bone marrow differential count and calculate and interpret the M:E ratio.
4. Estimate and interpret bone marrow cellularity.
5. Correlate results of marrow iron stores with various diseases.
6. Explain the role of the clinical laboratory professional in the bone marrow procedure.
7. Identify key features of a bone marrow report.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Indications for bone marrow evaluation
- ▶ Bone marrow procedure
- ▶ Bone marrow processing for examination
- ▶ Morphologic interpretation of bone marrow
- ▶ Special studies on bone marrow
- ▶ Bone marrow report
- ▶ Summary
- ▶ Review questions
- ▶ References

KEY TERMS

Dry tap
 Granulomatous
 Hematogone
 Immunohistochemical stain
 Ringed sideroblast

BACKGROUND BASICS

The information in this chapter builds on concepts from previous chapters. To maximize your learning experience, you should review these concepts before beginning this chapter.

Level I

- ▶ Review the development and differentiation of hematopoietic cells.
- ▶ Describe the structure and function of the bone marrow.
- ▶ Describe normal erythropoiesis and leukopoiesis.

Level II

- ▶ Identify the changes that lead to bone marrow hyperplasia or hypoplasia.

CASE STUDY

We will refer to this case study throughout the chapter.

Robert, a 32-year-old male, visited his primary care physician with complaints of weakness and fatigue. He had been in good health until two months ago when he noted he was becoming increasingly tired after usual daily work activity. Physical examination reveals no lymphadenopathy, hepatomegaly, or splenomegaly. CBC shows the following:

Hemoglobin	9 g/dL (90 g/L)
Hematocrit	27%
WBC	$2.0 \times 10^9/L$
Platelet count	$30 \times 10^9/L$

Evaluate these results and consider additional tests that should be done and a possible diagnosis.

OVERVIEW

Bone marrow examination may be necessary to diagnose, make a prognosis, and/or evaluate therapeutic response for a variety of hematologic and nonhematologic problems. The clinical laboratory professional is responsible for preparing the specimen and performing the preliminary examination of the bone marrow sample. This chapter discusses the indications for performing a bone marrow procedure, as well as the preparation and evaluation of a bone marrow specimen. Emphasis

is on the processing and preparation of the specimen for morphologic study. The evaluation and interpretation of bone marrow findings are discussed. Specimen requirements and indications for ancillary studies are also included. The content of the bone marrow report is described.

INTRODUCTION

Hematopoiesis takes place in different locations during embryogenesis. It begins in the yolk sac as early as 19 days gestation. At about the third month of fetal life, the liver becomes the chief site of hematopoiesis. (To a lesser extent, hematopoiesis occurs in the spleen, kidney, thymus, and lymph nodes.) In the third trimester, after birth, and throughout adult life, the bone marrow is the primary source of hematopoiesis.

Bone marrow, the hematopoietic compartment of bone, is a highly vascularized loose connective tissue located between the trabeculae of spongy bone. It has a volume of 30–50 mL/kg of body weight. The marrow is composed of two major compartments, hematopoietic and vascular. The hematopoietic compartment includes both hematopoietic cells and stromal cells (supporting cells). It is composed of hematopoietically active red marrow (erythroid and myeloid cells) and hematopoietically inactive yellow marrow. The yellow marrow occupies the central cavity and is composed of adipocytes. The vascular compartment of the bone marrow is composed of the nutrient artery, vein, arterioles, and sinuses.

INDICATIONS FOR BONE MARROW EVALUATION

Evaluation of the bone marrow is necessary for diagnosing, managing, making prognoses, and following up a variety of hematologic and nonhematologic disorders (Table 1). The bone marrow should always be evaluated in conjunction with the peripheral blood counts and smear, which often reflect changes in the marrow.

CASE STUDY (continued)

Review of the peripheral blood smear confirms the presence of thrombocytopenia. Red cells are normochromic and normocytic with no increase in reticulocytes. A few teardrop cells are present. White cells show a left shift but no toxic granulation or Döhle bodies. No circulating blasts are seen.

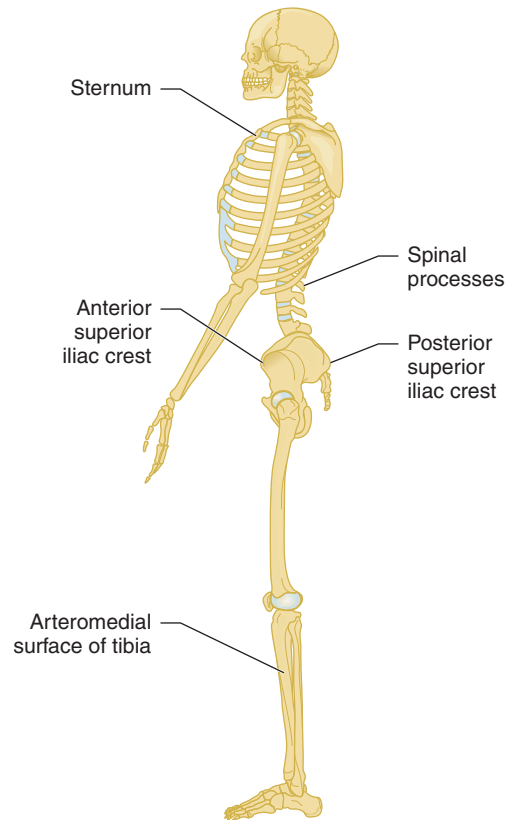

Robert denies any history of alcohol abuse. The test for HIV is negative, and he is not on any medications. Vitamin B₁₂ and folic acid levels are normal.

1. Is a bone marrow evaluation indicated in this patient? Why or why not?

★ TABLE 1

Conditions for Which a Bone Marrow Evaluation Is Indicated

- Primary diagnosis of hematopoietic and lymphoid malignancies
 - Acute leukemias
 - Chronic myeloproliferative disorders
 - Chronic lymphoproliferative disorders
 - Myelodysplastic syndromes
 - Hodgkin and non-Hodgkin lymphomas
 - Plasma cell neoplasms
- Staging of lymphoid malignancies and solid tumors
- Post-treatment follow-up
 - Postchemotherapy and radiation therapy
 - Poststem cell transplant
- Detection of infection and/or source of fever of unknown origin
 - Mycobacterium and fungal infections
 - Granulomas
 - Unknown infectious agents using cultures and special stains
 - Hemophagocytic syndrome
- Primary diagnosis of systemic diseases
 - Metabolic disorders (Gaucher's disease, etc.)
 - Systemic mastocytosis
- Miscellaneous
 - Evaluation of storage iron
 - Evaluation of unexplained cytopenias

■ FIGURE 1 Sites used for aspiration and biopsy of bone marrow.

► **BONE MARROW PROCEDURE**

Sites of hematopoiesis also differ by age. At birth, hematopoietic red marrow fills all bone cavities. With age, adipose tissue (fat) replaces hematopoietic tissue in some bones. By adolescence, hematopoietic marrow is only in centrally located bones including the skull, scapulae, ribs, sternum, clavicles, vertebrae, and the proximal ends of the long bones of the arms and legs. In certain disease states (e.g., thalassemia, sickle cell anemia), red marrow in the adult can extend into the long bones. Cellularity within red marrow decreases with age. At birth, red marrow is about 90% cellular. This decreases to about 50% in an elderly adult. This change in sites of hematopoiesis and cellularity has implications for where to sample the bone marrow and how to interpret cellularity. Most marrow specimens are taken from the posterior superior iliac crest (Figure 1 ■) after adolescence, although the sternum and anterior iliac crest are occasionally used in adult patients. The anteromedial surface of the tibia is sometimes used in children less than 2 years of age. The spines of the lumbar vertebral bodies L1 and L2 occasionally are used in older children. The composition of marrow obtained from different sites has been shown to be

similar (the proportion of different cells at different sites is similar).

The bone marrow aspirates and biopsies are obtained using disposable needles that are modifications of the needle first introduced by Jamshidi.¹ A sterile technique is always used. The skin over the biopsy site is first cleaned with a disinfectant solution, and then 1–2% lidocaine (local anesthetic) is infiltrated into the skin, subcutaneous tissue, and periosteum. Some patients require additional sedation with intravenous or intramuscular medications. A small skin incision is made with a blade to facilitate needle penetration. Performing the biopsy first and then the aspirating to avoid distortion of the marrow architecture in the biopsy specimen is recommended. However, because the aspirate can clot if the biopsy is done first, some institutions prefer performing the aspirate first. When it is done first, performing the biopsy on a different site on the periosteal surface is recommended.² In adults, a *trephine core biopsy* commonly uses an 11-gauge cutting needle to obtain a core of marrow tissue. This is followed by aspiration of about 2 mL of marrow using an 18-gauge needle.

Complications of bone marrow biopsy and aspiration are rare, especially when performed by experienced practitioners. The most common complications are localized bleeding or infection. Most patients experience discomfort during the

aspiration procedure even with adequate infiltration of local anesthetic. If not carefully performed, going through the entire thickness of the bone and damaging the underlying tissues is possible. This risk is higher with a sternal aspiration. After the biopsy procedure, the patient is advised to lie on the biopsy site. The patient's site should be reevaluated in 15–30 minutes for any bleeding or oozing. The actual procedure usually is performed with the assistance of a clinical laboratory professional. The laboratory professional's responsibility is to determine the adequacy of the samples.

Neither thrombocytopenia, coagulation factor deficiency, or anticoagulant therapy is contraindicated for the bone marrow procedure. Applying pressure at the biopsy site and having the patients lie on their back for 20–30 minutes can control local bleeding in thrombocytopenic patients. Correcting severe coagulation factor deficiencies before the procedure is indicated in hemophiliacs because they can experience intense local bleeding. The only time a bone marrow biopsy should not be performed is when a bone marrow will not assist in diagnosing or evaluating the patient's condition. The indication criteria for performing a bone marrow examination are listed in Table 1.

✓ Checkpoint! 1

A 25-year-old male was recently diagnosed with ALL and received chemotherapy. It is 21 days after the chemotherapy. A bone marrow biopsy has been scheduled to determine whether residual leukemia is present. His platelet count is $10 \times 10^9/L$. Does this patient have a significant risk of bleeding? Is it necessary to cancel the procedure until the platelet count is more than $50 \times 10^9/L$?

► BONE MARROW PROCESSING FOR EXAMINATION

A laboratory professional with experience in bone marrow preparation accompanies the physician performing the bone marrow aspirate and biopsy.

BONE MARROW ASPIRATE SMEARS, PARTICLE PREPARATION, AND CLOT SECTIONS

Approximately 1.0–1.5 mL of aspirate is needed to evaluate bone marrow morphology. Although each laboratory has its own preferences for processing the aspirate, a commonly used procedure is described here. Depending on the clinical setting, additional aspirate can be obtained for cytogenetics, flow cytometry, molecular studies, and cultures.

A small amount (about 0.5 mL) of the aspirate is placed on a glass slide and examined to determine whether bone marrow is present in the sample (sometimes it is blood rather than marrow). The presence of particles consisting of fat, granules, and/or small pieces of bone in the aspirate sample that can be

visualized on the slide is evidence that the bone marrow cavity was entered and that marrow was effectively aspirated.² The laboratory professional immediately communicates the adequacy of the bone marrow aspirate to the physician. Bone marrow occasionally cannot be aspirated, resulting in a **dry tap**. This can be caused by inadequate technique or more commonly alterations in the bone marrow architecture such as extensive fibrosis (e.g., hairy cell leukemia, chronic idiopathic myelofibrosis) or very increased cellularity (e.g., leukemia). In these cases, bone marrow biopsy is especially important.

Direct smears of bone marrow aspirate are prepared at the bedside using a technique similar to that for preparing peripheral blood smears.³ Good organization of supplies and speed in making these smears is essential because the aspirate clots quickly. Bone marrow particle crush smears can be prepared by pouring a small amount of marrow aspirate onto a watch glass. Using a glass pipette, the marrow particles are transferred onto several glass slides. A second slide is placed gently on top of the slide with the drop containing the particles. The top slide is pulled apart to evenly distribute the marrow particles. Cell morphology is better appreciated on the aspirate smears, and the architecture and cellularity are assessed on the trephine core biopsy and particle preparation. The clinical laboratory professional usually prepares several aspirate smears for special stains that may be necessary for classifying of acute leukemias and myelodysplastic syndromes and evaluating storage iron. The remaining bone marrow particles can be used for histologic evaluation.

Tissue particles admixed with blood can be left to clot and then fixed in 10% buffered formalin or B-5 (a fixative containing mercury, which is environmentally unfriendly and difficult to dispose of, and is thus rarely used) and processed for histologic sectioning (clot sections). However, better results are obtained if the blood and particles are placed in an ethylenediaminetetraacetic (EDTA) tube and mixed before clotting begins. The blood and particles are filtered through histowrap filter paper, and the concentrated particles on the paper are fixed in 10% buffered formalin. In the histology laboratory, the particles left on paper are collected and embedded in paraffin for further processing.⁴

Some laboratories mix a portion of the marrow aspirate with EDTA. This anticoagulated marrow is placed in a Wintrobe tube and centrifuged. The marrow is separated into four layers: fat and perivascular cells, plasma, buffy coat, and red cells. The ratio between the fat/perivascular and the erythroid/myeloid layers reflects the overall marrow cellularity. Concentrate smears can be prepared from the buffy coat. The direct, concentrate, and particle crush smears are stained with Wright's stain.

TOUCH IMPRINTS AND CORE BIOPSY

Immediately after obtaining the bone marrow core biopsy, touch imprints of the biopsy can be made by gently touching or rolling the tissue several times on 2–4 glass slides.

Some cells from the core specimen will stick to the slide. Some of these slides are stained with Wright's stain, and the rest can be used for special stains in case a good aspirate is not available. After making the touch preparations, the core biopsy specimen is immediately immersed in 10% buffered formalin fixative. The fixed trephine core biopsy, particle, and clot preparations undergo histologic processing including decalcifying, dehydrating, embedding in paraffin blocks, sectioning of 2–3 μm thick sections, and histologic staining with hematoxylin and eosin (H&E). Some laboratories prefer to fix bone marrow particles, clot, and core biopsy in B-5 first followed by 10% buffered formalin fixative. The B-5 fixed samples have better morphologic sections than 10% formalin.

Trephine core biopsies are performed for primary diagnosis as well as for disease staging purposes. When performed for clinical staging of lymphoma, multiple myeloma, and carcinoma, bilateral biopsies are recommended.

► MORPHOLOGIC INTERPRETATION OF BONE MARROW

Morphologic review of bone marrow includes cytologic assessment of hematopoietic cells on the aspirate smear as well as histologic assessment of the clot, particle preparation, touch imprint, and core biopsy. Review of these preparations provides a wealth of information about hematopoiesis including estimation of cellularity, details of cell morphology, estimation of the quantity of iron and its distribution, and presence of abnormal cells such as tumor cells.

BONE MARROW ASPIRATE

It is good practice to review the complete blood count (CBC) data and the corresponding peripheral blood smear in conjunction with the bone marrow. The number and appearance of the blood cells guide the morphologist to a differential diagnosis. The bone marrow aspirate is used to evaluate the number, morphology, and maturation process of erythroid and myeloid precursors and megakaryocytes (Figure 2 ■).

The bone marrow aspirate smears are scanned at 100 \times magnification to determine cellularity and to select a suitable area for examining and performing the differential count. Optimal areas are where the cells are spread out and intact. Areas where the marrow cells are destroyed due to squashing or stripping of their cytoplasm by fibrin thread should be avoided. These areas are characterized by the presence of bare nuclei.

Bone marrow cellularity is determined by estimating the percent of bone marrow space occupied by hematopoietic tissue. The reference range decreases with age. As mentioned, infants have the highest cellularity (90%) and older adults the lowest (50%). While scanning for cellularity, the number and the distribution of the megakaryocytes are usually noted.

■ **FIGURE 2** Bone marrow aspirate smear showing normal maturing trilineage hematopoiesis (Bone marrow; Wright-Giemsa stain; 200 \times magnification)

Megakaryocytes are usually adjacent to a spicule, a fragment of spongy bone along which hematopoietic cells cluster and mature. An optimal aspirate has some spicules present, and most particles should contain at least one megakaryocyte. Direct smears should contain 5–10 megakaryocytes in the readable portion of the slide, and concentrate smears should contain numerous megakaryocytes.²

After the initial scan at 100 \times magnification, the details of nuclear and cytoplasmic maturation are evaluated at higher magnification (500 \times or 1000 \times). Evaluation of maturation is an important step when reviewing the marrow aspirate. Abnormal maturation can be seen in any of the three cell lines. For example, abnormal maturation is a diagnostic criteria in the myelodysplastic syndromes (MDS). In MDS, abnormalities of the red cell precursors include multinucleation and nuclear/cytoplasmic dysynchrony (nuclear maturation is delayed compared to cytoplasmic maturation). Myeloid precursors can show abnormal granule development, and megakaryocytes can reveal hypoblobulation of the nucleus.

Bone Marrow Differential Count

A 500–1000 cell differential (a 500 cell differential can be performed on each of two slides) is usually performed by an experienced clinical laboratory professional or pathologist using 1000 \times magnification on the direct smear or the crush particle preparation (the morphology is better preserved on these preparations).² The concentrate and/or touch imprint is a useful source when the bone marrow is very hypocellular or aspirate could not be obtained (dry tap), although the morphology is not as good as that on direct smears and crush particle preparations. Overall marrow cellularity can be estimated on the particle preparation.

Because the bone marrow composition changes with age, knowing the patient's age when evaluating bone marrow specimens is important. In infants during the first month after birth, dramatic alterations occur in the distribution of the different marrow compartments. Myeloid precursors are usually increased at birth followed (within few weeks) by a predominance of lymphoid cells. These lymphoid cells are called **hematogones** and represent normal immature B cells (Figure 3 ■).⁵ Morphologically and phenotypically, differentiating hematogones from lymphoblasts is difficult. In young children, lymphocytes can represent about one-third of marrow cellularity, which decreases gradually after puberty.

Bone marrow is not as homogeneous as blood. During the bone marrow procedure, the needle can be placed in an area that has aggregates of erythroid or lymphoid cells. In adult bone marrow, lymphocytes are usually present as interstitial infiltrate and sometimes form lymphoid follicles, which are collections or aggregations of lymphocytes. These lymphocytes can be malignant or benign (see section on benign versus malignant lymphoid aggregates). Depending on the placement of the bone marrow needle, the cells in the follicle can be aspirated. This can give an estimate of markedly increased lymphocytes in the marrow and introduce significant variation in the differential count from sample to sample in the same patient.

Megakaryocytes are not included in the differential count but are evaluated by scanning the smear at 100× because megakaryocytes are not evenly distributed in the marrow or on the smear.

■ **FIGURE 3** A bone marrow aspirate smear from a 21-year-old woman following chemotherapy for acute lymphoblastic leukemia (ALL). Hematogones typically display homogenous chromatin with a smudged appearance, indistinct nucleoli, and scant cytoplasm. Many hematogones (arrows) are indistinguishable from ALL blasts but the morphology of hematogones is variable, reflecting the maturation of the hematogones toward mature lymphocytes (arrows). (Wright stain; 1000× magnification)

The greatest mass of the adult marrow is composed of granulopoietic and erythropoietic precursors. For the purpose of the differential count, these hematopoietic cells are enumerated within different categories according to their stage of maturation. Cells not normally found in the peripheral blood including macrophages, mast cells, osteoblasts, and osteoclasts can be found in the bone marrow.

Myeloid to Erythroid Ratio

When adequate numbers of cells are counted (500–1000) and differentiated, the percentage of each category is calculated. The ratio between all granulocytes and their precursors and all nucleated red cell precursors represents the myeloid:erythroid ratio (M:E ratio). This parameter indicates significant changes in the cellularity of the myeloid and erythroid cells. The M:E ratio should always be interpreted in context with the overall cellularity. For instance, a low M:E ratio can mean erythroid hyperplasia or myeloid hypoplasia. If it is known, however, that the bone marrow cellularity is increased, a low M:E ratio means erythroid hyperplasia or ineffective erythropoiesis.

The reference range for the M:E ratio differs depending on whether the segmented neutrophils are included in the counts. If they are considered a part of the bone marrow storage pool and not included in the count, the M:E reference range is between 1.5:1 and 3:1. If segmented neutrophils are included in the count, the M:E reference range is between 2:1 and 4:1.

The granulocytic tissue occupies 2 to 4 times more marrow space than the erythrocytic precursors because of the shorter survival of the granulocytes in the circulation (i.e., neutrophils' 6–10 hours versus erythrocytes' 120 days). Changes in the survival time of granulocytes and erythrocytes are reflected in changes in the M:E ratio. Normal, increased, or decreased M:E ratios are associated with certain disease entities. For example, patients with chronic myelogenous leukemia usually have an increased ratio; in contrast, patients with myelodysplastic syndrome usually have a decreased ratio.

✓ Checkpoint! 2

A 60-year-old male complained to his local physician of abdominal fullness. The CBC showed an elevated leukocyte count with absolute neutrophilia and basophilia. The peripheral blood smear revealed numerous myelocytes. A bone marrow biopsy was performed. The bone marrow differential was reported as follows: blasts 1%, myelocytes 35%, metamyelocytes 20%, bands 10%, segmented neutrophils 20%, eosinophils 1%, basophils 3%, pronormoblasts 1%, basophilic normoblasts 3%, polychromatophilic normoblasts 2%, orthochromatic normoblasts 4%, lymphocytes 0%, and monocytes 0%. What is the M:E ratio?

TOUCH IMPRINTS

When the bone marrow is a dry tap secondary to underlying fibrosis (myelofibrosis, hairy cell leukemia) or when the marrow aspirate lacks spicules and is hemodiluted, the touch imprints of the bone marrow biopsy can be the only source for studying the sample's cellular detail and maturation sequence. Sometimes the touch preparations contain enough cells for performing a differential count and cytochemical stains (Figure 4 ■).

BONE MARROW PARTICLE PREPARATION, CLOT AND CORE BIOPSY

The advantage of bone marrow biopsy is that it represents a large sample of marrow and bone structures in their natural relationship. Some marrow particles obtained during the aspiration procedure and the biopsy specimen can be processed for histologic examination.

Various other stains also can be used. Iron stain can be performed to evaluate storage iron; however, because of decalcification, the core biopsy might not be good to study marrow iron stores. Iron stores should be evaluated on aspirate smears, particle preparations, or clot sections. Reticulin and trichrome stains are used to evaluate the presence of fibrosis. Acid-fast organisms and fungi in **granulomatous** (a distinctive pattern of chronic reaction in which the predominant cell type is an activated macrophage with an epithelial-like appearance) diseases can be detected quickly with specific stains, offering great advantages in diagnosing these infections. When metastatic tumors and lymphomas are found in the bone marrow, **immunohistochemical stains** can be used on histologic sections to demonstrate specific tumor markers. Immunohistochemical stains use la-

■ **FIGURE 4** Touch imprint from a case with ALL showing many lymphoblasts. Marrow was inaspirable and therefore was not available for the morphologic review. Cytochemical stains were performed on these imprints, and blasts were negative for all stains. (BM touch imprints; Wright-Giemsa stain; 500× magnification)

beled antibodies to identify specific markers (antigens) on cells. Thus, a very precise diagnosis of the origin of a tumor can be made without elaborate, expensive, and more invasive techniques. Immunophenotyping by flow cytometry can be performed only on fresh unfixed bone marrow samples (aspirate or core biopsy); immunophenotyping by immunohistochemistry is performed on paraffin fixed samples.

A disadvantage of the bone marrow biopsy is that it loses fine cellular details in the processing; therefore, it is of little value in diagnosing leukemias and some refractory anemias. In these situations, the touch preparation from the biopsy could supply the missing morphologic details.

Molecular studies can be done on marrow specimens to aid in diagnosing and managing some diseases. Polymerase chain reaction (PCR) can be performed on fresh samples and paraffin embedded formalin fixed marrow biopsy. PCR technology can be used to detect B cell or T cell gene rearrangements, various leukemias, and minimal residual disease and to diagnose infectious diseases.

Bone Marrow Cellularity

The overall bone marrow cellularity is estimated by comparing the amount of hematopoietic tissue with the amount of adipose (fat) tissue. Fat appears as a clear space. An easy way to determine the normal expected cellularity range in an adult is to subtract the patient's age from 100% and add and subtract (+/-) 10%. For example, a normal 70-year-old adult has an overall cellularity between 20% and 40%. Variation in cellularity within the bone marrow can occur. The subcortical and paratrabeular areas are more hypocellular than the deeper medullary area, and variability occurs in cellularity within the sample itself. For these reasons, estimated cellularity is based on an average percentage. If both hypercellular and hypocellular areas are present within the medullary area, the variation should be described in the report because average cellularity can be difficult to estimate.

Although cellularity can be estimated on aspirate smear, clot section, and particle preparation, the bone marrow biopsy is the optimal sample for this purpose and is typically evaluated at 10× objective. After considering the patient's age, bone marrow cellularity is reported as decreased (less than the expected number of hematopoietic cells), normal, or increased (more than the number of expected cells). With experience, reproducible and reliable results can be achieved when evaluating marrow cellularity (Figure 5 ■).

BENIGN LYMPHOID AGGREGATES VERSUS MALIGNANT LYMPHOMA

Reactive lymphoid aggregates can be seen in the bone marrow biopsy of elderly individuals. When one sees these aggregates, distinguishing between reactive (benign) versus

■ **FIGURE 5** These bone marrow biopsies are from 40-year-old patients **a.** is a hypocellular marrow, **b.** is a normocellular marrow, and **c.** is a hypercellular marrow. (Bone marrow; paraffin section, hematoxylin-eosin stain; 100× magnification)

lymphoma (malignancy) becomes important. Features favoring benign aggregates are nonparatrabeular, single, small, well-defined, polymorphic populations of lymphocytes (small and large lymphocytes) with plasma cells at the periphery and presence of blood vessels within the aggregate (Figure 6 ■). On the contrary, lymphoid aggregates in lymphoma are ill defined, small to large, and composed of monomorphic cells. The malignant aggregates can be paratrabeular or interstitial, diffuse, and patchy (Figure 7 ■). In case of doubt, immunohistochemical stains and/or PCR can be performed on the marrow biopsy specimen to differentiate between benign lymphoid aggregates and lymphoma. Presence of an aberrant phenotype or clonal B or T cells would favor lymphoma involving the bone marrow.

BONE MARROW IRON STORES

Iron is stored as ferritin (iron complexed with apoferritin protein) and hemosiderin in reticuloendothelial cells and erythroblasts. The storage iron in the bone marrow that can be visualized is in the form of hemosiderin. On Wright-Giemsa-stained smears, hemosiderin appears as brownish blue granules while on unstained smears, it is golden yellow. To precisely evaluate intracellular storage iron, slides are usually stained with Prussian blue stain.

Prussian Blue Stain for Iron

The Prussian blue stain provides the most direct means for assessing body iron stores. It is designed to demonstrate the

■ **FIGURE 6** Bone marrow biopsy showing a well circumscribed lymphoid aggregate indicating a benign lymphoid aggregate. (Bone marrow; paraffin section, hematoxylin-eosin stain; 100× magnification)

presence of hemosiderin in histiocytes, erythroblasts (sideroblasts), and/or erythrocytes (siderocytes). The EDTA chelating method should be used to decalcify the bone marrow biopsies if iron studies are being performed. Rapid acid decalcifying solutions extract iron; therefore, these specimens must not be used.

In this staining procedure, a weak acid solution is needed to free the iron from the loose protein bonds present in the hemosiderin molecule. This free iron combines with potassium ferrocyanide to produce ferric ferrocyanide. Free iron appears greenish blue.

Histiocytes contain marrow iron that is usually seen as fine cytoplasmic granules. Sideroblasts are marrow erythroid

■ **FIGURE 7** Bone marrow biopsy showing two paratrabeular lymphoid infiltrates suggesting involvement of marrow by a follicle center cell lymphoma. (Bone marrow; paraffin section, hematoxylin-eosin stain; 100× magnification)

precursors that contain iron specks (Figure 8 ■). Storage iron can be reported as absent, decreased, adequate, or increased. Some institutions give a numerical value ranging from 0 to 4 (2 representing adequate iron stores in an adult).

Evaluating and grading iron stores can be subjective; thus, for consistency and precision, some guidelines such as increased storage when clumps of iron are easily seen at 100× magnification should be followed; a few specks of iron found after looking at several microscopic fields at 500× or 1000× magnification indicate decreased iron storage. When no stainable iron is detected in the bone marrow smear or tissue sections, iron is depleted or absent. Iron is also stored as intracellular ferritin. All developing normoblasts and reticulocytes contain dispersed ferritin but may not stain with Prussian blue. Small amounts of ferritin enter the blood and can be measured as serum ferritin. The amount of circulating ferritin parallels the concentration of storage iron in the body. Nonspecific increases are associated with chronic infection and inflammation, liver disease, and malignancy. Thus, serum ferritin is not as accurate an indicator of iron sufficiency as hemosiderin in the presence of these conditions.

Use of Bone Marrow Iron Evaluation

Evaluating marrow iron stores is essential in diagnosing anemias, especially in refractory and dyserythropoietic anemias. When the morphologic characteristic of the iron particles in the histiocytes and red cell precursors is an important diagnostic consideration (as in myelodysplastic syndrome), an iron stain is performed on a particle smear. If the overall

■ **FIGURE 8** Bone marrow clot section stained with Prussian blue. The bluish granules indicate the presence of iron. (Bone marrow; clot section, Prussian blue stain; 400× magnification)

distribution of the amount of iron is of clinical importance (iron-deficiency anemia, anemia of chronic diseases), then histologic sections of bone marrow particles and marrow clotted particles are stained for iron.

The determination of bone marrow storage iron is useful in the classifying anemias associated with defective hemoglobin synthesis. Storage iron is markedly decreased or absent in iron-deficiency anemia. When storage iron is present in the bone marrow, anemia cannot be a result of iron deficiency unless the patient has been transfused with red cells or treated with iron supplements. Iron stores are normal or increased in anemia of chronic disease and thalassemias. Iron stores are also increased in sideroblastic anemia. The presence of **ringed sideroblasts** is diagnostic for sideroblastic anemia and/or myelodysplastic syndrome. However, ringed sideroblasts can also be seen in myeloproliferative disorders, megaloblastic anemia, alcoholism, and post-chemotherapy situations. Ringed sideroblasts are erythroid precursors that have a deposition of excess iron around the nucleus arranged like a necklace. This iron is located within the mitochondria that surround the nucleus.

✓ Checkpoint! 3

A pathologist is evaluating a bone marrow biopsy from a patient suspected of having a myelodysplastic syndrome. Evaluation of the peripheral blood reveals both hypochromic and normochromic red cells. The bone marrow aspirate shows dysplastic (abnormal cell development) changes in the red cell precursors. The pathologist ordered an iron stain on the particle crush preparation. Why is the iron stain useful in this case?

▶ SPECIAL STUDIES ON BONE MARROW

In most cases, a thorough examination of a well-stained bone marrow aspirate smear and core biopsy provides enough information by which diagnoses of hematopoietic disorders are made. However, several ancillary studies can provide additional information that help support or confirm the morphologic diagnosis. These studies can also provide prognostic information and, in some cases, can predict response to therapy. The most commonly used ancillary studies are flow cytometry, conventional cytogenetics, fluorescent in situ hybridization (FISH), molecular genetic studies, and cytochemical stains.

FLOW CYTOMETRY

Flow cytometry allows the simultaneous analysis of multiple characteristics of cells in suspension as they pass through a laser light beam. The size and internal complexity of the cells can be estimated, and with the use of fluorochrome-labeled antibodies, the presence of specific cell markers can be determined. Flow cytometry has a wide range of uses in the evaluation of hematologic disorders. It is commonly used to establish the presence of clonality, diagnose and classify malignant lymphomas and leukemias, and detect minimal residual disease after chemotherapy use. The immunophenotyping of peripheral blood, bone marrow, lymph node (and other) tissues, and body fluids is performed only on fresh samples (Table2).

★ TABLE 2

Specimen Requirements for Special Studies on Bone Marrow			
Specimen	Flow Cytometry	Cytogenetics	Molecular Studies
Blood	5 mL in EDTA, heparin sodium, or ACD	5 mL preferably in heparin sodium	1–3 mL in EDTA
Bone marrow	1 mL in EDTA, heparin sodium, or ACD	1–3 mL preferably in heparin sodium; bone marrow preferable over blood	1–3 mL in EDTA (preferable over heparin)
Fluids	As much as possible, anticoagulated if contaminated with blood	As much as possible, anticoagulated if contaminated with blood	5–10 mL
Tissue	0.5 cm ² fresh in transport media or saline	1 cm ² fresh in transport media	3–5 mm ² fresh or frozen; fixed specimens good for PCR analysis
All specimens: transport and storage	Should be kept at room temperature and analyzed within 24 hours; up to 72 hours is acceptable in some cases; should be refrigerated if analysis will not occur within 24 hours; frozen or fixed specimens unacceptable	Should be kept at RT and transported to the laboratory within 24 hours; frozen or fixed samples unacceptable	If not analyzed within 24 hours, should be refrigerated (2–8°C) for up to 1 week; samples frozen at –20°C or –70°C should be stored for 2 weeks or 2 years, respectively

EDTA = ethylenediaminetetraacetic acid; ACD = acid citrate dextrose; RT = room temperature

CYTOGENETICS

Chromosome analysis is frequently used in the study of hematopoietic disorders because certain malignancies have characteristic chromosomal alterations. In addition, the presence of some specific chromosomal abnormalities has prognostic implications. Chromosome analysis is routinely used in the primary diagnosis of acute leukemias, malignant lymphomas, myelodysplastic syndromes, and myeloproliferative disorders. Because lymphoma cells are more difficult to grow, adequate clinical history needs to be provided when the sample is sent to the cytogenetics laboratory to allow the cytogenetic technologist to make procedural adjustments. Analysis is performed on fresh samples (Table 2). More recent techniques such as FISH have allowed specific cytogenetic questions to be answered more quickly. Triaging the bone marrow samples depends on what clinical answer is

being considered and thus can vary case by case. A guideline is presented (Table 3) that can be modified in any lab depending on the need and/or protocols.

MOLECULAR GENETICS

Although molecular genetic techniques were initially used in research laboratories, they are now performed in clinical laboratories. For hematolymphoid disorders, PCR has emerged as the leading adjunctive technology. The PCR method is used to demonstrate cell clonality and lineage and to identify specific genetic rearrangements. Additionally, PCR can be used to detect minimal residual disease. Fresh and frozen samples are preferable for PCR; however, samples fixed in formalin or embedded in paraffin are acceptable for PCR analysis (Table 2).

★ TABLE 3

Triaging Bone Marrow Samples for Ancillary Studies

Diagnosis/History	Flow Cytometry	Cytogenetics/FISH	Molecular
Acute Leukemia (new, follow-up or post stem cell transplant)	Yes	Yes	Maybe* Post stem cell transplant – Chimerism studies can be performed by PCR
CLL	Yes	Yes	No
CML	No**	Yes	Yes (BCR/ABL mutation)
Chronic myeloproliferative disorders - Polycythemia vera - Essential thrombocythemia - Chronic idiopathic myelofibrosis	No	Yes	Yes (JAK-2 mutation)
Chronic Myelomonocytic leukemia (CMML)	Yes	Yes	No***
Myelodysplasia	No	Yes	No
Multiple myeloma	No	Yes	No
Hodgkin lymphoma	No	No	No
Non-Hodgkin lymphoma	Yes	Maybe****	Maybe****

*Molecular studies are usually not needed (depends upon subtype of acute leukemia) as most genetic abnormalities seen in acute leukemias can be detected by cytogenetics/FISH. However, the distinction between p210 and p190 chimeric protein in ALL with t(9;22) is made by molecular analysis. If uncertain about submitting for molecular studies it's a good idea to store cell pellet with possibility of doing the assay if needed.

**When suspecting CML in blast crisis, send it for flow cytometry.

***Some cases of CMML may need molecular or FISH studies (for example: if suspecting t(5;12) and the cytogenetics are normal)

****When suspecting certain lymphomas (example: Mantle cell, Burkitt's/Burkitt's-like vs large cell lymphomas or anaplastic large cell lymphoma send it for cytogenetics and/or FISH).

When suspecting follicle center cell lymphoma; send it to molecular lab or FISH for Bcl-2 rearrangement.

Note: This table can be modified in any lab depending on the need and/or protocols.

CLL = Chronic Lymphocytic Leukemia; CML = Chronic Myelogenous Leukemia; FISH = Fluorescence in-situ hybridization.

**CASE STUDY** (continued from earlier in this chapter)

A bone marrow procedure was performed. The marrow was difficult to aspirate, but the physician was able to obtain some hemodiluted marrow. Bilateral marrow biopsy was also performed. Review of the aspirate smears showed a very hemodiluted sample, but the pathologist was able to see an increased number of blasts. There was not enough aspirate sample to do flow cytometry or cytogenetic and cytochemical stains.

2. How should the marrow evaluation proceed?

CYTOCHEMICAL STAINS

In hematology, *cytochemistry* refers to in vitro staining of cells to allow microscopic examination of the cells' chemical composition. Cells of different lineages have different cytochemical compositions. The staining process does not significantly alter cell morphology. Cytochemical stains are usually performed on specimens from patients who have a neoplasm of hematopoietic cells. These stains help differentiate the lineage of immature cells so that an accurate diagnosis of the type of neoplasm can be made. See Table 12.

Smears are usually made from peripheral blood and bone marrow. Although bone marrow aspirate is usually used to make smears for cytochemical stains, the touch imprints from the biopsy can be used if aspirate is insufficient. The smears are incubated with substrates that react with specific cellular constituents (organelle-associated enzymes, carbohydrates, and proteins). If the specific constituent is present in the cell, its reaction with the substrate is confirmed by the formation of a colored product within the cell. The stained slides are evaluated with an ordinary light microscope. Most stains can be performed on air-dried smears. All cytochemical stains should be performed on recently prepared slides. Some cellular constituents are sensitive to heat, light, storage, and processing technique. If stains cannot be performed on recently prepared slides, the unstained smears can be protected from light in the refrigerator. However, a fresh smear is preferred for the myeloperoxidase (MPO) stain.

▶ BONE MARROW REPORT

The bone marrow report must contain all relevant information and optimally is composed of two components: clinical information and morphologic interpretation. The clinician should provide the patient's biographic data, clinical differential diagnosis, and relevant therapeutic information. The morphology and interpretation by the pathologist and labo-

ratory professional must include site of sampling (e.g., sternum), types of sample obtained, differential counts from both peripheral blood and bone marrow, and morphologic abnormalities in any cell lines in the patient's peripheral blood or bone marrow. The results must be interpreted in conjunction with any additional studies (special stains, flow cytometry, cytogenetics, molecular studies). If the additional studies are significant in establishing the diagnosis but are unavailable when the bone marrow report is written, an addendum report should mention the significance of these studies. The comparison of the current marrow specimen to the previous tissue samples (marrow or other nonmarrow biopsies) is essential in some situations.

Finally, the pathologist's diagnostic interpretation should be rendered within a reasonable period of time. For example, if 50% blasts were present in the blood or the bone marrow, it is reasonable to call the clinician about the preliminary diagnosis of acute leukemia. However, the final diagnosis can be made only after completing the special stains and flow cytometry studies. Comments, if needed, should be concise and relevant to the case and can include a recommendation for additional tests and a possible differential diagnosis.

**CASE STUDY** (continued)

Processing of bone marrow biopsy usually is done overnight.

3. Can a diagnosis be made from tests on the aspirate rather than waiting for the biopsy slides?

SUMMARY

The bone marrow is the primary site of blood cell production after birth. Evaluation of bone marrow is indicated in the diagnosis, management, and follow-up of a variety of hematopoietic disorders including some anemias and malignancies. Bone marrow specimens include aspirates and biopsy. The marrow is processed and evaluated in the laboratory.

Differentiation and classification of acute leukemias depend on accurate identification of the blasts. Because the lineage of the cells is difficult to differentiate using only morphologic characteristics, the immunophenotyping by flow cytometry and/or immunohistochemistry (and cytochemical stain) are used to help identify blast lineage. Cytogenetic analysis is commonly used in diagnosis because certain malignancies have characteristic chromosome abnormalities. Molecular analysis can be used to demonstrate clonality, cell lineage, and genetic abnormalities. It is useful in diagnosing and evaluating minimal residual disease.

REVIEW QUESTIONS

LEVEL I

1. What is the site for bone marrow collection in children under 2 years of age? (Objective 1)
 - a. spleen
 - b. sternum
 - c. tibia
 - d. lumbar vertebral bodies
2. Which of the following indicates that a bone marrow biopsy should be performed? (Objective 2)
 - a. 20-year-old male with suspected leukemia
 - b. 60-year-old female diagnosed with megaloblastic anemia
 - c. 30-year-old male diagnosed with HIV
 - d. 20-year-old pregnant woman diagnosed with iron-deficiency anemia
3. What site is most commonly used in adults for bone marrow biopsies? (Objective 1)
 - a. sternum
 - b. posterior iliac crest
 - c. anterior iliac crest
 - d. tibia
4. The marrow specimen that is best for preserving the architecture of the bone marrow is: (Objective 3)
 - a. aspirate
 - b. clot section
 - c. particle smear
 - d. biopsy
5. Which of the following is the best specimen for evaluating the morphology of the hematopoietic precursors? (Objectives 3, 4)
 - a. bone marrow aspirate
 - b. clot preparation
 - c. iliac crest biopsy
 - d. none of the above
6. Which of the following diseases is more likely to have a decreased M:E ratio? (Objective 5)
 - a. chronic blood loss
 - b. granulocytic leukemia
 - c. lymphocytic leukemia
 - d. chronic infection
7. What is the expected overall cellularity in a bone marrow biopsy of a normal 50-year-old male? (Objective 6)
 - a. $80\% \pm 10\%$
 - b. $100\% \pm 10\%$
 - c. $50\% \pm 10\%$
 - d. $30\% \pm 10\%$
8. Which of the following stains is used to evaluate the presence of storage iron? (Objective 6)
 - a. Wright-Giemsa
 - b. Prussian blue
 - c. PAS
 - d. reticulín

LEVEL II

1. The following is characteristic of a benign lymphoid aggregate: (Objective 1)
 - a. The patient has a history of lymphoma.
 - b. It is composed predominantly of small lymphocytes.
 - c. It is large with ill-defined borders.
 - d. It is paratrabecular and lacks plasma cells at the periphery.
2. A hypercellular bone marrow M:E ratio is 10:1. This indicates: (Objective 3)
 - a. decreased erythropoiesis
 - b. increased erythropoiesis
 - c. increased leukopoiesis
 - d. decreased leukopoiesis
3. The following is the differential obtained from a patient with a diagnosis of AML: blasts 65%, myelocytes 4%, metamyelocytes 4%, bands 1%, segmented neutrophils 8%, pronormoblasts 2%, basophilic normoblasts 3%, polychromatic normoblasts 3%, orthochromatic normoblasts 3%, lymphocytes 4%, and monocytes 3%. What is the M:E ratio? (Objective 3)
 - a. 10:1
 - b. 5.4:1
 - c. 7.4:1
 - d. 1:7.4
4. When evaluating bone marrow biopsy for estimating the marrow cellularity, which ratio is being estimated? (Objective 4)
 - a. hematopoietic cells to fat
 - b. hematopoietic cells to bony trabeculae
 - c. hematopoietic cells to vessels
 - d. granulocytes to fat
5. A pathologist is evaluating a bone marrow biopsy from a patient recently diagnosed with lymphoma. The bone marrow evaluation should include which of the following? (Objective 1)
 - a. malignant lymphoid aggregate
 - b. granulomatous lesions
 - c. iron stores
 - d. presence of parasites
6. A pathologist is evaluating a bone marrow biopsy in a patient recently diagnosed with Hodgkin lymphoma. Inadvertently, the lab performed an iron stain on a particle crush preparation. The pathologist saw a few ringed sideroblasts but did not see any dysplastic changes suggestive of myelodysplastic syndrome. In which of the following conditions might ringed sideroblasts appear? (Objective 5)
 - a. iron-deficiency anemia
 - b. thalassemia
 - c. alcoholism
 - d. Hodgkin's disease

REVIEW QUESTIONS (continued)

LEVEL I

9. Why would special stains be performed on a bone marrow specimen? (Objective 8)
 - a. to differentiate leukemias
 - b. to determine the M:E ratio
 - c. to estimate bone marrow cellularity
 - d. to identify hematogones
10. The hematology laboratory's role in bone marrow evaluation is to: (Objective 7)
 - a. make direct bone marrow smears
 - b. perform the bone marrow aspirate procedure
 - c. administer the anesthetic before the procedure
 - d. determine the appropriate therapy

LEVEL II

7. A clinical laboratory professional evaluating the bone marrow particle preparation of a patient suspected of having acute leukemia identifies a large number of undifferentiated blasts. What ancillary test should be done? (Objective 2)
 - a. molecular diagnostics
 - b. cytochemical stains
 - c. fluorescent in situ hybridization
 - d. HIV testing
8. A physician performs a bone marrow biopsy and aspirate on a 65-year-old male. The cellularity is estimated at 80% and the M:E ratio is 0.5 to 1. The correct description of this marrow is: (Objectives 3, 4)
 - a. hypercellular with a decreased M:E ratio
 - b. hypercellular with an increased M:E ratio
 - c. hypocellular with a decreased M:E ratio
 - d. hypocellular with an increased M:E ratio
9. A physician performing a bone marrow biopsy on a patient with a possible diagnosis of acute leukemia is unable to obtain any aspirate but was able to obtain two core biopsies. What is the best way for the clinical laboratory professional to use the material obtained? (Objectives 2, 6)
 - a. Place both core biopsies in formalin and process one immediately; save the other for ancillary tests.
 - b. Place one core biopsy in formalin and freeze the second one at -70°C .
 - c. Place one core biopsy in formalin after making touch imprints; put the second in saline.
 - d. Place both core biopsies in saline; freeze one at 0°C and process the other immediately.
10. A 20-year-old patient presented with severe headache. A lumbar puncture performed showed a marked increase in atypical mononuclear cells. The differential diagnosis is acute leukemia or malignant lymphoma. What would be most helpful in distinguishing the two diagnoses? (Objective 2)
 - a. molecular diagnostic tests
 - b. flow cytometry
 - c. cytogenetics tests
 - d. cytochemical stains

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Robert was pancytopenic. Clinical history and further laboratory tests revealed no cause for the pancytopenia. A bone marrow aspirate and a biopsy were obtained. Evaluation revealed the presence of many blasts. The diagnosis based on bone marrow testing was acute myelocytic leukemia.

Question:

1. Is a bone marrow evaluation indicated for this patient? Why or why not?

Explanation:

CBC data indicate that the patient is pancytopenic. Presence of pancytopenia in a young patient is worrisome. The common causes of pancytopenia in a young patient include HIV infection, alcoholism, medications, and B₁₂ and folic acid deficiency. Presence of teardrop cells with pancytopenia indicates marrow fibrosis or marrow infiltration by leukemia, lymphoma, or granulomas. Bone marrow evaluation for this patient is definitely indicated. The patient does not have lymphadenopathy, hepatomegaly, or splenomegaly, so the chance of lymphoma involving the marrow is very unlikely.

Question:

2. How should the marrow evaluation proceed?

Explanation:

Fortunately, the laboratory professional made several touch imprints from the biopsy. There is no reason for doing cytochemical stains on the

aspirate smear if one has a good quality and good number of touch imprint slides. These touch imprints were of good quality and showed many blasts. The touch imprints were stained with cytochemical stains. No differentiation was present among these blasts. The cells stained consistent with myeloblasts. The hemodiluted marrow was sent for flow cytometry and cytogenetics. The aspirate can be sent for flow cytometry because flow is more sensitive in detecting the lineage of blasts. Flow cytometry was positive for myeloid markers and negative for lymphoid markers. The remainder of the aspirate was sent for cytogenetics with a hope that some cells might be able to grow and show any specific cytogenetic abnormality.

Question:

3. Can a diagnosis be made from tests on the aspirate rather than waiting for the biopsy slides?

Explanation:

Yes, the presence of many blasts in the bone marrow aspirate smears and on the touch imprints indicates acute leukemia. The lineage of blasts can be determined based on cytochemical stains and/or flow cytometry. Bone marrow biopsy in this case would not provide any added information.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

A 25-year-old male was recently diagnosed with ALL and received chemotherapy. It is 21 days after chemotherapy. A bone marrow biopsy has been scheduled to determine if residual leukemia is present. His platelet count is $10 \times 10^9/L$. Does this patient have a significant risk of bleeding? Is it necessary to cancel the procedure until the platelet count is over $50 \times 10^9/L$?

Answer

Bone marrow biopsies can be performed in thrombocytopenic patients. Applying pressure at the biopsy site and having the patient lie on the back for 20–30 minutes can control the local bleeding seen in

thrombocytopenic patients. Evaluating this patient's marrow is more important than delaying because of the risk of local bleeding.

Checkpoint! 2

A 60-year-old male complained to his local physician of abdominal fullness. The CBC showed an elevated leukocyte count with absolute neutrophilia and basophilia. The peripheral blood smear revealed numerous myelocytes. A bone marrow biopsy was performed. The bone marrow differential was reported as follows: blasts 1%, myelocytes 35%, metamyelocytes 20%, bands 10%, segmented neutrophils 20%, eosinophils 1%, basophils 3%, pronormoblasts 1%, basophilic normoblasts 3%, polychroma tophylic normoblasts 2%, orthochromatic normoblasts 4%, lymphocytes 0%, and monocytes 0%. What is the M:E ratio?

Answer

The myeloid precursors include blasts, myelocytes, metamyelocytes, bands, segmented neutrophils, eosinophils, and basophils. Thus, the total number of myeloid cells is 90 (1 + 35 + 20 + 10 + 20 + 1 + 3). The nucleated red cell precursors include pronormoblasts, basophilic normoblasts, polychromatic normoblasts, and orthochromatic normoblasts. The sum of erythroid precursors is 10(1 + 3 + 2 + 4), which produces an M:E ratio of 9:1. This elevated M:E ratio with the clinical history and peripheral blood findings suggests chronic myelogenous leukemia.

Checkpoint! 3

A pathologist is evaluating a bone marrow biopsy from a patient suspected of having a myelodysplastic syndrome. Evaluation of the peripheral blood

reveals both hypochromic and normochromic red cells. The bone marrow aspirate shows dysplastic (abnormal cell development) changes in the red cell precursors. The pathologist ordered an iron stain on the particle crush preparation. Why is the iron stain useful in this case?

Answer

The pathologist is most probably looking for the presence of ringed sideroblasts, nucleated red cells in which one-third of the nucleus is encircled by iron granules. The presence of ringed sideroblasts is diagnostic for sideroblastic anemia and/or myelodysplastic syndrome. However, ringed sideroblasts can also be seen in myeloproliferative disorders, megaloblastic anemia, and alcoholism as well as following chemotherapy.

- ▶ Review questions
- ▶ References

Automation in Hematology and Hemostasis

Cheryl Burns, M.S.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Cite the electrical impedance principle of cell counting, and identify the instruments that use this technology.
2. Describe the use of radio frequency in cell counting, and identify the instruments that use this technology.
3. State the principles of light scatter used in cell counting, and identify the instruments that use this technology.
4. List the reported parameters for each blood cell-counting instrument.
5. Categorize cell parameters as directly measured and derived from a histogram, scattergram or cytogram, or calculation.
6. Describe the principle of reticulocyte count enumeration by automated blood cell-counting instruments.
7. State the electromechanical principle of clot detection, and identify instruments that use this technology.
8. State the photo-optical principle of clot detection, and identify instruments that use this technology.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Compare and contrast the methods of analysis for the described histograms, scatterplots, scattergrams, and cytograms, and interpret the results.
2. Describe and interpret the automated reticulocyte parameters.
3. Describe the application of immunological techniques to coagulation instruments, and identify instruments that use this technology.

KEY TERMS

Aperture
 Cellular hemoglobin concentration mean (CHCM)
 Cluster analysis
 Coincidence
 Continuous flow analysis
 Contour gating
 Hemoglobin distribution width (HDW)
 Histogram
 Hydrodynamic focusing
 Isovolumetric sphering
 Mean platelet volume (MPV)
 Platelet distribution width (PDW)
 Random access
 Reagent blank
 Reticulated platelet
 Scatterplot
 Threshold limit
 Viscosity

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts prior to beginning this unit of study.

Level I

- ▶ State the principles of cell enumeration by hemacytometer.
- ▶ State the principle of the cyanmethemoglobin method for hemoglobin determination.
- ▶ Calculate the erythrocyte indices.
- ▶ Describe the peripheral blood smear examination process and correlate peripheral blood smear findings with complete blood counts (CBC).
- ▶ Describe and state the principle of the manual reticulocyte count procedure.
- ▶ Describe the basic procedures for evaluation of secondary hemostasis (i.e., prothrombin time and activated partial thromboplastin time).

Level II

- ▶ Summarize the diagnostic use of the reticulocyte count in evaluating hematologic disorders and monitoring various therapies such as iron replacement and bone marrow transplant.

▶ OVERVIEW

Automation is firmly established within the hematology/coagulation laboratory. This chapter reviews the fundamental principles of the hematology and coagulation instruments

and describes examples of instrumentation that are currently used. The basic principles of operation are discussed, and samples of normal test results are displayed for each instrument.

▶ AUTOMATED BLOOD CELL-COUNTING INSTRUMENTS

The evolution of instrumentation in hematology began in the mid-1950s. Until that time, clinical laboratory professionals performed manual hemacytometer blood cell counts, spun hematocrits, spectrophotometrically determined hemoglobins, and microscopic blood smear evaluations. With the advent of the first single automated blood cell counter, manual hemacytometer blood cell counts for erythrocyte enumeration and leukocyte enumeration were replaced. In general, automated blood cell counters provide data with increased reliability, precision, and accuracy.

With the many advances in hematology instrumentation, automation currently encompasses the primary testing in the hematology laboratory. Automated instruments can perform a complete blood cell count (CBC) including the platelet count, a five-part leukocyte differential, and absolute reticulocyte count. A number of principles for cell counting and differential analysis have been utilized in the past. The two principles of blood cell counting currently used by the hematology instruments are impedance and optical light scattering.

The impedance principle of blood cell counting is based on the increased resistance that occurs when a blood cell with poor conductivity passes through an electrical field. The number of pulses indicate the blood cell count, and the amplitude (i.e., height) of each pulse is proportional to the volume of the cell.¹ Examples of instruments using this principle are the Beckman-Coulter, Sysmex Corporation, and Abbott Diagnostics instruments.

The optical light-scattering principle of blood cell counting is based on light scattering measurements obtained as a single blood cell passes through a beam of light (optical or laser). Blood cells create forward scatter and side scatter that photodetectors detect. The degree of forward scatter is a measurement of cell size, and the degree of side scatter is a measurement of cell complexity or granularity.² The Siemens Healthcare (formerly Bayer) instruments utilize this principle for all blood cell counts, and newer models manufactured by Sysmex Corporation and Abbott Diagnostics use this principle for leukocyte enumeration.

The automated reticulocyte count has essentially replaced the manual reticulocyte count for evaluating the bone marrow's erythropoietic activity. Among the hematology instruments, the method of enumeration varies and is discussed with each instrument. These automated methods determine additional reticulocyte parameters including reticulocyte hemoglobin concentration (CHr or Ret He), reticulocyte mean

cell volume (MCV_r), and immature reticulocyte fraction (IRF). The reticulocyte hemoglobin concentration is determined by directly measuring the reticulocyte's hemoglobin by light-scattering characteristics. The reticulocyte mean cell volume is derived from the reticulocyte cytogram and reflects the average size of the reticulocyte population. The immature reticulocyte fraction, or high-intensity ratio, reflects reticulocytes with an increased amount of RNA or early immature reticulocytes. The presence of increased numbers of immature reticulocytes can be used as an indicator of an erythropoietic response. The reticulocyte hemoglobin concentration is an assessment of iron incorporation into hemoglobin and reflects functional availability of iron to the erythron. Thus, these new parameters can be useful in (1) measuring bone marrow engraftment following transplant, (2) determining bone marrow response to iron or erythropoietin therapy, (3) recognizing the potential cause for poor response to erythropoietin therapy, and (4) diagnosing iron-deficient states in infants and adolescents.³⁻⁷

This section reviews the basic operating principles of several hematology instruments that are seen in the field. Other instruments use a combination of these principles.

✓ Checkpoint! 1

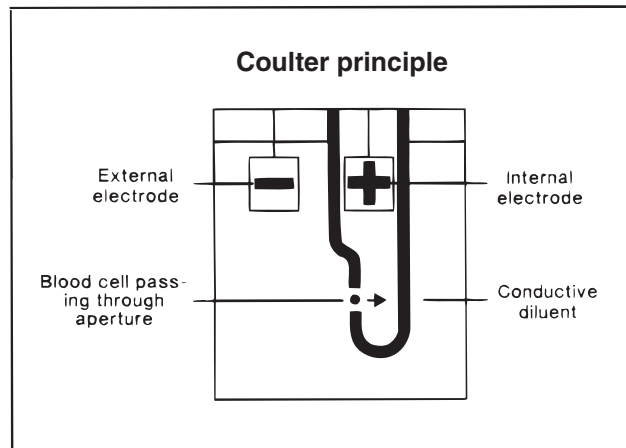

What is the basis of the impedance principle for cell counting?

IMPEDANCE INSTRUMENTS

Four instruments that use the impedance principle in cell counting are described here. Two are Coulter instruments, one is a Sysmex instrument, and one is an Abbott Diagnostics instrument.

Coulter® Gen·S

Introduced by Beckman-Coulter in 1996, the Coulter® Gen·S is a multiparameter blood cell-counting instrument capable of determining a CBC, five-part leukocyte differential, and reticulocyte count.⁸ The basic principles of blood cell counting it uses are similar to earlier models such as the Coulter® S-Plus and STKS.⁹ However, improvements were made to the determination of the five-part leukocyte differential and enumeration of reticulocytes.¹⁰⁻¹⁴ The ethylenediaminetetraacetic acid (EDTA) anticoagulated blood sample is aspirated by a closed tube system and divided into four aliquots. The first aliquot is delivered to the RBC/platelet dilution chamber where blood cells are diluted in an electrically conductive diluent. Within the dilution chamber is an external electrode and three **apertures**, each of which has an internal electrode (Figure 1 ■). As individual blood cells pass through an aperture, there is an increase in resistance (i.e., pulse height) between the external and internal electrodes that is proportional to the cell volume. A steady stream of diluent flows behind each aperture to prevent cells from reentering the aperture. **Threshold limits** are established

■ **FIGURE 1** Coulter principle. Increased electrical resistance, or impedance, occurs when the poorly conductive blood cell passes through the aperture. (Reprinted, with permission, from Pierre R. *Seminars and Case Studies: The Automated Differential*. Hialeah, FL: Coulter Electronics, Inc.; 1985)

for enumerating cells based on cell volume. Particles (cells) of more than 36 fL are counted as erythrocytes. Because three apertures are within the dilution chamber, three erythrocyte (red blood cells [RBC]) counts are obtained. These counts are compared and evaluated by the instrument's data analysis system. If there is agreement, the reported RBC count represents the average of the counts from the three apertures.

An erythrocyte (RBC) **histogram** (size distribution curve) is created based on cell volume and relative cell number (Figure 2 ■). The RBC histogram allows the visualization of changes in size within the erythrocyte population. For example, a shift to the left of the erythrocyte population correlates with microcytic erythrocytes, and the appearance of two separate peaks correlates with a dual population of erythrocytes (e.g., mixture of microcytic erythrocytes and normocytic erythrocytes). This information can be useful in the diagnosis of certain erythrocyte disorders.

The erythrocyte data obtained from the RBC/platelet dilution includes the RBC count by direct measurement and the mean cell volume (MCV) and red cell distribution width (RDW), which are derived from the RBC histogram (Figure 3 ■). The calculated RBC parameters are the hematocrit (Hct), which is calculated from the MCV and the RBC count (calculated Hct = MCV × RBC); the mean cell hemoglobin (MCH), which is calculated from the RBC count and hemoglobin concentration; and the mean cell hemoglobin concentration (MCHC), which is calculated from the hemoglobin concentration and hematocrit. The hemoglobin concentration is obtained from the WBC/hemoglobin dilution chamber.

The platelet count is also obtained from the RBC/platelet dilution chamber. Particles between 2 and 20 fL are counted

■ **FIGURE 2** Histogram, or size distribution curve, allows the visualization of the blood cell population based on the relative cell number and its volume (in fL). (Reprinted, with permission, from *Significant Advances in Hematology*. Hialeah, FL: Coulter Electronics, Inc.; 1983)

as platelets, and a raw platelet histogram is obtained (Figure 4■). The raw platelet histogram is evaluated to determine whether it is a log normal curve. The raw platelet histogram is electronically smoothed and extrapolated over 0–70 fL. The platelet count is derived from the extrapolated histogram. Two additional parameters are obtained from the platelet histogram: **mean platelet volume (MPV)**, which is analogous to the MCV, and **platelet distribution width (PDW)**, which is analogous to the RDW.

■ **FIGURE 4** Normal platelet histogram, Coulter® Gen·S. The jagged line represents the raw data collected from 2–20 fL. The smooth line represents the extrapolated histogram from 0–70 fL.

The second aliquot is delivered to the WBC/hemoglobin dilution chamber where the leukocyte (WBC) count and hemoglobin determinations are made. The WBC count is directly measured by electrical impedance from the leukocyte dilution after lytic agent is added to the dilution. The lytic agent serves to lyse the erythrocytes, convert released hemoglobin to cyanmethemoglobin, and shrink the leukocyte cell membrane and cytoplasm. Therefore, the WBC count represents a measure of the cell volume rather than native cell size as it passes through the aperture. Particles larger than 35 fL are counted as leukocytes. Similar to the RBC count, WBC counts are obtained from the three apertures in the WBC/hemoglobin dilution chamber, and the data analysis system compares and evaluates them. The reported WBC count represents an average of the counts.

The leukocyte (WBC) histogram represents the size distribution curve for the leukocyte data and allows visualization of subpopulations of cells based on their relative sizes. The

■ **FIGURE 3** RBC histogram and count. The shaded area represents those cells used in the RDW (i.e., RDW-CV) calculation. The excluded cells can represent large platelets, platelet clumps, or electrical interference on the left and RBC doublets, RBC triplets, RBC agglutinates, or aperture artifacts on the right. (Reprinted, with permission, from *Significant Advances in Hematology*. Hialeah, FL: Coulter Electronics, Inc.; 1983)

■ **FIGURE 5** WBC histogram and count. In a normal patient, the lymphocyte region represents lymphocytes, the mononuclear region represents monocytes, and the granulocyte region represents neutrophils, eosinophils, and basophils. (Reprinted, with permission, from *Significant Advances in Hematology*. Hialeah, FL: Coulter Electronics, Inc.; 1983)

leukocyte histogram is the basis of the three-part differential identifying lymphocytes as cells between 35 and 90 fL, mononuclear cells as cells between 90 and 160 fL, and granulocytes as cells between 160 and 450 fL (Figure 5 ■). The instrument’s data analysis system examines the WBC histogram for presence of interferences within one or more of the leukocyte populations and using a system of region flags, alerts the clinical laboratory professional (Table 1 ☆). The reason for the region flag can be found by careful examination of the peripheral blood smear. For example, presence of nucleated erythrocytes or clumped platelets is associated with a region 1 flag.

The hemoglobin concentration is determined by measuring the absorbance of cyanmethemoglobin in the WBC/hemoglobin chamber at 525 nm. Through the application of Beer’s law, this absorbance reading is proportional to the concentration of hemoglobin. Additionally, this instrument utilizes a **reagent blank** at the beginning of each operating

cycle to negate the effect of the reagent alone on the sample’s absorbance reading.

✓ **Checkpoint! 2**
 Why is lytic agent added to the leukocyte dilution?

A third sample aliquot is delivered to the orbital mixing chamber. Within this chamber, blood is mixed by gentle agitation with heated lysing reagent to remove the erythrocytes while leaving the leukocytes in their near native state. A second stabilizing reagent is added to stop the lytic reaction and preserve the integrity of the leukocytes. This dilution is sent to the volume · conductivity · scatter (VCS) flow cell for the determination of the five-part leukocyte differential. The cells pass through the flow cell singly by **hydrodynamic focusing**. As each cell passes through the flow cell, three separate measurements are taken simultaneously. The mea-

☆ **TABLE 1**

Coulter® WBC Histogram Region Flags

Region Flag	Affected Position	Possible Abnormalities
R1	Lymphocyte population does not begin at baseline (~35 fL)	Nucleated erythrocytes, large platelets, clumped platelets, or intracellular parasites (e.g., malaria)
R2	No valley between lymphocyte and mononuclear populations (~90 fL)	Reactive lymphocytes, blast cells
R3	No valley between mononuclear and granulocyte populations (~160 fL)	Eosinophilia, basophilia, immature neutrophils
R4	Granulocyte population does not return to baseline (~450 fL)	Granulocytosis
RM	Interference detected in multiple positions	

Other impedance-based instruments providing three-part leukocyte differentials use a flagging system similar to the Coulter® instruments.

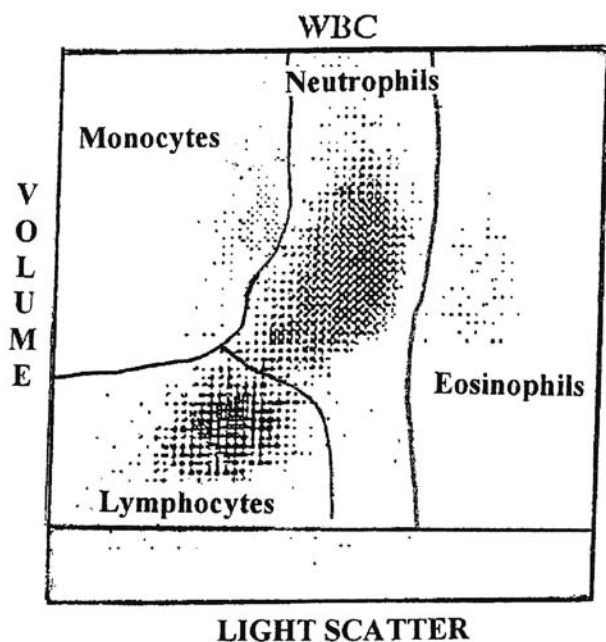

surements include cell volume, cell conductivity, and cell's light scatter characteristics. Cell volume is determined by impedance; cell conductivity that evaluates internal physical and chemical constituents is determined by high-frequency electromagnetic probe; and light scatter characteristics such as cell surface, shape, and reflectivity are determined by a helium-neon laser. The Gen·S instrument's internal system monitors and adjusts reaction characteristics and the data analysis of the VCS-derived characteristics to differentiate the leukocyte cell types.

The Intellikinetics™ application monitors and reacts to changes in the external environment (e.g., changes in ambient room temperature). With this application, the Gen·S system is able to maintain consistent reaction conditions and eliminate cellular analysis problems due to inconsistent location of cells within three-dimensional space. Data analysis is improved through the use of AccuGate™ computer program. The different leukocytes within a sample are identified and classified by **contour gating** that is individualized for each sample (Figure 6 ■). The advantage of contour gating over traditional linear gating is the ability to differentiate overlapping cell populations (e.g., monocytes from reactive lymphocytes).

In the heated reticulocyte dilution chamber, the fourth aliquot is mixed with new methylene blue reagent. The residual RNA is precipitated within the reticulocytes. The stained sample is then mixed with an acidic, hypotonic solution that (1) elutes hemoglobin from the erythrocytes but

permits precipitated RNA to remain and (2) spheres the erythrocytes. This dilution is sent to the VCS flow cell for analysis. The light scatter data generated by flow cytometric examination of sphered erythrocytes and reticulocytes are more reproducible than data generated from non-sphered erythrocytes and reticulocytes. The sphering of mature erythrocytes and reticulocytes eliminates the inherent error in flow cytometric examination of erythrocytes created by irregularly shaped erythrocytes. Contour gating of the VCS-derived characteristics is used to classify reticulocytes versus mature erythrocytes and to identify the immature reticulocyte fraction. The reticulocyte parameters obtained by this analysis include absolute reticulocyte count, reticulocyte percentage, immature reticulocyte fraction, and mean reticulocyte volume (i.e., reticulocyte mean cell volume, MCVr).

The computer system compiles all data obtained from the instrument's analysis. For the cell counts, the instrument's computer corrects the counts for **coincidence** (two or more cells passing through the aperture at the same time) and compares the counts for replication (e.g., compares the three RBC counts). If two or three of the counts do not agree, the count (e.g., RBC count) is not reported but recorded as "vote-out." If there is agreement, the reported count represents the average of the counts. The instrument's computer also evaluates the data to detect abnormalities and determines the reported parameters. The reported results and selected histograms/**scatterplots** are displayed on the computer screen, printed to a hard copy (Figure 7 ■), or transferred to the laboratory information system (LIS). If abnormalities are detected, the clinical laboratory professional is alerted by suspect flags (software-generated flags) or user-defined flags (definitive flags). The clinical laboratory professional uses this information to correlate CBC data with peripheral blood morphology to improve the identification and confirmation of abnormalities.

■ **FIGURE 6** Coulter® Gen·S WBC scatterplot. WBC scatterplot graphs volume versus light scatter and reveals the locations of four leukocyte populations in two-dimensional space. The basophil population is located behind the lymphocytes, but in three-dimensional space is clearly delineated.

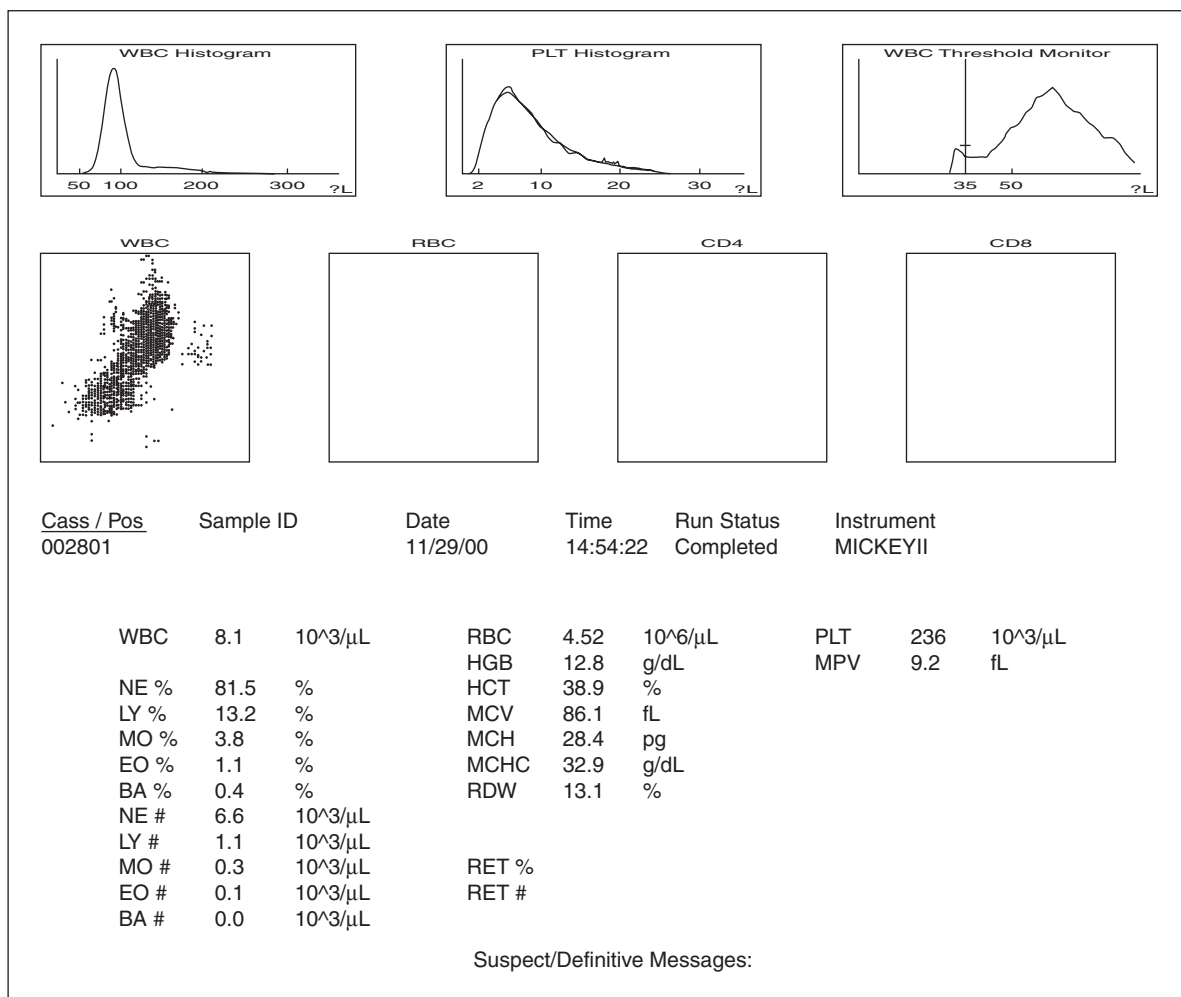

✓ Checkpoint! 3

Explain how the Coulter® Gen·S determines the five-part leukocyte differential.

Coulter® LH Series

Like previous models, the LH 750 (introduced in 2003) and the LH 780 (introduced in 2006) provide a CBC, five-part leukocyte differential, and reticulocyte count from a single blood sample aspiration. When the LH SlideMaker and LH SlideStainer are added to the workstation, Wright-stained peripheral smears are prepared and labeled from the same sample decreasing the number of times the sample is handled and the potential for introducing random errors.

The LH series instruments utilize the basic principles of blood cell enumeration, reticulocyte enumeration, and

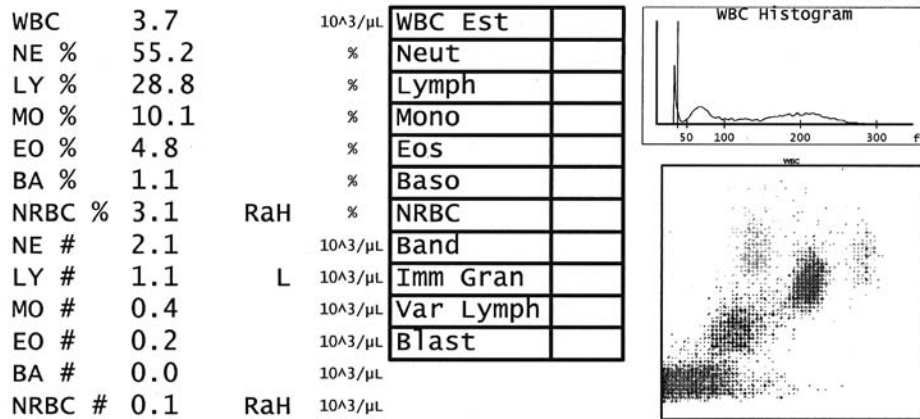

■ **FIGURE 7** Coulter® GEN-S report from a normal individual. (Courtesy of Celia Jimenez, MT(ASCP), San Antonio, TX)

determination of the five-part leukocyte differential that were discussed with the Gen-S instrument.¹⁵ These instruments provide several additional parameters, which are advantageous to the differentiation of normal individuals from individuals with certain disease states. These parameters include the nucleated red blood cell count (NRBC%) and corrected WBC count which were introduced with the LH 750 instrument and the RDW-SD which was introduced with the LH 780 instrument.

If nucleated red blood cells are detected during the analysis of a CBC and differential, the number of nucleated red blood cells (i.e., NRBC%) is determined. Enumeration of nucleated red blood cells begins with their detection on the WBC scatterplot generated by VCS technology (Figure 8■).¹⁵ If nucleated red blood cells are suspected based on their characteristic signature, the computer system examines the WBC histogram generated by impedance for the presence of cells to the left of the lymphocyte population. If

both plots indicate that nucleated red blood cells could be present, the computer system evaluates the combined information to rule out giant platelets or small lymphocytes. If all data analyses point to the presence of nucleated red blood cells, the number of nucleated red blood cells per 100 leukocytes (NRBC%) is derived from data collected by VCS technology and the application of an algorithm to the WBC count. The NRBC# represents the total number of nucleated red blood cells in the blood sample and is calculated from the NRBC% and the total WBC count (i.e., NRBC# = NRBC% × WBC count). Because increased numbers of nucleated red blood cells falsely increase the total WBC count, this count is corrected for their presence, and the corrected WBC count is reported.

The red cell distribution width-standard deviation (RDW-SD) is determined from the RBC histogram by calculating the width in femtoliters (fL) of the RBC population at the 20% height level on the histogram when the peak height is con-

■ **FIGURE 8** Coulter® LH 750 WBC scatterplot and WBC histogram depicting presence of nucleated erythrocytes. On the WBC scatterplot, detection of cells between the lymphocyte population and RBC ghosts is suggestive of nucleated erythrocytes, which are suspected if there is a population of cells to the left of the lymphocyte population on the WBC histogram. The NRBC% is determined if both observations are made and other potential interferences are ruled out (e.g., giant platelets).

sidered 100% (Figure 9 ■).¹⁶ Like the RDW-coefficient of variation (CV) (i.e., RDW) the RDW-SD reflects the degree of anisocytosis within the erythrocyte population. The RDW-SD differs from the RDW-CV in that it directly measures the erythrocyte population while the RDW-CV bases its calculation on the population's SD and MCV ($RDW = 1\ SD/MCV \times 100\%$). Thus, a false RDW-CV can be observed in certain situations. For example, if both the SD and MCV are elevated, the RDW-CV can appear normal when anisocytosis is actually present or if the SD is normal but the MCV is decreased, the RDW-CV can appear increased when in fact there is no anisocytosis. Because the MCV does not affect the RDW-SD, it is potentially a better indicator of the degree of anisocytosis within a given erythrocyte population. The RDW-SD is re-

ported in fL and its reference interval is 39–47 fL in adults. The RDW-SD can be used with other test results in the differentiating iron deficiency anemia from heterozygous beta thalassemia because a low RDW-SD is more closely associated with heterozygous beta thalassemia.¹⁷

The results generated by an LH instrument are displayed on its computer screen, printed as a hard copy (Figure 10 ■), or sent to the LIS for the clinical laboratory professional's review. (See Web Table 1 for the reported parameters.) The clinical laboratory professional is alerted to abnormalities by a system of software-generated flags (suspect flags) or user-defined flags (definitive flags). This information can then be used in a more thorough evaluation of the patient's data, examination of a peripheral blood smear, and determination of appropriate reflex tests.

■ **FIGURE 9** Calculation of RDW-SD. The RDW-SD represents the width of the erythrocyte population at the 20% height level on the RBC histogram and is reported in fL. For example, if Channel_L is 70 fL and Channel_R is 111 fL, the RDW-SD is 41 fL (i.e., 111–70 = 41). (Reprinted, with permission, from Red Cell Distribution Parameters—(1) RDW-SD (2) RDW (CV), Technical Bulletin 9617. Brea, CA: Beckman-Coulter®; 2007)

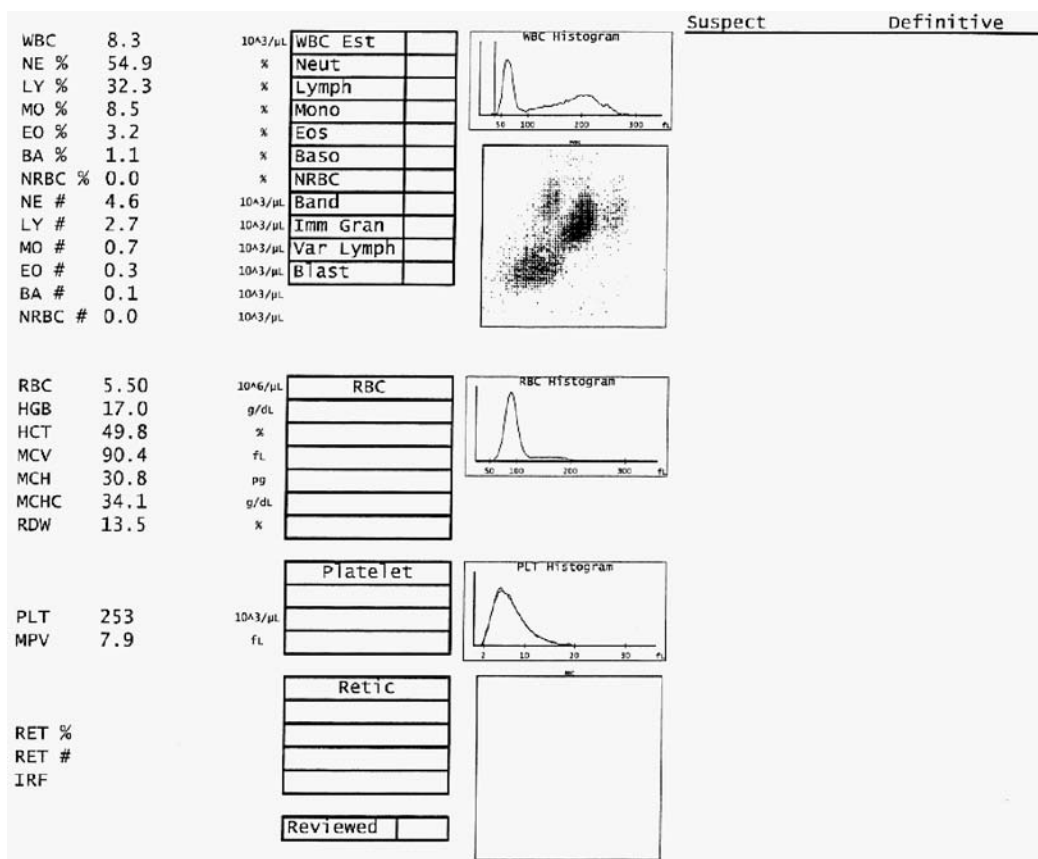

✓ **Checkpoint! 4**

The following results were obtained from a blood sample analyzed by the Coulter® LH 750: NRBC# $2.7 \times 10^9/L$ and corrected WBC $18.1 \times 10^9/L$. What was the uncorrected WBC count?

Sysmex XE-2100™

The XE-2100™ is a member of the XE-Series™ of Sysmex instruments currently on the market. This instrument uses four different technologies including impedance (i.e., direct current), radio frequency, absorption spectrophotometry, and flow cytometry with fluorescent dyes to determine CBC, 5-part leukocyte differential, and reticulocyte count.^{18–22}

Hemoglobin is measured in a designated channel using the sodium lauryl sulfate (SLS) method. A portion of the

■ **FIGURE 10** Coulter® LH 750 report from a normal individual. (Courtesy of Charlene A. Ruiz, MT(ASCP), San Antonio, TX)

aspirated blood sample is first diluted with reagent diluent and then SLS-hemoglobin reagent is added. The surfactants within this reagent lyse the erythrocytes and release hemoglobin. Sodium lauryl sulfate converts ferrous iron to ferric iron, forming methemoglobin. Methemoglobin combines with SLS to form the SLS-hemichrome molecule. The absorbance of this molecule is measured at 555 nm to determine the hemoglobin concentration (g/dL) using Beer's law. This method is advantageous for two reasons: (1) free hemoglobin is rapidly converted to detectable chromogen decreasing measurement time and (2) the reagent is cyanide-free.

The erythrocytes and platelets are enumerated using impedance with hydrodynamic focusing. The blood sample is diluted with isotonic diluent and sent to the RBC/PLT sample chamber. A sheath fluid injector piston delivers the diluted blood sample to the direct current (DC) detection block. The blood cells flow through the aperture and resistance (i.e., pulse height) is detected between the internal and external electrodes. The hydrodynamic focusing created by the sheath fluid aligns the blood cells to enter the center of the aperture singly, thus eliminating abnormal cell pulses generated when cells touch the sides of the aperture as they pass through. At the rear of the aperture, blood cells are prevented from drift-

ing back and generating false pulses due to the sweeping flow of the back sheath fluid. From the RBC/PLT dilution, the RBC count and PLT count are directly measured; RBC and PLT histograms are generated; and the hematocrit (HCT) is calculated from the pulse heights of the individual erythrocytes within the erythrocyte population. The pulse height of an individual erythrocyte is directly proportional to its volume.

The RBC and PLT counts are determined from the generated data using automatic discriminators. The RBC count represents the number of cells that fall between a lower discriminator (25–75 fL) and an upper discriminator (200–250 fL). For each blood sample, the data analysis system examines the data to set its specific lower and upper discriminator for this determination. Likewise, the PLT count represents the number of cells that fall between a lower discriminator (2–6 fL) and an upper discriminator (12–30 fL). A fixed discriminator at 12 fL is also used in determining the platelet count to determine whether potential interferences exist that can result in an erroneous platelet count (e.g., presence of erythrocyte fragments). This platelet count is compared to the platelet count determined from the reticulocyte (RET) channel.

Other parameters that are derived or calculated based on data from the RBC/PLT dilution include MCV, MCH, MCHC,

RDW-SD, RDW-CV, and MPV (See Web Table 1 for the reported parameters.). The RDW-SD and RDW-CV are determined in the same manner as described for the Coulter® LH 780 instrument.

Two separate channels (i.e., DIFF and WBC/BASO) are used to generate the total leukocyte (WBC) count and five-part leukocyte differential (neutrophils, lymphocytes, monocytes, eosinophils, and basophils). In the DIFF channel, a portion of the aspirated blood sample is diluted with lyse reagent. The lyse reagent removes the erythrocytes and creates “holes” in the cytoplasmic membrane of nucleated cells allowing a polymethine dye (i.e., fluorescent dye) to enter the cell and bind to its DNA and RNA. This dilution is sent to the Optical Detection block. Within the Optical Detection block, the cells pass singly through a laser beam ($\lambda = 633 \text{ nm}$) emitted by the semiconductor diode laser. Each cell generates forward scatter (reflects cell size), side scatter (reflects cell complexity), and fluorescent intensity (reflects amount of bound fluorescent dye) depending on the cell type. The DIFF scattergram represents a plot of side scatter versus fluorescent intensity. The instrument’s adaptive cluster analysis system (ACAS) allows clear separation of the cell populations depicted on DIFF scattergram including RBC ghosts, lymphocytes, monocytes, eosinophils, and neutrophils + basophils (Figure 11■). By applying the IG Master software to the data generated in the DIFF channel, the immature granulocyte (IG) population is enumerated (Web Figure 2■). The IG count includes metamyelocytes, myelocytes, and promyelocytes. Studies indicate that the au-

tomated IG count is an acceptable replacement to the manual morphology count for IG, but studies regarding the usefulness of the IG count to screen for sepsis and infection are conflicting.^{23–25} Further studies are needed to clarify its use.

In the WBC/BASO channel, the blood sample is diluted, and special lyse reagent that lyses erythrocytes and shears all leukocytes except basophils is added. This dilution is analyzed by the Optical Detection block to capture each cell’s forward scatter and side scatter as it passes through the laser beam. The adaptive cluster analysis system evaluates this information to determine a total leukocyte (WBC) count and the basophil count (i.e., basophil percentage and absolute basophil count). The WBC/BASO scattergram (Figure 12■) is a plot of side scatter versus forward scatter. On this scattergram, the basophils are easily distinguished from the other leukocytes and RBC ghosts due to their size and complexity (i.e., high forward scatter and high side scatter).

In the IMI channel, reagents act selectively on the lipid membranes of the leukocytes. Mature leukocytes with phospholipid-rich membranes are completely lysed, leaving only bare nuclei. The immature myeloid cells remain intact. In the IMI channel, the cells are analyzed by direct current and radio frequency (reflecting a cell’s internal structure and density) to determine the degree of immaturity (Web Figure 3■). This channel allows a clear delineation of immature granulocytes and blasts. With the HPC Master software, this channel provides the hematopoietic progenitor cell (HPC) count. Studies have shown that the HPC count correlates well with the CD34^+ cell count by flow cytometry.²⁶ Thus, HPC counts can be used to determine peripheral blood stem cell counts to assess optimal harvesting time following peripheral blood stem cell mobilization.

This instrument also determines the presence of nucleated erythrocytes in the blood sample and corrects the total leukocyte (WBC) count and lymphocyte count for their presence. The lymphocyte count is affected because nucleated erythrocytes and lymphocytes fall in the same cluster on the DIFF scattergram. Within the NRBC channel, the blood cells are diluted with a lyse plus fluorescent dye reagent. This reagent hemolyzes the erythrocytes, removes the nucleated erythrocytes’ cytoplasmic membrane, and shrinks the nucleus. The fluorescent dye binds to the nuclei. For the leukocytes, the reagent perforates only the cytoplasmic membrane allowing fluorescent dye to enter the cell and bind to intracytoplasmic organelles and the nucleus, but the leukocytes’ shape is not altered. Thus, leukocytes exhibit stronger fluorescence. As the nuclei of the nucleated erythrocytes and the intact leukocytes pass through the laser beam of the Optical Detection block, they generate forward scatter, side scatter, and fluorescence. This information is used to create the NRBC scattergram, which is a plot of fluorescent intensity versus forward scatter (Figure 13■; Web Figure 4■). Leukocytes are clearly delineated from the nucleated erythrocytes due to their high fluorescent intensity and high forward scatter (i.e., larger size). This analysis provides a sensitive method to determine NRBC as low as 0.1 NRBC/100 WBCs.

■ **FIGURE 11** DIFF scattergram, Sysmex XE-2100™. RBC ghosts, lymphocytes, monocytes, eosinophils, and neutrophils + basophils are identified. Basophils are specifically identified in the WBC/BASO scattergram. (Courtesy of Sysmex Corporation, Kobe, Japan)

■ **FIGURE 12** WBC/BASO scattergram, Sysmex XE-2100™. Basophils are clearly distinguished from other leukocytes and RBC ghosts based on their larger size (i.e., forward scatter) and increased complexity (i.e., side scatter). (Courtesy of Sysmex Corporation, Kobe, Japan)

✓ **Checkpoint! 5**

How does the determination of the five-part leukocyte differential for the Coulter® LH 750 instrument and the Sysmex XE-2100™ instrument differ?

■ **FIGURE 13** NRBC scattergram, Sysmex XE-2100™. Nucleated erythrocytes are clearly delineated from leukocytes based on their lower fluorescence intensity and smaller size (i.e., less forward scatter) as seen on this schematic pattern. (Reprinted with permission from Rowan RM, Linssen J. A Picture Is Worth a Thousand Words. Sysmex Journal International: 2005;15(1):27–38.)

The reticulocyte count is determined in the RET channel. Within this channel, the fluorescent dye containing oxazine and polymethine penetrates the cell membranes and stains the blood cells. Oxazine binds to residual RNA within the reticulocytes, and polymethine binds to RNA and DNA within nucleated cells. The diode laser of the Optical Detection block evaluates each blood cell and determines its forward scatter and fluorescence. The data analysis system integrates these two characteristics to create the RET scattergram. From this scattergram, cells are classified as mature erythrocytes, reticulocytes and platelets (Figure 14■). The reticulocytes are further classified based on fluorescent activity to determine reticulocyte maturity (Web Figure 5■). Reported parameters include absolute reticulocyte count, reticulocyte percentage, low fluorescence ratio (LFR), middle fluorescence ratio (MFR), high fluorescence ratio (HFR), immature reticulocyte fraction (IRF), reticulocyte hemoglobin content (Ret He), and platelet count. The IRF represents the MFR and HFR combined and is reported as a percentage of the total reticulocyte count.

The platelet count from the RET channel is compared to the platelet count from the RBC/PLT dilution. If the platelet count is extremely low, the platelet count from the RET channel is the reported platelet count because it is more accurate due to the additional cellular characteristics that are evaluated. The immature platelet fraction (IPF) is an additional platelet parameter derived from the RET channel that

■ **FIGURE 14** RET scattergram, Sysmex XE-2100™. Mature erythrocytes, reticulocytes, and platelets are identified. (Reprinted with permission from Rowan RM, Linssen J. A Picture Is Worth a Thousand Words. *Sysmex Journal International*: 2005;15(1):27–38.)

represents the **reticulated platelets** (Figure 15 ■). Reticulated platelets are newly released platelets that possess residual RNA. An increased IPF reflects increased thrombopoiesis, while a decreased IPF reflects decreased platelet production. The IPF is useful in a variety of clinical situations: as an indicator of platelet engraftment following stem cell transplantation; in the diagnosis of thrombocytopenia associated with increased platelet destruction versus bone marrow failure; and as a requirement of platelet transfusion associated with cytotoxic therapy or stem cell transplant.^{27–30}

All data, including cell counts, histograms, and scattergrams, are analyzed by the data analysis system. The results are displayed on the computer screen, printed to a hard copy (Figure 16 ■), or transferred to the LIS. An extensive flagging program with interpretive comments alerts the clinical laboratory professional to abnormal results. Use of the flagging

■ **FIGURE 15** Optical platelet (PLT-O) scattergram, Sysmex XE-2100™. Mature platelets lacking RNA are found in the lower portion of the platelet population while the immature platelet fraction is found in the upper portion of the platelet population due to increased size and higher fluorescence. (Reprinted with permission from Rowan RM, Linssen J. A Picture Is Worth a Thousand Words. *Sysmex Journal International*: 2005;15(1):27–38.)

system and observations of the scattergrams and histograms allow the clinical laboratory professional to focus on specific abnormalities when performing a peripheral blood smear evaluation.

✓ Checkpoint! 6

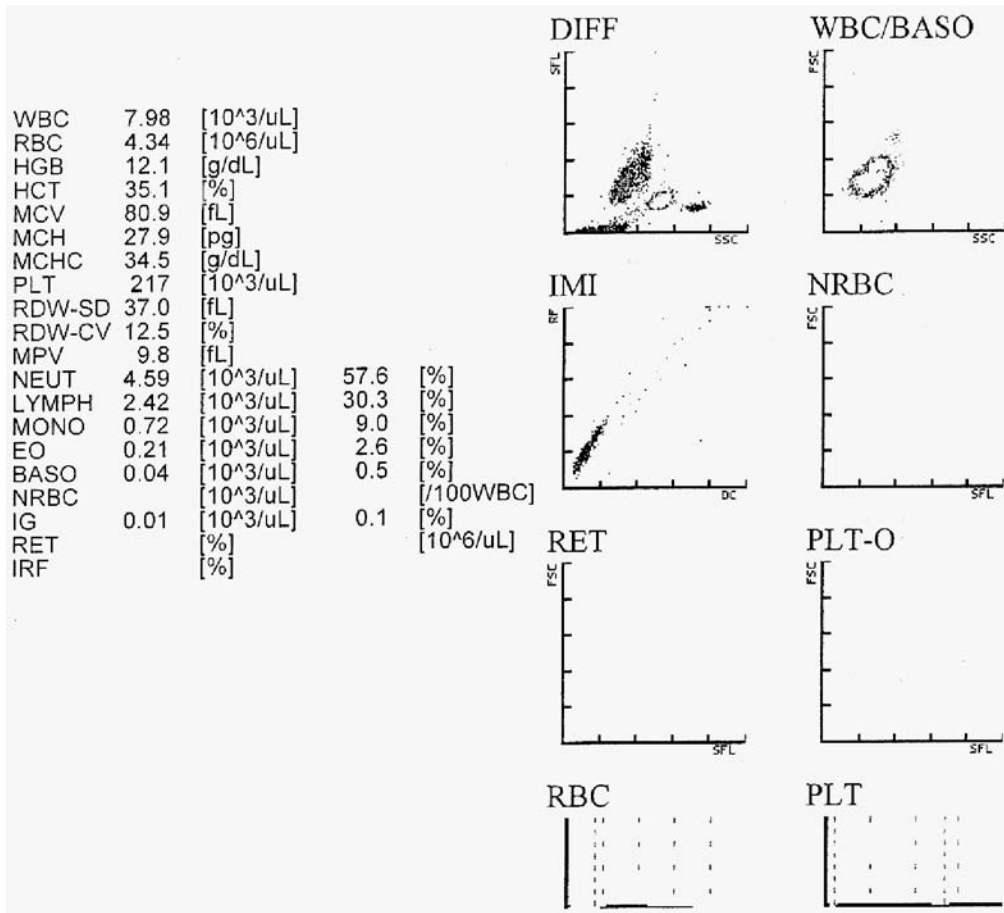

Which cellular characteristics are used to determine the immature platelet fraction (IPF) on the Sysmex XE-2100™ instrument?

Abbott CELL-DYN Sapphire®

Like other automated cell counting instruments, the CELL-DYN Sapphire® utilizes a combination of technologies to enumerate erythrocytes, leukocytes, platelets, and reticulocytes and determine a five-part leukocyte differential.^{31,32} Flow cytometry, fluorescence staining, and impedance are used to make these determinations.

The instrument aspirates a sample of EDTA anticoagulated blood and sends a portion of this sample to the hemoglobin dilution cup. Hemoglobin reagent dilutes the blood sample, lyses erythrocytes, and converts free hemoglobin to a single chromogen by forming a complex with imidazole. The hemoglobin concentration is determined spectrophotometrically at 540 nm. A reagent blank is used to minimize optical interferences whereas leukocyte interference is minimal because the reagent destroys leukocytes and cellular fragments. This cyanide-free reaction shows good correlation with the cyanmethemoglobin reference method.

In the WBC dilution cup assembly, the sample is diluted for the enumeration of total leukocyte (WBC) count, detection and quantitation of nucleated erythrocytes, and determination of the five-part leukocyte differential. The preheated WBC reagent dilutes the leukocytes, lyses erythrocytes, strips the cytoplasmic membrane from nucleated erythrocytes and fragile leukocytes, and stains DNA of the exposed nuclei with propidium iodide, a fluorescence dye. This dilution is sent to the optical flow cell. Hydrodynamic focusing directs cells through the flow cell in single file. A solid-state laser interacts with each intact cell or exposed nuclei to create light scatter and fluorescence (PI excites @ 488 nm and emits @ 630 nm). Using multi-angle polarized scatter separation (MAPSS™) technology, the following light scatter characteristics are determined as follows: (1) 0° light scatter or forward scatter that reflects cell size; (2) 7° light scatter that reflects cell complexity; (3) 90° light scatter or side scatter that reflects nuclear lobularity; and (4) 90° depolarized light scatter that reflects cytoplasmic granularity (Figure 17 ■). Data generated by MAPSS technology is used in different ways to classify leukocyte subpopulations and identify certain morphologic flags.³¹ For example, discriminant line analysis is used to isolate and identify various cell populations. A histogram is created based on one-dimensional data (e.g., size) or two-dimensional data (e.g., size vs. DNA). The data management system identifies the valley between the cell populations and sets a discriminant line. Scatterplots and contour plots of the data are used to further classify

■ **FIGURE 16** Sysmex XE-2100™ report from a normal individual (Courtesy of Cynthia Pittman, MT(ASCP)SH, San Antonio, TX)

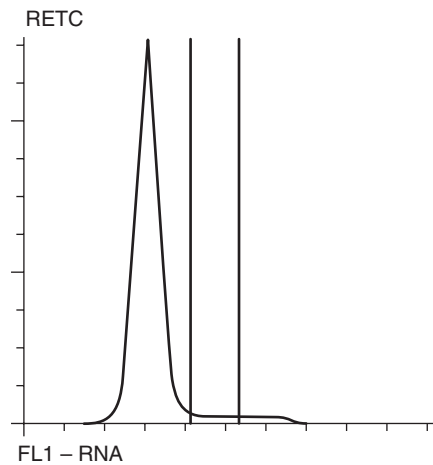

■ **FIGURE 17** Four light scatter measurements from the CELL-DYN Sapphire. The 0° scatter reflects cell size; 7° scatter reflects cell complexity; 90° scatter reflects nuclear lobularity; and 90° depolarized scatter reflects cytoplasmic granularity.

subpopulations of leukocytes. The 0° (size) versus 7° (complexity) scatterplot allows differentiation of neutrophils, monocytes, and lymphocytes (Figure 18■). Eosinophils are differentiated from neutrophils in the 90°D (granularity) versus 90° (lobularity) scatterplot. Finally, lymphocytes are separated from basophils based on size and complexity. The data management system analyzes these characteristics to determine the total leukocyte (WBC) count and the five-part leukocyte differential. Additional information obtained from evaluation of this dilution includes the enumeration of nucleated erythrocytes and identification of nonviable or fragile leukocytes, which are based on light scatter characteristics and fluorescence intensity (i.e., DNA content). Because the nucleated erythrocytes are clearly distinguished from leukocytes in this dilution, the total leukocyte count and five-part differential are unaffected by their presence.

Two different dilutions are prepared in the RBC/PLT dilution cup assembly. One dilution represents the erythrocyte/platelet dilution. The diluent dilutes the blood sample and spheres the erythrocytes. Using the principles of

■ **FIGURE 18** 0° (size) vs 7° (complexity) scatterplot, CELL-DYN Sapphire. Neutrophils, monocytes, and lymphocytes are identified. Lymphocytes are located lower left in the scatterplot; the middle cell population is monocytes; and neutrophils are located upper center in the scatterplot.

■ **FIGURE 19** Reticulocyte histogram, CELL-DYN Sapphire. Reticulocytes are found between the two gates. The peak to the left represents mature erythrocytes.

hydrodynamic focusing and impedance, the erythrocytes and platelets are evaluated as they pass singly through the impedance transducer from which the erythrocyte count, erythrocyte size distribution curve (histogram), platelet size distribution curve, and platelet count are obtained. A second portion of the erythrocyte/platelet dilution is sent to the optical flow cell for enumeration of these cells based on light-scatter characteristics. The erythrocyte count from the optical flow cell and the platelet count from the impedance transducer are used as internal quality control checks against the reported erythrocyte count from the impedance transducer and the reported platelet count from the optical flow cell. The second dilution represents the reticulocyte dilution. The blood sample is diluted with the isotonic diluent and nucleic acids are stained with a fluorescence dye (i.e., fluorescein isothiocyanate) that excites @ 488 nm and emits @ 530 nm. This dilution is sent to the optical flow cell, where the number of reticulocytes is determined based on fluorescence intensity and light-scatter characteristics (i.e., 7° light scatter). From this information, a reticulocyte histogram is created that allows the determination of the reticulocyte count and the immature reticulocyte fraction (Figure 19 ■).

The data management system analyzes and compiles all data obtained from the instrument and determines the reported parameters. The results are displayed on a computer screen, printed to a hard copy for the clinical laboratory professional's review (Figure 20 ■), or transferred to the LIS. System-initiated messages and data flags alert the clinical laboratory professional to potential abnormalities or errors in the results. This information is used to correlate CBC data with peripheral blood morphology to improve the identification and confirmation of abnormalities.

✓ **Checkpoint! 7**

- Which CELL-DYN scatterplot allows differentiation of eosinophils from neutrophils?
- The CELL-DYN Sapphire's WBC dilution contains propidium iodide, so why don't the neutrophils fluoresce?

Two additional assays can be performed on the CELL-DYN Sapphire, Immuno T-cell Assay, and ImmunoPlt™ (CD61) assay. Both assays represent fluorescent immunophenotyping methods. The Immuno T-cell Assay uses monoclonal antibodies with different fluorescent labels to identify the T cell population (i.e., fluorescein isothiocyanate labeled anti-CD3) and its two subpopulations, T_{helper} cells (i.e., phycoerythrin labeled anti-CD4) and T_{cytotoxic} cells (i.e., phycoerythrin labeled anti-CD8). Enumeration of these subpopulations is important in evaluating patients with immunodeficiency syndromes and monitoring certain therapeutic interventions.

The Immuno T-cell Assay consists of two reagent tubes, CD3/CD4 and CD3/CD8. The instrument prepares the reaction mixture in each tube by adding the patient sample and the diluent to the tube's monoclonal antibodies. The instrument rocks the reagent tube gently, incubates the reaction mixture for 2 minutes at room temperature, and then aspirates a portion of the reaction mixture from the tube and places it in the WBC dilution cup. WBC reagent is added to create a final dilution of 1:36, which is sent to the optical flow cell for light scatter and fluorescence intensity measurements. Fluorescence intensity, 0° light scatter (i.e., size) and 7° light scatter (i.e., cell complexity) are used to identify and enumerate the different lymphocyte populations. The

scatterplot of 0° light scatter versus 7° light scatter is used to isolate the lymphocyte population for further examination. The scatterplot of CD3 fluorescence intensity (measured at fluorescein isothiocyanate's emission wavelength of 530 nm) versus CD4 fluorescence intensity (measured at phycoerythrin's emission wavelength of 630 nm) determines the

percentage of T_{helper} cells; likewise, the scatterplot of CD3 fluorescence intensity versus CD8 fluorescence intensity determines the percentage of T_{cytotoxic} cells. The total CD3 fluorescence intensity on a given scatterplot reflects the percentage of T cells present in the patient sample. Comparison of the percentage of CD3 positive cells from each scatterplot

can be used as an internal control. The computer system uses established algorithms to process the light scatter and fluorescence measurements and generate the reported parameters. These parameters include total T cell count, percentage of T cells, absolute T_{helper} cell count, percentage of T_{helper} cells, absolute $T_{\text{cytotoxic}}$ cell count, percentage of $T_{\text{cytotoxic}}$ cells, and the ratio of T_{helper} to $T_{\text{cytotoxic}}$ cells. The concentration of these cells can be determined because a CBC is performed on the patient sample prior to preparation of the assay's reagent tubes. This CBC also provides a check of the lymphocyte's viability.

The ImmunoPlt™ (CD61) assay utilizes a platelet-specific monoclonal antibody, anti-CD61 that is labeled with fluorescein isothiocyanate. This assay is useful when a patient's platelet count is very low (e.g., less than $10 \times 10^9/L$) or when leukocyte or erythrocyte fragments within the patient sample interfere with platelet enumeration. Because of the specificity of this assay, it provides an accurate platelet enumeration. Like the T-cell assay, the monoclonal antibody is present within a reagent tube. Patient sample and diluent are added to this tube, which are gently mixed. The reagent tube incubates for 1 minute at room temperature. At this point, additional diluent is added to the reagent tube to further dilute the mixture. A portion of this reaction mixture is aspirated into the RBC/PLT dilution cup and diluent is added to create a final dilution of 1:290. A portion of the final dilution is injected into the optical flow cell for measurement. Measurements include 0° light scatter, 7° light scatter, and fluorescence intensity at 530 nm (i.e., fluorescein isothiocyanate's emission wavelength). The instrument's computer system uses established algorithms to process the data generated by these measurements and determines the platelet count. Due to CD61's specificity for platelets, this platelet count is not affected by other cells or cell fragments.

LIGHT-SCATTERING INSTRUMENTS

Technicon Instruments Corporation was important in the development of hematology instrumentation that utilized light scattering technology to enumerate blood cells. Its first instruments were based on **continuous flow analysis** similar to its chemistry instruments. The Hemolog D performed leukocyte differentials based on continuous flow analysis and peroxidase cytochemical staining. The Technicon H-6000 was capable of performing a complete blood cell count and five-part leukocyte differential using continuous flow analysis and an improved cytochemical staining method. The Technicon H*1 was the first of a series of instruments that combined these principles of cell detection and identification with flow cytometry.³³⁻³⁵ The two instruments described next represent current models whose basic principles of cell enumeration and determination of the leukocyte differential can be traced back to methodologies introduced by the Technicon Instruments Corporation.

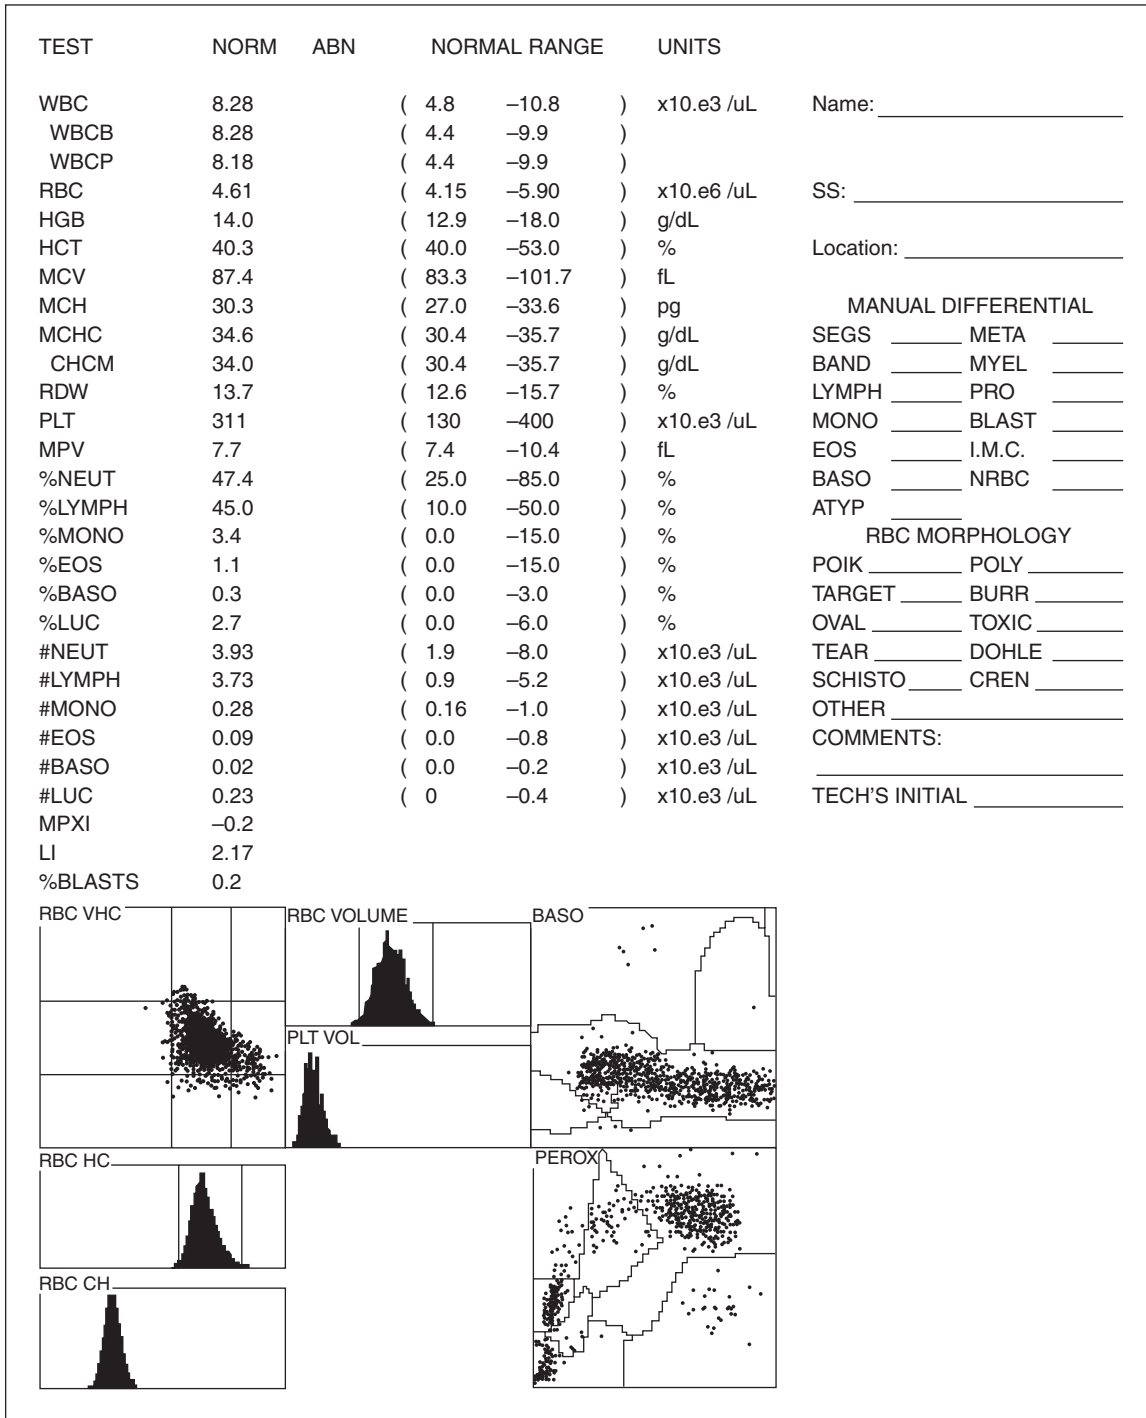

Siemens (formerly Bayer) Healthcare ADVIA 120

The ADVIA 120 is capable of performing a CBC, five-part leukocyte differential, and reticulocyte count.³⁶ It has five measurement channels. The erythrocyte/platelet channel determines the erythrocyte and platelet counts by the light-scattering measurements obtained as diluted cells pass singly through a helium-neon laser beam. The diluent utilized for erythrocyte and platelet counts causes **isovolumetric sphering** of the erythrocytes and platelets. Isovolumetric sphering of erythrocytes eliminates cell volume errors due to variation in erythrocyte shape.^{37,38} The erythrocytes are counted and sized by both high-angle ($5-15^\circ$) and low-angle ($2-3^\circ$) light-scattering measurements. Individual erythrocyte hemoglobin concentration is determined by the high-angle measurement, and cell volume is determined from the low-angle measurement; thus, the mean cell volume (MCV) and **cellular hemoglobin concentration mean (CHCM)** are obtained. Together, these measurements are used to generate the erythrocyte cytogram, erythrocyte histogram, and hemoglobin histogram (Figure 21 ■). The RDW and the **hemoglobin distribution width (HDW)** are derived from these histograms.

Platelets are evaluated simultaneously with the erythrocytes using both high-angle light scatter and low-angle light scatter; however, these signals are amplified for platelet enumeration. This information is used to create a platelet cytogram, and the actual platelet count is obtained by integrated analysis of the platelet cytogram and erythrocyte cytogram to include large platelets while excluding erythrocytes, erythrocyte fragments, and erythrocyte ghosts.

Within the hemoglobin channel, a portion of the EDTA-anticoagulated blood is mixed with the hemoglobin diluent. The erythrocytes are lysed, and free hemoglobin is converted to cyanmethemoglobin. The concentration of cyanmethemoglobin is determined photometrically at 546 nm.

The leukocyte count and five-part leukocyte differential are obtained utilizing two different methods and two separate channels, the peroxidase channel and the basophil/lobularity channel. The peroxidase channel identifies neutrophils, monocytes, and eosinophils by the degree of peroxidase positivity (i.e., increased absorption) and the amount of forward light scatter. Lymphocytes and large unstained cells (LUCs) are identified by the amount of forward light scatter and the fact that they remain unstained by this peroxidase cytochemical-staining method. Erythrocytes are removed prior to the peroxidase staining by lytic action. The amount of forward scatter and degree of peroxidase positivity (i.e., increased absorption) are detected as the cells pass through a tungsten halogen-based flow cell, and this information is used to create the peroxidase cytogram. Within the basophil/lobularity channel, EDTA-anticoagulated blood is mixed with basophil diluent. The basophil diluent lyses erythrocytes and platelets and strips all leukocytes except basophils of their cytoplasm. The he-

■ **FIGURE 21** ADVIA 120 report from a normal individual. (Courtesy of David Teplicek, MT(ASCP), San Antonio, TX)

limum-neon laser flow cell measures this dilution and determines the degree of high-angle scatter and low-angle scatter for each cell that is examined. This information is used to create the basophil/lobularity cytogram. The data management system uses **cluster analysis** to identify individ-

ual cell populations within a given cytogram. Each population is identified by its position, area, and density. Thresholds are set, and the number of cells in each population is determined. For the basophil/lobularity cytogram, the nor-

mal cell pattern is referred to as the *worm* with the head region representing mononuclear cells and the body region representing polymorphonuclear cells as classified by their high-angle scatter signatures. Basophils have large, low-angle scattered signatures and are located in the region above the worm. For the peroxidase cytogram, the normal cell pattern depicts the neutrophils in the upper right quadrant, eosinophils in the lower right quadrant, and monocytes in the center triangular region; lymphocytes are located adjacent to the y-axis in the center left quadrant and LUCs are located in the upper left quadrant of the peroxidase cytogram. The absolute count for each leukocyte population is obtained from the appropriate channel (e.g., absolute neutrophil count from the peroxidase channel and absolute basophil count from the basophil/lobularity channel). The absolute lymphocyte count is obtained by subtracting the absolute basophil count from the absolute lymphocyte count that was obtained from the peroxidase channel. This is necessary because lymphocytes and basophils cannot be differentiated from each other based on analysis of the peroxidase cytogram. The percentage values are calculated from the absolute cell counts. The total leukocyte count is obtained from both channels. The data management system compares these counts and flags the total leukocyte count if the results do not compare. An advantage of this method of determining cell counts is the capability of performing WBC counts and differentials on samples with very low counts ($WBC < 0.1 \times 10^9/L$).

The fifth channel is the reticulocyte channel where cellular RNA of the reticulocytes is stained with oxazine 750, a nucleic acid dye. The helium-neon laser flow cell evaluates the erythroid cells for light-scattering and absorbance characteristics. The high-angle light scatter reflects the hemoglobin concentration within the individual erythroid cells, and low-angle light scatter reflects the size of each cell. Reticulocytes are differentiated from mature erythrocytes based on their RNA content, which is determined by the cell's absorbance reading. Reticulocytes have a higher absorbance compared to mature erythrocytes. In addition to the absolute reticulocyte count and relative reticulocyte percentage, reticulocyte analysis includes a measure of the reticulocyte cellular hemoglobin concentration (CHr™), reticulocyte mean cell volume (MCVr), and the reticulocyte cellular hemoglobin concentration mean.

The ADVIA 120's data management system evaluates the information from the two flow cells, determines the reported parameters, and displays the information on the computer screen. The results can be printed to hard copy (Figure 21) or transferred to the LIS. If abnormalities are detected in cell counts, histograms, or cytograms, the instrument flags the appropriate result(s). The flagging criteria assist the clinical laboratory professional in defining the abnormalities to be reviewed by peripheral blood smear examination.

✓ Checkpoint! 8

What is the similarity in the reticulocyte methods performed on the ADVIA 120 and XE-2100 instruments?

Siemens Medical ADVIA 2120

The ADVIA 2120 represents the latest model in this series of hematology instruments. The basic principles of blood cell enumeration, reticulocyte enumeration, and determination of the five-part leukocyte differential are the same as those discussed in detail for the ADVIA 120. The hemoglobin determination is a cyanide-free methodology that demonstrates strong correlation with the cyanmethemoglobin method of the ADVIA 120.³⁹ A disadvantage of the ADVIA 2120 and ADVIA 120 is that neither is currently capable of determining and reporting a nucleated erythrocyte count, although a method is being investigated.⁴⁰

A potential new parameter is the %Hypo or percentage of hypochromic erythrocytes obtained from the red cell erythrogram, a derivation of the erythrocyte cytogram. This parameter is currently designated for "research use only." Studies indicate that the combined use of % Hypo and the CHr™ can be useful in detecting iron deficiency in patients on hemodialysis for chronic renal disease. These patients could experience a superimposed iron deficiency with anemia of chronic disease, which decreases their response to erythropoietin therapy. Early detection of iron deficiency results in appropriate therapeutic intervention to resolve the iron deficiency and, therefore, decrease the poor response rate of hemodialysis patients to erythropoietin therapy.^{41,42}

▶ AUTOMATED COAGULATION INSTRUMENTS

Instrumentation was actually introduced into coagulation testing in the early twentieth century. These first instruments, like the majority of instruments utilized today, analyzed the coagulation system through the detection of clot formation.^{43,44} The coaguloviscometer developed by Kottman in 1910 determined clotting times by measuring the change in blood **viscosity** as it clotted. The change in viscosity was determined by plotting the voltage against time. Kugelmass introduced a second method of clot detection in 1922. He adapted the nephelometer to coagulation testing. In nephelometry, the clotting time was determined by measuring variations in transillumination as registered by a galvanometer. Baldes and Nygaard introduced the photoelectric technique for determining clotting times in 1936. With their instrument, clotting times were determined by the measurement of increasing optical density as the plasma clotted. Coagulation instrumentation continued to improve, and by the 1960s, semiautomated coagulation instruments began to replace manual techniques in the clinical laboratory. These first

instruments were based on electromechanical or optical density methods of clot detection. Coagulation testing evolved in the 1970s with the introduction of fully automated instruments capable of performing multiple coagulation assays.

With the new directions in coagulation testing including chromogenic and immunologic methods, coagulation instruments are now capable of performing these test methods and the clot-based tests. The introduction of instrumentation into coagulation testing has led to increased precision and accuracy and, therefore, improved diagnostic testing and monitoring of therapeutic interventions.

The two principles of clot-based detection currently used by coagulation instruments are electromechanical and optical density. Other available instruments use a combination of these principles.

ELECTROMECHANICAL INSTRUMENTS

These instruments measure the time for a clot to form in plasma by detecting changes in the reaction mixture. One instrument (Fibrometer) detects the completion of an electrical circuit between two electrodes when a clot forms. The other (STArt® 4 Clot Detection) detects a decrease in movement of an iron ball in an electromagnetic field when a clot forms.

BBL FibroSystem

The FibroSystem, a semiautomated coagulation instrument, was introduced in the 1960s. It is composed of a Fibrometer coagulation timer, a thermal prep block to prewarm reagents and samples to 37°C, and an automatic pipet to deliver the appropriate amount of sample or reagent to the test cuvette.⁴⁵ The Fibrometer probe, an integral part of the Fibrometer coagulation timer, is the clot detector. The probe consists of two sensory electrodes (stationary and moving) and a probe foot, which is an extension of the moving electrode beyond the base of the probe assembly. In the timing sequence, the moving electrode cycles through the reaction mixture in an elliptical pattern created by raising and lowering the probe foot. The stationary electrode remains in the reaction mixture and is responsible for establishing the electric potential between the two electrodes. The moving electrode becomes electrically active when it is above the reaction mixture. As the fibrin clot is formed, it is picked up by the small hook on the tip of the moving electrode. The electric circuit is completed when the moving electrode becomes activated as it moves out of the reaction mixture; current flows from the stationary electrode through the reaction mixture and fibrin clot to the moving electrode. The creation of this electric circuit causes the timing device to stop, and the clotting time in seconds is recorded. Thus, the principle of clot detection is the electromechanical principle. An advantage of the FibroSystem is that it can be adapted to any coagulation assay that is clot based.

Diagnostica Stago STArt® 4 Clot Detection Instrument

The STArt® 4 Clot Detection instrument is a semiautomated instrument for coagulation testing, a variation of the electromechanical clot detection principle based on the increasing viscosity of plasma as clot formation occurs.^{46,47} This stand-alone instrument consists of four independently timed incubation stations with 16 wells, a dispensing pipet, both room temperature and 37°-thermostated reagent storage wells, four measurement channels, and a microprocessor system. The increasing viscosity is detected by the movement of an iron ball located at the bottom of the reaction cuvette. A constant pendular swing of the ball is created by alternating an electromagnetic field on opposite sides of the cuvette utilizing two independent driving coils. As clot formation begins, the plasma viscosity increases with a corresponding decrease in ball movement. The clotting time is determined from an algorithm of the variations in oscillation amplitude. Clotting time results are displayed on the liquid crystal display (LCD) screen, and printed results are obtained from the thermal printer. This instrument can be adapted to any clot-based coagulation assay.

Checkpoint! 9

Compare the clot detection methods for the Fibrometer system and the STArt 4 system.

OPTICAL DENSITY INSTRUMENTS

Trinity Biotech Coag-A-Mate XM

The Coag-A-Mate XM was first introduced in 1989 by Organon Teknika and is currently supported by Trinity Biotech. According to the January 2008 CAP survey of coagulation instruments, the Coag-A-Mate XM is still utilized in the clinical laboratory.⁴⁸ Because it is a good example of a coagulation instrument whose clot detection is optical density, it is discussed here.

The Coag-A-Mate XM is a semiautomated instrument utilizing the change in optical density that occurs with clot formation as its principle of clot detection.⁴⁹ The instrument consists of a reagent storage compartment, incubation test plate, photodetection system, and microprocessing system. The test procedures are programmed using the touch entry keypad. Reagents and patient samples are manually pipeted into the test cuvettes. The reaction mixture is warmed to 37°C in the incubation test plate. For determination of the clotting time, the test cuvette is placed in one of two measuring stations. The addition of the final reagent to the test cuvette initiates the timer. The photoelectric cell detects the sudden increase in optical density occurring with fibrin formation, and the timer is stopped. The results are displayed on the LCD panel below each measuring station. This instrument is capable of performing two tests simultaneously. It can perform all clot-based coagulation assays.

CHROMOGENIC/CLOT DETECTION INSTRUMENTS

Several manufacturers currently market coagulation instruments that combine the traditional clot-based detection principle with chromogenic analysis and immunological techniques.

Because the coagulation cascade is a series of enzymatic reactions catalyzed by serine proteases, the activity of these enzymes can be measured by conventional clinical chemistry methods. Chromogenic analysis is an example of a clinical chemistry methodology that has been adapted to coagulation testing. In a chromogenic analysis, the enzyme of interest (e.g., activated coagulation factor) cleaves the chromogenic substrate at a specific site, releasing the chromophore tag. The color intensity is measured spectrophotometrically and is directly proportional to the concentration of the chromophore tag according to Beer's law. Depending on the assay's sequence of reactions, the chromophore tag's concentration is either directly or indirectly related to the concentration (or activity) of the measured substance (e.g., factor VIII activity or antithrombin activity, respectively). Chromogenic assays can be used for testing individual coagulation proteins, biochemical inhibitors, and fibrinolytic proteins based on choice of substrates used in a given assay. In addition to coagulation instruments, chromogenic assays have been adapted for use on a number of spectrophotometric chemistry instruments.

Trinity Biotech AMAX Destiny Plus

The AMAX Destiny Plus is a **random access**, fully automated coagulation instrument capable of performing four different methodologies: electromechanical, optical density, chromogenic, and immunologic.⁵⁰ The instrument can perform all methodologies simultaneously. Both samples and reagents are stored at 15°C. A temperature-controlled probe (37°C) is used to transfer the appropriate amount of sample or reagent to the reaction cuvette for measurement.

Electromechanical measurement of clot formation is based on the AMELUNG ball method. The test cuvette contains a stainless steel ball. After sample and reagent (e.g., activated partial thromboplastin reagent) are added to the cuvette, it is placed in a mechanical measurement well. The addition of the starting reagent (e.g., calcium chloride) initiates the rotation of the ball. A magnet holds the rotating ball in a predetermined position within the cuvette. As the fibrin clot forms, fibrin strands draw the ball away from its steady-state position. A sensor detects the change in ball position, stopping the time. The clotting time represents the time elapsed between addition of the starting reagent and detection of the ball movement. The advantage of this measurement is that accurate results are obtained on icteric samples, lipemic samples, and samples from patients on medications that affect optical measurement.

The second method of clot detection available on the AMAX Destiny Plus is optical density. To determine clotting

time, sample and reagent (e.g., activated partial thromboplastin reagent) are added to the measuring cuvette, which is moved to the photo-optical measurement position. When the starting reagent (e.g., calcium chloride) is added to the cuvette, the instrument measures the initial absorbance of the reaction mixture at 405 nm and monitors the change in absorbance over time (i.e., creates a clotting curve). The clotting time represents the time elapsed between the addition of starting reagent and the detection of the maximum slope of the clotting curve. Because the clotting time is measured as the time difference between the initial absorbance of the reaction mixture and the absorbance at the maximum slope of the clotting curve, the effect of icteric and lipemia on the clotting time is minimized.

The chromogenic assays are performed in the photo-optical measurement well because the final enzymatic reaction in these assays yields paranitroaniline with an absorbance maximum at 405 nm. The temperature-controlled probe delivers the appropriate amount of sample and reagent to the test cuvette. The photodetector cell monitors the optical density over the assay's reaction period at 405 nm. A curve is created by plotting the optical density against time, and the change in optical density (ΔOD) is determined during the linear phase of the reaction. The change in optical density is compared to the assay's calibration curve, and the result is calculated from this comparison and reported in the appropriate units.

The immunologic assays are also performed in the photo-optical measurement well. However, these assays are used not for clot detection but to detect and/or quantitate the presence of certain coagulation proteins or products. For example, immunologic methodology on the AMAX Destiny Plus detects and quantitates D-dimers. In this assay, the reagent is polystyrene microparticles coated with monoclonal antibodies against D-dimer. The temperature-controlled probe delivers the reagent and sample to the test cuvette and the photodetector cell monitors the increase in absorbance at 405 nm that occurs as immune complexes form between the sample's D-dimers and the monoclonal antibodies, thus aggregating the microparticles. The increase in absorbance is directly proportional to D-dimer concentration. Comparison to a standard curve is used to calculate the concentration.

Checkpoint! 10

What is the basis of clot detection for the optical density principle?

Diagnostica Stago STA Compact®

Like other automated coagulation instruments, the STA Compact® is a continuous random access instrument that performs clotting assays by electromechanical principle as well as chromogenic and immunological assays.⁵¹ Within this instrument, patient samples and dilution buffers are

loaded in the sample drawer and reagents, controls, and calibrators are stored in designated positions within the product drawer maintained at 15–19°C. For the clotting assays (e.g., activated partial thromboplastin time), the sample is aspirated by the sample pipetting needle and placed in a test cuvette containing a stainless steel ball. Then, the reagent (i.e., activated partial thromboplastin) is added by pipetting needle 2. The test cuvette is moved from the measurement station to the incubation area where the temperature of the reaction mixture is warmed to 37°C; the incubation area has 16 positions. After brief incubation, the test cuvette is moved to the measurement area (which has four positions) and pipetting needle 3 adds the starting reagent (i.e., calcium chloride). Together, the alternating electromagnetic field created by two independent driving coils and the rail tracks in the cuvette promote the pendular movement (i.e., oscillation) of the stainless steel ball through the reaction mixture. As the fibrin clot forms, the increasing viscosity of the reaction mixture decreases the ball's oscillation as detected by electromagnetic sensors. The instrument uses an algorithm to calculate the clotting time based on the variations in oscillation amplitude. The clotting times are not affected by lipemic or icteric samples because the determination does not depend on light absorbance.

The chromogenic assays are measured photometrically. The final product of each assay is a chromogen, paranitroaniline with an absorbance maximum of 405 nm. The reaction mixture is set up similarly to that described for the clotting assay. For photometric measurement, monochromatic light is created when incident light from the tungsten-halogen lamp passes through the appropriate interference filter (i.e., 405 nm or 540 nm filter). The monochromatic light then passes through the reaction cuvette, and the chromogen absorbs some of the light. The photodetector measures the amount of absorbance. This absorbance reading is compared to the assay's calibration curve, and the result is calculated from this comparison and reported in the appropriate units.

As previously discussed, the immunological assays are used to detect and/or quantitate the presence of certain coagulation proteins or products (i.e., VWF and D-dimers). For example, STA Compact® measures the concentration of von Willebrand factor (VWF) in plasma using the immunological assay. In this assay, microlatex beads coated with rabbit anti-human VWF are added to a test cuvette containing patient sample. After incubation, the cuvette is moved to the measuring station. The interaction of VWF with its monoclonal

antibody causes the microlatex beads to aggregate or clump, thus increasing the absorbance of monochromatic light at 540 nm as measured by the photodetector. This reaction follows Beer's law so that the VWF concentration is directly proportional to absorbance. The VWF concentration is determined by comparison to a standard curve.

SUMMARY

This chapter briefly reviewed the ever-increasing uses of technology for the automated hematology laboratory. The blood cell-counting instruments include those using a combination of technologies such as impedance, light scatter, radio frequency, and fluorescent detection to determine CBC and five-part leukocyte differentials. Most instruments also measure reticulocytes and nucleated erythrocytes. Reticulocyte evaluation includes not only quantitative data but also data on the immaturity of reticulocytes, which indicates the erythropoietic response of the bone marrow to therapy for anemia. The hematology instruments' data analysis systems examine the data for possible interference or abnormalities and if found, the laboratory professional is alerted by suspect or user-defined flags. The laboratory professional uses the flags to correlate the CBC data with peripheral blood morphology and confirm the abnormalities or correct erroneous results. Automated coagulation instruments include those that use electromechanical and/or optical density to detect clot formation in a plasma mixture. In the electromechanical instruments, the formation of a clot completes an electrical circuit between two electrodes. Those instruments using optical density, detect a change in optical density when a clot forms. The addition of chromogenic and immunological assays to these instruments enhances their test assay menus. In chromogenic assays, the activated coagulation factor cleaves a chromogenic substrate, releasing a chromophore tag. The color intensity is measured spectrophotometrically and is related to the factor's concentration. Immunological assays detect coagulation proteins using monoclonal antibodies. The immunologic assay does not measure the protein's functional ability.

To operate these instruments to their fullest potential, it is important that qualified clinical laboratory professionals evaluate the data created by the instrument's analysis of an individual cell's characteristics or clotting characteristics. Through careful review of that data, new applications of these instruments can arise to aid in the early detection of abnormalities. Automation has increased precision and accuracy within the hematology laboratory and shortened the amount of time needed for analysis, but it has also increased the need for the individual laboratory professional's interpretive skills.

REVIEW QUESTIONS

LEVEL I

- Which instrument uses the optical light scatter method to determine the erythrocyte count? (Objective 3)
 - GEN-S
 - XE-2100
 - CELL-DYN Sapphire
 - ADVIA 120
- What is hydrodynamic focusing used for in automated blood cell-counting instruments? (Objective 3)
 - ensure that only a single cell enters the detection area at any given time
 - direct the beam of light onto the center of the photodetector
 - select the appropriate wavelength of light for analysis
 - focus the beam of light on the detection area
- Which parameter does the GEN-S instrument calculate? (Objective 5)
 - erythrocyte count
 - MCV
 - reticulocyte percentage
 - absolute neutrophil count
- Which dye is used to stain cellular RNA for reticulocyte counting on the ADVIA 120? (Objective 6)
 - thiazole orange
 - oxazine 750
 - new methylene blue
 - auramine-O
- For which coagulation instrument is clot formation detected by the flow of current between two sensory electrodes? (Objective 7)
 - AMAX Destiny Plus
 - Fibrometer
 - Coag-A-Mate XM
 - STArt 4
- Both electromechanical and photo-optical principles of clot detection are available on this instrument. (Objective 7)
 - Fibrometer
 - STA Compact
 - STArt 4
 - AMAX Destiny Plus
- On what is the photo-optical principle of clot detection based? (Objective 8)
 - observation of increased light transmission as a fibrin clot forms
 - optical detection of ball movement as a fibrin clot forms
 - observation of increased absorbance as a fibrin clot forms
 - photometric detection of an oscillating magnetic force as a fibrin clot forms

LEVEL II

- What information is needed to create an erythrocyte histogram? (Objective 1)
 - cell volume and relative cell number
 - cell size and cell complexity
 - nuclear size and cellular density
 - cell forward scatter and cell side scatter
- Which of the following technologies does the Sysmex XE-2100 *not* use to categorize leukocyte cell types? (Objective 1)
 - fluorescence
 - radio frequency
 - optical light scatter
 - differential cell lysis
- Using the ADVIA 120 instrument, which leukocyte cell type is located in the body of the worm of the basophil/lobularity cytogram? (Objective 1)
 - basophil
 - monocyte
 - neutrophil
 - lymphocyte
- The Coulter LH 750 five-part leukocyte differential is determined by the analysis of cellular characteristics as defined by: (Objective 1)
 - light scatter, cytochemical staining, and radio frequency
 - light scatter and radio frequency
 - impedance and cytochemical staining
 - impedance, conductivity, and light scatter
- The reticulocyte hemoglobin concentration (CHr) is determined by measuring the cell's: (Objective 2)
 - absorbance and light scatter characteristics
 - absorbance and radio frequency characteristics
 - fluorescence intensity and impedance characteristics
 - fluorescence intensity and conductivity characteristics
- What does the photodetector measure in the immunological assays performed on the AMAX Destiny Plus? (Objective 3)
 - decrease in light reflected by antigen-antibody complexes
 - increase in percent of transmittance because microparticles aggregate
 - decrease in light scatter because less individual particles are present
 - increase in absorbance because turbidity accumulates in the reaction mixture

REVIEW QUESTIONS (continued)

LEVEL I

8. Which parameter does the CELL-DYN Sapphire directly measure? (Objective 5)
 - a. hematocrit
 - b. platelet count
 - c. relative neutrophil percentage
 - d. absolute reticulocyte count
9. Which automated blood cell-counting instrument does *not* use the analysis of fluorescence intensity and light scatter to determine the reticulocyte count? (Objective 6)
 - a. XE-2100
 - b. ADVIA 120
 - c. CELL-DYN Sapphire
 - d. LH 750
10. Which parameter does the Sysmex XE-2100 derive from a histogram or scattergram? (Objective 5)
 - a. absolute monocyte count
 - b. erythrocyte count
 - c. mean cell volume
 - d. hematocrit

ANSWERS TO CHECKPOINTS

Checkpoint! 1

What is the basis of the impedance principle for cell counting?

Answer

The impedance principle is based on the fact that blood cells are poorly conductive particles. Increased resistance is observed when a poorly conductive particle passes through an electrical field.

Checkpoint! 2

Why is lytic agent added to the leukocyte dilution?

Answer

Lytic agent is added to the leukocyte dilution for several reasons. First, the lytic agent will lyse the erythrocytes and eliminate their interference with the WBC count (i.e., falsely elevated WBC count). The lytic agent also perforates the leukocyte’s membrane and shrinks the membrane around the nucleus. This allows the instrument to measure each leukocyte’s cell volume and create the WBC histogram. Finally, the lytic agent converts the released hemoglobin to cyanmethemoglobin for the measurement of hemoglobin concentration.

Checkpoint! 3

Explain how the Coulter® Gen • S determines the five-part leukocyte differential.

Answer

The Coulter® Gen • S utilizes impedance, conductivity, and light scatter to determine the leukocyte differential. Impedance identifies each cell's volume and is traditionally used to generate a three-part differential. With the additional data generated for each cell by conductivity (i.e., cell's internal conductivity) and light scatter (i.e., cell's size and granularity) and the use of contour gating to analyze the data in three-dimensional space, the five-part leukocyte differential can be determined (i.e., neutrophil, lymphocyte, monocyte, eosinophil, and basophil).

Checkpoint! 4

The following results were obtained from a blood sample analyzed by the Coulter® LH 750: NRBC# $2.7 \times 10^9/L$ and corrected WBC $18.1 \times 10^9/L$. What was the uncorrected WBC count?

Answer

Since the corrected WBC count is the uncorrected WBC count—the absolute number of nucleated red blood cells (NRBC)—the uncorrected WBC count is $20.8 \times 10^9/L$.

Checkpoint! 5

How does the determination of the five-part leukocyte differential differ between the Coulter® LH 750 instrument and the Sysmex XE-2100™ instrument?

Answer

The Sysmex XE-2100™ instrument utilizes fluorescent staining of nucleic acids and forward/side scatter characteristics to determine lymphocytes, monocytes, eosinophils, and neutrophils + basophils. The basophils are separated from the neutrophils in a second dilution utilizing a specific lyse reagent that leaves the basophils intact. The light scatter characteristics of the basophils versus other leukocytes allows clear delineation of basophils. For the Coulter® LH 750 instrument, a combination of impedance, conductivity, and forward/ side scatter characteristics is used to determine the five-part leukocyte differential.

Checkpoint! 6

Which cellular characteristics are used to determine the immature platelet fraction (IPF) on the Sysmex 2100™ instrument?

Answer

During the reticulocyte analysis, the immature platelet fraction is isolated based on the size of the immature platelets and their fluorescence intensity. The fluorescence intensity is due to oxazine binding to the residual RNA within these platelets.

Checkpoint! 7

- a. Which CELL-DYN scatterplot allows differentiation of eosinophils from neutrophils?
- b. The CELL-DYN Sapphire's WBC dilution contains propidium iodide. Why don't the neutrophils fluoresce?

Answer

- a. The 90°D versus 90° scatterplot allows differentiation of eosinophils from neutrophils based on their different granularity and lobularity characteristics.
- b. Propidium iodide binds specifically to DNA within the cell but is unable to pass through intact cell membranes. As a result, the neutrophils and other intact leukocytes do not fluoresce because the propidium iodide was unable to enter the cell and bind to its DNA.

Checkpoint! 8

What is the similarity in the reticulocyte methods performed on the Advia 120 and XE-2100 instruments?

Answer

Both methods use oxazine for the detection of residual RNA. (Yes, they both use flow cytometric analysis, but that is common to all instruments discussed in this chapter.)

Checkpoint! 9

Compare the clot detection methods for the Fibrometer system and STArt 4 system.

Answer

For the Fibrometer system, the completion of an electric circuit between two electrodes by the fibrin strand indicates clot formation. The STArt 4 system detects clot formation by a decrease in the iron ball's movement as plasma viscosity increases.

Checkpoint! 10

What is the basis of clot detection for the optical density principle?

Answer

Detection of clot formation is based on an increase in absorbance (i.e., optical density) or decreased transmittance as measured by a photodetector.

Flow Cytometry

Fiona E. Craig, M.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Describe the components of a flow cytometer and the principles of cell analysis.
2. Illustrate by example the clinical applications of flow cytometry.
3. Appraise the use of fluorochrome-labeled antibodies in immunophenotyping by flow cytometry.
4. Give examples of the clinical applications of immunophenotyping by flow cytometry, and interpret single dot plots.
5. Define *clonality* and identify methods for detecting a monoclonal population of cells by immunophenotyping.
6. List the specimens appropriate for immunophenotyping by flow cytometry.
7. Describe how flow cytometry can be used in cell quantitation.
8. Calculate and interpret the absolute CD4 count.
9. Describe reticulocyte counting by flow cytometry, and define *immature reticulocyte fraction (IRF)*.
10. Explain how flow cytometry can be applied to DNA analysis.
11. List the cells positive for CD34, and explain the purpose of a CD34 count.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Compare and contrast the immunophenotyping results characteristic of chronic lymphocytic leukemia, hairy cell leukemia, and non-Hodgkin lymphoma.
2. Identify the pitfalls that can be encountered in immunophenotyping mature lymphoid malignancies by flow cytometry, and generate potential solutions.
3. Compare and contrast the immunophenotyping results characteristic of acute lymphoblastic leukemia and acute myelogenous leukemia.
4. Identify the pitfalls that can be encountered in immunophenotyping acute leukemia and lymphoma by flow cytometry, and generate potential solutions.
5. Compare and contrast the usefulness of the sucrose hemolysis test, Ham test, and flow cytometry immunophenotyping in diagnosing paroxysmal nocturnal hemoglobinuria.
6. Select and explain the quality measures that must be enforced in quantitative flow cytometry.
7. Compare and contrast the absolute CD4 count and HIV viral load in the surveillance of HIV infection.

OBJECTIVES—LEVEL II (continued)

8. Calculate and interpret the S phase fraction and the DNA index, and give the principle of DNA analysis by flow cytometry.
9. Assess the findings of flow cytometry cell analysis using two or more dot plots, and select the most likely cell represented.
10. Evaluate flow cytometry results to identify problems and generate solutions.
11. Compare reticulocyte counting by flow cytometry with manual methods, and assess the advantages of flow cytometry.
12. Interpret the immature reticulocyte fraction (IRF).
13. Summarize the uses of analysis for the CD34 antigen, and choose recommended procedures to analyze this antigen.

KEY TERMS

Biphenotypic leukemia

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Describe the cellular characteristics that differentiate T and B lymphocytes; differentiate the stages of development of granulocytes, lymphocytes, and monocytes.
- ▶ Describe reticulocytes and methods to quantify them.
- ▶ Summarize the classification of malignant leukocyte disorders.

Level II

- ▶ Summarize the subtypes of malignant disorders and laboratory tests used to help classify them.
- ▶ Describe the abnormality associated with paroxysmal nocturnal hemoglobinuria (PNH).
- ▶ Outline the cell cycle.
- ▶ Describe the application of immature reticulocyte fraction (IRF).

**CASE STUDY**

We will address this case study throughout the chapter. Andrew, a 76-year-old male, had a complete blood count (CBC) performed during hospitalization for pneumonia. He was found to have a WBC of $76 \times 10^9/L$ with 80% lymphocytes. Consider the conditions that are associated with these results and the follow-up testing that might be necessary to confirm a diagnosis.

OVERVIEW

The purpose of flow cytometry is to detect and measure multiple properties of cells so that they can be identified and quantitated. This chapter introduces the principles of flow cytometry and discusses its clinical applications. First, the method of detecting and quantitating particles by flow cytometry is described. This description includes specimen requirements and processing and the concept of gating to isolate cells of interest. The remainder of the chapter addresses the uses of flow cytometry in the clinical laboratory. Flow cytometry is currently used to analyze individual cells for the presence of antigens (immunophenotyping) and to quantitate ribonucleic acid (RNA) or deoxyribonucleic acid (DNA). Immunophenotyping is one of the tools used for diagnosing mature lymphoid malignancies, acute lymphoblastic leukemia (ALL), acute myeloid leukemia (AML), and paroxysmal nocturnal hemoglobinuria (PNH), and monitoring HIV infection. This chapter also introduces the application of flow cytometry in reticulocyte counting and DNA analysis.

INTRODUCTION

A *flow cytometer* is an instrument capable of detecting molecules on the surface of or inside individual particles such as cells. Detection of molecules is achieved by isolating single particles/cells and labeling the molecule of interest with a fluorescent marker. Particles/cells that possess the molecule of interest are recognized by the emission of fluorescent

light following excitation. Information is acquired from many thousands of particles/cells and stored on a computer for further analysis. The current applications of flow cytometry in the clinical laboratory include immunophenotyping (identifying antigens using detection antibodies) leukocytes and erythrocytes, enumerating reticulocytes, and analyzing DNA (Table 1 🌟).

▶ **PRINCIPLES OF FLOW CYTOMETRY¹**

ISOLATION OF SINGLE PARTICLES

Flow cytometry is performed on particles in suspension (e.g., cells or nuclei). Leukocytes from peripheral blood and bone marrow specimens are often analyzed after the removal of red blood cells (RBC) by lysis. The cell suspension is aspirated and injected into a **flow chamber** (Figure 1 ■), the specimen-handling area of a flow cytometer where cells are forced into single file and directed into the path of a laser beam.

The flow chamber contains two columns of fluid. The particles/cells are contained in an inner column of sample fluid that is surrounded by a column of sheath fluid. The sheath and sample fluids are maintained at different pressures and move through the flow chamber at different speeds. This gradient between the sample and sheath fluid keeps the fluids separate (laminar flow) and is used to control the diameter of the column of sample fluid. The central column of sample fluid is narrowed to isolate single particles/cells that pass through a laser beam (**hydrodynamic focusing**) like a string of beads. Laser light is focused on these single particles/cells and can be measured by **photodetectors** as it is scattered off particles/cells when they pass in front of the beam. If particles/cells have fluorescent molecules attached, the laser light excites the mole-

■ **FIGURE 1** Flow chamber. The sample fluid, containing a suspension of single cells, is injected into a stream of sheath fluid. The stream is narrowed and directed through the laser beam (hydrodynamic focusing).

cules, which then emit light of a specific wavelength, which is also detected.

LIGHT SCATTERING

When the laser beam interacts with a single particle/cell, light is scattered but its wavelength is not altered. The amount of light scattered in different directions can be used to identify the particle/cell because it is related to the physical properties of the particle (size, granularity, and nuclear complexity). Light scattered at a 90° angle (**side light scatter**) is related to the internal complexity and granularity of the particle/cell. Neutrophils produce much side scatter because of their numerous cytoplasmic granules. Light that proceeds in a forward direction (**forward light scatter**) is related to the particle's size. Large cells produce more forward scatter than small cells. Therefore, light scattering can be used to distinguish particles and is currently employed by several hematology analyzers to perform differential counting of leukocytes.

✓ **Checkpoint! 1**
Would a lymphocyte or monocyte have more forward light scatter?

DETECTION OF FLUOROCHROMES

In addition to light scattering, the flow cytometer can be used to detect bound fluorescent markers (**fluorochromes**), which are molecules that are excited by light of one wavelength and emit light of a different wavelength (fluorescent light). Fluorochromes can be used to label detec-

tion antibodies or to bind stoichiometrically to DNA or RNA (Table 2 🌟). Flow cytometers use light of a single wavelength generated by a laser to excite fluorochromes bound to the particle of interest. Light emitted from the fluorochrome is separated from the incident laser light using a combination of filters and mirrors. A photomultiplier tube then detects and quantifies the emitted light.

Clinical flow cytometers usually contain an argon laser that generates light at 488 nm. This single wavelength is often used to excite three different fluorochromes, each emitting light at different wavelengths. Using three different fluorochromes allows detection of three different antigens on the cell. Excitation of additional fluorochromes to detect further antigens usually requires a second laser light source (e.g., helium neon, emission 633 nm). Currently, clinical immunophenotyping studies frequently utilize two laser light sources to identify five or six antigens on each cell analyzed. (Table 2). Some flow cytometers used in a research setting are capable of detecting up to 18 different fluorochromes.

A fluorochrome unfortunately does not emit light at a single wavelength. Mirrors, filters, and photodiodes are used to detect the peak wavelength of emitted light from each fluorochrome. However, some overlap between the light emitted from different fluorochromes usually exists. For example, although the peak emissions for the two fluorochromes fluorescein isothiocyanate (FITC) and phycoerythrin (PE) are different, PE emits some light at the wavelength used to detect FITC. The overlap is compensated for either by adjusting the settings on the flow cytometer or by performing a mathematical correction either before or after the data are collected. This process is called **compensation**.

The next section discusses the principles of immunophenotyping, specimen requirements, and techniques for isolating the cells of interest. That discussion is followed by a description of the use of immunophenotyping in identifying abnormal cell populations for diagnosing and classifying leukocyte neoplasms. The last two sections describe the application of flow cytometry to quantitate reticulocytes and to analyze the DNA of solid tumors.

✓ Checkpoint! 2
A laboratory wants to identify cells that have two different antigens. How many laser light sources are needed?

▶ IMMUNOPHENOTYPING BY FLOW CYTOMETRY^{2,3,4}

Immunophenotyping is the identification of antigens using detection antibodies. Antibodies are utilized because they bind specifically to antigens and can be labeled with fluorochromes to provide a sensitive and specific detection method. Most immunophenotyping studies involve detecting cell surface antigens. Intracytoplasmic and intranuclear antigens can be detected following permeabilization of cell membranes with detergent and/or alcohol. Detection antibodies can be either polyclonal or monoclonal. Polyclonal antibodies are made by injecting antigen into animals (e.g., rabbit anti-human antibodies). The animal produces many antibodies that are directed against different portions of the antigen. Therefore, the antigen can be recognized even if some parts of it are abnormal. However, polyclonal antibodies are often difficult to standardize and prone to nonspecific binding.

Monoclonal antibodies are directed against a single portion of the antigen. They are produced in myeloma/tumor cell lines and therefore have high purity and reproducibility. Often several different monoclonal or polyclonal antibodies are available from different suppliers to detect a single antigen and can be given a unique company-specific designation. An international workshop has been developed to systematically review antibodies and group those recognizing the same antigen into a cluster of differentiation (**CD designation**). For example, the commercially available antibodies Leu-4 and OKT3 are both designated CD3. Many fluorochrome-labeled detection antibodies are available commercially (Table 3 🌟). Combinations of these antibodies are currently used in the clinical laboratory to help identify cells (Table 4 🌟).

🌟 TABLE 2

Example Fluorochromes Used in Flow Cytometry

Application	Fluorochrome	Excitation Wavelength (nm)	Detection Wavelength (nm)
Immunophenotyping	FITC	488	519
Immunophenotyping	PE	488	575
Immunophenotyping	APC	650	660
Immunophenotyping	PerCP-Cy5.5*	488/675	694
Reticulocyte count	Acridine orange	488	530–640
DNA analysis	Propidium iodide	488	617

*PerCP-Cy5.5 is a conjugate of two fluorochromes. PerCP is excited at 488 nm; the emitted signal (675 nm) excites the Cy5.5 component of the molecule.
 FITC = fluorescein isothiocyanate; PE = phycoerythrin; APC = allophycocyanin.

★ TABLE 3

Antibodies Used for Immunophenotyping by Flow Cytometry

CD Designation	Normal Distribution	Use
CD1a	Immature T cells	Lymphoblastic leukemia/lymphoma
CD2	T cell, NK cell	Lineage of lymphoma or leukemia
CD3	T cell	Lineage of lymphoma or leukemia
CD4	T cell	Lineage of lymphoma or leukemia
CD5	T cell	Lineage of lymphoma/leukemia or aberrant expression on B cell SLL/CLL and mantle cell lymphoma
CD7	T cell, NK cell	Lineage of lymphoma or leukemia
CD8	T cell	Lineage of lymphoma or leukemia
CD11c	Monocytes, lymphoid cells	Hairy cell leukemia: bright+; SLL/CLL: dim+
CD11b	Neutrophils	Myelodysplastic syndrome
CD13	Monocytes	Lineage of leukemia
	Myeloid cells	Myelodysplastic syndrome
CD14	Monocytes	Lineage of leukemia
CD15	Monocytes	Lineage of leukemia
	Myeloid cells	
CD16	NK, NK-like T cells	Large granular lymphocyte leukemia
	Granulocytes	Myelodysplastic syndrome
CD19	B cell	Lineage of lymphoma or leukemia
CD20	B cell	Lineage of lymphoma or leukemia
CD22	B cell	Lineage of lymphoma or leukemia, SLL/CLL: dim+; PLL: bright+
CD23	B cell	SLL/CLL+, mantle cell-
CD25	Many cell types	Hairy cell leukemia bright+
CD33	Monocytes	Lineage of leukemia
	Myeloid cells	
CD34	Stem cells, progenitor cells	Stem cells for transplantation, acute leukemia
CD38	Plasma cells, some lymphocytes, monocytes, myeloid cells	Plasma cell neoplasms Prognostic marker in CLL
CD42	Megakaryocytes	Acute megakaryocytic leukemia
CD45	All leukocytes	Lineage of malignancy Gating
CD55	GPI-anchored protein	Paroxysmal nocturnal hemoglobinuria
CD56	NK, NK-like T cells	Large granular lymphocyte leukemia
CD57	NK, NK-like T cells	Large granular lymphocyte leukemia
CD59	GPI-anchored protein	Paroxysmal nocturnal hemoglobinuria
CD61	Megakaryocytes	Acute megakaryocytic leukemia
CD79a	B cells (blasts to plasma cells)	Lineage of lymphoma or leukemia
CD103	Subset of intramucosal T cells	Hairy cell leukemia Enteropathy associated T cell lymphoma
Glycophorin A	Erythroid	True erythroleukemia
Myeloperoxidase	Myeloid cells	Lineage of leukemia
Kappa	B cell	Maturity, clonality, SLL/CLL dim
Lambda	B cell	Maturity, clonality, SLL/CLL dim

CLL = chronic lymphocytic leukemia; SLL = small lymphocytic lymphoma; PLL = prolymphocytic leukemia; dim = weak intensity of emitted fluorescence; bright = strong intensity of emitted fluorescence; NK = natural killer; GPI = glycosyl phosphatidyl inositol.

TABLE 4

Applications of Immunophenotyping by Flow Cytometry

- Diagnosis and classification of mature lymphoid malignancies
- Prognostic markers in chronic lymphocytic leukemia (CD38 and ZAP-70)
- Diagnosis and classification of acute leukemia
- Detection of minimal residual leukemia following therapy
- Diagnosis of paroxysmal nocturnal hemoglobinuria
- Enumeration of T cell subsets (e.g., CD4 counts in HIV)
- Enumeration of CD34+ progenitor cells for transplantation

Checkpoint! 3

A cell population is positive with both Leu1 and T1 monoclonal antibodies. As a result, the cell is classified as CD5 positive. Explain.

SPECIMEN REQUIREMENTS AND PREPARATION FOR IMMUNOPHENOTYPING

Immunophenotyping by flow cytometry requires a suspension of individual cells (Table 5). Anticoagulated blood or bone marrow aspirate, body fluid specimens, and fine needle aspiration samples are ideal for immunophenotyping by flow cytometry because they already contain cells in suspension. Leukocytes can be isolated from these samples either by erythrocyte lysis or density gradient centrifugation. Lysis methods are favored because the leukocytes are retained in their original proportions without the risk of losing cell subtypes. Hematopoietic and lymphoid cells can also be isolated from fresh tissue biopsy specimens by manual disaggregation.

Once a suspension of leukocytes without erythrocytes has been prepared, the sample is stained using fluorochrome-labeled antibodies. (In some studies, the leukocytes are stained before the erythrocytes are lysed.) The labeled sample is aspirated into the flow cytometer, and the amount of scattered light and the intensity of each fluorescent signal is recorded for every cell analyzed. The acquired data are then displayed

TABLE 5

Specimen Requirements for Immunophenotyping by Flow Cytometry

Specimen type	Requirements	Storage
Peripheral blood	5 mL in EDTA or heparin	<24 hrs, RT
Bone marrow	1 mL in EDTA or heparin	<24 hrs, RT
Fluids	as much as possible	<24 hrs, 4°C
Tissue	Preferably >1/2cm ³	<24 hrs, 4°C

RT = room temperature; EDTA = ethylenediamine tetraacetic acid.

graphically on histograms or dot plots. Dot plots usually display the intensity of fluorescent light emitted from two fluorochromes (Figures 2 and 3). The plot is divided into quadrants indicating cells labeled with one fluorochrome, the other fluorochrome, or both fluorochromes.

Cells are considered positive for an antigen if they have a fluorescence intensity greater than either the negative control or a negative population of cells present in the same analysis tube (Figures 2 and 3). The intensity of light emitted is determined by comparison with the known range of intensities for that antibody/fluorochrome combination and divided roughly into three portions: dim or weak intensity, intermediate intensity, and bright or strong intensity. The intensity of emitted light is related to the density of antigens.

ISOLATION OF CELLS OF INTEREST BY GATING

Immunophenotyping requires isolation of the cells of interest (e.g., lymphocytes from monocytes and granulocytes). Cells can be separated either during specimen processing (density gradient centrifugation) or during data analysis (gating). **Gating** is the process of isolating cells by placing an electronic gate around those with the same light-scattering or fluorescence properties. For example, lymphocytes can usually be separated from neutrophils by their location on the forward versus side light scatter dot-plot (Figure 2). Fluorescence dot plots can then be set up to display only information obtained from cells falling within the chosen gate. If the gate is too wide, many cell types are included, and identifying the phenotype of the cells of interest becomes difficult. If the gate is too narrow, the cells of interest can be excluded.

The forward versus side light scatter dot plot unfortunately is not always capable of separating the cells of interest. For example, blasts and lymphocytes often appear in the same region on the forward versus side light scatter dot plot. Therefore, a different gating strategy can be required for analyzing acute leukemia. Blasts often have dim CD45 expression while lymphocytes have bright CD45 staining. Therefore, blasts and lymphocytes can be distinguished on a dot plot displaying CD45 intensity versus side angle light scatter (Figure 4). Fluorescence staining can be used for gating only if the chosen antibody (CD45) is present in each analysis tube.

CASE STUDY (continued from earlier in this chapter)

Flow cytometry immunophenotyping was requested on Andrew.

1. What is the optimal specimen?
2. Which cells are of interest and should be included in the gate?
3. What are the typical forward and side scatter properties of the cells of interest?

■ **FIGURE 2** Flow cytometry histograms from analysis of peripheral blood from Andrew, the patient described in the case study. Lymphocytes (green) are included in the rectangular gate. Neutrophils (blue) are excluded from the gate. A few monocytes (red) are included in the gate (i.e., the gate is not pure). The plot of CD45 versus CD14 indicates the gate's composition. Lymphocytes (green) stain strongly with CD45. Monocytes (red) stain with CD14 and CD45. The negative control (Mouse IgG2a versus Mouse IgG1) shows very little nonspecific binding. (Histograms generated using SimulSET software, BD Immunocytometry Systems.) SSC = side scatter; FSC = forward scatter.

✓ **Checkpoint! 4**

Explain why lymphocytes and neutrophils can be separated on a forward versus side light scatter dot plot.

DIAGNOSIS AND CLASSIFICATION OF MATURE LYMPHOID MALIGNANCIES

Flow cytometry immunophenotyping can be used to identify cell lineage (B, T, or natural killer [NK] cell) and the presence of an abnormal population of lymphocytes. This information can assist in detecting malignant cells and identifying a subtype of malignancy. Neoplasms are made up of a population of identical cells (clone). A clone of B lymphocytes can be recognized by uniform expression of one immunoglobu-

■ **FIGURE 3** Flow cytometry histograms from the population gated in Figure 2. The majority of cells stain for CD19, CD5, CD20, CD23, CD11c (dim), and monoclonal surface immunoglobulin lambda light chain. A few reactive T cells stain for CD5 only. (Histograms generated using SimulSET software, BD Immunocytometry Systems.)

■ **FIGURE 4** Flow cytometry histogram of CD45 versus side scatter from a case of acute leukemia. The gate R1 (events colored red) includes lymphocytes with bright intensity staining for CD45. The gate R2 (events colored green) includes a population of blasts with dim expression of CD45 and low side scatter. The blasts and lymphocytes have lower side scatter than monocytes and neutrophils. (Histograms generated using CellQuest software, BD Immunocytometry Systems.)

lin light chain (kappa or lambda light chain class restriction). In contrast, a reactive population of B lymphocytes contains a mixture of cells, each with expression of either kappa or lambda immunoglobulin light chain.

Clonality can also be detected by identifying a population of cells that display an abnormal phenotype (aberrant expression of a lymphoid antigen). For example, mature T lymphocytes normally express CD3, CD2, CD5, and CD7. A clone of malignant T lymphocytes could lack detectable CD5 and/or CD7. Another example of an abnormal phenotype is acquisition of an antigen that is not normally present. For example, the T cell marker CD5 is aberrantly expressed on a subset of B cell malignancies (small lymphocytic lymphoma/chronic lymphocytic leukemia and mantle cell lymphoma) (Figure 3). Therefore, the presence of CD5-positive B lymphocytes can assist in identifying a lymphoid malignancy and diagnosing a specific subtype. Panels of antibodies are usually selected to separate the common subtypes of lymphoproliferative disorders (Table 6). In addition, flow cytometric immunophenotyping can be used to demonstrate the presence of antigens for directed therapy (for example, CD20 for anti-CD20 monoclonal antibody therapy), identify prognostic markers such as ZAP-70 expression in CLL,⁵ and identify a small population of abnormal cells following treatment (**minimal residual disease**).

CASE STUDY (continued from earlier in this chapter)

Flow cytometry revealed the results displayed in Figure 3.

4. What is the phenotype?
5. Which features indicate clonality?
6. What is the diagnosis?

Pitfalls Encountered in the Diagnosis of Mature Lymphoid Malignancies

Although immunophenotyping usually provides useful information, potential pitfalls can lead to an incorrect diagnosis. A malignant B cell lymphoproliferative disorder is easily

overlooked if it lacks surface immunoglobulin. Some lymphoid malignancies frequently lack diagnostic surface antigens, including plasma cell neoplasms, HIV associated lymphoma, and mediastinal lymphoma. T cell lymphoma can be difficult to detect because many cases do not demonstrate an abnormal phenotype. Hodgkin lymphoma is difficult to detect by flow cytometry for several reasons: Hodgkin lymphoma lacks many cell surface lymphoid antigens, the neoplastic cells are rare, and a single cell suspension is often difficult to produce because of the presence of fibrosis. Another potential pitfall in flow immunophenotyping is the presence of an abnormal phenotype that is not specific for a single subtype of lymphoid malignancy. For example, CD10 expression can be seen in follicular lymphoma, diffuse large B cell lymphoma and Burkitt lymphoma. Therefore, it is important to interpret immunophenotyping data in conjunction with morphology.

DIAGNOSIS AND CLASSIFICATION OF ACUTE LEUKEMIA^{6,7,8,9}

Using the World Health Organization (WHO) classification, a diagnosis of acute leukemia requires manual differential counting to identify more than 20% blasts in the peripheral blood or bone marrow. Once a diagnosis of acute leukemia has been established, flow cytometry can be used to assist in identifying the subtype of leukemia. Currently most treatment protocols require the distinction of acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML). The recognition of Auer rods or the presence of staining with cytochemical stains allows the identification of AML. Until the advent of immunophenotyping, all cases of acute leukemia lacking these features were assumed to be ALL. However, immunophenotyping studies have revealed that this assumption is erroneous. Some AML cases lack cytochemical staining and are recognized only by immunophenotyping (AML NOC [not otherwise categorized], minimally differentiated). In addition to the accurate separation of ALL from AML, flow cytometry phenotyping can be used to assist in identifying

TABLE 6

Characteristic Immunophenotype of Lymphoproliferative Disorders

Diagnosis	CD19	CD5	CD23	CD11c	CD22	CD25	slg
Chronic lymphocytic leukemia	+	+	+	+/-	+w	+/-	+w/-
Prolymphocytic leukemia	+	-/+	-	-	+	+/-	+
Hairy cell leukemia	+	-	-/+	+br	+br	+	+
Small lymphocytic lymphoma	+	+	+	+/-	+w	+/-	+w/-
Mantle cell lymphoma	+	+	-	-	+	-	+
Follicular lymphoma	+	-	+/-	-	+	-	+

br = bright or strong fluorescence intensity; w = weak or dim fluorescence intensity; + = antigen present; - = antigen absent; +/- = variable expression (often present); -/+ = variable expression (often absent).

subtypes of leukemia that have a different prognosis (e.g., T cell ALL has a worse prognosis in general than B cell ALL) or require an alternate therapeutic regimen (e.g., acute promyelocytic leukemia).

Acute Lymphoblastic Leukemia⁶

Immunophenotyping is essential for the diagnosis of ALL, separation of T and B lineage ALL, and identification of subtypes of B lineage ALL.

ALL belonging to the B lymphocyte lineage can be divided into subtypes that resemble stages of normal B lymphocyte maturation. During normal maturation in the bone marrow, B cells gain and lose antigens in synchrony until they acquire a mature B cell phenotype. Normal immature B cell bone marrow precursors at all stages of maturation are referred to collectively as **hematogones**.

ALL with a precursor B cell phenotype (pre-B and early pre-B) makes up 80% of childhood ALL. B cell lineage is usually defined by the presence of surface CD19 and/or cytoplasmic CD22 expression. Immaturity of the cells is recognized by the presence of CD10 and terminal deoxynucleotidyl transferase (TdT), a template-independent DNA polymerase. However, this phenotype overlaps with a significant proportion of normal bone marrow precursors. Therefore, recognition of small populations of residual ALL cells following treatment often requires identification of cells with an abnormal phenotype. Aberrant expression of a single myeloid antigen (e.g., CD33 or CD13) is found in 30–50% of cases of pre-B cell ALL. Although this abnormal phenotype can be used as a marker of disease, it is not associated with a change in prognosis. Another, more subtle, abnormality is the loss of the synchronous expression of B cell antigens. For example, although CD34 and surface CD22 are both expressed during normal B lymphocyte maturation, they are not usually present together. Cells expressing both surface CD22 and CD34 can be seen in B cell ALL.

CASE STUDY (continued from earlier in this chapter)

7. Which of the flow cytometry results presented in this case indicate that this is a malignancy of mature lymphocytes (chronic lymphocytic leukemia), not acute lymphoblastic leukemia?

ALL with a T cell phenotype is present in 15–20% of cases. The vast majority of cases of T cell ALL express the T cell antigens CD1, CD2, CD3, CD5, and CD7. Unlike mature T cells, T lymphoblasts express CD3 only in the cytoplasm, not on the cell surface. In addition, blasts differ from mature T cells in either expressing both CD4 and CD8 (cortical thymocyte phenotype) or lacking both CD4 and CD8. TdT is present in more than 90% of cases, and CD10 can be present. The phenotype of T cell ALL can be abnormal with loss

of one or more of these T cell antigens. Myeloid markers are aberrantly expressed in 25–30% of pre-T cell ALL cases. In general, the prognosis for patients with T cell ALL is worse than for precursor B cell ALL.

Checkpoint! 5

Why is it important to do immunophenotyping in a case of ALL?

Acute Myeloid Leukemia⁷

The WHO classification scheme recognizes several subtypes of AML. Most subtypes can be identified using morphology and/or cytogenetics. Immunophenotyping has a limited role in the diagnosis of AML. However, the detection of an abnormal phenotype, such as aberrant expression of a lymphoid antigen, can assist in identifying residual disease following treatment. Immunophenotyping is also required for the diagnosis of AML NOC, minimally differentiated, and is often used for the diagnosis of acute megakaryocytic leukemia. AML NOC, minimally differentiated, is diagnosed when Auer rods are absent and cytochemical stains are negative but there is evidence of nonlymphocytic differentiation by the expression of myeloid antigens. The diagnosis of acute megakaryocytic leukemia relies on identifying megakaryocytic differentiation by immunophenotyping (CD41, CD61) or electron microscopy (platelet peroxidase). Although acute promyelocytic leukemia characteristically lacks staining for CD34 and HLA-DR, this phenotype is not specific. Therefore, morphology in combination with cytogenetic studies still remains the *gold standard for the diagnosis of AML*. In addition to diagnosis and classification, flow cytometry can be used to demonstrate the presence of the antigens for directed therapy, for example the anti-CD33 monoclonal antibody therapy.

Flow cytometry has also been used to identify abnormalities in the phenotype of myeloid populations in myelodysplastic syndromes.⁸ Abnormalities include aberrant expression of lymphoid antigens on neutrophilic cells and abnormal gain and loss of antigens as cells mature from promyelocytes to segmented neutrophils.

Pitfalls Encountered in the Diagnosis of Acute Leukemia

Some cases of acute leukemia do not fit neatly into the categories ALL and AML. There may be aberrant expression of antigens (lineage heterogeneity) or a lack of specific antigen expression (undifferentiated leukemia).

Acute Leukemia with Lineage Heterogeneity The term **biphenotypic leukemia** is used when leukemic blasts express several antigens from two different lineages (myeloid and lymphoid). However, identification of lineage requires careful selection of antigens because few are re-

stricted to a single lineage. Myeloperoxidase is found only on cells with myeloid differentiation (restricted to a myeloid lineage). Therefore, the presence of myeloperoxidase indicates myeloid differentiation with a great degree of certainty. By contrast, CD15 is associated with myeloid differentiation but can also be expressed on cells of a T cell lineage. Therefore, CD15 expression does not predict myeloid differentiation with the same degree of certainty as myeloperoxidase. The term *biphenotypic* should be restricted to leukemia that demonstrates equal evidence of differentiation toward more than one lineage. Although scoring systems have been proposed to assist in weighing the phenotypic evidence for each lineage, they do not include all antigens currently evaluated by flow cytometry and do not consider cytochemical and cytogenetic evidence.⁹

Acute Undifferentiated Leukemia Blasts occasionally lack expression of lineage-restricted antigens. For example, the presence of only CD7 does not distinguish T cell ALL from AML. CD7 is normally present on immature T cells and is aberrantly expressed in approximately 10% of AML. Morphologic analysis, cytochemical stains, molecular diagnostic studies, and cytogenetics can assist in determining lineage.

DIAGNOSIS AND SURVEILLANCE OF IMMUNODEFICIENCY DISORDERS

Immunophenotyping by flow cytometry can be used to analyze leukocyte subsets to identify deficiency of a cell type. The most frequent clinical application of flow cytometry is monitoring the immunodeficiency acquired following HIV virus infection. Less frequently, immunophenotyping is used to detect inherited immunodeficiencies such as the severe combined immunodeficiency disorder (SCID) and X-linked agammaglobulinemia.

The HIV virus uses the CD4 antigen to infect T lymphocytes and monocytes. After viral fusion, internalization, replication, and dissemination, CD4+ cells are destroyed. The resultant decrease in CD4+ cells leads to immunodeficiency. The absolute number and percentage of CD4+ T lymphocytes present in the peripheral blood can be used to monitor the immune system. HIV surveillance is used to predict the course of disease, decide when to start prophylactic therapy for opportunistic infections, and determine when to commence antiretroviral therapy. An absolute number of CD4+ T lymphocytes less than 200/ μL in the peripheral blood also is used to diagnose AIDS in HIV infected individuals.

The CD4 count is determined by staining with fluorescent-tagged antibodies against CD3 (found on T cells but not monocytes) and CD4 followed by whole blood RBC lysis. The percentage of CD4+ lymphocytes is determined by flow cytometry. Gating is critical to avoid exclusion of lymphocytes and contamination by cells other than lymphocytes such as CD4+ monocytes. The absolute CD4 count can be

determined directly by flow cytometry (single platform) by comparing the number of CD4+ cells identified per unit volume analyzed with an absolute number of highly fluorescent beads added to the analysis tube (Figure 5 ■). Alternatively, the CD4 count can be calculated from the percentage of CD4+ lymphocytes and the absolute number of lymphocytes determined by a hematology analyzer (dual platform).

$$\text{Absolute CD4 count} = \text{Absolute lymphocyte count} \times \text{Percent CD4+ lymphocytes}/100$$

$$\text{Absolute lymphocyte count} = \text{WBC count} (\times 10^9/\text{L}) \times \text{Percent lymphocytes from WBC differential}/100$$

A precise and accurate CD4 count is essential (Table 7 ✪). Results from a patient are often compared with previous results and published diagnostic and therapeutic levels. Therefore, the procedure used for quantitative flow cytometry should attempt to eliminate preanalytical and analytical variables. Preanalytical variables include biologic variability (age, diurnal rhythm, medications), specimen collection, and storage. Analytical variables include sample preparation and errors associated with flow cytometers and hematology analyzers. The CDC publishes guidelines for standardization of CD4 determination. Two levels of stabilized quality control material must be run with each batch of CD4 assays. In addition, proficiency testing for professionals is available through the College of American Pathologists (CAP) surveys.

The HIV viral load is another monitor of HIV infection. Viral load testing measures plasma viral RNA. The CD4 count and the HIV viral load often provide complementary information. The CD4 count is the best indicator of the balance between immune cell production versus destruction and therefore indicates the risk of opportunistic infection or secondary malignancy. The HIV viral load indicates the burden of disease and therefore can be used to monitor response to antiviral therapy and the acquisition of drug resistance.

✓ Checkpoint! 6

A patient has 10% CD4+ lymphocytes, a WBC count of $5 \times 10^9/\text{L}$, and 30% lymphocytes. What is the absolute CD4 count? Is this count compatible with a diagnosis of AIDS in an HIV-infected individual?

CD34 ENUMERATION¹⁰

CD34 enumeration is used to support bone marrow and peripheral blood stem cell transplantation. CD34 is an antigen restricted to multipotential hematopoietic stem cells and early progenitors of all lineages. Hematopoietic stem cells are responsible for reconstituting bone marrow function following transplantation. CD34 enumeration is used to determine whether the product collected for transplantation has enough cells. For rapid engraftment, $2.0\text{--}8.0 \times 10^6$ CD34+

■ **FIGURE 5** CD4 enumeration. CD4-positive lymphocytes are isolated by gating on cells displaying strong intensity CD45 (within green circle) in top left histogram (all lymphocytes), bright CD3 (red circle) in lower left histogram (all T cells), and CD4 (orange circle) in lower right histogram. The specimen contains a known concentration of fluorescent beads (pink). The absolute CD4 count is determined by comparing the number of CD4-positive events with the number of beads counted (purple circle in upper right histogram). (Histograms generated using MultiSET software, BD Immunocytometry Systems.)

★ **TABLE 7**

cells/kg body weight are needed, and for long-term engraftment, $0.5\text{--}2.0 \times 10^6$ CD34+ cells/kg body weight are needed. CD34+ cells can be collected by either bone marrow aspiration or peripheral blood apheresis. Hematopoietic progenitor cells are often mobilized into the peripheral blood using a combination of cytotoxic drugs and growth factors. CD34 enumeration can also be performed on the peripheral blood to determine the optimal time for peripheral blood stem cell collection. CD34 determination is challenging because it needs to be fast, accurate, and precise even at low numbers (0.1% of cells or 5 cells/ μL). The European Working Group on Clinical Cell Analysis (EWGCCA) have made recommendations in an attempt to optimize and standardize CD34 determination by flow cytometry (Table 8★).

Several different analysis protocols (e.g., Milan, ISHAGE, SIHON) exist.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA (PNH)^{11,12}

PNH is a chronic hemolytic disorder caused by an acquired mutation of the *PIG-A* gene, which encodes an enzyme critical in the synthesis of the glycosylphosphatidylinositol (GPI) anchor that links many proteins to the cell membrane. Flow cytometry can be used to detect the presence of GPI-anchored membrane proteins. In addition, some flow cytometric assays assess the ability of white blood cells to bind a fluorescent-labeled modified toxin (FLAER) that attaches through GPI anchors. Flow cytometric immunophenotyping for CD55 and CD59 on erythroid cells and CD55, CD59, and other GPI-linked antigens on granulocytes appears to be a more sensitive and specific test for diagnosing PNH than the sucrose hemolysis test or Ham test. Erythrocyte immunophenotyping is easier to interpret than analysis of neutrophils but can give a false negative result if hemolysis is active or a transfusion was recently given. Erythrocytes deficient in CD55 and CD59 have also been identified in patients with aplastic anemia and myelodysplastic syndromes and in very small numbers in normal individuals.

▶ RETICULOCYTE COUNTING¹³

Reticulocytes are immature circulating erythrocytes. They lack a nucleus but contain more RNA than a mature RBC. An increased number of reticulocytes indicates a bone marrow response to anemia. Manual reticulocyte counting is performed on a blood smear stained with a supravital stain (e.g., new methylene blue). Reticulocytes contain a reticulum of stained precipitated RNA and are counted per 1000 erythrocytes. Automated reticulocyte counting is offered by many hematology analyzers and frequently employs many of the principles of flow cytometry. A peripheral blood spec-

TABLE 8

Recommendations for CD34 Enumeration (EWGCCA)

- Lyse red cells, do not use wash procedure to avoid centrifugation and possible loss of cell populations.
- Use bright (e.g., PE) fluorochrome conjugates of class II or III monoclonal antibodies that detect all glycoforms of CD34.
- Use vital nuclei acid dye to exclude platelets, unlysed red blood cells, and debris, or 7-amino actinomycin (7-AAD) to exclude dead cells during acquisition.
- Perform dual staining with CD45 to assist in detection of leukocytes.
- Include in the strategy the identification of cells with low levels of CD45 expression and low side scatter.
- Include CD34 bright and dim staining populations.
- Acquire sufficient events to generate at least 100 CD34 positive cells.

TABLE 9

Fluorescent Reagents Used in Automated Reticulocyte Counting

- Thiazole orange (Becton Dickinson FACScan flow cytometer)
- New methylene blue (Coulter Beckman, STKS/MAXM, and manual)
- Acridine orange (Coulter Beckman, Gen-S System)
- CD4K530 (Abbott Diagnostics, Cell-Dyn 4000)
- Oxazine 750 (Bayer Diagnostic, Miles H.3/Advia 120)
- Auramine O (Sysmex, R Series, and SE-Avante)

imen is stained with a fluorescent dye that binds to RNA (Table 9). The amount of dye bound is proportional to the amount of RNA present. The labeled specimen is passed in front of a laser light source, and cells emitting more than a threshold amount of fluorescent light are counted as reticulocytes (Figure 6). This automated method is more precise than the manual method because many more cells are analyzed (usually 30,000 or more). Automated instruments are also capable of determining the maturity of reticulocytes by quantitating the amount of RNA present. The *immature reticulocyte fraction (IRF)* is the proportion of reticulocytes with the highest content of RNA. An increased IRF is the first indication of bone marrow recovery following transplantation or successful replacement therapy with erythropoietin, iron, B₁₂, or folate.

FIGURE 6 Automated reticulocyte count as performed on the Cell-Dyn 4000. The RNA in reticulocytes reacts with the fluorochrome CD4K530 (Abbott Diagnostics), and the fluorescence is picked up by the FL1 RNA detector. The immature reticulocyte fraction contains more RNA and therefore has a higher fluorescence intensity.

✓ Checkpoint! 7

What are the advantages of automated reticulocyte counting over manual counts?

▶ DNA ANALYSIS

DNA analysis is usually performed on solid tumors to provide prognostic information. Either fresh frozen tissue or a thick section of fixed, paraffin-embedded tissue is processed to produce individual cells or nuclei. The suspension is permeabilized (the cell and/or nuclear membrane is made permeable to allow access of the fluorescent dye to the DNA) and stained with a fluorochrome that binds to DNA. If the fluorescent dye (propidium iodide) binds to both DNA and RNA, RNA is removed by digestion. The amount of fluorochrome bound is proportional to the amount of DNA. The DNA content varies during cell division (proliferation) and is abnormal in cells with numerical chromosome abnormalities (aneuploid) (Figure 7 ■). Computer software uses mathematical formulas to calculate the cells in each phase of the cell cycle, calculate indexes, and identify abnormal populations...

PROLIFERATION

Tumors with an increased number of dividing cells often have a worse prognosis but in some instances are susceptible to therapy directed at dividing cells. The DNA content of cells can be used to determine the proportion of dividing cells. During cell division and prior to mitosis (G₂/M phase),

■ **FIGURE 7** Fluorescence intensity of DNA-bound dye during phases of the cell cycle. Mathematical programs are used to distinguish three areas under the curve (cell cycle phases G₀/G₁, S, and G₂/M).

★ TABLE 10

Calculations for DNA Analysis by Flow Cytometry

- S-phase fraction (SPF) = $100 \times S / (G_0/G_1 + S + G_2/M)$
- Proliferation index (PI) = $100 \times (S + G_2/M) / (G_0/G_1 + S + G_2/M)$
- DNA index = DNA content G₀/G₁ sample / DNA content G₀/G₁ diploid control

the DNA content increases (synthetic, or S, phase) until there are two copies of the entire genome prior to mitosis (G₂/M-phase) (Figure 7). The *S-phase fraction* is the proportion of all cells (G₀/G₁ + S + G₂/M) that are in the S phase. The proliferative index is the proportion of all cells that are in proliferative phases (S + G₂/M) (Table 10 ★).

PLOIDY

All nondividing, normal human cells contain 46 chromosomes (2 each of 23 chromosomes) and are therefore referred to as being *diploid*. The presence of tumor cells containing an abnormal number of chromosomes is often associated with a worse prognosis. The **DNA Index (DI)** is the DNA content of tumor cells relative to a diploid population of cells. It is calculated as the DNA content of cells in the tumor in the G₀/G₁ phase of the cell cycle relative to the DNA content of G₀/G₁ cells in a diploid control. For example, diploid cells have a DI of 1.0. Tetraploid cells (four copies of all chromosomes) have a DI of 2.0, and cells with only one copy of each chromosome (haploid) have a DI of 0.5. *Aneuploidy* is the presence of cells with an abnormal DNA content that is not a multiple of the DNA content of haploid cells, for example, a DI of 1.3.

CLINICAL APPLICATIONS OF DNA ANALYSIS¹⁴

The clinical utility of DNA analysis remains controversial. One of the most extensively studied tumors is breast carcinoma. A correlation exists between increased S-phase fraction and other markers of a poor prognosis (large breast tumor, the presence of metastatic disease in axillary lymph nodes, high histologic grade, and absence of steroid receptors). However, the main value of DNA analysis in breast carcinoma can be the identification of patients who have a low S-phase fraction and might not require chemotherapy in addition to surgical excision. Interlaboratory variability in methodology and interpretation of results has delayed the routine use of this technique.

SUMMARY

Flow cytometry is a technique that involves the analysis of single particles for their ability to scatter light and fluoresce. This technology is used by stand-alone instruments (flow cytometers) and has also been incorporated into other instruments such as hematology

cell analyzers. Flow cytometry is used in the clinical laboratory for immunophenotyping, reticulocyte counting, and DNA analysis. Immunophenotyping uses fluorochrome-labeled detection antibodies to identify cellular antigens. Its primary use is to classify and sub-

type leukemia and lymphoma. Reticulocyte and DNA analysis utilize fluorescent dyes that bind to nucleotides. DNA analysis is used to analyze solid tumors. The amount of DNA present helps in making prognosis and treatment decisions.

REVIEW QUESTIONS

LEVEL I

- Which of the following is a (are) component(s) of a flow cytometer? (Objective 1)
 - flow chamber
 - laser light source
 - light detectors
 - all of the above
- Which of the following properties of the cells analyzed by flow cytometry is related to forward angle light scatter? (Objectives 1, 7)
 - granularity
 - nuclear complexity
 - size
 - shape
- Which of the following statements explains the use of fluorochromes in immunophenotyping by clinical flow cytometry? (Objectives 3, 5)
 - All fluorochromes emit light at the same wavelength.
 - Fluorochromes bind nonspecifically to leukocytes.
 - The wavelength of the emitted light is the same as that of the incident light.
 - Several fluorochromes can be excited by light of a single wavelength.
- Which of the following properties is (are) used for gating in clinical flow cytometry? (Objective 1)
 - forward angle light scatter
 - side angle light scatter
 - intensity of CD45 staining
 - all of the above
- Which of the following is a (are) clinical application(s) of flow cytometry? (Objective 2)
 - DNA quantitation
 - immunophenotyping
 - reticulocyte counting
 - all of the above
- Which of the following flow cytometry methods is the most appropriate for diagnosing and classifying chronic lymphocytic leukemia? (Objectives 4, 5, 7)
 - CD34 enumeration
 - DNA quantitation
 - immunophenotyping
 - RNA quantitation

LEVEL II

- A 45-year-old female presented with pancytopenia. Flow cytometry performed on the peripheral blood revealed the following results:

- Which is the predominant cell type in the gate? (Objective 9)
- eosinophil
 - lymphocyte
 - monocyte
 - neutrophil

- Further flow cytometric analysis performed on the sample described in question 1 revealed the following results:

- What is the phenotype of the cells present? (Objective 9)
- CD19+, CD5-, CD11+, CD25+
 - CD19+, CD5+, CD11+, CD25+
 - CD19+, CD5-, CD11c-, CD25-
 - CD19-, CD5-, CD11c-, CD25-

REVIEW QUESTIONS (continued)

LEVEL I

7. Which of the following is detected during immunophenotyping by flow cytometry? (Objective 3)
 - a. antibodies using detection antigens
 - b. antibodies using detection fluorochromes
 - c. fluorochromes using detection antibodies
 - d. antigens using detection antibodies
8. Which of the following specimens is most appropriate for flow cytometry immunophenotyping? (Objective 6)
 - a. formalin-fixed bone marrow aspirate clot
 - b. fresh lymph node biopsy
 - c. frozen bone marrow biopsy
 - d. one-week-old EDTA anticoagulated peripheral blood
9. A peripheral blood sample needs to be shipped to a reference lab for flow cytometry immunophenotyping. Which of the following procedures is most appropriate? (Objective 6)
 - a. overnight delivery at room temperature
 - b. overnight delivery at 4°C
 - c. regular mail service at room temperature
 - d. regular mail service at 4°C
10. An 80-year-old male was found to have lymphocytosis. Flow cytometry of the peripheral blood revealed the following results:

What is the phenotype of the majority of lymphocytes represented in this diagram? (Objective 4)

- a. CD19+, CD5-
- b. CD19+, CD5+
- c. CD19-, CD5-
- d. CD19-, CD5+

LEVEL II

3. Which of the following phenotypes is indicated by the kappa and lambda light chain dot plot displayed in question 2? (Objective 9)
 - a. absence of surface immunoglobulin
 - b. monoclonal lambda immunoglobulin light chain
 - c. monoclonal kappa immunoglobulin light chain
 - d. polyclonal immunoglobulin light chains
4. Which of the antigens expressed in question 2 indicates a mature B lymphocyte phenotype? (Objective 1)
 - a. CD5
 - b. CD11c
 - c. CD19
 - d. surface immunoglobulin
5. Which of the following is the most likely diagnosis for the case described in question 2? (Objective 1)
 - a. acute lymphoblastic leukemia
 - b. chronic lymphocytic leukemia
 - c. hairy cell leukemia
 - d. infectious mononucleosis
6. Flow cytometric analysis of a lymph node fails to reveal an abnormal phenotype. The pathologist is convinced that the node is involved by lymphoma. A touch preparation performed from the specimen received in the laboratory contains numerous large cells that are absent from a cytocentrifuge slide made from the cell suspension prepared for staining. Which of the following is the most likely explanation? (Objective 4)
 - a. The sample received for flow cytometry is not representative of the malignancy.
 - b. The malignant cells were lost during manual disaggregation of cells.
 - c. The malignant cells were excluded from the gate.
 - d. The malignant cells have a normal phenotype.
7. Repeat analysis of the case described in question 6 increases the number of large cells present in the suspension stained and analyzed on the flow cytometer. An abnormal phenotype is still not detected. Which of the following neoplasms could be difficult to detect by flow cytometry cell surface antigen studies? (Objective 2)
 - a. Hodgkin's disease
 - b. T cell lymphoma
 - c. plasma cell neoplasms
 - d. all of the above
8. A patient presented with circulating blasts. Flow cytometry immunophenotyping performed on the peripheral blood revealed the following phenotype: CD19+, CD10+, surface immunoglobulin IgM kappa. Which of the following is the most likely diagnosis? (Objective 3)
 - a. Burkitt lymphoma
 - b. acute lymphoblastic leukemia, precursor B cell type
 - c. acute lymphoblastic leukemia, precursor T cell type
 - d. acute myeloid leukemia

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

9. Which of the following is the most likely karyotype for the cells described in question 8? (Objective 3)
 - a. t(9;22)
 - b. t(14;18)
 - c. t(8;14)
 - d. t(15;17)
10. A patient was found to have circulating blasts. No Auer rods were identified, and all cytochemical stains were negative. Flow cytometry immunophenotyping revealed the presence of myeloid antigens. Which of the following is the most appropriate diagnosis? (Objective 3)
 - a. acute lymphoblastic leukemia
 - b. acute myeloid leukemia
 - c. chronic lymphocytic leukemia
 - d. chronic myeloid leukemia

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: The case is an example of chronic lymphocytic leukemia involving the peripheral blood. It demonstrates the technique of gating the cells of interest, determining a phenotype, and using of a characteristic phenotype in establishing a diagnosis of a subtype of lymphoid malignancy.

Question:

1. What is the optimal specimen?

Explanation:

The CBC revealed peripheral blood lymphocytosis. Therefore, flow cytometry of the peripheral blood would be appropriate. An EDTA anticoagulated specimen is ideal. The CBC sample could be used if it was processed within 24 hours of being drawn. Other anticoagulants (e.g., heparin and ACD) are adequate.

Question:

2. Which cells are of interest and should be included in the gating?

Explanation:

The cells of interest are the lymphocytes.

Question:

3. What are the typical forward and side scatter properties of the cells of interest?

Explanation:

Lymphocytes have low side scatter (granularity) and variable forward scatter (size).

Question:

4. What is the phenotype?

Explanation:

The majority of the lymphocytes have the following abnormal phenotype: CD45+, CD19+, CD20+, CD23+, CD5+, lambda+, kappa-.

Question:

5. Which features indicate clonality?

Explanation:

Expression of only one immunoglobulin light chain (lambda, but not kappa) and the aberrant expression of CD5 indicate a clonal population of B cells.

Question:

6. What is the diagnosis?

Explanation:

The diagnosis is chronic lymphocytic leukemia, B cell (CLL), or small lymphocytic lymphoma (SLL). CD5-positive B cells are characteristic of CLL, SLL, or mantle cell lymphoma (MCL). CD23 expression is found in CLL and SLL but not MCL. Although lymphoma primarily involves the lymph nodes and other lymphoid organs, there may be secondary involvement of the peripheral blood and bone marrow.

Question:

7. Which of the flow cytometry results presented in this case indicate that this is a malignancy of mature lymphocytes (chronic lymphocytic leukemia), not acute lymphoblastic leukemia?

Explanation:

The strong expression of CD45, presence of surface immunoglobulin, and absence of CD34 and CD10 expression all indicate a mature B lymphocyte phenotype.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Would a lymphocyte or monocyte have more forward light scatter?

Answer

Forward light scatter depends on cell size; larger cells have more forward scatter. A monocyte is larger than a lymphocyte and would have more forward light scatter.

Checkpoint! 2

A laboratory wants to identify cells that have two different antigens. How many laser light sources are needed?

Answer

One laser light source is needed because a single wavelength can excite up to three fluorochromes.

Checkpoint! 3

A cell population is positive with both Leu1 and T1 monoclonal antibodies. As a result the cell is classified as CD5 positive. Explain.

Answer

The Leu1 and T1 antibodies detect the same antigen. This antigen has been given the cluster of differentiation designation CD5.

Checkpoint! 4

Explain why lymphocytes and neutrophils can be separated on a forward versus side light dot-plot.

Answer

Granulocytes have more side light scatter than lymphocytes because of their granularity.

Checkpoint! 5

Why is it important to do immunophenotyping in a case of ALL?

Answer

Immunophenotyping is necessary to differentiate T cell ALL from B cell ALL, and mature B cell ALL from precursor B cell ALL. Treatment and prognosis in these different subtypes differ.

Checkpoint! 6

What is the absolute CD4 count? Is this count compatible with a diagnosis of AIDS in an HIV infected individual?

Answer

$$5 \times 10^9/L \times 0.30 = 1.5 \times 10^9/L \times 10\% = 0.15 \times 10^9/L (150/\mu L)$$

A CD4 count less than $200/\mu L$ is diagnostic of AIDS in an HIV infected individual.

Checkpoint! 7

What are the advantages of automated reticulocyte counting over manual counts?

Answer

Many more cells are counted in automated counts than in manual counts. Automated counts by flow cytometry can determine the cells' maturity.

Chromosome Analysis of Hematopoietic and Lymphoid Disorders

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Chromosome structure and morphology
- ▶ Mitosis
- ▶ Cytogenetic procedures
- ▶ Chromosome abnormalities
- ▶ Cytogenetic nomenclature
- ▶ Cytogenetic analysis of hematopoietic and lymphoid disorders
- ▶ Summary
- ▶ Review questions
- ▶ References

Chromosome Analysis of Hematopoietic and Lymphoid Disorders

Kathleen S. Wilson, M.D, FCAP, FACMG

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define *chromosome* and *mitosis*.
2. List the basic steps of cytogenetic analysis, and select the most appropriate type of specimen for analysis of suspected constitutional and neoplastic (acquired) disorders.
3. Identify two major types of chromosome abnormalities, describe how they occur, and use the appropriate terminology to describe them.
4. List the practical uses of cytogenetics in the diagnosis and prognosis of hematolymphoid disorders.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Describe chromosome morphology and mitosis.
2. Describe each step of the cytogenetic harvest procedure.
3. Define and compare *aneuploidy*, *nondisjunction*, and *anaphase lag*.
4. Define and compare *translocation*, *deletion*, *inversion*, and *isochromosome*.
5. Identify the general categories of hematopoietic disorders for which cytogenetic analysis is useful for patient care.
6. Correlate diagnostic chromosome aberrations with types of hematolymphoid disorders, and assess their prognostic and therapeutic implications.
7. Assess the prognostic impact of cytogenetic results in acute lymphoblastic leukemia.
8. Explain the clinical utility of cytogenetics in transplantation.
9. Correlate chromosome abnormalities with specific oncogene activation, and assess the role of the oncogene in the neoplasm.

KEY TERMS

Acquired aberration

 Nondisjunction
 Polymorphic variant
 Polyploid
 Pseudodiploid
 Satellite DNA
 Submetacentric
 Trisomy

BACKGROUND BASICS

The information in this chapter builds on the concepts presented in other chapters relating to cell division and hematopoietic and lymphoid neoplasms. In order to maximize your learning, you should review these concepts before beginning this unit of study.

Level I

- ▶ Know the stages of the cell cycle, particularly the steps of mitosis.
- ▶ List the major types of neoplastic hematopoietic and lymphoid disorders.

Level II

- ▶ Outline the classification of acute myeloid leukemia and acute lymphoblastic leukemia.
- ▶ Describe the various typical laboratory findings and criteria for classification of myeloproliferative disorders.
- ▶ Describe the typical laboratory findings and classification of the myelodysplastic states.
- ▶ Summarize the chronic lymphoproliferative disorders, list the criteria for distinction of Hodgkin's disease versus non-Hodgkin lymphomas, and define the major classification terminology.

**CASE STUDY**

We will address this case study throughout the chapter.

Gregory, a healthy 25-year-old man, has a routine physical examination and laboratory studies for new employment. The total white blood cell (WBC) count is $30,000 \times 10^9/L$. Consider what conditions may result in this clinical picture and the follow-up studies that should be done.

OVERVIEW

This chapter is designed to give the reader a background for understanding the terminology and application of cytogenetics in diagnosis and treatment of *hematolymphoid neoplasms* (term commonly used to encompass both hematopoietic and lymphoid neoplasms). The chapter begins with a review of chromosome structure and morphology followed by a summary of the procedure used to prepare specimens for chromosome study. Chromosomal abnormalities are discussed, and the terminology used to describe cytogenetic findings is defined. The remainder of the chapter discusses practical uses of cytogenetic analysis in hematolymphoid neoplasms.

INTRODUCTION

Cytogenetics is the study of chromosome structure and number, particularly as they relate to a normal or pathologic state. In 1956, the normal number of chromosomes per human cell was established as 46, and since that time, many chromosome abnormality syndromes have been reported. The use of cytogenetics has markedly improved patient diagnosis and family counseling in the field of constitutional aberrations, including important advances in prenatal diagnosis. Cytogenetic studies are also responsible for major advances in the field of hematolymphoid malignancies and solid tumors. Chromosome analysis of many malignant disorders has become a critical component for patient diagnosis and prognosis as well as for research studies of these disorders.

CHROMOSOME STRUCTURE AND MORPHOLOGY

Nuclear chromatin of human cells is composed of nucleic acid and protein and is organized into 46 chromosomes. The nucleic acids, deoxyribonucleic acid (DNA), and ribonucleic acid (RNA), are composed of polynucleotides. A single nucleotide consists of a phosphate, a sugar (deoxyribose for DNA and ribose for RNA), and a base. The base may be a purine (A = adenine, G = guanine) or a pyrimidine (C = cytosine and T = thymine [DNA] or U = uracil [RNA]). The bases are aligned on the polynucleotide strand in a triplet code so that three bases code for a single amino acid; the succession of

bases in the triplet code determines the protein products that will result from transcription of the DNA and translation of the messenger RNA produced. There are approximately 30,000 genes in human cells, each located at a specific site on a specific chromosome (gene locus). The different possible expressions of a gene are known as *alleles*. For example, the gene for the ABO blood group has three major alleles: A, B, and O.

DNA exists as a double-stranded helix with the two polynucleotide strands held together by hydrogen bonds between complementary bases so that G will bind only with C and A only with T (or U for RNA). The bonding of A-T and G-C is called a *base pair*. This double helix has a diameter of approximately 20 Å and is of variable length. For example, the amount of DNA contained in the smallest chromosome, number 21, is composed of approximately 50 million base pairs while the largest chromosome, number 1, has approximately 250 million base pairs. The double helix initially coils around histone proteins resulting in a series of structures called *nucleosomes* (Figure 1■). These nucleosomes form a superhelix with the six nucleosomes per turn forming a chromatin fiber (called a *solenoid*) with a diameter of 250 Å. These fibers are looped back and forth on a protein-RNA scaffold to form an identifiable chromatid with a diameter of 0.2–0.5 μm. After DNA replication, identical sister chromatids are connected at the centromere giving the final structure of a mitotic chromosome.

The centromere divides chromosomes into short p arms and long q arms (Figure 2■). If the centromere is in the center of the chromosome so that the length of p = q, it is referred to as a **metacentric** chromosome (chromosomes 1, 3, 16, 19, and 20). If the centromere is not in the center, so that p < q, the chromosome is called **submetacentric** (chromosomes 2, 4, 5, 6–12, 17, 18, and X), and when the centromere is located close to the end of the chromosome so that p is very short, the chromosome is called **acrocentric** (chromosomes 13–15, 21, 22 and Y). The area of the chro-

■ **FIGURE 2** Chromosome structure of a typical submetacentric chromosome and an acrocentric chromosome. short arm = p; long arm = q

somosome around the centromere contains highly repetitive DNA in long clusters of tandem repeats, also known as **satellite DNA**, which is permanently coiled tightly into heterochromatin. Heterochromatic stains darkly and is transcriptionally inactive; euchromatic areas stain lightly and are transcriptionally active during interphase. The heterochromatin on the end of the p arm of acrocentric chromosomes is attached to the rest of the p arm by less tightly coiled chromatin stalks (Figure 2).

A normal human cell has 46 chromosomes consisting of 23 pairs. Chromosome pairs 1–22 are autosomes, and the X and Y chromosomes are sex chromosomes. Before banding techniques were developed, the chromosome numbers were assigned by total length of the chromosome beginning with number 1 as the longest and number 22 as the shortest. With the advent of chromosome banding, chromosome 21 was determined to be shorter than 22, but the designations were not changed. A **homologous** chromosome pair consists of two morphologically identical chromosomes that have identical gene loci but can have different alleles at a given locus because one member of a homologous pair is of maternal origin and the other is of paternal origin. For example, a homologous pair consisting of both chromosomes number 9 has the gene locus for the ABO blood group on the long arm. An individual can inherit the allele for blood group A on the maternal number 9 chromosome and the allele for blood group B on the paternal number 9 chromosome. A **heterologous** pair (i.e., the sex chromosomes, X and Y, in a male) consists of morphologically nonidentical chromosomes that have different gene loci.

▶ **MITOSIS**

Cells that go through a proliferative division do so by a series of stages called the *cell cycle*; it consists of four major phases: G1, S, G2, and mitosis (Figure 3■). A cell that is not

■ **FIGURE 3** Diagram of the cell cycle beginning with G1, the stage in which the cell is performing its designated duties. The DNA is uncoiled and exists as 46 single chromatids. S phase is the time of DNA synthesis after which the DNA is still uncoiled and consists of 46 chromosomes (sister chromatids joined at the centromere). G2 is a resting phase followed by mitosis.

dividing but is performing its designated function is in interphase. Interphase begins at phase G1 of the cell cycle and continues until the end of phase G2. During G1, the nuclear chromatin is dispersed, and chromosome morphology is not

identifiable. The next phase, S, is the time of DNA synthesis: The DNA is replicated, and identical sister chromatids are attached at the centromere. This is followed by a short resting phase, G2, after which the cell enters mitosis. The length of time that a cell spends in each phase is quite variable. The average time that a cell spends in mitosis is estimated to be ~45 minutes.

To study human chromosomes, the cells must be mitotically active. *Mitosis* is the process of division of somatic cells by which each daughter cell ends with the same genetic composition as the parent cell. *Prophase* is the first stage of mitosis (Figure 4 ■), during which the DNA begins to coil, chromosome morphology becomes recognizable, and a pair of cytoplasmic organelles known as *centrioles*, which are attached to the mitotic spindle, migrate to opposite poles of the cell. In *metaphase*, the DNA is tightly coiled and the chromosomes align in the center of the cell (equatorial plate, metaphase plate) while the mitotic spindle apparatus attaches to the kinetochores of the chromosome centromere via microtubules. *Anaphase* begins with the contraction of the spindle fibers pulling apart the sister chromatids so that one sister chromatid migrates to one pole of the cell and the other sister chromatid migrates to the opposite pole of the cell. During *telophase*, the daughter nuclei begin to form at

■ **FIGURE 4** Mitosis. **a.** Interphase. Chromatin is dispersed. **b.** Prophase. Chromosome structure is discernible and centrioles begin to migrate. **c.** Metaphase. Chromosomes are lined up in the center, spindle fibers from the centrioles connect to the centromeres, and the nuclear membrane is not visible. **d.** Anaphase. Spindle fibers contract and sister chromatids migrate to opposite poles of the cell. **e.** Telophase. Chromatid migration is complete and the cytoplasmic membrane forms down the center, completing the cell division.

the opposite poles of the cell, and cytokinesis begins. At the end of telophase, *cytokinesis* (the division of the cytoplasm into two daughter cells) completes, and each of the daughter cells then re-enters the G1 phase of the cell cycle. Each resultant daughter cell has the identical genetic composition as the parent cell.

Meiosis is the specialized division of diploid (46 chromosomes) primary gametocytes that results in each gamete (oocyte, and sperm) having a haploid number of chromosomes (23). The understanding of meiosis is critical for the study of constitutional chromosome aberrations and is not discussed in this chapter.

► **CYTOGENETIC PROCEDURES**

SPECIMEN PREPARATION

Specimens submitted for cytogenetic analysis must have viable cells capable of undergoing mitosis; the choice of appropriate specimens depends on the patient’s clinical situation (Table 1). For the evaluation of possible **constitutional cytogenetic aberrations** (aberrations present in every cell in a patient’s body, i.e., its constitution), peripheral blood is the most appropriate sample because circulating lymphocytes can be easily manipulated to undergo mitosis by the use of mitogens. For example, phytohemagglutinin (PHA) stimulates predominantly T lymphocytes. If the patient has a lymphocytopenia or if there is a suspicion that cells from different tissue types can have different karyotypes (mosaicism), a punch-biopsy of skin can be obtained for fibroblast culture. When the clinical situation involves a spontaneous abortion (miscarriage), stillbirth, or death shortly after birth, the appropriate sample is fetal tissue (products of conception) or autopsy-acquired organ samples (lung, liver, kid-

ney, diaphragm). A prenatal evaluation requires culturing either amniotic fluid cells or a chorionic villus biopsy processed by direct harvest and tissue culture. These various cultures are harvested at the time of maximal mitotic activity, usually 72–96 hours for peripheral blood and 7–21 days for amniotic fluid and fibroblast cultures.

Acquired aberrations (those happening after birth in a single cell) occur in neoplastic processes such as leukemia, lymphoma, and other tumors. Evaluation of these disorders requires that the neoplastic cells be sampled directly either by peripheral blood, bone marrow, or solid tumor biopsies. These samples are harvested immediately (direct harvest) or by short-term unstimulated cultures to obtain mitoses of the neoplastic cells, not the associated nontumor cells.

The first step of the cytogenetic procedure is to induce cells into mitosis. Once this has been accomplished by any of the methods named, the cells are “harvested.” The harvest procedure processes cells that are mitotically active to visualize the chromosomes. The major steps are metaphase inhibition, hypotonic incubation, and fixation.

 **CASE STUDY** (continued from earlier in this chapter)

The differential WBC count shows 7% blasts, 3% promyelocytes, 25% myelocytes, 10% metamyelocytes, 5% bands, 25% segmented neutrophils, 10% basophils, 5% eosinophils, and 10% lymphocytes. The differential diagnosis includes leukemoid reaction, chronic myelogenous leukemia (CML), and myeloproliferative disorders other than CML. A bone marrow aspirate is performed.

1. What is the most appropriate specimen to submit for cytogenetics, and how should it be processed?

★ **TABLE 1**

Appropriate Specimens for Cytogenetic Analysis

Clinical Situation	Appropriate Specimen	Type of Processing
Constitutional aberrations	Peripheral blood	Mitogen stimulation of lymphocytes with phytohemagglutinin
	Skin biopsy	Tissue culture
	Autopsy organ samples	Tissue culture
	Products of conception	Tissue culture
	Amniotic fluid	Tissue culture
	Chorionic villus sample	Direct harvest, tissue culture
Neoplastic (acquired) aberrations	Peripheral blood/bone marrow	Direct harvest, unstimulated cultures; stimulated cultures of mature B cell malignancies; all cultures from cell suspension
	Lymph node/spleen	Direct harvest, unstimulated cultures; stimulated cultures of mature B cell malignancies; all cultures from cell suspension
	Solid tumor biopsy	Monolayer and suspension tissue culture

HARVEST PROCEDURE AND BANDING

Mitotically active cells are stopped in metaphase by incubation with agents that disrupt the spindle apparatus, most commonly colchicine or colcemid.¹ The cells are then incubated with a hypotonic solution (frequently 0.075 M KCl) that hemolyzes erythrocytes and partially swells the nucleated cells. Fixation of the cells is then accomplished with Carnoy’s fixative, 3:1 methanol:glacial acetic acid. After fixation, a trial slide is prepared by dropping three to four drops of the final cell suspension onto a clean glass slide. The slide is dried and examined by phase microscopy for appropriate spreading and number of mitotic figures. If the first slide does not show optimal quality, the suspension can be concentrated or diluted, or other manipulations can be made to obtain improved chromosome morphology. The remainder of the slides are then prepared and “aged” for banding; this often involves heating the slides in a 60°C oven overnight.

Chromosome banding is obtained by various staining procedures that result in a specific pattern of dark-to-light-

stained bands for each homologous chromosome pair. The first chromosome banding technique was reported in 1970 with the use of quinacrine (Q), a fluorescent stain that reveals a pattern of bright and dull bands (Q-bands).² Q-banding techniques are relatively simple; however, the banding fades when examined microscopically with ultraviolet illumination, and the resolution of bands is not as detailed as are G-bands (G = Giemsa). Most laboratories routinely analyze G-bands using Giemsa stain and some form of enzyme pretreatment, usually trypsin.³ These techniques result in a high-quality banding pattern that does not fade with microscopic examination. The pattern of bright or dull Q-bands and dark- or pale-staining G-bands is essentially the same. Reverse banding (R-bands) yields a band pattern opposite to that of Q- and G-bands so that a pale G-band will be dark staining with R-banding. Other banding techniques and special harvest procedures can be helpful for evaluation in certain clinical situations (Table 2).

The study of chromosome morphology has been enhanced by the development of fluorescently labeled DNA probes for

TABLE 2

Cytogenetic Banding Techniques and Special Procedures

Type of Banding or Special Procedure	Procedure Description	Result
Q banding	Quinacrine fluorescence A-T rich areas = bright G-C rich areas = dull	Reveals distinct bright and dull band patterns of homologous chromosomes
G banding	Giemsa stain after enzyme pretreatment A-T rich areas = dark G-C rich areas = pale	Reveals distinct dark and pale band patterns of homologous chromosomes identical to Q bands
R banding	A-T rich areas = pale G-C rich areas = dark	Reveals distinct pale and dark band patterns of homologous chromosomes reverse of Q and G bands
C banding	Giemsa stain after acid-alkali denaturation	Stains heterochromatic pericentric regions of chromosomes 1, 9, 16 and long arm of Y chromosome
NOR staining	Silver stain of nucleolar organizing region	Stains stalk region of acrocentric chromosomes 13, 14, 15, 21, and 22
FISH	Fluorescently labeled DNA probes	Depending on probe used, hybridizes with a specific chromosome centromere, arm, whole chromosome, or gene
Synchronization	Synchronization of cells in cell cycle with blocking agent (high dose thymidine)	Increases number of cells in mitosis
High-resolution banding	Cells synchronized and stopped in late prophase or early metaphase	Reveals chromosomes that are less condensed, more toward the prometaphase, and banded at a greater than 800 band stage
Fragile site	Cells cultured with folate/thymidine deprivation	Reveals areas of chromosome gaps, previously used for fra(X)
SCE	Sister chromatid exchange detected by incubation through two cell cycles in BrdU and stained with fluorescent Hoechst-33258	Stains sister chromatids dark or light showing areas of exchange, indicating mutagenicity

FISH = fluorescence in situ hybridization; NOR = nuclear organizing region; SCE = sister chromatid exchange

■ **FIGURE 5** Metaphase spread of chromosomes belonging to a single cell obtained by direct harvest of a bone marrow aspirate. (G-banded, 1000× magnification)

specific chromosome centromeres, whole arms, whole chromosomes, and individual genes (fluorescence in situ hybridization [FISH]).⁴ Fluorescent labeled probes allow both specific identification of chromosomes involved in structural or numerical aberrations and analysis of interphase cells. The labeled probe is hybridized directly to cells mounted on glass slides. In this procedure, the morphologic information of the cell with the mutation is preserved. However, the cells must be permeabilized and the DNA denatured for hybridization to occur. The molecular probe is allowed to hybridize to the chromosomes in the tissue specimen on the slide. Probe binding can be visualized using a fluorescent microscope.

CHROMOSOME ANALYSIS

Analysis of chromosomes is best performed microscopically. The adequacy of analysis depends on the mitotic rate of the cells and on banded chromosome morphology. An optimal preparation has mitotic spreads with moderately long chromosomes, few chromosome overlaps, and good quality banding (Figure 5 ■). A *karyotype* is a representation of the chromosome makeup of a cell and can now be constructed using a video-computer-linked analysis system. To prepare a karyotype, the chromosomes are grouped initially by size and centromere position and then by the specific pattern of dark-to-light-staining bands (Figure 6 ■). The number of cells

■ **FIGURE 6** Karyotype of normal male cell with numbered chromosome pairs, G-banded.

analyzed per case varies according to the clinical situation. Standardized guidelines for cytogenetic evaluation have been set by accrediting agencies such as the College of American Pathologists (CAP).

✓ Checkpoint! 1

A newborn baby boy has multiple congenital malformations, and a chromosome abnormality is suspected as the cause. What is the most appropriate specimen to submit for chromosome analysis, and how should the laboratory professional process the specimen?

▶ CHROMOSOME ABNORMALITIES

Chromosome abnormalities are either numerical or structural and can involve the autosomes (1–22) and/or the X and Y sex chromosomes. Constitutional abnormalities are present at the time of birth and are present in all cells if they are inherited from a parent carrier or if they occurred during gametogenesis. Constitutional aberrations can also occur in the embryo shortly after fertilization resulting in a **mosaic**: some cells have the aberration and some are normal. If the aberrations occur some time after birth, they are acquired, and this usually is seen in a single cell line identifying a neoplastic clone.

NUMERICAL ABERRATIONS

A normal human cell with 46 chromosomes is called **diploid**. The word *haploid* is used to designate half the number of chromosomes, 23, and *n* is an abbreviation for the haploid number. Therefore, a cell with $2n$ (2×23) has 46 chromosomes (diploid), and a cell with $3n$ has 69 chromosomes (triploid). **Aneuploid** refers to a chromosome count other than 46 that is not a multiple of *n*. If a cell has more than 46 chromosomes, the word **hyperdiploid** is used, and if a cell has fewer than 46 chromosomes, it is called **hypodiploid**.

Most numerical aberrations are thought to be caused by a process of **nondisjunction**, which occurs during meiotic or mitotic cell division when a spindle fiber from the centriole does not connect to the chromosome centromere or when the spindle fiber connects but does not contract (Figure 7 ■). This situation results in one daughter cell with an extra chromosome (**trisomy**) and one daughter cell with a chromosome loss (**monosomy**). In most cases, the cell with the chromosome loss does not survive the next cell cycle. Another process, termed *anaphase lag*, results when one chromatid does not completely migrate to the opposite pole but lags behind and gets caught outside the nuclear membrane (Figure 8 ■), yielding one daughter cell with a chromosome loss and one daughter cell that is normal.

The word **polyploid** refers to cells that have a chromosome count that is a multiple of the *n*. Hence, a *tetraploid* cell is polyploid and has a chromosome count of $4n$, or 92.

■ **FIGURE 7** Nondisjunction. During anaphase, the sister chromatids of a chromosome do not disjoin, resulting in one daughter cell with an extra chromosome (trisomy) and the other with a chromosome loss (monosomy).

■ **FIGURE 8** Anaphase lag. Chromatid does not complete migration, resulting in one daughter cell with a normal chromosome count and the other with a chromosome loss.

Endomitosis is the process that results in polyploid cells when there are multiple rounds of S phase (DNA synthesis) without karyokinesis (nuclear division) or cytokinesis (cytoplasmic division). The megakaryocyte is an example of a normal polyploid cell. The word **pseudodiploid** is used when a cell has a chromosome count of 46 but is not normal because of numerical and/or structural aberrations. For example, a cell with a karyotype of 46, XX, +8, -21 is an abnormal cell but has a chromosome count of 46 and therefore is pseudodiploid: it has 46 chromosomes including the 2 sex chromosomes, XX, because although it is missing a number 21 chromosome (-21), it has 3 number 8 chromosomes (+8).

STRUCTURAL ABERRATIONS

Structural chromosome aberrations occur when chromosome breakage occurs and the repair process results in structural loss or in abnormal recombinations. Table 3 lists structural aberrations with a short description and example nomenclature. Any of these can be seen as constitutional or acquired with the exception of homogeneously staining regions and double minutes that have been seen only in neoplastic cells as acquired aberrations.

POLYMORPHIC VARIATION

Morphologic variations are known to occur in certain chromosomes. These variations have no clinical significance but, if present, will be inherited consistently through each generation. **Polymorphic variants** (chromosomes with variant

morphology that have no clinical consequence) are easily demonstrated with various banding techniques and can be used to identify maternal versus paternal origin of homologous chromosomes. Some of the more commonly seen polymorphic variants include a pericentric inversion of chromosome 9, variable amounts of pericentric heterochromatin on chromosomes 1, 9, and 16, and a variable amount of heterochromatin on the long arm of the Y chromosome. Also, amounts of satellite material on the short arms of the acrocentric chromosomes can be variable.

▶ CYTOGENETIC NOMENCLATURE

An international committee whose goal is to have one standardized system has established the designation of chromosome number, region, band, and karyotype nomenclature. The International System for Human Cytogenetic Nomenclature (ISCN) has published guidelines including specific rules for cancer cytogenetics for use by clinical and research laboratories.⁵ The short and long arms of each chromosome are divided into regions by major landmark bands (Figure 9). Each region is further divided into distinct light-, intermediate-, and dark-staining bands. The numbering of regions and bands begins at the centromere and proceeds distally to the terminal portions, *pter* and *qter*. The numbering of bands begins with the number 1 for each region. To designate a specific band of a chromosome, the order is written as chromosome number, arm, region, and band.

TABLE 3

Examples of Structural Chromosome Aberration Nomenclature with Explanations

Structural Aberration and Nomenclature	Explanation
Chromosome/chromatid breaks	Break occurs in chromosome/chromatid and is usually repaired. Increased random breaks can be seen with toxins, radiation, and virus exposure.
Dicentric (dic) example: dic(7;8)(q32;q23)	Breaks occur in two chromosomes and the chromosomes—including centromeres—are repaired together resulting in a chromosome with two centromeres; the acentric fragments are lost.
Double minutes (dmin)	Small acentric pieces of DNA, usually paired, indicate gene amplification.
Homogeneously staining region (hsr) example: hsr(11)(q23)	Region of chromosome that stains homogeneously and indicates gene amplification.
Deletion (del), interstitial example: del(7)(q31q32)	Two breaks occur in one arm and material between breaks is lost; break ends are repaired by joining together.
Deletion, terminal example: del(7)(q32)	Break occurs and acentric fragment is lost during mitosis/meiosis.
Duplication (dup) example: dup(7)(q31q32)	Region of a chromosome is duplicated and can be direct or inverted.
Isochromosome (i) example: i(7p) or i(7q)	Centromere splits horizontally and results in chromosome with only short or long arm material. The remaining arm of the chromosome is usually lost.
Inversion (inv), paracentric example: inv(7)(q21q32)	Two breaks occur, and the material between the breaks inverts and then is repaired. When the inversion does not involve the centromere it is referred to as a paracentric inversion.
Inversion, pericentric example: inv(7)(p15q21)	Two breaks occur, and the material between the breaks inverts and then is repaired. When the inversion involves the centromere it is referred to as a pericentric inversion.
Ring chromosome (r) example: r(7)(p21q35)	Breaks occur in the short and long arms, and the broken ends are repaired together; the acentric fragments are lost.
Translocation (t), balanced example: t(7;8)(q32;q23)	Breaks occur in two different chromosomes with fragments repaired (joined) to the opposite chromosome; no loss of DNA occurs.
Derivative (der) chromosome example: der(7)t(7;8)(q32;q23)	This is a structurally rearranged chromosome derived most often from two or more chromosomes. In this example, the derivative, der (7), is the abnormal chromosome 7 that results from a translocation between chromosome 7 and 8 at the designated break points.
Translocation, Robertsonian example: der(14;21)(q10;q10)	A unique type of translocation, breaks occur at or near the centromeres of two acrocentric chromosomes; the centromeric regions fuse, and the short arm/satellite material is lost. The chromosome is derived (der) from the long arms of each chromosome.

A standardized nomenclature system also exists for gene names. The HUGO Gene Nomenclature Committee (HGNC) is the recognized body that approves a gene name and symbol for each known human gene. All approved symbols are stored in the HGNC database. Approved gene names and symbols are readily accessible electronically.⁶

The karyotype of a cell is designated first by the total number of chromosomes followed by the sex chromosomes (XX for female and XY for male). If aberrations are present, sex chromosome abnormalities are listed first followed by abnormalities of autosomes listed in numerical order of the chromosomes involved. Numerical abnormalities are designated by + or – before the chromosome number. Structural abnormalities are listed by the appropriate abbreviation followed by the chromosomes involved in parenthesis and then by the break point band designation in parentheses. Therefore, normal female and normal male karyotypes, respectively, are 46,XX and 46,XY. A male cell with trisomy for chromosomes 8 and 21 is designated: 48, XY, +8, +21. A fe-

male cell with trisomy for chromosomes 3, 8, and 15 and a translocation involving chromosomes 9 and 22 is designated 49,XX,+3,+8, t(9;22)(q34;q11.2),+15. The q34;q11.2 refers to the long arms (q), regions 3 and 1, and bands 4 and 1.2, respectively. (See Table 3 for other examples of nomenclature.)

▶ **CYTOGENETIC ANALYSIS OF HEMATOPOIETIC AND LYMPHOID DISORDERS**

Cytogenetic analysis has become an essential part of the diagnostic evaluation of patients with known or suspected neoplasms. Many chromosome aberrations ascertained by either conventional (G-banded) techniques or FISH are now considered diagnostic of or have significant prognostic implications for hematolymphoid malignancies⁷ and solid tumors.⁸ The cloning of genes at critical chromosome breakpoints in various

FIGURE 9 Diagram of bands on chromosome 7 with arm, region, and band designations. The band located at the arrow is designated 7q32.

neoplasms has permitted the discovery of the role that these genes play in tumorigenesis and has provided specific DNA sequence targets that can be utilized for the molecular cytogenetic technique of FISH for patient diagnostics. A chromosome aberration found in neoplastic cells is referred to as an *acquired, clonal aberration*; it is an aberration that occurs sometime after birth and is present only in the neoplastic cells.

A clone exists if numerical and/or structural aberrations are identical in at least two cells unless the abnormality is a single chromosome loss (monosomy); then, three cells must have the same chromosome loss. The presence of an abnormal clone is evidence of a neoplasm. Table 4 lists the most common uses of cytogenetic analysis in hematolymphoid disorders.

✓ Checkpoint! 2

Cytogenetic studies were performed on a bone marrow specimen from a female patient with a myelodysplastic state with the following results:

1 cell—47,XX,+8
 1 cell—45,XX,-20
 5 cells—46,XX,del(5)(q13q34),-7,+21

Which of these aberrations are clonal? What term would apply to the five cells?

Constitutional chromosome aberrations occasionally are found when analyzing neoplastic cells, most often constitutional abnormalities that might not be associated with an ab-

TABLE 4

Present Applications of Conventional Cytogenetics and Molecular Cytogenetics (FISH) in Hematolymphoid Disorders

- Confirm or establish the diagnosis of a number of leukemias and lymphomas.
- Predict response to specific agents such as tyrosine kinase inhibitors.
- Confirm or predict accelerated phase of chronic myelogenous leukemia (CML).
- Confirm or establish remission and monitor minimal residual disease.
- Aid in the diagnosis and prognosis of myelodysplastic states.
- Evaluate bone marrow transplant for donor versus recipient cells and possible recurrence of original neoplasm.
- Evaluate clonal evolution, which portends a more aggressive phase of disease.

normal phenotype. For example, a female patient with acute leukemia and a 47,XXX karyotype could have the +X as an acquired aberration indicative of the malignant cells, or the +X could represent a constitutional abnormality and be present in all of the patient's cells. If the karyotype is 45,XX,-7, however, this is most likely an acquired aberration because monosomy 7 as a constitutional aberration is not compatible with life. The presence of constitutional aberrations must be accurately interpreted and distinguished from acquired clonal aberrations. This is most often accomplished by stimulating peripheral lymphocyte analysis or occasionally by performing skin biopsy fibroblast culture because these cells are not part of the neoplastic clone and any aberrations are constitutional.

PROCESSING OF SPECIMENS

The best sample for cytogenetic analysis of hematolymphoid disorders, excluding lymphomas, is a bone marrow aspirate; even when blast cells are present in the peripheral blood, a higher mitotic rate is usually achieved from the bone marrow sample. These cells are processed by direct harvest and/or unstimulated cultures. The overall cellularity of the marrow aspirate or peripheral blood sample can vary greatly and affects the mitotic yield and chromosome morphology. Therefore, it is best for the cytogenetic laboratory to evaluate the cell count of each specimen, usually with an automated cell counter. Optimal cultures are obtained by inoculating 1 million cells per milliliter of media. The best specimen for study of lymphoma is an involved lymph node. In general, the resolution of chromosomes from an unstimulated peripheral blood or bone marrow/lymph node specimen is not as good as that from a phytohemagglutinin stimulated study, which can reflect an inherent feature of the malignant cells. In fact, cells with particularly poor morphology can represent the abnormal clone whereas the cells with better morphology can be the remaining normal population. Therefore, when working in cancer cytogenetics, the laboratory professional must be careful to

analyze each mitotic spread and to evaluate the metaphase preparations with poor resolution and morphology.

Processing cells from lymphoma can include incubation with mitogens in addition to the unstimulated cultures. The neoplastic cells from mature B cell lymphomas often respond to pokeweed or lipopolysaccharide antigens and to stimulation with phytohemagglutinin in the presence of interleukin-2. A summary of specimen processing is given in Table 5.

CHRONIC MYELOGENOUS LEUKEMIA

The first chromosome abnormality reported to be associated with a malignancy was described in 1960 as an abnormally small chromosome seen in patients with chronic myelogenous leukemia (CML).⁹ This abnormality was designated the Philadelphia or Ph¹ (now designated as Ph) chromosome and was believed to be due to a deletion of the long arm of chromosome 22. With the advent of banding techniques, the abnormality was found to actually be a balanced translocation involving chromosomes 9 and 22, t(9;22)(q34;q11.2).¹⁰ This translocation is seen in 90–95% of patients with CML.

Investigators attempted for some time to decipher why a specific chromosome translocation should be so closely associated with a single morphologic type of leukemia. It is now known that the proto-oncogene *ABL1*, normally located at 9q34, is translocated and juxtaposed next to the *BCR* gene at 22q11.2 in the Philadelphia translocation.¹¹ A proto-oncogene is a normal gene involved in cell division/proliferation and has the capability of becoming an oncogene. The Ph translocation results in a new chimeric gene consisting of a portion of the *ABL1* from chromosome 9 and a portion of the *BCR* from chromosome 22. The *ABL1* is activated to a functioning oncogene, and a 210 kD (kD = kilo Daltons) polypeptide product of *BCR/ABL1* is present in the leukemic cells.¹² An oncogene is involved in deregulating cell growth and prolifer-

ation and is responsible for neoplastic proliferation usually by mutation, overexpression, or amplification.

Of CML patients, 5–10% lack the classic t(9;22) and instead have a variant translocation involving at least one other chromosome in addition to chromosomes 9 and 22 or a cryptic translocation of chromosomes 9 and 22. *Cryptic translocations* are molecular genetic rearrangements that cannot be identified by conventional cytogenetics and must be evaluated by the molecular techniques of FISH (Figure 10) or the reverse transcriptase polymerase chain reaction (rtPCR) for *BCR/ABL1* gene rearrangement. Patients with variant or cryptic translocations have the same clinical features and prognosis as those with the typical (9;22) translocation.

In the past, CML was difficult to treat, and patient survival was poor because the t(9;22) and concurrent *BCR/ABL1* gene rearrangement occur in a pluripotent hematopoietic stem cell (HSC) and has the potential to affect all marrow cells derived from that HSC. The identification of the *BCR/ABL1* fusion transcript and the subsequent cloning of these genes permitted an understanding of the endogenous tyrosine kinase activity of *ABL1* and prompted the development of an agent targeted specifically at the protein product of the *ABL1* gene. This group of agents, called *tyrosine kinase inhibitors* (TKIs), is now a model for the development of novel treatments in various types of cancer because genetic rearrangements of many other hematolymphoid malignancies and solid tumors are known to involve genes also with tyrosine kinase activity. The TKIs have been shown to significantly prolong overall survival in a number of leukemias, lymphomas, and solid tumors and have revolutionized the treatment of these neoplasms by targeting specific genetic loci.^{13,14}

When CML patients enter accelerated phase or blast crisis, the majority have a change in the karyotype with chromosome aberrations in addition to the t(9;22) (i.e., clonal evolution). The most frequently observed additional aberrations

TABLE 5

Appropriate Specimens and Type of Processing for Cytogenetic Analysis of Neoplastic Cells

Possible Diagnosis	Specimen	Processing
Acute leukemias (myeloid and lymphoid)	Bone marrow at diagnosis	24–72-hour unstimulated cultures; FISH analysis with appropriate probes
Myeloproliferative disorders	Peripheral blood for FISH evaluation to monitor minimal residual disease	
Myelodysplastic syndromes		
Therapy-related myeloid disorders		
Lymphoproliferative disorders	Morphologically involved lymph node, spleen, bone marrow, peripheral blood	Unstimulated cultures; T cell: phytohemagglutinin stimulation; B cell: pokeweed, lipopolysaccharide, PHA, and IL-2
Solid tumor	Morphologically involved tumor tissue	Monolayer and/or suspension cultures
	Effusion (pleural, peritoneal, etc.)	Direct harvest, unstimulated cultures

FISH = fluorescence in situ hybridization; PHA = phytohemagglutinin; IL-2 = interleukin-2

FIGURE 10 Identification of the *BCR/ABL1* gene rearrangement with a dual color, dual fusion probe set. The *ABL1* probe is labeled in red and the *BCR* probe in green. One normal *ABL1* gene and one normal *BCR* gene are located on separate chromosomes. The *BCR* and *ABL1* genes are juxtaposed on the two chromosomes involved in the translocation, resulting in two yellow fusion signals.

are an extra Ph [$+\text{der}(22)\text{t}(9;22)$], an extra chromosome 8 [$+8$], an isochromosome for the long arm of chromosome 17 [$i(17q)$], and an extra chromosome 19 [$+19$]. This clonal evolution can be detected days or weeks before the actual morphologic transformation to blast crisis is seen in the marrow or peripheral blood, allowing more rapid institution of appropriate treatment.¹⁵

The $t(9;22)$ is also seen at diagnosis in approximately 15% of cases of acute lymphoblastic leukemia (ALL), more commonly in adults. Although the translocation appears the same cytogenetically as that seen in CML, there is a difference in the site of breakage at the *BCR* locus, resulting in a 190 kD protein. The cases of Ph-positive ALL must be distinguished from a patient presenting in lymphoid blast crisis of CML because the prognosis and treatment are different.

CASE STUDY (continued from earlier in this chapter)

Cytogenetic analysis of bone marrow shows all of the cells to have this karyotype: $46,XY,t(9;22)(q34;q11.2)$.

1. Is this a constitutional or acquired aberration?
2. Is it a clonal aberration?
3. What is the significance of this finding for the diagnosis?

MYELOPROLIFERATIVE DISORDERS OTHER THAN CML

The other myeloproliferative disorders, polycythemia vera (PV), chronic idiopathic myelofibrosis, and essential thrombocythemia (ET), have acquired clonal chromosome aberrations in approximately 50–60% of cases. Diagnosis of these disorders now requires documented absence of *BCR/ABL1* gene rearrangement.⁷ Recurrent aberrations in these myeloproliferative disorders include abnormalities of 1q, +8, +9, $\text{del}(13q)$, and $\text{del}(20q)$. In addition to negative *BCR/ABL1* gene rearrangement status, molecular genetic evaluation for a particular mutation in the *JAK2* gene, the V617F mutation, has become the standard of care for the diagnosis of these patients. Patients who have the V617F mutation can definitively be diagnosed with a myeloproliferative disorder, have a high response rate to a particular chemotherapeutic agent called *hydroxyurea*, and have been shown to have shorter overall survivals.¹⁶

ACUTE MYELOID LEUKEMIA

Approximately 70% of patients with de novo acute myeloid leukemia (AML) have acquired clonal chromosome aberrations in the leukemic cells. These aberrations are present only in the leukemic blasts, not in the other hematopoietic precursors. Therefore, de novo AML appears to be a malignancy of the committed progenitor cell.^{17,18} The chromosome abnormalities found can be single, numerical, or structural or complex. Some aberrations such as trisomy 8 occur frequently in AML but are not diagnostic for a specific type of leukemia. Chromosome aberrations when present in the diagnostic specimen can be valuable in following the leukemia's progression or regression. If the original leukemic cells have a clonal aberration, such as +8, a complete remission sample should have only a normal karyotype. In subsequent samples, the presence of even one cell with +8 would indicate an early relapse, which might not be detectable morphologically. Some patients clonally evolve, usually indicating cytogenetic transformation to a more aggressive and treatment-resistant disease.

The World Health Organization (WHO) has established a classification system for AML according to the presence or absence of recurrent cytogenetic abnormalities. Specific cytogenetic aberrations now define particular subtypes of AML that have specific treatment implications. Although these cytogenetic entities are characterized by particular morphologic and clinical features, the primary diagnostic modality is genetic. The WHO AML classification includes the aberrations in Table 6. If a patient with AML lacks one of these recurrent aberrations or other clonal cytogenetic abnormality, classification is based on morphologic categorization established by the French-American-British (FAB) system.

The $t(8;21)$ and $\text{inv}(16)/t(16;16)$ both disrupt the same transcription factor, core binding factor (CBF), and are there-

★ TABLE 6

Acute Myeloid Leukemia (AML) with Recurrent Cytogenetic Abnormalities

Cytogenetic Aberration	Gene Rearrangement	Comments
t(8;21)(q22;q22)	<i>ETO(RUNX1T1)/AML1(CBFA or RUNX1)</i>	Favorable prognosis
inv(16)(p13.1q22) or t(16;16)(p13.1;q22)	<i>CBFB/MYH11</i>	Favorable prognosis
t(15;17)(q22;q12)	<i>PML/RARA</i>	Responsive to ATRA
Variants		
t(11;17)(q23;q21)	<i>PLZF(ZBTB16)/RARA</i>	Resistant to ATRA
t(5;17)(q32;q12)	<i>NPM1/RARA</i>	Responsive to ATRA
t(11;17)(q13;q21)	<i>NUMA1/RARA</i>	Responsive to ATRA
11q23 abnormalities	<i>MLL</i>	Poor prognosis
Complex karyotypes including 5/7 aberrations and 3q21 and 3q26.2 rearrangements	Genes unknown	AML with multilineage dysplasia; abnormal megakaryopoiesis, poor prognosis
Therapy related		
Chromosome 5 and 7 aberrations		Alkylating agent related
11q23 and 21q22 aberrations	<i>MLL and AML1(RUNX1)</i>	Topoisomerase-II inhibitor related

ATRA = all transretinoic acid

fore categorized together by the WHO as the Core Binding Factor Leukemias (CBFL). The t(8;21) disrupts the alpha chain of CBF that is encoded by *AML1(RUNX1)*, and the inv(16)/t(16;16) disrupts the beta chain of CBF. The CBFL have relatively favorable prognoses, are more common in younger patients, and can have a unique type of presentation with a particular type of disease called *myeloid sarcoma*, a soft tissue infiltration by the myeloblasts.

The t(8;21), previously reported predominantly in cases of AML-M2 by FAB classification (AML with differentiation) occurs in 5–12% of AML. The protein product of the *ETO(RUNX1T1)/AML1(RUNX1)* gene rearrangement promotes leukemogenesis by blocking myeloid cell differentiation.¹⁹ Frequently seen with the t(8;21) is a loss of a sex chromosome, Y in the male and X in the female. FAB classification previously reported the inv(16)/t(16;16) in cases of AML-M4eo (acute myelomonocytic leukemia with increased marrow eosinophils), which occurs in 10–12% of AML.^{7, 20, 21}

The t(15;17) is present in acute promyelocytic leukemia (APL), previously classified as AML-M3 by FAB, and accounts for 5–8% of AML. The translocation results in the fusion of the retinoic acid receptor alpha (*RARA*) gene at 17q12 with the nuclear regulatory factor promyelocytic leukemia (*PML*) gene at 15q22. These patients respond to treatment with all transretinoic acid (ATRA), which induces differentiation of the abnormal promyelocytes followed by chemotherapy with an anthracyclin agent. Three variant translocations also rearrange the *RARA* gene but involve different partner chromosomes (Table 6). Identification of these variant translocations is clinically important because some are resistant to treatment with ATRA while others are responsive.⁷

AML with 11q23 abnormalities has monocytic features and is present in 5–6% of AML. The *MLL* gene at band 11q23 is rearranged, and many partner chromosomes are reported. Patients with this aberration have short overall survivals.

The WHO also recognizes an entity of AML with multilineage dysplasia that is characterized by myeloblasts and dysplastic morphologic features in two or more myeloid cell lineages, most commonly including the megakaryocytes. These patients have complex karyotypes often including aberrations of chromosomes 5 and 7 as well as rearrangements at bands 3q21 and 3q26.2. These patients have a poor prognosis with decreased likelihood of achieving complete remission and short overall survival.⁷

SECONDARY (THERAPY-RELATED) LEUKEMIA

Acute myeloid leukemia and myelodysplasia are known to occur with increased incidence in patients who have previously received chemotherapy or radiation therapy. These cases are called *secondary* or *therapy-related myeloid disorders* and are considered as a distinct entity by the WHO. Two major types are recognized based on the causative agent, and each is associated with specific cytogenetic abnormalities. Alkylating agent-related myeloid disorders occur approximately 5–6 years after treatment and are associated with aberrations of chromosomes 5 and 7. Topoisomerase II inhibitor-related myeloid disorders present within 2–3 years of exposure and are associated with break points at band 11q23 and concurrent *MLL* gene rearrangement.^{7, 22}

✓ Checkpoint! 3

A 35-year-old man has acute leukemia. Cytogenetic studies of the bone marrow reveal the following: 46,XY,t(15;17)(q22;q12). What type of leukemia does this patient have, and what will cytogenetic studies show after treatment if he achieves complete remission?

MYELODYSPLASTIC SYNDROMES

Myelodysplastic syndromes (MDS) are clonal neoplastic disorders of hematolymphoid stem cells characterized by dysplasia and subsequent ineffective hematopoiesis in two or more myeloid cell lines. An internationally recognized scoring system for predicting survival of MDS patients and transformation to AML, International Prognostic Scoring System (IPSS), has been developed; its major prognostic variables are the type of cytogenetic abnormality, percentage of blasts, and degree and number of cytopenias. According to the scoring system, good-risk cytogenetics include a normal karyotype, del(5q) as the sole abnormality, del(20q) as the sole abnormality and $-Y$. Poor-risk cytogenetics include more than or equal to three chromosome aberrations and chromosome 7 abnormalities. Intermediate risk refers to all other abnormalities. These specific cytogenetic aberrations define particular categories of MDS and play a major role in diagnosis, treatment, and management of patients with them.²³

✓ Checkpoint! 4

Five years ago, a 46-year-old woman received chemotherapy and radiation treatment for breast cancer. She now has pancytopenia. Cytogenetic analysis of the bone marrow is performed and shows 10 of 20 cells with the following: 45,XX,del(5)(q13q34),-7. What is the significance of this finding?

ACUTE LYMPHOBLASTIC LEUKEMIA

Approximately 60–75% of patients with ALL have clonal acquired aberrations of the malignant cells. Cytogenetic findings are a crucial part of the leukemia workup for pediatric cases, and the results are directly related to prognosis. Patients who have the most favorable prognosis have hyperdiploid karyotypes with a chromosome count ranging from 54–65 with concurrent trisomies of chromosomes 4, 10, and 17. Most cases of hyperdiploid ALL have other clinically favorable findings such as 3–7 years of age, total leukocyte count less than $10 \times 10^9/L$, and precursor B cell CALLA positive (CD10+) immunophenotype. The t(12;21)(p13;q22) also confers a favorable prognosis: It rearranges the *TEL* (now known as *ETV6*) gene at 12p13 and the *AML1*(*RUNX1*) gene at 21q22, and it is a cryptic aberration, undetectable in conventional metaphase preparations because the size of the translocated segments are of similar size and staining intensity. To ascertain the presence of this rearrangement, molecu-

lar methods, either FISH or RT-PCR, must be employed. Hypodiploidy, the t(4;11)(q21;q23) that rearranges the *AF4* and *MLL* genes and the t(9;22)(q34;q11.2) that rearranges the *BCR* and *ABL1* genes are associated with a poor outcome.^{7, 24, 25}

The patient's age influences the prognostic impact of these cytogenetic aberrations. ALL patients with the t(9;22) ranging in age from 1–18 years have more favorable outcomes than adults. Infants and adults with the t(4;11) have significantly shorter overall survivals than children with the same translocation. See Table 7  for some of the more commonly seen aberrations in ALL.

✓ Checkpoint! 5

A 5-year-old girl has fatigue and easy bruising. A CBC shows a leukocyte count of $40 \times 10^9/L$ with 85% blasts. Bone marrow cytogenetic studies are performed and show all cells with the following karyotype: 53,XX,+X,+4,+6,+10,+18,+20,+21. What is the prognostic significance of this finding?

LYMPHOMA AND LYMPHOPROLIFERATIVE DISORDERS

In recent years, chromosome analysis in lymphoma and lymphoproliferative disorders has added greatly to the understanding of the importance of the gene loci involved in chromosome aberrations seen with specific types of lymphoma. The results of these analyses have also led to the development of molecular probes and their use in the clinical laboratory. The first abnormality described in the lymphomas was the 14q+ seen in Burkitt lymphoma.²⁶ This was later characterized as t(8;14)(q24.1;q32) and is seen in approximately 75% of cases of Burkitt lymphoma. Two variant translocations, t(2;8)(p11.2;q24.1) and t(8;22)(q24.1;q11.2), have been reported in 10–15% of Burkitt lymphoma. The 14q32 is the site of the gene for the heavy chain of immunoglobulin, and the break at 8q24.1 is just proximal to the site of the proto-oncogene *MYC*. Therefore, the *MYC* gene is translocated to the heavy chain locus at 14q32.²⁷ This was the first demonstration of a proto-oncogene that was translocated to a location known to be active in B cell lymphoma, resulting in the activation of the oncogene. The t(2;8) results in the juxtaposition of a gene for kappa light chain to *MYC*, and the t(8;22) results in the juxtaposition of a gene for lambda light chain to *MYC*. In cases of Burkitt lymphoma that have the two variant translocations, the tumor cells are found to mark with surface kappa chain when the t(2;8) is found and with lambda chain when the t(8;22) is found.

Many cytogenetic aberrations are now associated with specific types of lymphoma and play a major role in the diagnosis of these entities as well as have prognostic significance. Most of these translocations are known to involve genes that are critical for proliferation of the neoplastic cells or are involved in programmed cell death, apoptosis. Chronic lymphocytic leukemia (CLL) patients with trisomy 12, 11q, or

TABLE 7

Correlation of Chromosome Aberrations in ALL with Immunophenotype, Gene Loci, Prognosis, and Approximate Incidence by Age

ALL Chromosome Phenotype	Known Aberration	Gene Loci	Prognosis	% Incidence In	
				Pediatric	Adult
Precursor B-cell	Hyperdiploid: 54–65 chromosomes With trisomies 4, 10 and 17		Good	20–25	4

	t(2;8)(p11.2;q24.1)	IGK@/MYC	Good with intensive tx		
	t(8;22)(q24.1;q11.2)	MYC/IGL@	Good with intensive tx		
T cell	t(8;14)(q24.1;q11.2)	MYC/TRA@ or TRD@	Poor		
	inv(14)(q11.2q32)	TRA@ or TRD@/IGH@	Poor		
	t(v;14)(v;q11.2)	TRA@ or TRD@	Poor		
	t(7;v)(q34;v)	TRB@	Poor		
	t(7;v)(p14;v)	TRG@	Poor		
	t(5;14)(q35;q32)	TLX3/IGH@	Eosinophilia associated		
	9q34 aberration	ABL1 amplification	Good: responsive to TKIs		
	t(11;19)(q23;p13.3)	MLL/MLLT1	Good		

17p aberrations are associated with an atypical morphology and shorter overall survival.²⁸ The t(11;14) is diagnostic of mantle cell lymphoma in the appropriate morphologic and clinical context, an aggressive entity that requires chemotherapy and transplantation.²⁹ The presence of the t(11;18) or t(1;14) in extranodal gastric lymphoma of mucosa associated lymphoid tissue (MALT), a type of marginal zone lymphoma, defines it as malignancy and requires treatment with chemotherapy as opposed to antibiotics.³⁰ Patients with anaplastic large cell lymphoma bearing the t(2;5) have a significantly longer survival than those patients without this aberration.³¹ See Table 8 for the characteristic chromosome aberrations with the lymphoproliferative disorders and gene loci known to be involved in these rearrangements.

BONE MARROW TRANSPLANTATION

Some of the hematolymphoid disorders presented in this chapter are treated by bone marrow or peripheral blood stem cell transplantation, depending on the clinical situation and

availability of donors. Cytogenetics, particularly the molecular cytogenetic technique of FISH, is a valuable tool in evaluating the rate of engraftment of the donor cells in opposite sex transplants and monitoring for minimal residual disease. Following successful transplantation, only donor cells should be present. Occasionally, 1–2% of recipient cells are detectable shortly after transplant but then diminish. If recipient cells recur with a normal karyotype, it indicates the development of a **chimerism**, the presence of cells of two different genetic origins in an individual. For example, a female recipient after a male-donated transplant can show 30% XY and 70% XX by FISH analysis with probes for the X and Y centromeres, which is consistent with partial but not complete engraftment. Treatment to promote engraftment, such as increasing the immunosuppression or giving additional donor cells, can thus be employed. If the recipient marrow cells have an initial chromosome aberration, FISH of DNA probes specific for the genes that are rearranged by that aberration can be used to assess the degree of disease burden persisting.

CASE STUDY (continued from earlier in this chapter)

An allogeneic bone marrow transplant is performed with Gregory's sister as the donor. Three months after transplant, the karyotype is 46,XX.

5. What is the significance of this finding?

MOLECULAR CYTOGENETICS

Techniques are now available to evaluate not only the gross chromosome morphology but also the individual gene composition. FISH is an example of such technology, and the role it plays in the diagnosis and prognosis of patients with hematolymphoid disorders has been previously discussed. The advantage of these techniques over conventional cytogenetic studies is that molecular DNA techniques do not require viable cells capable of mitotic activity. Samples of tumor cells can include nonmitosing peripheral blood cells and paraffin embedded tissue. The disadvantage of certain molecular studies, such as FISH, is that they give information only about a single molecular genetic aberration based on the specific probe used, potentially missing other chromosome aberrations that might be present.

The following scenario illustrates the use of the two different techniques. A 25-year-old man is known to have CML and has received an allogeneic transplant from his sister. The first post-transplant specimen did not have dividing cells in the conventional cytogenetic preparations. FISH of DNA probes that are rearranged in this leukemia, the *BCR* and *ABL1* genes,

was done and was positive in 10 out of 200 interphase nuclei examined, consistent with a low-level persistence of disease. A second sample obtained 3 months later was sufficient for conventional cytogenetics and yielded the following results:

- 80% 46,XX
- 10% 46,XY,t(9;22)(q34;q11.2)
- 10% 47,XY,+8,t(9;22)(q34;q11.2)

In the first sample, the molecular FISH studies were critical to show the persistence of the leukemia. Cytogenetics performed on the second sample was critical to show a cytogenetic transformation toward blast crisis with the additional +8 abnormality. The molecular technique of rtPCR also has significant clinical utility in diagnosing and monitoring patients with hematolymphoid neoplasms including CML.

Comparative genomic hybridization (CGH) assays can be used to analyze changes in chromosome copy number (copy number variants). Because of the greatly increased resolution that these assays provide, it has been observed that the human genome has much more variability than previously thought with differences found at up to thousands of loci, most of which are not clinically significant. This variability makes interpretation of CGH assays potentially challenging. In addition, CGH assays have been designed to analyze critical regions of the DNA for well-defined genetic abnormalities. DNA from the patient and normal control DNA are labeled using different fluorescent dyes, mixed, and hybridized to normal metaphase chromosomes or to a slide containing hundreds to thousands of defined DNA probes (array CGH).

The color intensity ratio is analyzed along the DNA to detect regions of copy number gain or loss. The current technology is able to detect copy gain and loss of regions that are 50 kb in length.³²

The use of cytogenetics and/or molecular DNA studies in neoplastic disorders must be well coordinated so to prevent duplication of work and provide minimal cost to the patient.

CASE STUDY (continued from earlier in this chapter)

Six months after transplant, Gregory had bone marrow aspirated for analysis. The mitotic yield of the specimen was not sufficient for routine cytogenetic analysis.

6. What other studies that would be informative as to the status of the donor and recipient cells could be performed?
7. Five years after the transplant, cytogenetic analysis shows the following:
 - 5 cells—46,XX
 - 15 cells—47,XY,+8,t(9;22)(q34;q11.2),i(17)(q10)

What is the significance of these findings?

SUMMARY

Clinical specialists in the hematology laboratory are frequently asked when cytogenic studies are indicated and what specimens are appropriate to submit. For these reasons, it is important for these specialists to have a basic understanding of the specimen requirements, processing, and clinical indications for chromosome analysis. Acquired, clonal chromosome aberrations can be seen in most of the hematolymphoid disorders, including acute and chronic leukemias, myelodysplastic states, myeloproliferative disorders, and lymphomas. These results are used for diagnosis and prognosis in many cases. In addition, cytogenetics can be used to follow the progression or regression of a malignant cell line if the original pretreatment sample revealed a clonal aberration.

The chromosome aberrations found in hematolymphoid disorders are present only in the malignant cells. Many cytogenetic aberrations are now recognized as diagnostic of particular hematolymphoid neoplasms; for example, the t(15;17) is diagnostic of APL. Identification of these specific aberrations with DNA probes has clinical utility for evaluating the patient's response to treatment and degree of residual disease. The identification of these molecular cytogenetic targets has also lead to more effective treatment for many hematolymphoid neoplasms.

REVIEW QUESTIONS

LEVEL I

1. Which of the following is the major component of chromosomes? (Objective 1)
 - a. polynucleotides
 - b. enzymes
 - c. lipids
 - d. proteins
2. In which stage of mitosis is the chromosome morphology best observed? (Objective 1)
 - a. anaphase
 - b. interphase
 - c. metaphase
 - d. prophase
3. A 4-year-old boy has mental retardation and developmental delay. Which of the following would be the most appropriate specimen for chromosome analysis? (Objective 2)
 - a. bone marrow
 - b. skin biopsy
 - c. peripheral blood
 - d. lymph node
4. A 62-year-old man has acute myeloid leukemia. Which of the following would be the most appropriate specimen for chromosome analysis to determine whether there are acquired chromosome aberrations? (Objective 2)
 - a. bone marrow
 - b. lymph node
 - c. peripheral blood
 - d. skin biopsy

LEVEL II

Use this case history for questions 1–3.

Stanley, the patient, is a 35-year-old male who presented with a severe nosebleed. He has been previously healthy; however, in the last three weeks, he has noticed easy bruising, and on the day of admission to the hospital, he had a nosebleed that he could not stop. Initial CBC revealed:

Hgb	10 g/dL
Hct	0.30 L/L
MCV	85 fL
WBC	50 × 10 ⁹ /L
Plt ct	20 × 10 ⁹ /L

The peripheral smear showed the majority of cells to have a high nuclear:cytoplasmic ratio, immature chromatin, and cytoplasmic hypergranulation with azurophilic granules. Preliminary cytogenetic analysis performed on bone aspirate revealed 75% of cells to have t(15;17)(q22;q12); 25% of cells have a normal male karyotype.

1. The most likely diagnosis is: (Objective 6)
 - a. chronic myeloid leukemia
 - b. acute promyelocytic leukemia
 - c. acute myeloid leukemia with multilineage dysplasia
 - d. secondary (therapy-related) acute myeloid leukemia

REVIEW QUESTIONS (continued)

LEVEL I

5. Which of the following is a basic criterion of cells that would be processed for chromosome analysis? (Objective 2)
 - a. mitotic activity
 - b. protein production
 - c. presence of nucleolus
 - d. presence of mitochondria
6. In the harvest procedure, how are cells stopped in metaphase? (Objective 2)
 - a. colchicine/colcemid incubation
 - b. incubation with hypotonic solution
 - c. fixation with Carnoy's fixative
 - d. incubation with phytohemagglutinin
7. The ability to identify individual chromosomes depends on which of the following? (Objective 2)
 - a. banding
 - b. hypotonic incubation
 - c. type of specimen
 - d. fixation
8. Which of the following terms is appropriate to describe a human cell that has 47 chromosomes? (Objective 3)
 - a. diploid
 - b. aneuploid
 - c. polyploid
 - d. normal
9. Which of the following can result in trisomy? (Objective 3)
 - a. anaphase lag
 - b. endomitosis
 - c. nondisjunction
 - d. chromosome breakage
10. Which of the following can result in an abnormal amount of cellular DNA? (Objective 3)
 - a. balanced translocation
 - b. paracentric inversion
 - c. pericentric inversion
 - d. isochromosome

LEVEL II

2. The break point on chromosome 17 involves which gene? (Objective 9)
 - a. *ABL1*
 - b. *MYC*
 - c. *BCR*
 - d. *RARA*
3. The identification of this cytogenetic aberration (in question 2) in patients has led to their treatment with which of the following? (Objectives 5, 6)
 - a. interferon
 - b. interleukin
 - c. all transretinoic acid
 - d. vitamin K

Use this case study for questions 4–7.

A 16-year-old girl has fatigue and increased bruising. A CBC shows the following:

Hb 70g/L

Hct 0.21L/L

WBC $35 \times 10^9/L$

Platelet count $60 \times 10^9//L$

Differential, bone marrow aspirate:

50% blasts with monocytoid features

15% dysplastic eosinophils with large basophilic granules

10% myelocytes

10% metamyelocytes

13% red blood cell precursors

2% megakaryocytes

4. Which of the following is most likely to be seen on chromosome analysis of the bone marrow cells? (Objective 6)
 - a. t(8;21)
 - b. t(15;17)
 - c. inv(16)
 - d. +8
5. Which of the following genes does the chromosome rearrangement identified in question 4 involve? (Objective 9)
 - a. *BCR/ABL1*
 - b. *MLL*
 - c. *CBFB/MYH11*
 - d. *TEL(ETV6)/AML1(RUNX1)*
6. What is the other AML with a recurrent cytogenetic aberration that involves the same transcription factor as identified in question 5? (Objective 9)
 - a. t(8;21)
 - b. inv(16)
 - c. t(15;17)
 - d. 11q23 aberration

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

7. Which of the following is the most likely diagnosis? (Objective 6)
 - a. alkylating agent-related AML
 - b. core-binding factor leukemia
 - c. AML with multilineage dysplasia
 - d. AML of ambiguous lineage
8. Which of the following genetic abnormalities is associated with a good prognosis when it is found in ALL? (Objective 7)
 - a. chromosome count >54
 - b. t(9;22)
 - c. t(4;11)
 - d. chromosome count <45
9. Which of the following is associated with a poor prognosis when found in ALL? (Objective 7)
 - a. chromosome count >54
 - b. t(12; 21)
 - c. normal karyotype
 - d. t(9;22)
10. Which of the following is associated with Burkitt lymphoma? (Objective 6)
 - a. t(8;21)
 - b. t(14;18)
 - c. t(12;21)
 - d. t(8;14)

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Gregory had leukocytosis and a shift to the left when initially seen. The differential diagnosis was important in order to determine whether this abnormal blood picture was due to a benign or neoplastic process. Cytogenetic studies revealed an acquired clonal aberration t(9;22) diagnostic of CML. Gregory had a bone marrow transplant with his sister's donated cells. Five years later, cytogenetic studies revealed a relapse and impending blast crisis.

Question:

1. What is the most appropriate specimen to submit for cytogenetic analysis, and how should it be processed?

Explanation:

The most appropriate specimen to submit for chromosome analysis of CML is a bone marrow sample. If the bone marrow is not aspirable, peripheral blood can be used but sometimes will not yield mitoses. The processing must be performed by direct harvest and/or unstimulated cultures.

Question:

2. Is this a constitutional or acquired aberration?

Explanation:

This is an acquired aberration that is present only in the hematopoietic cells—RBC precursors, WBC precursors, megakaryocytes, and some lymphocytes.

Question:

3. Is it a clonal aberration?

Explanation:

This is a clonal aberration because it is present in more than one cell (in this case, it was present in 100% of cells analyzed, which is typical for CML).

Question:

4. What is the significance of this finding for the diagnosis?

Explanation:

The finding of the t(9;22) confirms the diagnosis of CML.

Question:

5. What is the significance of this finding?

Explanation:

This finding confirms the engraftment of female donor cells in the recipient bone marrow. While no cells with the t(9;22) are found by cytogenetic methods, molecular studies may show the presence of the *BCR/ABL1* gene rearrangement because these techniques are more sensitive than routine cytogenetics.

Question:

6. What other studies could be performed that would be informative as to the status of the donor and recipient cells?

Explanation:

FISH analysis can be performed on the interphase nuclei using probes for the X and Y chromosome to demonstrate the sex of the cells present. In addition, probes for the t(9;22) can be used if male cells are present to determine whether they are leukemic cells. Molecular studies can also be obtained for the BCR gene rearrangement.

Question:

7. What is the significance of these findings?

Explanation:

The cytogenetic results performed at 5 years posttransplant show not only a relapse of the CML, but also a cytogenetic transformation indicative of pending blast crisis as evidenced by the +8 and i(17)(q10) that were not seen in the original leukemic cells.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

A newborn baby boy has multiple congenital malformations, and a chromosome abnormality is suspected as the cause. What is the most appropriate specimen to submit for chromosome analysis? How should the laboratory professional process the specimen?

Answer

The most appropriate specimen to determine the presence of a constitutional aberration is peripheral blood. The specimen should be processed by culture stimulated with phytohemagglutinin to stimulate mitosis of the circulating lymphocytes.

Checkpoint! 2

Cytogenetic studies were performed on a bone marrow specimen from a female patient with a myelodysplastic state with the following results:

one cell—47,XX,+8

one cell—45,XX,-20

five cells—46,XX,del(5)(q13q34),-7,+21

Which of these aberrations are clonal? What term would apply to the five cells?

Answer

The clonal aberrations are the del(5), -7, and +21. The +8 and -20 are seen in only one cell each and are therefore nonclonal. The five abnormal cells would be referred to as *pseudodiploid*.

Checkpoint! 3

A 35-year-old man has acute leukemia. Cytogenetic studies of the bone marrow reveal the following: 46,XY,t(15;17)(q22;q12). What type of leukemia does this patient have, and what will cytogenetic studies show after treatment if he achieves complete remission?

Answer

The t(15;17) is diagnostic for acute promyelocytic leukemia, APL-M3. If the patient achieved complete remission, cytogenetic analysis of bone marrow cells would show a normal male karyotype.

Checkpoint! 4

Five years ago a 46-year-old woman received chemotherapy and radiation treatment for breast cancer. She now has pancytopenia. Cytogenetic analysis of the bone marrow is performed and shows 10 of 20 cells with the following: 45,XX,del(5)(q13q34),-7. What is the significance of this finding?

Answer

These results show clonal acquired aberrations indicative of a neoplastic cell line. The del(5) and -7 are consistent with a secondary myelodysplastic state/acute leukemia.

Checkpoint! 5

A 5-year-old girl has fatigue and easy bruising. A CBC shows a leukocyte count of $40 \times 10^9/L$ with 85% blasts. Bone marrow cytogenetic studies are performed and show all cells with the following karyotype: 53,XX,+X,+4,+6,+10,+18,+20,+21. What is the prognostic significance of this finding?

Answer

This karyotype in a pediatric patient with acute lymphoblastic leukemia would correlate with a good prognosis.

Molecular Analysis of Hematologic Diseases

Margaret L. Gulley, M.D.

■ OBJECTIVES—LEVEL II

This chapter differs from others in that it has only Level II objectives because the material in this chapter is at the advanced level and requires a background in genetics. At the end of this unit, the student should be able to:

1. Define terms and appropriately use nomenclature associated with molecular pathology.
2. Describe the principles and summarize the procedures for each of the common laboratory tests used in molecular diagnostics.
3. Describe and explain the applications of molecular tests in diagnosing and managing inherited disease, infectious disease, and cancer.
4. Explain the role of genes in acquired versus inherited disorders.
5. Identify common chromosomal translocations and molecular genetic abnormalities associated with chronic myelogenous leukemia, acute leukemia, and lymphoma.
6. Explain how B and T cell malignancies can be differentiated from other conditions by molecular testing.
7. Select the most appropriate molecular test for a given patient condition or provisional diagnosis.
8. Compare and contrast the various molecular methods with regard to diagnostic applications, tissue requirements, and principles.
9. Compare the advantages and disadvantages of molecular tests with other laboratory tests used in diagnosing and managing hematologic disorders.

CHAPTER OUTLINE

 Southern blot analysis
 Transcription
 Translation
 Translocation

BACKGROUND BASICS

This chapter builds on concepts learned in other chapters of this textbook. The reader should also have a background of genetic principles. To maximize your learning experience, you should review the following material:

- ▶ Summarize the pathophysiology and etiology of sickle cell anemia.
- ▶ Describe the role of oncogenes in the etiology and pathophysiology of cancer
- ▶ Describe the application of cytogenetic analysis in diagnosing hematologic disease.
- ▶ Summarize the etiology and pathophysiology of leukemia and lymphoma.
- ▶ Describe the congenital aberrations that lead to hypercoagulability and venous thrombosis.

CASE STUDY

We will address this case study throughout the chapter.

Carolyn, a 35-year-old female, saw her physician for complaints of fatigue and a 20-pound weight loss in the last 6 months. A complete blood count revealed a white blood cell count of $6.5 \times 10^9/L$, hemoglobin of 8 g/dL and platelet count of $25 \times 10^9/L$. The leukocyte differential showed 71% blasts. The bone marrow revealed 96% blasts. The blasts were negative for myeloperoxidase, Sudan black B, and combined esterase by cytochemical stains. Cytogenetics revealed t(9;22) (which is characterized by the presence of the Philadelphia chromosome), +8, and +18. Consider the possible disease processes that may be occurring in this patient and laboratory tests that may be helpful in diagnosis and monitoring of her disease.

OVERVIEW

Over the past decade, major advances have been made in applying molecular technology to the practice of laboratory medicine. Nowhere have these applications had more impact than in the field of hematology in which new and improved methods are available to diagnose a wide variety of hematologic diseases. It appears that this revolutionary progress will continue in the coming years as technology advances and new discoveries are brought from the basic science level to their practical realization in clinical laboratories. This chapter introduces molecular analysis of hematologic disorders and describes the most commonly used molecular tests. The application of these tests in selected inherited and malignant hematologic disorders follows.

INTRODUCTION

Molecular diagnostics involves the analysis of deoxyribonucleic acid (DNA) or ribonucleic acid (RNA). DNA is the fundamental substance of heredity that cells use to catalog, express, and propagate information. RNA is the messenger molecule that translates the DNA code so that proteins can be produced. Analysis of DNA and RNA can assist in diagnosing inherited diseases, which by definition have a genetic basis; infectious diseases for which the identification of foreign nucleic acid signals the presence of a particular pathogen; and cancer, which occurs when acquired genetic defects lead to uncontrolled cell proliferation. Laboratory detection of disease-specific genetic alterations is becoming increasingly important for the diagnosis, prognosis, and prediction of response to therapy as well as the monitoring of affected patients.

To understand how DNA technology is implemented in diagnostic laboratories, the basic structure of human DNA first must be reviewed. Each nucleated cell of a person's body contains a complete set of DNA inherited from the person's parents and constituting the person's **genome**. DNA of the human genome is composed of 3 billion pairs of **nucleotides** (one of four building blocks of DNA: A, T, C, G) divided among 46 chromosomes and encoding about 30,000 different genes. Genes are the functional units of DNA that serve as templates for RNA **transcription** (synthesis of RNA from a DNA template) and ultimately protein **translation** (synthesis of protein from an RNA template). The sequence of nucleotides in each gene determines the structure of the encoded protein. In general, every person has two copies of every gene, one that was inherited from the mother and the other from the father. One person's genome differs from another person's by only about 0.2%, or about 1 in every 500 nucleotide pairs. Interestingly, the human genome differs from the chimpanzee genome by only about 1%. Some **gene** sequences are so critical to cell function that they are nearly the same across all species, including bacteria, yeast, and humans. In contrast, other parts

■ **FIGURE 1** The structure of DNA. DNA is a double-stranded molecule composed of sequences of nucleotides. One strand is bound by hydrogen bonds (shown as diagonal bridges) to its complementary strand. According to the rules of complementary base pairing, the nucleotide adenine (A) is complementary to thymine (T), and guanine (G) is complementary to cytosine (C).

of the genome are highly variable and are exploited in forensic tests to distinguish one person from another.¹ For example, genes of the human leukocyte antigen (HLA) complex are highly variable among populations; genes involved in cell division and in repair of damaged DNA are virtually identical from person to person.

DNA is composed of two complementary strands of nucleotides (Figure 1 ■). In living cells, these complementary strands are bound together by hydrogen bonds. In the laboratory, however, the two strands of DNA can be fully dissociated by simply heating to nearly boiling (95°C) or by placing the DNA in an alkaline solution (high pH). Once the strands are separated, a particular nucleotide sequence of interest can be identified using a DNA **probe**. A probe is a single-stranded segment of DNA whose nucleotide sequence is complementary to the target sequence. The probe binds to the target DNA in a process called **hybridization**. This probe hybridization process forms the basis for all of the laboratory tests that have been developed to analyze specific portions of the human genome (Figure 2 ■).

■ **FIGURE 2** The two strands of DNA can be dissociated *in vitro* by heating them to 95°C or by treating with a solution of high pH. Once separated, the strands can bind to a DNA probe of complementary nucleotide sequence by a process known as *hybridization*.

▶ LABORATORY METHODS IN MOLECULAR DIAGNOSTICS

Following are brief descriptions of the most commonly used laboratory tests. They are described in more detail with potential medical applications in the remainder of this chapter.

- **Southern blot analysis** DNA is isolated, cleaved with restriction endonucleases that cut DNA at specific nucleotide sequences, separated by size using gel electrophoresis, transferred to a membrane, and detected with a probe that is complementary to the sequence of interest.
- **Polymerase chain reaction (PCR)** DNA is isolated, and a specific segment of the DNA is copied a billionfold so that it can be more easily detected and, in some cases, further analyzed for structural defects.
- **In situ hybridization (ISH)** DNA or RNA in tissue sections on glass slides is hybridized to a complementary probe and visualized by microscopy. The tissue architecture and cytology are preserved to permit localization of the DNA or RNA to particular cells in the tissue.
- **Fluorescence in situ hybridization (FISH)** Whole chromosomes (metaphase or interphase) are hybridized to a complementary probe labeled with a fluorochrome and visualized by microscopy.
- **DNA sequencing** The nucleotide sequence is determined in a segment of DNA by replicating the DNA strands and monitoring the order in which labeled nucleotides are added to the new strands. DNA sequencing is particularly useful for detecting point mutations located anywhere in the DNA segment.

See Table 1 📄 for the specimen requirements for these procedures.

Specimen Requirements for Molecular Diagnostic Procedures

Procedure	Typical Specimen
Southern blot analysis	Fresh or frozen tissue, fresh body fluid or frozen cell pellet, blood, or marrow
Polymerase chain reaction (PCR)	Fresh, frozen, or paraffin-embedded tissue, blood, or body fluid
In situ hybridization	Paraffin-embedded tissue section
Fluorescence in situ hybridization (FISH)	Fresh cells for metaphase analysis, fixed cells, or tissue sections for interphase analysis
DNA sequencing	Fresh, frozen, or paraffin-embedded tissue, blood, or body fluid

▶ INHERITED DISEASES

In the past few years, molecular biologists have identified specific genetic defects underlying various inherited diseases.² By analyzing the DNA from the relevant gene **locus** (specific location on a chromosome), we can now help diagnose a wide variety of diseases.³ See Table 2★ for some of the inherited hematologic diseases for which specific genetic defects have been identified.

The genetic defect responsible for inherited diseases is present in every nucleated cell of a person's body, even if gene expression or clinical manifestation is restricted to only one organ or one stage of development. Because the defect is present in all cells, it can be identified in specimens that are easily collected such as blood or buccal (inside cheek) swabs. Furthermore, the defect can be identified prior to the onset of clinical disease. For example, hemoglobinopathies involving the *HBB* (β -globin) gene can be identified in a fetus even though the *HBB* gene product is not yet expressed nor is there any clinical evidence of disease.⁴

★ TABLE 2

Inherited or Congenital Hematologic Disorders Amenable to Molecular Genetic Analysis

- Chronic granulomatous disease
- Gaucher disease
- Hereditary hemochromatosis
- Hemoglobinopathies, including sickle cell anemia and thalassemia
- Hemolytic anemias, such as glucose-6-phosphate dehydrogenase deficiency
- Bleeding and thrombotic disorders, including hemophilia
- Immunodeficiencies including adenosine deaminase deficiency, Wiskott-Aldrich syndrome, and X-linked lymphoproliferative disorder
- Myeloperoxidase deficiency
- Porphyrrias
- Red cell membrane defects including hereditary spherocytosis

Using correct gene nomenclature in clinical laboratories is important.⁵ Note that each human gene has an official name and symbol that can be confirmed on the website www.genenames.org. Gene symbols are displayed in italics, but the corresponding protein symbol is not. The next section describes the application of molecular analysis in two common inherited hematologic diseases, sickle cell anemia and venous thrombosis.

SICKLE CELL ANEMIA

Sickle cell anemia is an autosomal recessive disease that affects 1 in 260 African Americans and almost always shortens their lifespan. The biologic basis of sickle cell anemia is a defect in the *HBB* (β -globin) protein of hemoglobin. At the DNA level, the defect involves the substitution of a single nucleotide (thymine instead of adenine at the 20th nucleotide in the *HBB* gene), which translates to an amino acid sequence containing valine instead of glutamic acid in the seventh position of the β -globin protein. (*Note:* Because of confusion about numbering, older literature refers to the change as being in the sixth position, but it is actually in the seventh position of the amino acid chain.) That small change in both copies of the *HBB* gene results in a dramatic alteration of hemoglobin molecules so that they tend to polymerize under conditions of dehydration or low oxygen concentration. Hemoglobin polymerization diminishes erythrocyte deformability, thus impairing blood flow through small capillaries. Affected individuals suffer from chronic anemia and recurrent pain as a consequence of small-vessel occlusion and poor oxygen delivery to the tissues.

Laboratory diagnosis of sickle cell anemia traditionally has relied on examination of the blood smear combined with the HbS solubility test and hemoglobin electrophoresis. When these procedures are inconclusive or when prenatal diagnosis is requested, DNA technology is a useful means of identifying or excluding the genetic defect.

Southern Blot Analysis of the Sickle Mutation

To detect the sickle **mutation** by Southern blot analysis, DNA is first extracted from patient blood by (1) detergent solubilization of lipids in cell membranes, (2) protease digestion of proteins, and (3) purification of DNA from the remaining material. The purified DNA is then cleaved with a **restriction endonuclease** that reproducibly cuts the long strands of chromosomal DNA at a specific nucleotide sequence to produce smaller fragments of DNA. These fragments are size fractionated by gel electrophoresis and transferred to a nylon membrane where they are hybridized to a labeled probe targeting the gene of interest, in this case, *HBB*. The pattern of probe hybridization determines whether the sickle mutation is present or absent (Figure 3■).

The Southern blot assay can be adapted to detect many other disease-associated alterations besides the sickle mutation. Indeed, if a patient's DNA sequence is altered by any mutation, translocation, or small deletion, the number

■ **FIGURE 3** Southern blot analysis of the sickle cell mutation is accomplished by first extracting DNA and then cutting it with MstII restriction endonuclease that cleaves DNA at a specific nucleotide sequence (arrows). Because that specific sequence is present many times in the human genome, MstII cuts genomic DNA into many small fragments. The resultant DNA fragments are separated by size using gel electrophoresis, dissociated into single strands by soaking in an alkaline solution, and then transferred to a nylon membrane by a blotting procedure. To identify the fragment containing the *HBB* gene, the membrane is soaked in a radiolabeled DNA probe (bar) that hybridizes to a complementary segment of the *HBB* gene. The pattern of bands recognized by the probe reflects the size of the corresponding restriction fragments measured in kilobases (kb). An *HBB* gene harboring the sickle mutation (shown as a pink circle) fails to cut with MstII, thus altering the band pattern. In this way, a person affected by sickle cell anemia can be distinguished from a carrier (sickle trait) and from a person of normal genotype. *Note:* Restriction endonucleases are naturally occurring enzymes that recognize and cleave specific nucleotide sequences in DNA. Each restriction endonuclease is named for the bacteria from which it was purified. For example, EcoRI is derived from *Escherichia coli* and cleaves DNA having the sequence 5'-GAATTC-3', whereas HindIII, derived from *Haemophilus influenzae*, cleaves at 5'-AAGCTT-3'. In the example shown here, MstII cleaves the normal DNA when it recognizes the sequence 5'-CCTGAGG-3', but it cannot cleave DNA harboring the sickle mutation 5'-CCTGTGG-3'.

and/or size of the resulting restriction fragments will be altered accordingly. The restriction fragment(s) containing the gene of interest is identified by probe hybridization. The probe must be labeled to permit its subsequent detection on the Southern blot. A typical probe is labeled with radionucleotides, permitting its detection by autoradiography. Alternatively, the probe can be labeled with biotin or digoxigenin and detected using colorimetric procedures analogous to what is done in immunoassays of antigen-antibody complexes. Southern blot analysis is a very powerful technology but is also quite labor intensive, so it is used primarily as a backup method in modern molecular laboratories.

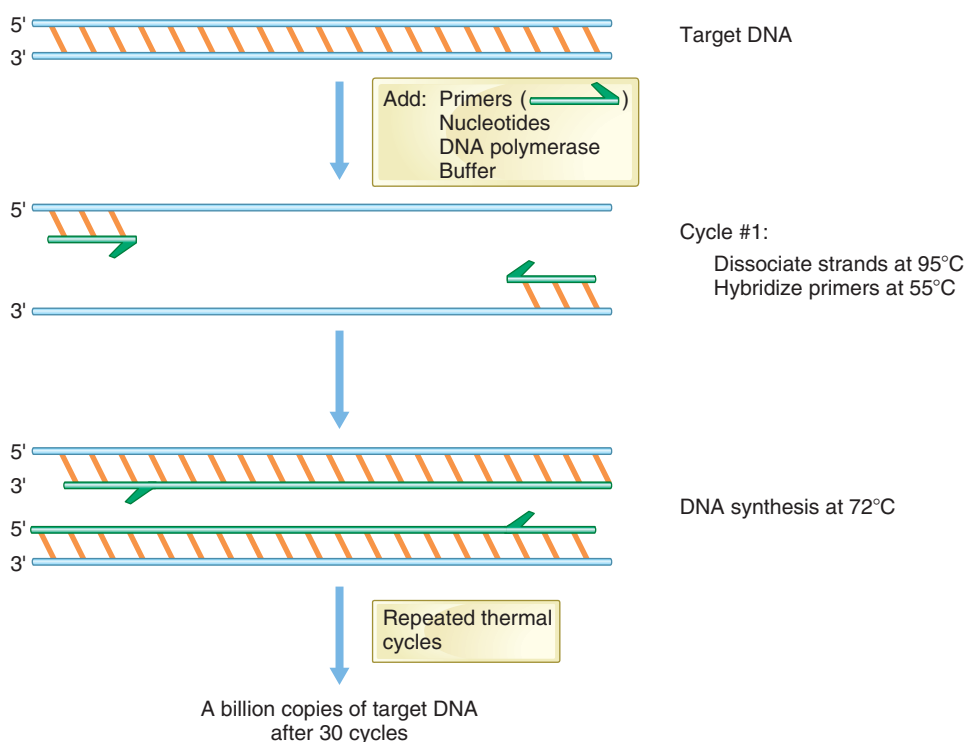

Detection of the Sickle Mutation by DNA Amplification Methods such as the Polymerase Chain Reaction

A more common method of detecting the sickle mutation is by DNA amplification, a procedure in which a particular segment of DNA is copied a billionfold. DNA amplification techniques have revolutionized our ability to analyze DNA in the clinical laboratory because we can now examine a rare segment of DNA from a small tissue specimen or even a sin-

gle cell. Several amplification methods have been introduced, but the first and most commonly used method is PCR, which works by enzymatically replicating one particular segment of DNA (typically about 100 nucleotides in length) from among the entire 3 billion base-pair human genome. This process permits rapid, sensitive, and specific identification of a segment of DNA that can then be further tested for a disease-specific genetic defect (Figure 4 ■).

Diagnosis of the sickle cell **genotype** can be accomplished by PCR amplification of a segment of the *HBB* gene harboring the sickle mutation site. The amplified DNA is then cleaved with the MstII restriction endonuclease and electrophoresed in an agarose gel. Because MstII differentially cleaves normal DNA compared with sickle DNA, a different electrophoretic band pattern is produced depending on whether the sickle mutation is present or not.

Using an alternate amplification strategy called *allele-specific PCR*, short DNA probes that serve as PCR primers have been designed to preferentially amplify either the normal *HBB* sequence or the defective sickle *HBB* sequence (Figure 5 ■). This preferential amplification is based on the premise that mutations interfering with primer hybridization result

■ **FIGURE 4** Polymerase chain reaction is a method of enzymatically amplifying a particular segment of DNA through a process of repeated cycles of heating, cooling, and DNA synthesis. First, patient DNA is mixed with the chemicals needed for DNA synthesis. Included are two short DNA probes (called *primers*, shown as half arrows) designed to flank the particular segment of DNA that needs to be amplified. A thermocycler instrument is programmed to sequentially heat and cool the sample. In cycle 1, the sample is heated to 95°C to dissociate complementary strands of DNA and then is cooled to 55°C to permit binding of the short DNA probes that serve as primers for subsequent enzymatic DNA replication at 72°C. This replication generates new complementary strands to produce an exact copy of the original target DNA. In subsequent cycles, the products of previous cycles can serve as templates for DNA replication, allowing an exponential accumulation of DNA copies. After 30 cycles, which takes only several hours, approximately 1 billion copies of the target DNA have been generated.

in failed amplification reactions. The success or failure of the amplification reaction can be determined while the reaction is occurring by using a strategy called **real-time PCR**, which can be performed in a few hours.

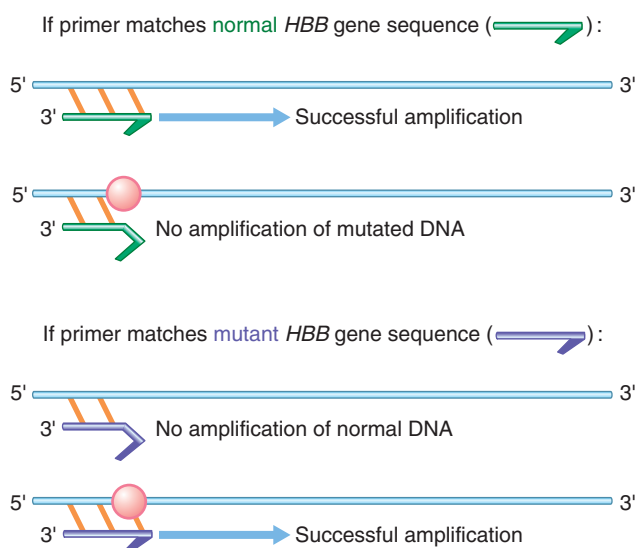

A major advantage of PCR over Southern blot analysis is that PCR can be performed on much smaller specimen volumes because the assay is designed to identify rare target sequences. PCR is also a more rapid laboratory procedure (1–2 days as compared with >4 days for Southern blot analysis), costs relatively less, and is amenable for use on formalin-fixed paraffin-embedded tissues. However, a drawback to PCR is the meticulous attention required to prevent carry-over or contamination of laboratory samples by extraneous DNA. To prevent carryover, three separate rooms can be required: one for reagent preparation, one for preamplification steps, and one for postamplification steps.

The sickle cell genotype is relatively easy to diagnose because the specific genetic mutation is identical among all af-

fected individuals. Not all inherited diseases are so straightforward—complex and diverse genetic defects can result in the same clinical syndrome. For example, only about half of all patients with hemophilia A have an identifiable mutation or deletion of the *F8* gene that encodes F8 (also called *FVIII*) protein while the remaining patients presumably have any of several occult genetic defects that somehow inhibit expression of the F8 protein.

INHERITED PREDISPOSITION TO VENOUS THROMBOSIS

Several inherited mutations predispose to venous thrombosis. The most common is a point mutation at position 1601 in the *F5* gene (also called *FV_{Leiden}*) that interferes with catabolism of the encoded coagulation factor. This mutation is quite common, affecting about 5% of the population; those who inherit it have a sevenfold increased risk of developing

■ **FIGURE 5** One way that polymerase chain reaction can be used to facilitate detection of the sickle mutation is to design primers (half arrows) that preferentially bind to either normal *HBB* or sickle *HBB* gene sequences. If a primer does not match its target sequence perfectly, particularly at the 5' end of the primer where the DNA polymerase initiates replication, amplification cannot occur. On the other hand, if the primer matches its target, abundant PCR products are generated. If both the normal and mutant primers generate a product, the patient is heterozygous, or a carrier of the sickle trait. (Pink circle represents the *HBB* gene mutation)

thrombosis. The second most common genetic risk factor for venous thrombosis is a point mutation at position 21538 in the *F2* gene encoding prothrombin protein (FII). (Note: Older literature referred to this mutation as being at position 20210 and is commonly called *Prothrombin G20210A*. However, the correct standard nomenclature for this mutation is *F2 AF478696.1:g21538G>A*).⁵ This mutation is found in about 2% of the population and is associated with a three-fold increased risk of venous thrombosis. The *F5* and *F2* gene mutations are readily detectable by real-time PCR followed by melt curve analysis^{6,7} (Figure 6 ■).

✓ Checkpoint! 1

A 40-year-old male is diagnosed with an inherited disease for which a specific point mutation is responsible. His mother died of a similar disease 10 years ago. For purposes of family counseling, the physician wants to know whether she had the same mutation. The histology laboratory has archival paraffin-embedded tissue from the mother. What laboratory method(s) is (are) best for detecting the gene mutation?

► MOLECULAR BASIS OF CANCER

DNA technology is a powerful tool to assist in the diagnosis of cancer.⁸ Unlike inherited disease in which every nucleated cell in the body contains defective DNA, cancer results when

one cell acquires genetic defects that stimulate uncontrolled cell division and tumor formation. Virtually all cancers are thought to harbor genetic defects. The specific genes that are altered in tumors and are thereby responsible for tumor formation are called *oncogenes*. The unaltered counterpart of an oncogene (called a *proto-oncogene*) generally functions to regulate cell growth or differentiation whereas in tumor cells, this function has gone awry as a result of abnormal expression or structural alteration of the gene.

Each time a malignant cell divides, the genetic defect is passed on to its progeny. Therefore, all of the cells within a particular tumor contain the same defective DNA, a concept known as *clonality*. Because cancers harbor clonal genetic defects, cancer cells can be distinguished from normal cells by DNA probe analysis of the defective gene sequences. Certain oncogene defects are highly characteristic of particular types of cancer and can be used to assist in diagnosing and classifying those cancers. This section describes the application of molecular analysis in diagnosing and managing selected leukemias and lymphomas.

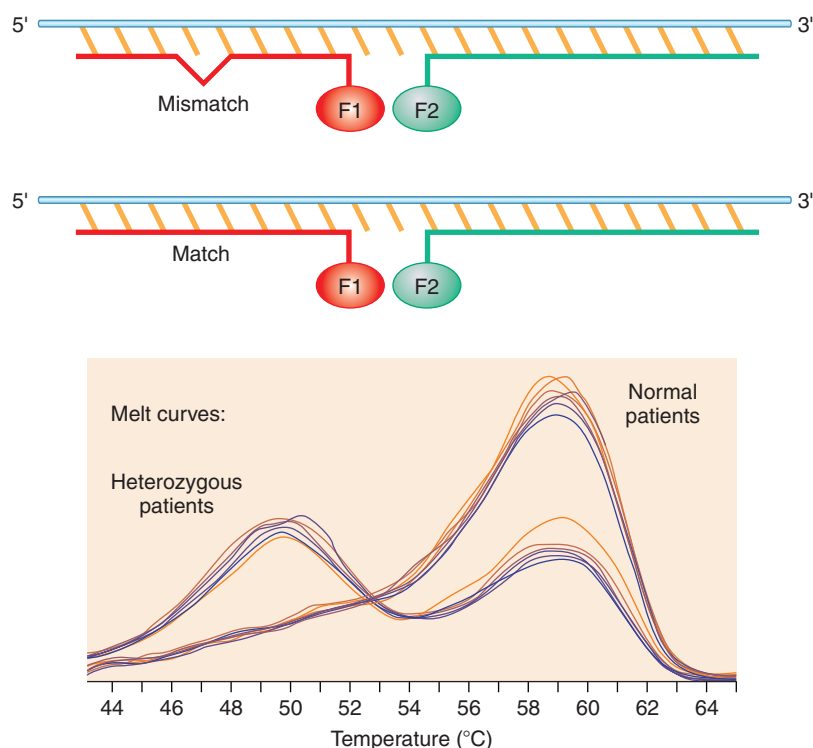

CHRONIC MYELOGENOUS LEUKEMIA AND THE *BCR/ABL1* TRANSLOCATION

Traditional cytogenetics demonstrates that hematopoietic neoplasms frequently harbor a characteristic chromosomal **translocation**, as exemplified by the t(9;22) of chronic myelogenous leukemia (CML). A translocation is caused by the breakage of DNA from one chromosome and its attachment to (and exchange with) DNA on another locus.

In CML, the characteristic Philadelphia chromosome represents a shortened chromosome 22 resulting from a reciprocal translocation between the *ABL1* gene on chromosome 9 and the *BCR* gene on chromosome 22. This translocation produces a new fusion gene called *BCR/ABL1* that encodes hybrid RNA and hybrid protein. The presence of *BCR* gene elements enhances the potency of the *ABL1* gene product (that functions as a tyrosine kinase enzyme), resulting in uncontrolled cell proliferation.

About 90% of all patients who have clinical and laboratory features of CML have t(9;22) by karyotyping. An additional 5% have an occult (cryptic) translocation that is detectable only by molecular analysis of *BCR/ABL1*. The remaining 5% of tumors suspected of being CML but lacking *BCR/ABL1* do not behave in the same fashion as CML, and these tumors represent other myeloproliferative diseases or myelodysplastic syndromes masquerading as CML. In contrast, those patients with molecular evidence of *BCR/ABL1* share a similar natural history and predisposition to blast crisis. In blast crisis, the transformed acute leukemia cell clone retains the *BCR/ABL1* defect; these cells also have acquired even more genetic defects that account for their more aggressive cytologic appearance and clinical behavior.

While DNA technology is more sensitive than karyotyping for detecting the CML-associated genetic defect, karyotyping has the advantage of revealing other chromosomal

■ **FIGURE 6** Melt curve analysis is a way to determine whether a particular mutation is present by evaluating the temperature at which a labeled probe (shown in red) melts away from its target DNA. To accomplish this, a mixture of probe and target DNA is gradually heated until the probe melts away. Melting occurs at a low temperature if there is a mismatch but at a high temperature if there is a perfect match between the probe and target sequence. The temperature at which dissociation occurs is detected in a real-time PCR instrument that analyzes the interaction between a fluorochrome linked to the probe (shown in red) and another fluorochrome (shown in green) on an adjacent probe. Proximity of the red and green fluorochromes generates a yellowish signal when both probes are bound to the target whereas the red and green fluorochromes floating apart indicates melting has occurred. The above graph depicts melt curves for a series of 20 patients who were tested for the *F2* mutation; those with two normal *F2* genes have a single melt peak at 60°C. In contrast, those patients having one mutant copy and one normal copy of the *F2* gene have two melt peaks, one at 50°C and the other at 60°C, indicating they are heterozygous for the mutation and at increased risk for venous thrombosis.

abnormalities in addition to t(9;22). Therefore, a cost-effective approach to the laboratory workup of suspected CML is first to perform a karyotype and proceed to molecular testing only if the karyotype is nondiagnostic. A white cell pellet can be frozen or stored in Carnoy's fixative in case molecular testing is needed at a later time.

CASE STUDY (continued from earlier in this chapter)

1. What is the classification of this neoplastic hematologic disorder based on the peripheral blood and bone marrow results?

Minimal residual disease (MRD) refers to the post-treatment presence of tumor cells that are not detectable by routine morphologic methods but that result in relapse if they are not eliminated. Amplification strategies such as PCR are exquisitely sensitive for detecting minimal residual disease because abnormal cells are detectable down to 0.01% (1 cell in 100,000 cells) whereas karyotype and FISH typically detect tumor cells at about 1% (1 cell in 100 cells). Another advantage of molecular technology over karyotyping is the capability to analyze cells that are resistant to entering the cell cycle and are therefore difficult to evaluate by traditional cytogenetic methods. For example, neutrophils are fully amenable to DNA analysis, but they

are not amenable to karyotyping because they are not capable of dividing.

Molecular Analysis of the *BCR/ABL1* Junction by DNA Amplification

To amplify the *BCR/ABL1* translocation, one typically uses a variant of PCR called *reverse transcriptase PCR* (rtPCR). In this procedure, RNA is extracted from tissues and then converted to **complementary DNA (cDNA)** using an enzyme called *reverse transcriptase*. (The cDNA represents only the exons of the gene because the introns have been removed naturally during the formation of RNA.) The cDNA is then subjected to PCR amplification using primers flanking the transloca-

tion break point, and the product is detected by quantitative real-time PCR (Figure 7 ■).⁹ This strategy permits an accurate assessment of the amount of *BCR/ABL1* in the patient sample, thus allowing tumor burden to be measured at multiple time points following initiation of treatment.¹⁰ Current treatment regimens typically begin with Gleevec (imatinib mesylate) or similar agents that specifically inhibit the ABL1 tyrosine kinase enzyme activity. Failure to respond to the drug (e.g., increasing tumor levels) could indicate that a mutation-conferring drug resistance has occurred, and such mutations can be characterized by DNA sequencing of the *BCR/ABL1* fusion gene to help predict which drug is most likely to be effective.¹¹

■ **FIGURE 7** The rtPCR procedure is a means of determining whether a particular RNA transcript is present in a tissue sample. RNA is extracted from the sample and then converted to complementary DNA (cDNA) using the enzyme reverse transcriptase. This cDNA serves as a template for DNA amplification by the polymerase chain reaction. After 30 cycles, about 1 billion copies of the target cDNA sequence have been generated. These abundant copies can then be readily detected or further analyzed to provide valuable information about the RNA in the patient sample.

A unique benefit of rtPCR is the ability to distinguish *BCR/ABL1* break points that are characteristic of CML (called *p210*) from *BCR/ABL1* break points of de novo acute lymphoblastic leukemia (called *p190*).¹² Although these alternate break points appear identical by karyotyping, they are distinct at the molecular level and from a clinical standpoint. They help separate patients with a new diagnosis of acute leukemia from those presenting in blast crisis of CML. Furthermore, detection of *BCR/ABL1 p190* identifies a subset of acute lymphoblastic leukemia patients who are poorly responsive to standard chemotherapy regimens and should be considered for novel or more aggressive therapy.¹³

Another method of detecting the *BCR/ABL1* translocation is by FISH (∞ Chapter 38 for details) using probes targeting the *BCR* and *ABL1* genes.

✓ Checkpoint! 2

A patient with CML was treated with chemotherapy. On subsequent marrow samples, the physician ordered molecular testing to detect residual disease after treatment. The *BCR/ABL1* translocation was not detected 3 months after treatment but was detected at the 6th and 7th months after treatment. Interpret this result.

ACUTE PROMYELOCYTIC LEUKEMIA AND THE *PML/RARA* TRANSLOCATION

Refer to Table 3 **★** for the characteristic chromosomal defects of myeloid leukemias. One of the most interesting of these cancers is acute promyelocytic leukemia in which t(15;17) juxtaposes the *PML* gene on chromosome 15 with the retinoic acid receptor alpha (*RARA*) gene on chromosome 17. Amazingly, leukemias harboring this genetic defect respond to treatment with retinoic acid derivatives, providing one of the first examples of cancer therapy specifically targeting a gene product thought to be involved in tumorigenesis. Retinoic acid therapy alone unfortunately is insufficient for a cure because the tumor cells eventually become resistant to

■ FIGURE 8 Tumor burden in acute promyelocytic leukemia patients can be measured using real-time PCR targeting *PML/RARA* transcripts. The higher the tumor burden, the more fusion transcripts are present, so the more template cDNA is present and the earlier the products appear during PCR amplification cycles.

its effects. Nevertheless, retinoic acid used in combination with other chemotherapeutic agents appears to improve outcomes in affected patients.¹⁴

Karyotyping and molecular tests (rtPCR or FISH) are used to detect the characteristic *PML/RARA* translocation.¹⁴ These molecular tests assist in diagnosing and classifying acute leukemia and predict response to retinoic acid therapy. The most sensitive test for monitoring levels of residual tumor burden after therapy is rtPCR, and its results appear to predict which patients will relapse.¹⁵ The rtPCR test converts RNA that has been purified from the patient’s blood or marrow to cDNA and uses primers flanking the break point between the *PML* and *RARA* genes to specifically amplify the translocation region. Amplified products can be measured using a real-time PCR instrument (Figure 8 **■**).

★ TABLE 3

Chromosomal Abnormalities in Selected Subtypes of Myeloid Leukemia

Leukemia	Karyotype	Genes	Clinical Significance
CML	t(9;22)	<i>BCR/ABL1</i>	Predisposed to blast crisis, Gleevec responsive
CMML	t(5;12)	<i>PDGFRB/ETV6</i>	Gleevec responsive
CEL	t(5;12)	<i>FIP1L1/PDGFRB</i>	Gleevec responsive
AML	t(8;21)	<i>RUNX1/RUNX1T1</i>	Good response to chemotherapy
APL	t(15;17)	<i>PML/RARA</i>	Responds to retinoic acid therapy
AML	inv(16)	<i>MYH11/CBFB</i>	Good response to chemotherapy
AML	11q23 defects	<i>MLL</i>	Poor response to chemotherapy

CML = chronic myelogenous leukemia; CMML = chronic myelomonocytic leukemia; CEL = chronic eosinophilic leukemia; t = translocation; APL = acute promyelocytic leukemia; inv = inversion; AML = acute myelogenous leukemia

Theoretically, the patient's DNA (rather than RNA) could be used to detect *PML/RARA* by PCR, but the translocation break points vary widely from patient to patient, so multiple primer sets would be needed to detect all possible translocations. In contrast, RNA encoded from the fusion gene is remarkably homogeneous and therefore more amenable for analysis using rtPCR. Keep in mind that RNA is much less stable than DNA and must be handled carefully to avoid degradation.

CASE STUDY (continued from earlier in this chapter)

2. What molecular defect is consistent with the presence of the Philadelphia chromosome?
3. Would molecular analysis assist in diagnosis? Explain.
4. If molecular analysis is required, which laboratory procedure should be used, and what specimen should be obtained?

ONCOGENE TRANSLOCATIONS IN LYMPHOID LEUKEMIAS AND LYMPHOMAS

Lymphomas and lymphoid leukemias commonly contain chromosomal translocations involving the antigen receptor genes, namely the immunoglobulin (Ig) genes expressed by B cells and the T cell receptor (TR) genes expressed by T cells. Translocations involving these genes are thought to represent errors occurring during physiologic gene rearrangement (to be described in the next section). Any gene located at or near the reciprocal translocation break point is a putative oncogene whose expression can be dysregulated by juxtaposition of the antigen receptor gene.

See Table 4 for the translocations most characteristic of lymphoid neoplasms. In most of these tumors, either Ig or TR genes are juxtaposed with genes that function in regulating cell growth. For example, the *MYC* oncogene of Burkitt lymphoma and the putative *BCL1* oncogene of mantle cell lymphoma encode proteins that promote cell division.¹⁶ In follicular lymphoma, the protein product of the *BCL2* oncogene inhibits cell death. Overexpression of these oncogenes appears to be responsible, at least in part, for the development of lymphoid tumors.

Clonal genetic defects often can be detected by karyotype, Southern blot analysis of the affected oncogene, or PCR amplification of the translocation break point. These types of assays in conjunction with traditional morphologic examination and other laboratory studies are helpful for diagnosing and classifying tumors. Karyotyping and Southern blot analysis are too insensitive to detect minimal residual disease (they detect tumors comprising only 1% or more of a specimen), but PCR assays detect much lower tumor burden and can help predict which patients are likely to relapse following treatment for follicular lymphoma.¹⁷

In theory, the best treatment for a tumor is to eliminate the genetic defect(s) responsible for its uncontrolled growth.

TABLE 4

Chromosomal Abnormalities Characterizing Lymphoma and Lymphoid Leukemia

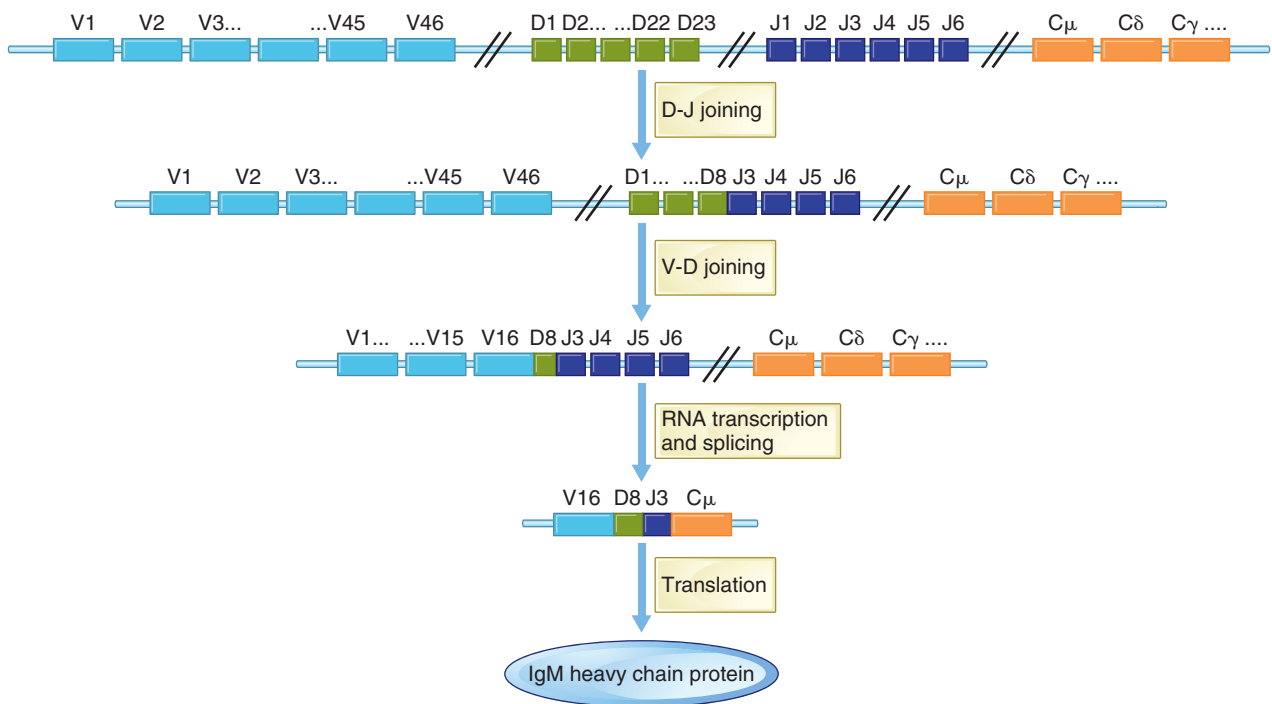

Lymphoid Neoplasm	Karyotype	Genes*
B cell lymphomas		
Burkitt	t(8;14, 2 or 22)	<i>MYC/IGH, IGK, or IGL</i>
Mantle cell	t(11;14)	<i>BCL1/IGH</i>
Follicular	t(14;18)	<i>IGH/BCL2</i>
Diffuse large cell	t(3;14)	<i>BCL6/IGH</i>
MALT	t(11;18)	<i>BIRC3/MALT1</i>
B cell leukemias		
Pre-B ALL	t(9;22)	<i>BCR/ABL1</i>
Pre-B ALL	t(1;19)	<i>PBX1/TCF3</i>
Pre-B ALL	t(12;21)	<i>ETV6/RUNX1</i>
Mixed lineage acute	t(various;11)	Various partner genes/ <i>MLL</i>
T cell leukemias/ lymphomas		
T-ALL	Deletion 1p	<i>STIL/TAL1</i>
Anaplastic large cell	t(2;5)	<i>ALK/NPM1</i>

*The order of the genes corresponds to the order of the karyotype except for *BCR/ABL1*. ALL = acute lymphoblastic leukemia; MALT = mucosa-associated lymphoid tissue

However, we have not yet succeeded in finding a way to correct the genetic defect that is present in every one of the trillion or so tumor cells that are typically present in a patient's body at the time of diagnosis. Alternatively, if we understood the consequences of a particular genetic defect, it might be possible to wisely intervene in the affected biochemical pathways to thwart tumor growth or trigger tumor cell death. Such has been the case with *BCR/ABL1* and *PML/RARA* inhibitors as described, but progress has been slower in identifying analogous targeted therapies for lymphoid malignancy. As further progress is made in tailoring therapy to specific genetic defects, demands on clinical laboratories to identify these defects in patient samples will increase.

IMMUNOGLOBULIN AND T CELL RECEPTOR GENE REARRANGEMENT

In addition to any translocation that a lymphoid neoplasm may have, B cell tumors have a marker of clonality in their rearranged Ig genes that code for antibody specificity (Figure 9). After all, B cell leukemia or lymphoma arises from a single transformed B cell harboring a particular Ig gene rearrangement that is inherited by all tumor cell progeny, resulting in a monoclonal cell population. Therefore, clonal gene rearrangement serves as a marker to distinguish tumor cells from normal cells.¹⁸ Southern blot analysis can evaluate

■ **FIGURE 9** During B cell differentiation, the immunoglobulin heavy chain gene rearranges to produce a unique coding sequence that determines antibody specificity. This occurs through a process of splicing and deletion whereby 1 of 23 diversity (D) regions is juxtaposed with 1 of 6 joining (J) regions and then with 1 of 46 variable (V) regions. Finally, constant (C) region splicing determines antibody isotype (IgM, IgD, IgG, IgA, or IgE). In the example here, V, D, J, and C_{μ} segments are sequentially spliced together to generate a nucleic acid sequence that encodes IgM heavy chain proteins. These heavy chain proteins complex with kappa or lambda light chain proteins (that are also encoded by rearranged genes) to produce a functional antibody molecule. Each developing B cell has different Ig gene rearrangements, so a population of normal B cells is characterized by polyclonal Ig genes. The diversity of these genes and their encoded antibodies permits immune recognition of many different antigens.

gene rearrangement using a probe targeting the *IGH* gene. *IGH* gene rearrangement also serves as a marker of commitment to the B cell lineage. Information on clonality and lineage is helpful in distinguishing a B cell neoplasm from benign lymphoid hyperplasia.

Analogous to the process by which B cells rearrange their Ig genes, T cells rearrange their TCR genes to encode a unique antigen receptor expressed on the surface of T lymphocytes. TCR gene rearrangement by Southern blot analysis can serve as a clonal marker for T cell tumors analogous to the description for B cell tumors. In the case of T cells, four different TCR genes (called *TRA*, *TRB*, *TRD*, and *TRG*) are capable of rearranging. Any particular T cell tumor can exhibit rearrangements of one, two, three, or all four of these TCR genes. In clinical laboratories, assays targeting the *TRB* or *TRG* genes are most commonly used to distinguish monoclonal T cell neoplasms from polyclonal reactive processes.¹⁹

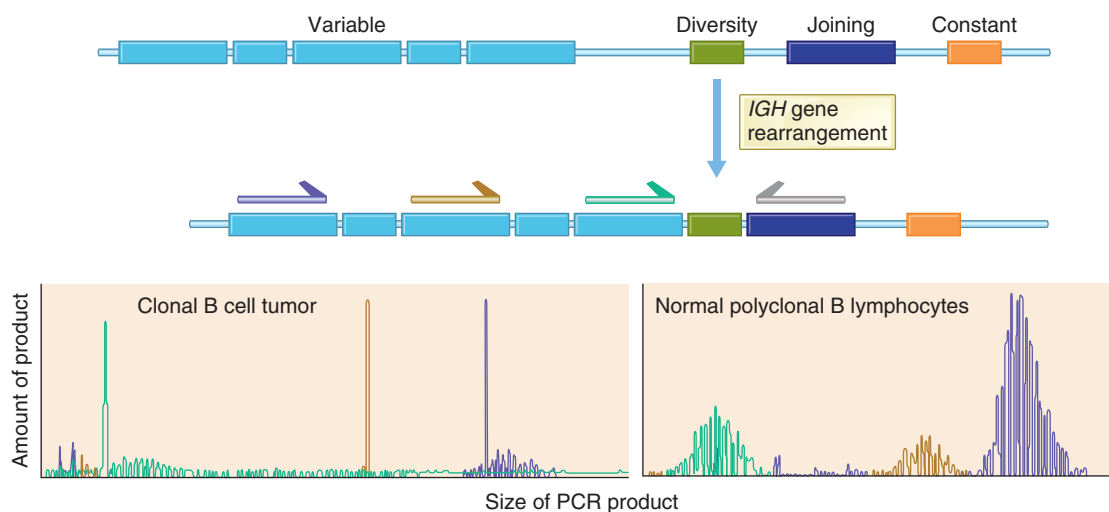

In recent years, PCR has been implemented as an alternate method of detecting clonal gene rearrangement^{18,20} (Figure 10■). Current protocols successfully identify clonal *IGH* gene rearrangement in about 95% of B cell neoplasms.²¹

Although this is less productive than Southern blot assays (which detect virtually 100% of B cell neoplasms), amplification techniques are popular laboratory tools because they are fast, inexpensive, applicable to paraffin-embedded tissue and require a small amount of tissue. Furthermore, the particular rearranged sequence that characterizes each lymphoid tumor can be exploited as a tumor-specific marker to assist in monitoring response to therapy.²² As with all clinical laboratory tests, appropriate quality control and proficiency testing are essential.

Clinical Utility of Gene Rearrangement Testing

The most valuable contribution of gene rearrangement testing is in distinguishing benign from malignant lymphoproliferations. In general, a malignant lymphoid tumor exhibits clonal antigen receptor **gene rearrangement** while a benign, reactive lymphoid hyperplasia does not.

The converse principle is not always true as exemplified by a few hematopoietic disorders for which clonality does not necessarily imply malignancy. These include large granular lymphocytosis and lymphomatoid papulosis, either of which can harbor clonal gene rearrangement even though they

■ **FIGURE 10** Rearrangement of the immunoglobulin heavy chain (*IGH*) gene involves random splicing of V, D, and J segments to produce a unique coding sequence. This process brings the V and J segments so close together that it becomes possible to PCR-amplify across the rearranged gene by using several primers (shown as half arrows) targeting various V and J segments. In a B cell tumor, all tumor cells contain exactly the same *IGH* rearrangement that was present in the original transformed B cell from which the tumor arose. This tumor-related clonal rearrangement is identified by capillary gel electrophoresis as a spike (representing a single-size PCR product with each primer set). In contrast, benign tissue has normal B lymphocytes whose polyclonal rearrangements appear as multiple different-size PCR products.

often regress without therapy. Because clonality is not always synonymous with malignancy, DNA probe results must be interpreted in the context of clinical information and in correlation with morphologic examination of the tissue to obtain accurate diagnostic and prognostic information.

Although Ig or TCR gene rearrangement can be used to help assign B or T cell lineage to a lymphoid neoplasm, immunophenotypic methods (such as flow cytometry or immunohistochemistry) are more reliable than gene rearrangement tests for assigning the lineage of a hematopoietic neoplasm. Indeed, whenever morphologically equivocal hematopathology specimens are being worked up, immunophenotyping is generally the first-line ancillary laboratory test with gene probe studies reserved as a secondary option.

✓ Checkpoint! 3

An enlarged lymph node was biopsied and sent to the laboratory for molecular analysis. Lymphoma was suspected. What molecular test(s) could be done on the specimen to determine whether the lesion is likely to be malignant?

► INFECTIOUS DISEASES

Molecular technology has provided new tools for detecting microorganisms based on the unique genetic code of each species.²³ DNA amplification strategies are most useful be-

cause they are sensitive, specific, and rapid for detecting pathogen-specific nucleic acid sequences. Quantitative real-time PCR assays are useful for monitoring the level of organisms during treatment.

Molecular tests are already available for numerous hematology-related pathogens (Table 5). Some organisms exist in the human body as normal flora, and they can eventually cause disease. To investigate this problem, in situ hybridization is helpful for identifying lesion-specific pathogens in biopsy samples.

★ TABLE 5

LYMPHOMA-ASSOCIATED VIRUSES

Three viruses have been consistently linked to lymphoid neoplasms: human T lymphotropic virus type 1 (HTLV1), Epstein-Barr virus (EBV), and human herpesvirus 8 (HHV8).²⁴ HTLV1 infects T helper lymphocytes and causes them to proliferate by upregulation of interleukin 2 and its receptor. Asymptomatic HTLV1 infection is found in 15% of people in Japan and the Caribbean islands. About 0.1% of infected individuals eventually develop adult T cell leukemia/lymphoma characterized by hypercalcemia and a proliferation of peculiar multilobated helper T lymphocytes harboring the virus. Viral cDNA can be detected in blood or tissues using PCR.²⁵

EBV infects the oropharyngeal mucosa, where it resides in a subset of B lymphocytes. Virtually all persons are infected before adulthood and, once infected, periodically shed infectious virus in their saliva for the remainder of their lives. EBV is known to cause infectious mononucleosis and is suspected of playing a role in the development of some lymphomas. EBV DNA is found in the majority of immunodeficiency-related lymphomas, 40% of all Hodgkin lymphomas, 20% of sporadic Burkitt lymphomas, and in a small subset of carcinomas and sarcomas. The best analytic test for confirming tumor-associated EBV is in situ hybridization to EBV encoded RNA (EBER).²⁶ In this procedure, EBV probe hybridizes to viral RNA in paraffin-embedded tissue sections on glass slides. Microscopic visualization allows localization of the virus to particular cells in the lesion, such as the Reed-Sternberg cells of Hodgkin lymphoma (Figure 11 ■). In a separate type of procedure performed on whole blood or plasma, EBV viral load measurement by quantitative real-time PCR facilitates diagnosis by virtue of the high circulating levels of EBV

DNA in affected patients, and serial viral load measurements are then performed to monitor the efficacy of therapy.²⁷

HHV8 rarely causes disease in healthy individuals, but in AIDS patients, it is strongly associated with Kaposi sarcoma, primary effusion lymphoma, and an atypical lymphoproliferative disorder called *multicentric Castleman's disease*. The virus can be detected in lesional tissue by in situ hybridization. Affected patients can be monitored using HHV8 viral load assays that rely on measurement of HHV8 genomic sequences in blood or plasma using quantitative real-time PCR.²⁸

CASE STUDY (continued from earlier in this chapter)

5. Molecular analysis revealed the *BCR/ABL1* translocation with a p190 break point. What is the most likely diagnosis?
6. Why is this molecular finding helpful in therapeutic decision making?

SUMMARY

DNA technology provides a powerful new tool for laboratory diagnosis of a wide variety of hematologic diseases including inherited disease, infectious disease, and cancer. The laboratory methods commonly used include Southern blot analysis, PCR, in situ hybridization, and FISH. Inherited hematologic diseases that are amenable to molecular diagnosis include sickle cell anemia and venous thrombosis resulting from FV as FII mutations. Leukemias and lymphomas are quite amenable to molecular diagnosis because these malignancies frequently harbor chromosomal translocations or clonal gene rearrangements. All infectious organisms are suitable targets for molecular detection because each species of organism has a unique genome that hybridizes to a complementary

■ **FIGURE 11** In situ hybridization to Epstein-Barr virus EBER transcripts reveals the localization of the virus to Reed-Sternberg cells of Hodgkin's disease (a) and the malignant cells of a diffuse large B cell lymphoma arising in an immunocompromised patient (b). The nuclei of the virus-infected cells are darkly stained as a consequence of a colorimetric reaction occurring at the site of the bound probe.

probe. This facilitates molecular diagnosis of infectious diseases and the virus-associated lymphomas. Newer methods such as DNA sequencing and array technology are now in our toolbox.²⁹ Automation and manufactured kits are beginning to make molecu-

lar testing more accessible and reproducible as well as increasing throughput. The pace of progress is rapid in this exciting corner of the clinical laboratory.

REVIEW QUESTIONS

Use this case history for questions 1 and 2.

A 38-year-old woman complained of dizziness, fatigue, and abdominal pain. On physical examination she appeared pale, and her spleen was enlarged. Laboratory studies revealed anemia and an elevated leukocyte count of $69 \times 10^9/L$. A complete spectrum of granulocytic cells from myeloblasts to neutrophils was present in the blood, and the number of basophils was increased. The leukocyte alkaline phosphatase (LAP) score was low. The bone marrow could not be aspirated, but a biopsy revealed that the marrow was packed with myeloid elements. Cytogenetics could not be performed because of the lack of an adequate marrow aspirate and the inability to induce cell division in peripheral blood leukocytes. Blood is submitted for molecular diagnostic testing.

- Which genetic defect is the most appropriate target for molecular testing to assist in diagnosing the patient's hematologic disorder? (Objective 5)
 - PML/RARA*
 - BCL2/IGH*
 - BCR/ABL1*
 - BCL1/IGH*
- Is there any reason to do molecular testing on the patient at a later date? (Objectives 3, 7)
 - No, the positive test results are definitive, and nothing more can be accomplished.
 - Yes, the patient can be monitored to detect residual disease following therapy.
 - No, but family members should be tested for the same molecular defect.
 - Yes, the translocation break point must be sequenced to prove which genes are involved.
- Which of the following reagents is most critical for making a polymerase chain reaction (PCR) reaction specific for the *F5* gene mutation (FV_{Leiden}) as opposed to a prothrombin gene mutation? (Objective 2)
 - primers
 - nucleotides
 - DNA polymerase
 - buffer
- All molecular tests that analyze specific portions of the human genome rely on the principle that: (Objective 2)
 - DNA is different in every cell of a particular individual.
 - Probes bind to their complementary target sequence through a process called *hybridization*.
 - Restriction endonuclease cut sites remain the same regardless of any mutations.
 - Heat or alkaline pH can convert single-stranded DNA to double-stranded DNA.
- Which of the following assays is most appropriate for detecting a tumor-associated genetic defect that is present in only 0.1% of the cells in a patient sample? (Objective 8)
 - polymerase chain reaction
 - Southern blot analysis
 - karyotype
 - immunophenotype
- Polymerase chain reaction (PCR) differs from reverse transcriptase PCR (rtPCR) in the following way(s): (Objectives 2, 8)
 - Ribonucleotides rather than deoxyribonucleotides are added to the reaction mixture of rtPCR.
 - Following amplification, PCR generates a DNA product whereas rtPCR generates an RNA product.
 - RNA rather than DNA serves as the substrate for rtPCR.
 - All of the above.
- Immunoglobulin and T cell receptor gene rearrangement studies can be used to: (Objective 6)
 - distinguish B cell leukemia from B cell lymphoma
 - determine whether a lymphoid clone is present in a tissue specimen
 - prove that a tissue sample is benign
 - detect Epstein-Barr virus in a tissue specimen
- Which of the following is true about the molecular genetics of cancer? (Objective 3)
 - Virtually all cancers are thought to harbor genetic defects.
 - DNA testing can be helpful in making a cancer diagnosis.
 - The genes responsible for tumor formation are called oncogenes.
 - All of the above.
- Which of the following is true about the Southern blot procedure? (Objective 2)
 - The patient's DNA is cut into fragments using proteinase enzymes.
 - The electrophoresis step permits the probe to penetrate into the gel.
 - The probe is labeled so that it can hybridize to its complementary strand.
 - Interpretation of results relies on visualization of the band pattern.
- Inherited diseases are characterized by: (Objective 4)
 - defective DNA having no effect on gene structure or protein function
 - acquired mutations that are detected only in diseased organs
 - lack of correlation between genotype and disease status among family members
 - a genetic defect that is generally present in all tissues of the patient's body

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: This patient had a high blast percentage in the peripheral blood and bone marrow that is typical of acute leukemia. However, she also had the t(9;22) with Philadelphia chromosome, which is associated with chronic myelogenous leukemia (CML). This translocation of *BCR/ABL1* implies this patient could be suffering from a blast crisis of CML. There are times when the chronic phase of CML may not be diagnosed before blast crisis. The other possibility here is that the patient has de novo acute leukemia. These leukemias also may harbor a Philadelphia chromosome, but the break points in the BCR gene at the molecular level are often different from the break points in CML. This patient had the de novo form of acute lymphocytic leukemia (ALL) as molecular analysis revealed *BCR/ABL1* with a p190 rather than a p210 breakpoint.

Question:

1. What is the classification of this neoplastic hematologic disorder based on the peripheral blood and bone marrow results?

Explanation:

This patient has an acute leukemia as indicated by the blast count, which is >20% in both the peripheral blood and bone marrow.

Question:

2. What molecular defect is consistent with the presence of the Philadelphia chromosome?

Explanation:

The *BCR/ABL1* translocation is the molecular equivalent of the Philadelphia chromosome. There is a reciprocal translocation between the *ABL1* gene on chromosome 9 and the *BCR* gene on chromosome 22. The Philadelphia chromosome represents the shortened chromosome 22. This fusion gene produces a new protein having increased tyrosine kinase activity.

Question:

3. Would molecular analysis assist in diagnosis? Explain.

Explanation:

Molecular analysis would assist in diagnosis. This patient has the Philadelphia chromosome associated with CML but has a peripheral blood and bone marrow picture of acute leukemia. Thus, she may be in the blast crisis of CML or have a de novo acute leukemia. In de novo acute leukemia, the break point in the BCR gene is often different, producing a fusion gene encoding a p190 protein.

Question:

4. If molecular analysis is required, which laboratory procedure should be used, and what specimen should be obtained?

Explanation:

The rt-PCR analysis of *BCR/ABL1* should be done. A bone marrow specimen or peripheral blood may be used.

Question:

5. The molecular analysis revealed *BCR/ABL1* translocation consistent with a p190 break point. What is the most likely diagnosis?

Explanation:

This defect is found in some cases of de novo ALL, and this is the most likely diagnosis.

Question:

6. Why is this molecular finding helpful in therapeutic decision making?

Explanation:

It identifies a set of patients who are less responsive to standard chemotherapy, and the prognosis is poor compared to Philadelphia-negative ALL.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

A 40-year-old male is diagnosed with an inherited disease for which a specific point mutation is responsible. His mother died of a similar disease 10 years ago. For purposes of family counseling, the physician wants to know if she had the same mutation. The histology laboratory has archival paraffin-embedded tissue from the mother. What laboratory method(s) are best for detecting the gene mutation?

Answer

PCR and DNA sequencing are often used to detect point mutations in paraffin-embedded tissue. In most cases, this tissue is not amenable to Southern blot analysis. In situ hybridization and FISH are not good choices for detecting point mutations.

Checkpoint! 2

A patient with CML was treated with chemotherapy. On subsequent marrow samples, the physician ordered molecular testing for residual disease after treatment. The *BCR/ABL1* translocation was not detected 4 months after treatment but was detected at the 8th and 9th months after treatment. Interpret this result.

Answer

The *BCR/ABL1* translocation may be detected for several months after successful therapy, presumably because some of the tumor cells have not died. However, the longer after therapy it is found and if it is persistent over several tests or if it reappears after previous negative testing, the higher is the likelihood of relapse.

Checkpoint! 3

An enlarged lymph node was biopsied and sent to the laboratory for molecular analysis. Lymphoma was suspected. What molecular test(s) could be done on the specimen to determine if the node is likely to be malignant?

Answer

Detection of clonal immunoglobulin or TR gene rearrangement by PCR or Southern blot can be used to differentiate clonal from polyclonal proliferation. Clonal gene rearrangement is characteristic of

malignant lymphoid tumors. B cell tumors usually have clonal rearrangements of Ig heavy chain and kappa light chain genes. T cell tumors usually have clonal rearrangement of TRB and TRG genes. Further classification of a lymphoma is aided by molecular tests for translocations such as *BCL1/IGH* in mantle cell lymphoma, *BCL2/IGH* in follicular lymphoma, or *MYC* translocation in Burkitt lymphoma.

Laboratory Testing in Coagulation

Carol Hillman-Wiseman, M.S.

OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Describe special precautions to take regarding specimen collection and processing for coagulation studies, and determine specimen appropriateness.
2. State the principle of each test: bleeding time (BT), prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin time (TT), fibrinogen assay, factor assays, fibrin degradation products (FDP), D-dimer assay, mixing studies.
3. Describe the procedure for determining the bleeding time (BT), prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin time (TT), fibrinogen assay, fibrin degradation products (FDP) and D-dimer assay.
4. Explain the clinical significance of each test listed in Objective 2.
5. Identify the appropriate laboratory procedure for monitoring heparin therapy and oral anticoagulant therapy.
6. Describe the international normalized ratio (INR).
7. Calculate the INR given patient's prothrombin time (PT), mean normal PT, and international sensitivity index (ISI).
8. Interpret the results of routine coagulation testing (i.e., prothrombin time (PT), activated partial thromboplastin time (APTT), fibrinogen assay, thrombin time (TT), fibrinogen degradation products (FDP) and, D-dimer assay).

OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Correlate collection and processing procedures of the blood specimen with potential problems in coagulation testing.
2. Defend the use of 3.2% sodium citrate as an anticoagulant for coagulation studies.
3. State the principle and determine the appropriate utilization for each of the following tests: platelet aggregation studies, reptilase time, prekallikrein screening test, F-XIII screening test, von Willebrand factor activity assay, von Willebrand factor antigen immunoassay, platelet neutralization procedure (PNP), dilute Russell's viper venom time, lupus anticoagulants, F-VIII inhibitor assay, euglobulin lysis, antithrombin (AT), protein C (PC), protein S (PS), plasminogen, antiplasmin, activated protein C resistance (APCR), and F-Xa inhibition.
4. Describe the procedure for each test listed in Level II Objective 3.

CHAPTER OUTLINE

BACKGROUND BASICS

The information in this chapter builds on the concepts you have already learned. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Describe the vascular contributions to hemostasis.
- ▶ Summarize the steps involved in the formation of the primary platelet plug.
- ▶ List the coagulation factors and the sequence of events involved in the coagulation cascade.
- ▶ Describe the biochemical inhibitors that regulate the coagulation cascade.
- ▶ List the factors and the sequence of events involved in fibrinolysis.

Level II

- ▶ Define the defect and identify the cause of impaired hemostasis in the following disorders of primary hemostasis: Bernard-Soulier syndrome, Glanzmann's thrombasthenia, drug-induced platelet disorders, and immune thrombocytopenic purpura.
- ▶ Define the defect and identify the cause of impaired hemostasis in the following inherited disorders of secondary hemostasis: von Willebrand disease, hemophilia A, and hemophilia B.
- ▶ Summarize the etiology and the pathophysiology of the acquired disorders of secondary hemostasis including disseminated intravascular coagulation, vitamin K deficiency, lupus-like anticoagulant (antiphospholipid antibody), and F-VIII inhibitor.
- ▶ Summarize the effect on the hemostatic system of factor V Leiden, protein C deficiency, antithrombin deficiency, and protein S deficiency.

► OVERVIEW

This chapter describes tests performed in the coagulation laboratory that are used to investigate a hemostatic disorder as indicated by either patient history or physical examination. Screening tests are used to place the defect in one of several broad categories followed by more specialized tests to establish a definitive diagnosis. Screening tests for defects of primary hemostasis include a platelet count and/or bleeding time; screening tests for defects of secondary hemostasis are generally the prothrombin time (PT) and the activated partial thromboplastin time (APTT). In some cases, screening tests are performed to assess the patient's hemostatic status before surgery.

Coagulation test results depend highly on the blood specimen's appropriateness and integrity. Thus, this chapter begins with a discussion of specimen collection and processing. The tests discussed are grouped according to the part of the coagulation system that they assess: primary hemostasis, secondary hemostasis, and fibrinolysis. One section of this chapter describes laboratory tests used to assess hypercoagulable states and monitor anticoagulant therapy. A general description of each test includes its theory, procedure summary, and expected results. A detailed procedure for selected tests can be found on the text's Companion Website, which can be downloaded for use in the laboratory component of a hemostasis class. The Website also contains a wealth of information on coagulation testing and refers the reader to other free information.

► INTRODUCTION

The clinical laboratory professional is an integral part of the medical team involved in the diagnosis of bleeding and clotting disorders. The more knowledgeable the individual, the more effectively he or she can interact with other team members to clarify items such as timing of blood draws, medication problems, and test results. The laboratory professional can sometimes solve the diagnostic coagulation mystery before the physician obtains the final results. Extensive knowledge of the physiology of hemostasis and coagulopathies is needed to understand the testing for the coagulopathies and provide the best care possible for the patient.

A physician should use a stepwise approach (reflexive testing) to diagnose a bleeding problem. When laboratory professionals are aware of the testing sequence, they can assist in determining sample volumes needed for comprehensive testing and work with the physician to prioritize the testing sequence. The stepwise approaches for bleeding problems (Web Figure 2) and thrombophilia (Web Figure 1) allow the clinical laboratory professional to follow the progression of screening tests ordered according to the rationale as to which specific tests should constitute follow-up testing.

In addition to describing testing for the adult population, this chapter provides additional information for the pediatric population, which includes the newborn, infant, toddler, and children to age 17. Laboratories must be cognizant of the need for smaller sample size (blood sampling and testing) for this group of patients. Because congenital deficiencies are more likely to be discovered and diagnosed in the pediatric age group, tests must be sensitive to the very low levels of the constituent being measured.

The chapter emphasizes the technical information concerning the blood sample(s) needed for the particular test(s). There is a common phrase regarding coagulation: "The result is only as good as the sample." Therefore, to provide meaningful results, the laboratory professional must be knowledgeable in properly drawing, processing, and storing the sample. When the final results on a particular patient do not fit the criteria for reporting a specific result (e.g., duplicates cannot be averaged) or the summary of the test results is not logical, the laboratory professional should consider the sample itself and question its merit. Care should be taken to report only accurate results that reflect the patient's condition.

It is essential that each laboratory establish its own normal range for each coagulation test. The range provided by the commercial company can be a guideline, but every laboratory should do its own testing using normal adults (equal number of males and females) with its own instrument/reagent combination. These normal individuals must be questioned for their medical history: bleeding and/or clotting histories, medications taken (e.g., birth control pills), pregnancy, and bleeding from dental work. Unacceptable sources for normals include blood samples from individuals' pre-employment physicals, presurgery patients, and patients who have tested normal with existing reagents. Testing to establish normal ranges must also be performed over a sufficient number of days (>5 days) to account for the day-to-day variability seen in the specific testing being performed. If normal individuals are not available, commercial companies can provide frozen citrated plasma samples from individuals who have been prescreened (see Website).

Specialized testing can include functional and antigenic measurement of the constituent being evaluated. For available functional assays, the theory is described. The physician needs to know whether the constituent measured is functioning normally. The antigenic assay is performed to determine whether the protein concentration is abnormal. Occasionally, the antigenic assay is normal but the functional assay is abnormal. Historically, antigenic measurement has been available first (e.g., protein C, protein S) and used clinically until functional assays became available. Currently, however, the functional assay usually is ordered when testing for a specific hemostasis constituent. If this functional assay result is decreased and is consistent with the diagnosis, the physician might not request the antigenic determination.

Some tests described in this chapter are not available even in a large hospital setting with an extensive coagulation

laboratory. These tests, however, are available from reference laboratories, and phlebotomists must properly collect the blood sample and carefully follow guidelines for transport to the testing site. Laboratory professionals must be familiar with these special assays (purpose, general technique, and details of the blood sample collection) to be able to assist the physician in ordering the correct test and determine when to draw the sample.

This book's Companion Website includes technical information for the clinical laboratory scientist (CLS) and clinical laboratory technician (CLT) working in a coagulation laboratory. The information is practical in nature and is included to improve coagulation testing. The figures and tables there can assist in modifying existing techniques and instituting new protocols (e.g., calculating F-VIII inhibitors, commercial sources of normal plasma for normal ranges).

► SPECIMEN COLLECTION AND PROCESSING

The accuracy of coagulation testing relies on properly collecting, processing, and storing the specimen, as discussed here. More technical information as noted is available on the Web.

SPECIMEN COLLECTION

A two-syringe or two-tube technique is preferable when collecting blood with a syringe or an evacuated tube system, with the blood from the second syringe or second tube used for the coagulation specimen.^{1,2} This helps to minimize contamination of the sample from tissue factor during phlebotomy. If the second (or third tube) is the coagulation specimen, the prior tube(s) should not contain an anticoagulant or clot-promoting substance because of the possibility of carry-over. When certain coagulation studies are requested or in cases of difficult phlebotomy, the two-syringe technique can be the appropriate option. The syringe is filled with sodium citrate so that the final ratio of citrate to blood is the same as in the evacuated tube system. After the sample is drawn, a small amount of air is allowed into the syringe, the needle discarded, and the syringe capped. The sample is then gently mixed to ensure the thorough mixing of citrate and blood. When platelet function testing is to be performed (see the Laboratory Investigation of Primary Hemostasis section), the syringe is the preferred method to obtain the specimen.

Butterfly needles (scalp vein 23 gauge needles with polystyrene tubing that can be attached to a syringe) are used for pediatric patients and with difficult phlebotomies.

When using butterfly needles the two-tube technique alleviates any problem of underfilling the citrate tube. The air in the tubing displaces an equivalent volume of blood in the

first tube, causing the first tube not to fill to the proper level. There is no air in the tubing when the second tube is drawn so this tube fills to the proper level. A complete fill is essential to achieve the proper ratio of blood to anticoagulant in the citrate tube.

When drawing blood through an indwelling catheter, care must be taken to avoid heparin contamination of the sample. Heparin is used to keep the catheter line free flowing. To prevent contamination, the catheter line should be flushed with saline, and the first 5 mL (less volume in pediatric patients) of blood should be discarded. If the laboratory suspects heparin contamination of the sample, various commercial absorbents can be added to the plasma to remove the heparin (the absorbent capacity is 2 USP units of unfractionated heparin in 1 mL of citrated plasma)³ (see Web) and the sample retested. This is a totally separate issue from the patient who is receiving heparin and needs to have the heparin level monitored.

Sodium citrate, 3.2%, is the anticoagulant of choice for coagulation studies.⁴ The proper ratio of anticoagulant: whole blood is 1:9. This 3.2% concentration, as opposed to the 3.8% concentration that had been standard, alleviates the problems associated with excess citrate in samples having high hematocrits.⁵ However, the Clinical Laboratory Standard Institute (CLSI) guideline recommends adjusting the amount of anticoagulant for the 3.2% concentration as well.⁴ A higher hematocrit (>55%) has a smaller volume of plasma relative to the citrate anticoagulant, and the excess free citrate binds the calcium subsequently added in the testing procedure. If the citrate is not adjusted for blood collection, the sample will produce falsely prolonged clotting times because of inadequate recalcification. By adjusting the citrate concentration (lowering the citrate volume in the collection tube and redrawing from the patient), proper test results can be obtained (Web Figure 1 ■). Evacuated citrate tubes that draw volumes of 4.5 mL, 2.7 mL, and 1.8 mL are available. A 0.9 mL citrate tube can be prepared in-house for pediatric use and difficult draws if careful guidelines are followed.⁶ (See Web.)

Obtaining the proper ratio of 1:9 (citrate: blood) is essential to obtain valid results. If the citrate tube is underfilled, too much calcium can be bound by the excess citrate during the testing procedure, and coagulation tests can be falsely prolonged (affecting the prothrombin time [PT] and the activated partial thromboplastin time [APTT] the most). If the citrate tube is overfilled, insufficient calcium can be bound, and clotting can occur in the tube (i.e., it would contain serum instead of plasma), producing falsely prolonged results as occur in a consumptive coagulopathy.

Accurate labeling of the citrated blood samples is critical (i.e., pre- or postinfusion, time of draw). The coagulation testing can be used to calculate a response to the administration of a specific factor concentrate, establish the baseline level of a factor, or determine which sample of a number of blood draws for the same patient is to be used for each

particular test. (See the later section on specific factor inhibitor assay.)

The interactions of the laboratory staff with the health care team are important for obtaining a sample at the proper time. It is beneficial to check the status of the patient's history of receiving blood products because if testing is done within the half-life of the administered clotting factor or platelet products, the tests could measure the transfused component as well as the patient's component. Certain fibrinolytic factors have diurnal variability; therefore, each laboratory needs guidelines on when to draw these samples (see Web, PAI-1). Before performing platelet function testing, the ordering physician, nursing, or laboratory staff must thoroughly question patients regarding medications because some affect the testing for the life of the platelet (7–10 days) (see Web).

SPECIMEN PROCESSING

To obtain plasma for coagulation testing, citrated whole blood is centrifuged. Depending on the test, either platelet-poor or platelet-rich plasma can be required. Properly processing the sample is required to obtain reliable results.

Platelet-Poor Plasma

To obtain platelet-poor plasma (PPP), the citrated specimen is centrifuged for 15 minutes at $2500 \times g$. PPP must have $<10 \times 10^9/L$ platelets. Depending on the coagulation instrumentation used, the separated plasma can either be left on top of the packed cells or removed using a plastic pipette and placed in a capped plastic tube. When removing the PPP, leaving a small amount of it on the surface of the packed cells is critical. This ensures that the platelet layer is undisturbed and that platelets have not been resuspended in what should be PPP.

The use of PPP is essential for three technical reasons. One is that platelets contain **platelet factor 4** (PF4), which neutralizes heparin (thus affecting sample's testing for the presence of heparin). Second, platelets contain phospholipids, which affect lupus anticoagulant testing and factor assay testing (especially if the sample is frozen and thawed). Third, platelets contain proteases, which, when released during the thawing of a frozen sample, alter results for von Willebrand factor testing.

A clot of any size in the sample renders it unacceptable. Therefore, after removing the PPP, a wooden applicator stick is twirled into the packed cells to assure that no clot is present. If numerous tests are ordered using the same sample, various aliquots can be prepared and frozen so that on successive days a freshly thawed sample can be tested. The separated plasma can be stored at $18\text{--}24^\circ\text{C}$ or $2\text{--}8^\circ\text{C}$ for up to 4 hours before testing. If the testing cannot be completed within the 4 hours, the PPP should be stored at -20°C for up to 1 week or -70°C for up to 6 months. Frozen samples must be thawed rapidly at 37°C because excessive heating (>5 minutes) can result in the loss of factor V and F-VIII. Sam-

ples for coagulation testing should never be stored in self-defrosting freezers, because the freeze-thaw cycles will compromise sample integrity.

Specialized testing (e.g., fibrinolytic and thrombotic assays, PF4, β -TG, fibrinopeptide 1+2, tPA), even if not being performed in one's own laboratory, has numerous requirements for processing the sample.⁷ Each laboratory must have procedures available for properly handling the citrated sample to ensure valid results when it is sent to reference laboratories.

Platelet-Rich Plasma

Platelet-rich plasma (PRP) is obtained to perform studies of platelet function. If the sample has been drawn into a citrated syringe, the needle should be removed and the sample gently expelled down the side of a polystyrene test tube, capped, and then centrifuged for 10 minutes at $200 \times g$ at room temperature. The PRP should be removed from the packed cells carefully using a plastic pipette and placed in a covered polystyrene tube. PRP usually contains $200\text{--}300 \times 10^9/L$ platelets. PRP can be stored at room temperature, and testing should be completed within 3 hours.

Citrated Whole Blood

For testing that requires citrated whole blood, the sample is drawn as previously described. This sample type can be used for platelet function testing (i.e., platelet function analyzer [PFA], whole blood aggregation, or one of the global tests of coagulation, such as thromboelastograph [TEG]). To check for clots, the citrated tube or syringe should be carefully scrutinized while mixing, and a wooden applicator stick should be inserted *after* testing has been completed to verify that no clot existed. Because platelets can be activated by foreign surfaces, the sample should not be checked for a clot with the wooden applicator before testing has been completed.

Checkpoint! 1

Why have most clinical laboratories switched from 3.8% to 3.2% sodium citrate for specimen collection in coagulation studies?

▶ LABORATORY INVESTIGATION OF PRIMARY HEMOSTASIS

Laboratory testing to evaluate primary hemostasis includes tests for platelet concentration and function. In testing for platelet function, the clinical laboratory scientist must be aware that a wide variety of drugs can affect platelet function for the entire life span of the platelet (7–10 days).^{8,9} Each laboratory should have a list of such drugs available so that an extensive platelet function workup is not performed

unnecessarily (Web Tables 1 🌟, 2 🌟, 3 🌟). Stress also affects the platelet release reaction.¹⁰ Repeat testing is advisable for abnormal results.

Screening tests for platelet function include the bleeding time (BT) and in vitro testing using the platelet function analyzer (PFA).¹¹ Definitive testing for platelet function includes PRP and/or whole blood platelet aggregation.

Platelet aggregation depends on the presence of Ca²⁺. Although sodium citrate binds calcium, the concentration of Ca²⁺ remaining after anticoagulation is sufficient to permit aggregation to occur. Blood drawn in 3.2% sodium citrate shows stronger aggregation than blood collected in 3.8%, presumably due to the increased availability of Ca²⁺. Therefore, if the normal range is established using 3.2% citrate, all patients must be drawn using that concentration.

Additional testing for platelet function can include flow cytometry and clot retraction. Acquired states of thrombocytopenia such as heparin-induced thrombocytopenia (HIT) and neonatal alloimmune thrombocytopenia (NAIT) require specific testing.

BLEEDING TIME

BT is an in vivo measurement of platelet function. In addition to platelet function, the BT is also affected by platelet number and vascular integrity. The BT measures the time required for bleeding to cease from a superficial skin cut. The testing depends on the temperature; amount of pressure applied to the arm; depth, location, and direction of the incision; movement of the arm (especially wiggling in young children); and the clinical laboratory professional's experience.

Several methods have been used over the years to determine the bleeding time. The oldest method, the Duke bleeding time, utilized a lancet to make a puncture in the ear lobe. In 1941, Ivy improved the BT technique by creating a constant venous pressure with a blood pressure cuff (40 mmHg) and performing the test on the forearm with a lancet. The variability in making the incision has been minimized by using a disposable bleeding time device. The most widely used method today is the modified Ivy BT using a template. Templates for this test are commercially available as sterile disposable devices that use a spring-loaded blade designed to make a skin incision of standard depth and width on the forearm. The general **reference interval** for the BT is 1–9 minutes.^{12,13} When screening for von Willebrand's disease (VWD), patients with **von Willebrand factor activity (VWF:A)** >30% generally have normal BT results.¹³ The Web describes the BT in detail. Patients with platelet counts <100,000 × 10⁹/L usually have a prolonged BT. See Table 1 🌟 for conditions associated with prolonged BT.

PLATELET FUNCTION ANALYZER

The PFA in vitro method for assessing and screening for platelet function is a more standardized technique, eliminat-

🌟 TABLE 1

Conditions Associated with a Prolonged Bleeding Time

- von Willebrand disease
- Bernard-Soulier syndrome
- Glanzmann's thrombasthenia
- Congenital storage pool disease
- Afibrinogenemia
- Severe hypofibrinogenemia
- Certain vascular bleeding disorders such as Ehlers-Danlos syndrome
- Uremia
- Acquired platelet function defects (drug induced)

ing the variables discussed with the BT (Web Figure 2 ■). The assay measures platelet function in whole blood at a high shear rate. This test adds citrated blood to each of two reservoirs, one with collagen/epinephrine and the other with collagen/adenosine diphosphate (ADP). The instrument aspirates whole blood through a capillary with a 150 μM aperture of a bioactive membrane coated with either collagen/epinephrine or collagen/adenosine diphosphate (ADP). A pressure sensor detects the formation of a platelet plug. The time to occlude the aperture (the "closure time") is a function of platelet count, platelet activity, VWF activity, and hematocrit. This method is sensitive to VWD, aspirin-induced platelet dysfunction, and aggregation defects (all resulting in prolonged or abnormal closure times). A reference range is established for each reservoir using a standardized blood-drawing technique (size of needle, citrate concentration).^{11,14}

The expected results with the PFA are:

Condition	Normal	Acetyl-salicylic acid	VWD	Glanzmann's
		(ASA)		Thrombasthenia
Reservoir				
COL/EPI	Normal	Abnormal	Abnormal	Abnormal
COL/ADP	Normal	Normal	Abnormal	Abnormal

PLATELET AGGREGOMETRY

Platelet aggregation studies are the foundation of platelet function testing in the laboratory. Platelet aggregometry is a challenging technique usually performed in specialized laboratories by experienced laboratory professionals. The testing is time consuming and requires attention to detail regarding sample collection (choice of anticoagulant, check of patient drug history), processing the sample and reagents, pH, time of storage, rate of stirring, and platelet count. A citrated sample is collected and can be used for whole blood testing (measuring luminescence and impedance) or centrifuged slowly for PRP to determine percent aggregation and the curves that are produced (Web Figure 3 ■).

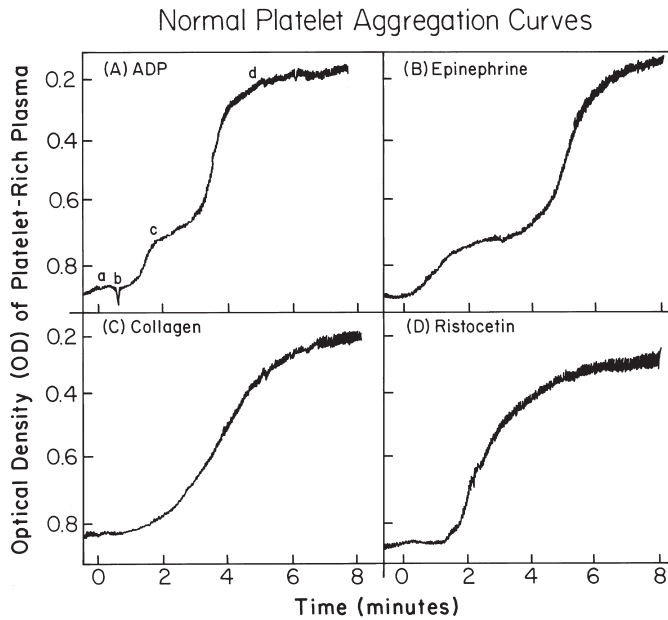

FIGURE 1 Normal platelet aggregation curves. Normal responses to the commonly used aggregating reagents: ADP, epinephrine, collagen, ristocetin. **a.** Baseline before addition of the reagent; **b.** Initial increase in absorbance that occurs immediately following the addition of reagent, representing a change in platelet shape; **c.** the primary wave of aggregation; **d.** secondary wave of aggregation.

Platelet-Rich Plasma (PRP) Aggregation

PRP is carefully prepared from a citrated blood sample by adjusting the platelet count with the patient's own PPP to a standard number (usually 200,000/ μ L). The sample is stirred, warmed to 37°C in a special photometric device (an aggregometer), and an **aggregating reagent** (agonist) is added. In the presence of the agonist, the platelets begin to aggregate which leads to a change in optical density (OD) of the PRP that the aggregometer records as a graph (curve). Commonly used platelet agonists include ADP, epinephrine, collagen, ristocetin, and arachidonic acid.

Depending on the agonist used and its concentration, a primary and/or secondary wave of aggregation occurs (see Figure 1 ■). The primary wave reflects the direct response of the platelets to the aggregating reagent and represents platelet shape change and the formation of small aggregates. The secondary wave represents the complete aggregation response, which occurs as a result of endogenous ADP being released from the activated platelet dense bodies. An aggregating reagent that results in both a primary and secondary wave is said to produce a *biphasic curve*, whereas an aggregating reagent that results in only one wave is said to produce a *monophasic curve*. Changes in platelet aggregation curves are interpreted to identify qualitative platelet disorders (Table 2 ♣).

TABLE 2

Typical Pattern of Response to Aggregating Reagents in Qualitative Platelet Disorders*

Qualitative Platelet Disorders	Aggregating Reagents				
	Collagen	ADP	Epinephrine	Ristocetin	Arachidonic Acid
Normal	Monophasic curve (secondary wave only) representing secondary platelet aggregation associated with release of endogenous ADP	Biphasic curve with 2×10^{-5} M ADP—demonstrating primary and secondary waves of platelet aggregation	Biphasic curve—demonstrating primary and secondary waves of platelet aggregation	Biphasic curve—primary wave resulting from immediate platelet agglutination; secondary wave associated with platelet release induced by platelet agglutination	Monophasic curve (secondary wave only) representing effect of thromboxane A ₂ on secondary platelet aggregation
von Willebrand disease	Normal	Normal	Normal	No response	†
Bernard-Soulier syndrome	Normal	Normal	Normal	No response	†
Glanzmann's thrombasthenia	No response	No response	No response	Normal	†
Storage pool disease	No response	Primary wave only	Primary wave only	Normal	Normal
Aspirin ingestion	No response	Primary wave only	Primary wave only	Normal	Suppressed response

*Chapter. † Not applicable. Arachidonic acid evaluates the thromboxane A₂ synthetic pathway.

Aggregating reagents produce typical aggregation patterns (Figure 1).¹⁵ **Ristocetin** is unique among the agonists in that its action depends on the interaction of plasma VWF and the platelet membrane receptor glycoprotein Ib (GPIb/IX) and technically represents platelet agglutination rather than aggregation. See the Website for additional information on using lower concentrations of ristocetin to aid in the diagnosis of type IIb VWD and Web Figure 4 ■. Although ristocetin-induced platelet agglutination (RIPA) can be abnormal in both VWD and Bernard-Soulier syndrome (BSS, a defect of GPIb/IX), plasma ristocetin cofactor activity (VWF:A, discussed later) is usually decreased in VWD but is normal in BSS. Additionally, the RIPA defect observed in VWD can be corrected by adding normal plasma to the patient's PRP because the defect is a deficiency of a plasma protein, not of the platelets. The agglutination defect in BSS is not corrected because it is due to a deficiency of the GPIb/IX complex on the patient's platelet membrane and is not corrected by the addition of normal plasma.

Arachidonic acid (AA) is useful to screen for a patient's ingestion of aspirin or any aspirin-containing products within the previous 7–10 days. This screening can help clarify results when the PRP produces no secondary wave of aggregation with ADP or epinephrine. Platelet release defects or storage pool disease, which produce results with ADP and epinephrine similar to those seen with aspirin ingestion, can be differentiated by using AA (Table 2, Figure 2 ■).

Decreasing concentrations of epinephrine, which produce aggregation of patient PRP but not normal control PRP, have been used to diagnose "sticky platelet syndrome" (Web Figure 5 ■), a term adopted by E.F. Mammen to describe patients with unexplained arterial vascular occlusions who had platelet hyper-responsiveness to low doses of ADP and/or epinephrine.¹⁶ (See Website.) The precise etiology of this syndrome is presently not known, but abnormal receptors on the platelet surface may be involved. Normal plasma levels

of PF4 and beta-thromboglobulin (β TG) suggest that the platelets are not activated at all times. This test is not sensitive for demonstrating this syndrome in pediatric populations.¹⁷

Aggregometers now have the ability to measure adenosine triphosphate (ATP) secreted from dense granules in PRP and whole blood samples. The luminescence produced improves the diagnosis of storage pool disease because an actual amount of ATP, which is directly proportional to the dense granule content, is measured. This is more accurate than evaluating whether the platelet aggregation curve produced is biphasic.^{18,19,20} (See Website Additional Information: Platelet Aggregation Testing.)

Whole Blood Aggregation

The use of whole blood aggregation (Web Figure 3) allows for a smaller sample size than is used in PRP aggregation to evaluate platelet function and is a quicker analytic method because PRP does not have to be prepared. However, there also is no standardization of the platelet count because the sample and the control are diluted in saline. The whole blood assay measures electrical resistance across two metal wires (probes). The whole blood sample is initially exposed to a small electric current that coats wires with a monolayer of platelets. Upon the addition of an agonist, platelets form aggregates on the monolayer, adding electrical resistance (ohms) to the circuit. The change in impedance is measured as a function of time. The citrated sample is challenged with ADP, collagen, and thrombin. The use of the agonist thrombin allows for the determination of the content of the dense granules. Thrombin causes dense granules to release ATP, so this testing can efficiently assess whether the patient has δ -storage pool disease. With certain instruments, the sample can also be evaluated for luminescence as was done with PRP.¹⁸

■ **FIGURE 2** Platelet aggregation patterns in various disorders. Typical tracings obtained using concentrations of collagen, ADP, and ristocetin illustrate the differences between platelet aggregation in normal subjects and that in patients with von Willebrand's disease (VWD), Bernard Soulier syndrome (BSS), thrombasthenia (TSA), storage-pool disease (SPD), and aspirin ingestion and aspirin-like disorders (ASA). Impaired release of ADP accounts for the SPD and ASA defects. VWF corrects the defective ristocetin aggregation in VWD but not in BSS.

ADDITIONAL TESTS EVALUATING PLATELET FUNCTION

Flow Cytometry

New approaches for laboratory diagnosis of the platelet disorders BSS (GPIb/IX deficiency) and Glanzmann's thrombasthenia (GPIIb/IIIa complex deficiency) involve flow cytometry using monoclonal antibodies directed against the platelets' respective glycoproteins. A panel of antibodies that recognize the resting, activated, and ligand-occupied forms of the GPIIb/IIIa complex has been developed.²¹ Thus, both the presence and the functional activity of this complex can be measured. Testing can also be performed to evaluate the presence of circulating activated platelets to aid in diagnosing thrombotic syndromes. This specialized testing requires much expertise.¹⁸

Clot Retraction

The clot retraction test is performed on blood without anticoagulant. A 1 mL sample of whole blood is placed in a glass tube in a water bath at 37°C and observed for 1–3 hours. Normal blood should clot and begin to retract 30–60 minutes after collection. Retraction should normally occur except in cases of Glanzmann's thrombasthenia, severe hypofibrinogenemia, and thrombocytopenia. To remove the variables of platelet count and fibrinogen level, a PRP retraction can be performed (with a control PRP tested as well). A volume of PRP, APTT reagent, and Ca²⁺ are added in a graduated glass test tube to produce a volume of 1.0 cc. A wooden stick is inserted into the mixture, mixed, and again placed in a 37°C water bath. After 1 hour, the stick is gently removed; the clotted and retracted platelets and fibrin will be attached to it. The test is quantitated by determining the serum remaining in the graduated tube. In Glanzmann's thrombasthenia, there is little or no retraction of the clot; therefore, very little serum is present after removal of the stick.²²

ACQUIRED STATES OF THROMBOCYTOPENIA

Heparin-Induced Thrombocytopenia (HIT)

Historically, a functional heparin-platelet aggregation assay using normal platelets and the patient's serum was used to screen for HIT. In the presence of HIT immunoglobulins in the patient's plasma, the normal platelets are activated when the heparin used for treatment was added to the PRP. The procedure was time consuming and often resulted in false negatives. The current gold standard for the diagnosis of HIT is a platelet ¹⁴C serotonin release assay whose complexity limits its availability to reference laboratories. An **enzyme-linked immunosorbent assay (ELISA)** for detecting antibodies against heparin-PF4 complexes is also available. The results obtained with the serotonin release assay and ELISA are generally in agreement in patients with a clinical diagnosis of HIT. However, the ELISA detects antiheparin antibodies in patients who do not have heparin-induced thrombocytopenia, therefore possibly producing false-positive results if being used to diagnose HIT.²³

Neonatal alloimmune thrombocytopenia (NAIT) is a syndrome causing transient, isolated, sometimes severe thrombocytopenia in newborns. NAIT results from placental transfer of maternal alloantibodies directed against paternally inherited antigens present on the fetal platelets but absent from maternal platelets. This condition is the platelet counterpart of hemolytic disease of the newborn. NAIT diagnosis is confirmed by serologic or genotypic testing including immunophenotyping of maternal and paternal platelets. The maternal serum also is examined for the presence of antiplatelet antibody. Because of the complexity of this testing, it is usually performed in large reference laboratories or specialized coagulation centers.²³

Neonatal Alloimmune Thrombocytopenia (NAIT or NATP)

Neonatal alloimmune thrombocytopenia (NAIT) is a syndrome causing transient, isolated, sometimes severe thrombocytopenia in newborns. NAIT results from placental transfer of maternal alloantibodies directed against paternally inherited antigens present on the fetal platelets but absent from maternal platelets. This condition is the platelet counterpart of hemolytic disease of the newborn. NAIT diagnosis is confirmed by serologic or genotypic testing including immunophenotyping of maternal and paternal platelets. The maternal serum also is examined for the presence of antiplatelet antibody. Because of the complexity of this testing, it is usually performed in large reference laboratories or specialized coagulation centers.²³

✓ Checkpoint! 2

What effect does aspirin taken daily for a heart condition have on a patient's bleeding time? Explain.

▶ LABORATORY INVESTIGATION OF SECONDARY HEMOSTASIS

Laboratory tests of secondary hemostasis evaluate coagulation factors and inhibitors. The testing of patients for secondary hemostasis starts with screening tests. Following the reflexive chart for guidelines for evaluating bleeding diathesis (Web Figure 2), the physician can order the appropriate definitive tests leading to the proper diagnosis. Laboratory professionals should be familiar with the reflexive testing found in the chart. They are occasionally asked to guide the physician who may be unclear concerning which test is most appropriate. The following section includes technical information to help understand the variability within each assay. The Website should also be consulted for methodologies, quality control, pediatric considerations, and expanded coverage of the topics.

SCREENING TESTS

The screening tests include the PT, APTT, thrombin time (TT), and quantitative fibrinogen. Abnormalities in any of these tests require further testing. The battery of reflex testing is based on the results of the screening tests (Web Figure 2). Poor blood sample integrity can unnecessarily cost time and expense investigating a possible bleeding or clotting disorder.

Prothrombin Time

The PT is an important screening test for the laboratory evaluation of patients with inherited or acquired deficiencies in

the extrinsic or common pathway of the coagulation cascade. Historically, it has also been used to monitor oral anticoagulant therapy. In vivo, tissue factor (TF) activates the coagulation cascade via the formation of the TF/F-VIIa complex.²⁴ In the PT test thromboplastin (TF/calcium mixture) is added to a citrated patient PPP or control PPP, and the time for fibrin formation is recorded. This test is the basis for determining the PT. Numerous commercial sources of thromboplastins (most commonly rabbit brain) are available; they vary in sensitivity to coagulation factor deficiencies. Variabilities result from differences in animal and tissue sources, as well as the method of reagent preparation. Each laboratory must establish its own reference interval (RI) for its reagent/instrument combination.

The procedure for establishing a specific reagent/instrument RI and technical information are on the text's Companion Website. Clot formation can be detected by optical or electromechanical methods using manual, semiautomated, or automated devices. The general reference interval for the PT is 10–13 seconds. See Web Table 4  for potential sources of error for procedures based on clot formation. The PT can be prolonged because of either a deficiency of factors VII, X, V, II (prothrombin), fibrinogen; or the presence of an inhibitor.²² (Historically the test was called the *prothrombin time* because Professor Armand Quick thought that the test measured only prothrombin.) The PT can be shortened in patients receiving treatment with recombinant factor VIIa concentrate (rF-VIIa), which has been used to produce hemostasis in hemophiliac patients with high-responding inhibitors.²⁵ As increased levels of rF-VIIa are infused, F-VIIa interacts with TF at the site of vascular injury, activating F-X, which in turn shortens the PT.

The PT is also used to monitor patients on oral anticoagulant therapy (coumadin or warfarin). Because of the wide variability among the various PT reagents and instrumentations, the results are usually reported using the international normalized ratio (INR). The PT of a patient on oral anticoagulation is inserted into a formula, which includes the manufacturer's international sensitivity index (ISI) value for its particular thromboplastin. The outcome of this mathematical calculation, the INR, is discussed later in this chapter (Oral Anticoagulant Therapy and the PT). Many current commercial thromboplastins use a recombinant TF and synthetic phospholipids with Ca²⁺. The goal in making commercial thromboplastins is to obtain a reagent that has an ISI of 1.0 (or close to it). With lower ISI values (the closer to 1.0), the calculation of the INR of a patient being tested in any location worldwide becomes much more reproducible (minimizing interlaboratory and intralaboratory variability). The lot-to-lot variability of the recombinant reagent is believed to be less than that obtained with products prepared from biologic sources. Most recombinant products are associated with a greater prolongation of PT results in patient samples than biologic products.

The same reagent is used for testing patients on oral anticoagulant therapy and patients for specific factor deficiencies. For patients not on oral anticoagulant therapy, usually

only the actual PT (in seconds) is reported (the INR value has no additional clinical value).

Prolongation of the PT is also seen with proteins induced by vitamin K-absence or antagonism (PIVKA). Factors II, VII, IX, X, protein C, and protein S are vitamin K-dependent coagulation factors. Hepatic production of these proteins in the absence of vitamin K or with vitamin K antagonism (warfarin therapy), dietary deficiency of vitamin K, some types of liver dysfunction, and certain genetic abnormalities results in proteins referred to as PIVKA. These proteins are immunologically similar to the naturally occurring factors but are dysfunctional because they lack the γ -carboxyglutamic acid residues required for Ca²⁺ and phospholipid binding during clotting. The proteins are also termed non- or descarboxylated proteins. Because PIVKAs lack normal coagulant activity, a prolonged PT results. The testing for PIVKA is by ELISA and is performed only at centralized reference laboratories.⁷

Activated Partial Thromboplastin Time

The APTT is an important screening test for the laboratory evaluation of patients with inherited or acquired deficiencies of proteins in the intrinsic or common pathway of the coagulation cascade. The APTT also can be used as a screening test for the detection of circulating inhibitors of blood coagulation (lupus anticoagulants).

The sensitivity of the various commercial APTT reagents to factor deficiencies and to lupus anticoagulants varies greatly. Therefore, each laboratory has to decide which APTT reagent to use depending on its individual needs. The screening tests (PT and APTT) detect a factor deficiency only when the factor decreases to a level of 25–40% of normal (depending on the reagent). A laboratory that wants to determine the sensitivity of its reagent to a particular factor can perform its own evaluation for factor sensitivity.²⁶ In general, most commercial APTT reagents have good sensitivity for F-VIII deficiency, but their sensitivity for F-IX deficiency is more variable.^{27,28,29}

The APTT remains the most common procedure used to monitor the effectiveness of standard (unfractionated) heparin therapy. (See the section on Laboratory Evaluation of Anticoagulant Therapy later in this chapter.) The APTT uses two reagents: an activated partial thromboplastin and Ca²⁺. The partial thromboplastin reagent simulates activated platelet surfaces by providing phospholipid surfaces on which enzymatic reactions in the coagulation cascade can occur, plus an activator (kaolin, celite, micronized celite, or ellagic acid) that provides the negatively charged surface for the activation of F-XII.²⁷ After a specific incubation time of citrated plasma (control or patient) with the APTT reagent which allows optimum activation of the contact factors, calcium chloride is added, and the time required for a fibrin clot to form is recorded. Details of this procedure are provided on the text's Companion Website. Clot formation can be detected by optical or electromechanical methods using

manual, semiautomated, or automated devices. The general reference interval for adults is 28–35 seconds.

The APTT also evaluates prekallikrein (PK) and high molecular weight kininogen (HK). Deficiency of F-XII, PK, or HK can result in a markedly prolonged APTT in the absence of clinically significant bleeding.

✓ Checkpoint! 3

Routine coagulation testing was performed on a properly collected and processed specimen. The PT result was prolonged, but APTT was normal. What is the best interpretation of these results?

Thrombin Time

TT has an important role as a screening test because it measures the conversion of fibrinogen to fibrin by adding excess thrombin to undiluted plasma. Because the additional clotting factors previously measured in the PT and APTT have no effect on this test, TT is generally useful for evaluating other parameters affecting the formation of fibrin. There can be interference with the conversion of fibrinogen to fibrin for three major reasons: the presence of hypofibrinogenemia or dysfibrinogenemia, the presence of heparin, and the presence of fibrin degradation products (FDP). In rare cases, autoantibodies against thrombin (e.g., induced by topical thrombin application or the use of fibrin sealants) and myeloma proteins can also interfere with fibrin formation and result in an abnormal TT.³⁰ The TT is useful in corroborating an abnormal FDP result and can verify that the citrated blood sample was drawn through an indwelling heparinized catheter that was not well flushed. An extremely prolonged TT usually indicates a heparin effect. If the sample is contaminated with heparin, it can be absorbed with Hepzyme (see Specimen Processing and Website). The testing can then be repeated, or the specimen can be redrawn.

The basic procedure is described on the Web. The general reference interval for the TT is 10–16 seconds. TT's sensitivity can be increased by diluting the thrombin reagent to give a control of 16–18 seconds. The TT in preterm and term infants is longer than the adult reference interval even though the fibrinogen level is within the same normal reference interval, which can be explained by the presence of a distinct fetal fibrinogen molecule with altered function. The TT generally becomes normal within a few days after birth.

Quantitative Fibrinogen

Several methods have been used to determine the fibrinogen concentration including turbidimetric precipitation or denaturation methods with some instrumentation calculating a result derived from the slope of the PT. The reference method for fibrinogen determination is the Clauss assay,

which is a clot-based functional measurement that adds thrombin to various dilutions of known concentrations of fibrinogen (reference plasma or calibrator) to produce a thrombin-clotting time in seconds. The clotting times are then plotted on a log/log graph (reference curve), with known concentrations on the x-axis versus clotting time (TT) on the y-axis (Figure 3 ■). Thrombin clotting times are performed using appropriate controls (normal and abnormal) and the patient PPP at a 1:10 dilution. The fibrinogen concentration is inversely proportional to the clotting time. If fibrinogen levels are low, more concentrated (i.e., less dilute) dilutions of patient plasma (1:5 or 1:2) are prepared so that fibrinogen can be accurately determined using the reference curve with the result divided by 2 (if a 1:5 dilution) or 5 (if a 1:2 dilution). FDPs do not affect the assay at the normal 1:10 dilution but can when the dilution is lower (i.e., 1:5 or 1:2). The fibrinogen results for the controls and the patient are determined from the reference curve using their respective clotting times. Additional technical information can be found on the Website. In general, the reference interval for fibrinogen (adults and the pediatric population) is 200–400 mg/dL.

Decreased levels of fibrinogen occur in acquired disorders such as disseminated intravascular coagulation (DIC), primary and secondary fibrinolysis, liver disease, and congenital disorders such as dysfibrinogenemia and hereditary afibrinogenemia. When an abnormal fibrinogen is suspected, an antigenic (immunological) test is performed. Increased levels of fibrinogen can occur in inflammatory disorders and pregnancy, and in women receiving oral contraceptives because fibrinogen is an acute phase reactant protein.

TESTS TO IDENTIFY SPECIFIC FACTOR DEFICIENCY

When the PT and/or APTT is prolonged, further testing can be performed to identify the specific cause of the abnormality. As each of the following specific tests is described, its sensitivity(ies) to decreased levels of clotting factor(s) and whether these levels would be detected in the specific screening test are discussed.

Mixing Studies

Mixing studies (also known as *circulating anticoagulant screen* or *screening test for circulating inhibitor*) are performed to differentiate a factor deficiency from the presence of a circulating inhibitor.^{22,31} These studies repeat the screening tests with abnormal results (PT, APTT) using several different dilutions of the patient's PPP mixed with a **normal pooled plasma** (Web Table 5 🟢). Because factor levels of ~50% of normal are generally sufficient to produce a normal PT and APTT result, repeating the PT and APTT with dilutions of patient and normal plasmas corrects the prolonged patient result if it is caused by a deficiency of one or more procoagulant factors.

■ **FIGURE 3** Fibrinogen standard curve. I, II, and III represent reference plasmas of known fibrinogen concentrations. The thrombin time in seconds is on the y-axis, and the fibrinogen concentration in mg/dL is on the x-axis.

The testing is performed immediately and then again after the incubation of the mixture of the patient's PPP and the normal plasma at 37°C. (See the Website Mixing Study for detailed procedures and comprehensive technical information.)

The clotting times for the various dilutions and time intervals are compared to determine whether the patient's prolonged clotting time has been corrected by the addition of normal plasma. Clotting times tend to increase with time and incubation due to the loss of labile factors (F-V and F-VIII); therefore, comparing the patient's diluted sample result with the result obtained from the normal pooled plasma is important. A clotting time is considered prolonged if it is longer than the normal plasma clotting time. The correction

of the prolonged test result (PT/APTT) by the normal plasma (Table 3 🌟) indicates a factor deficiency. The normal plasma replenishes the deficient factor in the patient's plasma. If a factor deficiency is detected, specific factor assays should be performed to identify and quantitate the specific factor's activity.

The lack of correction of the prolonged test by normal plasma indicates the presence of a circulating or a specific factor inhibitor. A circulating inhibitor inhibits both the coagulation factors in the patient plasma and in the normal plasma with which it is mixed. The detection of a circulating inhibitor (e.g., lupuslike anticoagulant) should be followed by specific tests to identify and verify the type of inhibitor.

🌟 **TABLE 3**

Differentiation of Factor Deficiency from Circulating Inhibitors Using the Mixing Study Procedure

Deficiency or Inhibitor	Mixing Study	
	Immediate PT or APTT after Mixing	Mix, Perform PT or APTT after 2-hr Incubation at 37°C
Factor deficiency	Correction	Correction
Lupuslike anticoagulant	No correction	No correction
F-VIII inhibitor	Correction	No correction

Some patient plasmas contain time- and temperature-dependent inhibitors and exhibit correction immediately after mixing them with normal pooled plasma; however, after incubation, the clotting time result is prolonged (Table 3). These inhibitors are called *slow acting*, and are characteristic of certain F-VIII inhibitors. These slow-acting, specific inhibitors can be quantitated by performing the F-VIII inhibitor assay (Bethesda assay; see Tests to Evaluate Specific Factor Deficiency). Lupus-like anticoagulants tend to act immediately but are occasionally time dependent.

Checkpoint! 4

Given the following coagulation test results, what is the appropriate follow-up or reflex test?

PT	Normal
APTT	Prolonged
Mixing studies	No correction

Specific Coagulation Factors

Factor assays are performed to confirm a specific factor deficiency and to determine the actual activity of that factor within the plasma. The basis of a factor assay is the ability of the patient's plasma to correct a prolonged PT or APTT of a known factor-deficient plasma (substrate).³²

Each clotting factor in the extrinsic (F-VII) and common (F-II, -V, and -X) pathways can be measured by using specific one-stage assays based on the PT. A specific factor assay measures the clotting time of a mixture of diluted test plasma (patient or control) and a specific factor-deficient substrate plasma, which supplies normal levels of all factors except the one being measured. TF and calcium chloride (PT reagent) are added to this mixture, and the clotting time is determined.

Each intrinsic pathway factor (F-VIII, F-IX, F-XI, and F-XII) can be measured by one-stage, APTT-based methods. In the case of F-VIII, the assay is referred to as a *factor-VIII:C assay*. As in the testing for extrinsic and common factors the specific factor assay for intrinsic factors measures the clotting time of a mixture of diluted test plasma (patient or control) and a specific factor-deficient substrate plasma, which provides all factors except the one being measured.

For each clotting factor assay based on the PT or APTT test results, the clotting times of factor-deficient substrate plasma containing varying dilutions of a reference pooled plasma (commercially available calibrator that has been assayed against a national or international standard)^{33,34} in buffer are used to construct a standard curve (Table 4) (Figure 4). Most laboratories use automated instruments to perform the assays, and the data are plotted using the preprogrammed software included with the instrument. The clotting times of the individual dilutions are plotted against the percentage of factor activity of each respective dilution of the assayed standard. The patient's clotting time using at least two dilutions (usually 1:10 and 1:20) with the specific factor-deficient plasma is obtained by performing a PT or APTT test on the mixture. These times are converted to percent of activity from the standard curve. The results of the two dilutions should be linear, showing that no "inhibitory effect" is seen. If the results are not linear, an inhibitory effect, which may be seen with lupus-like anticoagulants, is suspected. The same test is also performed on normal and abnormal controls. For many coagulation factors, the normal factor activity reference range is ~50–150%. (See the Web for factor assays.)

The normal levels of various clotting factors (i.e., F-IX, -XI, and -XII) are quite low at birth (Table 13). Therefore, to distinguish newborn factor deficiencies from normal

★ TABLE 4

Dilutions for Factor Assays

Tube*	Buffer (mL)	Plasma (mL)	Activity (%)	Dilution
1	0.9	0.1	100.0	1:10
2	1.9	0.1	50.0	1:20
3	0.5	0.5 mL from tube 2	25.0	1:40
4	0.5	0.5 mL from tube 3	12.5	1:80
5	0.5	0.5 mL from tube 4	6.3	1:160
6	0.5	0.5 mL from tube 5	3.2	1:320
7†	0.5	0.5 mL from tube 6	1.6	1:640
8†	0.5	0.5 mL from tube 7	0.8	1:1280

*The example is based on a reference plasma value of 100%. If using a reference plasma with an assayed value other than 100%, the activity would be based on its stated value.

†Additional dilutions are prepared when patient values are possibly less than 1% activity. These dilutions are made and clotting times are determined on each dilution to construct an activity curve. The percent activity is plotted on the x-axis and the clotting time on the y-axis (Figure 4).

newborn levels, the laboratory testing must be accurate when assaying samples with levels <10% of normal. In laboratories where hemophilic patients (F-VIII deficiency) are routinely evaluated, the ability to differentiate between factor levels of <1% and 2–5% is essential.

Commercial chromogenic kits are available to test for F-VIII and other clotting factors. F-VIII exists in the plasma as a complex with VWF. Testing involves its activation by thrombin, with F-VIII acting as a cofactor in the conversion of F-X to F-Xa by F-IXa in the presence of calcium and phospholipid. The amount of F-Xa generated is determined using a specific chromogenic substrate for F-Xa and is directly proportional to the amount of F-VIII in the citrated sample. Currently, these kits are less commonly used in clinical laboratories because of their high cost and the ready availability of the one-stage F-VIII assay. (See Web Figures 18a, 18b, 20). The measurement of antithrombin is also available as a chromogenic assay and can usually be performed with the same instrument.

✓ Checkpoint! 5

What is the function of the factor-deficient substrate reagent and the reference plasma in a factor assay?

Reptilase Time

The reptilase time, which is not affected by the presence of heparin in the sample, is used in conjunction with the thrombin time to detect heparin contamination of the sample and to help differentiate dysfibrinogenemia from the presence of fibrin degradation products (Table 5).

Reptilase is a serine protease found in the venom of the *Bothrops atrox* snake. This thrombin-like enzyme cleaves fibrinopeptide A from fibrinogen, whereas thrombin cleaves both fibrinopeptide A and B.^{35,36} The addition of reptilase to PPP initiates clot formation, which can be detected by optical or electromechanical methods using manual, semiauto-

TABLE 5

Differentiation of Conditions Associated with a Prolonged Thrombin Time Using the Reptilase Time

Condition	Thrombin Time	Reptilase Time
Heparin contamination	Prolonged	Normal
Dysfibrinogenemia	Prolonged	More prolonged
Presence of fibrin degradation products	More prolonged	Prolonged

mated, or automated devices. The general reference interval for a reptilase time is 18–22 seconds. An increase to 25 seconds or longer is considered significant and indicates dysfibrinogenemia, hypofibrinogenemia, or afibrinogenemia.

Prekallikrein Screening Test

Individuals with a PK deficiency (also known as *Fletcher factor deficiency*) have a prolonged APTT. Correction of the prolonged APTT of the patient's citrated plasma to normal, or near the upper limit of the normal APTT reference range, after a 10-minute incubation period (before adding calcium chloride) suggests PK deficiency. The longer incubation period increases contact activation of F-XII in the absence of PK. The normal control plasma APTT should remain within or near its control range following the extended incubation period. Kaolin, celite, or silica is the activator of choice for the APTT reagent. Prolonged incubation with ellagic acid might not correct the APTT in PK deficiency.^{37,38} PK deficiency can be confirmed by performing a specific factor assay using PK-deficient substrate. As with the F-VIII assay, a quantitative chromogenic substrate assay can quantitate the level of PK in plasma samples.³⁹

Factor XIII (Screening Test)

F-XIII activity is necessary for the formation of a stable fibrin clot that occurs by forming covalent bonds between fibrin monomers. Routine screening tests (PT, APTT) detect clot formation, not cross-linking, and thus are not sensitive to F-XIII deficiency. A F-XIII determination should be performed for a patient with clinical symptoms of delayed bleeding or a bruising disorder in whom the screening tests are normal. The screening test for F-XIII deficiency is based on the observation that the fibrin clot has increased solubility because of the lack of cross-linking of the fibrin polymer in the absence of F-XIII.

The patient's PPP is mixed with 0.025M calcium chloride and allowed to clot for 1 hour at 37°C. The clot is removed and placed in another tube containing 5M urea or 1% monochloroacetic acid in a 37°C water bath. A normal control plasma is tested at the same time. If the patient's clot dissolves within the 24-hour period, the result indicates a F-XIII activity of less than 1–2%. The normal control plasma clot resists solubilization by these agents. Patients with levels of 1–2% F-XIII produce clots that typically dissolve within the first 30 minutes,^{40,41} the level at which clinical manifestations of F-XIII deficiency occurs.

More accurate quantitative assays for F-XIII that are more sensitive than the screening test described here have been developed. These assays have not gained widespread acceptance because they are relatively infrequently requested and thus are most likely performed in research or reference laboratories.³⁰

LABORATORY TESTS FOR VON WILLEBRAND FACTOR (VWF)

The diagnosis of von Willebrand disease (VWD) involves quantitating VWF by both functional and antigenic methods. A large number of analytical variables affect its accurate determination.

The first variable is the difference over time of laboratory findings in patients with VWD. Serial studies of these patients show variability in VWF results over a 24-month span (see Web Figure 6 ■). Because some VWD patients occasionally have VWF antigen and/or activity (VWF:Ag; VWF:A) levels within the normal reference range, VWD diagnosis cannot be ruled out by a single evaluation.⁴²

The second variable is that the results of screening tests (bleeding time and APTT) can be normal in patients with type I VWD. Typically, these patients have factor VIII:C, VWF:A, and VWF:Ag levels of approximately 45–55%, usually producing normal screening test results. Patients with significant bleeding histories should thus be further tested with specific assays (VWF:A and VWF:Ag) even when screening test results are within normal limits. VWD cannot be ruled out on the basis of a normal APTT and bleeding time.²⁵

The third variability is the fact that an endogenous release of adrenaline can result in a transient increase in plasma F-VIII and VWF, so a patient who has VWD type I can appear normal. The stress of a difficult phlebotomy, especially in anxious young children, can double or triple the level of VWF, making it impossible to rule out VWD without repeated testing.²⁵ The patient should be as calm as possible before having the citrated blood sample drawn.

The fourth technical variability is in the processing of the citrated sample. Samples that are centrifuged at 1500 g for 5–10 minutes can have a residual platelet count in the plasma as high as 30,000 to 40,000/mL. Freezing this plasma releases platelet proteases, altering VWF multimeric structure and resulting in an apparent increase in the VWF antigen level and decrease in the VWF activity.²⁵ Using such samples is inappropriate for von Willebrand testing.

The fifth variability is the reference standard used in the clinical laboratory, which can affect the various assays for VWF. Clinicians sometimes use the ratio of VWF:Ag to VWF:A to subclassify type 2A and 2M variants. Therefore, it is imperative that both of these assays be interpreted against an acceptable and identical reference plasma sample.

The sixth variability is the fact that the patient's blood type affects the VWF plasma level. Individuals with blood group AB have a 60–70% higher level of VWF than those with blood group O. As a result, some laboratories interpret VWF levels referenced to specific normal ranges for blood types.⁴³ See Table 6 🍀 for the mean level of VWF for the various blood groups.

A variety of clinical disorders also can affect the level of VWF.²⁵ Web Table 6 🍀 provides classification of VWF variants for clinical disorders that affect assays for VWF.

★ TABLE 6

Relationship between Blood Groups and von Willebrand Factor Level

Blood Groups	von Willebrand Factor Level (%)
O	74.8
A	105.9
B	116.9
AB	123.9

The treatment of choice for the classic type (1) of VWD is desmopressin (Desamino-D-arginine vasopressin [DDAVP]), which causes a twofold to fourfold increase in a patient's VWF plasma level.⁴⁴ A test dose of DDAVP is given to a patient prior to scheduled surgery to measure his or her response to it. Citrated plasma samples are drawn preinfusion as well as 30 minutes and possibly 4 hours postinfusion and are assayed for F-VIII activity, VWF:Ag, and VWF:A. Clinical laboratory professionals must be cautious in handling, centrifuging, and labeling these timed samples.

von Willebrand Factor Activity (VWF:A)

Ristocetin was used as an antibiotic until the early 1970s when it was recognized as causing thrombocytopenia in normal individuals but not in certain individuals with bleeding problems.⁴⁵ Although no longer used clinically as an antibiotic, laboratories use it as a diagnostic tool in testing for VWD. The test also is referred to as the **ristocetin cofactor (RCoF) assay**. (See Platelet Aggregometry section.)

In the presence of ristocetin, VWF induces platelet agglutination, which a platelet aggregometer can measure. Decreased RIPA in patient PRP occurs in patients with VWD caused by VWF deficiency or BSS (VWF receptor/GPIb/IX deficiency).

The quantitative test for VWF activity uses ristocetin to induce VWF to bind to the glycoprotein Ib/IX receptor (VWF receptor) on formalin-fixed platelets rather than the patient's own platelets. This test system adds ristocetin to formalin-fixed platelets suspended in patient plasma (the source of VWF) and uses a platelet aggregometer to measure the resultant platelet agglutination. The slope of the agglutination is plotted versus the percent activity of a reference plasma. Other modifications of the assay use the time elapsed expressed in millimeters on the graph instead of slope of agglutination.⁴⁶

A reference (standard) curve is prepared by making dilutions of reference plasma (100%, 50%, 25%, and 12.5%) and performing the ristocetin platelet agglutination test on each dilution. The rate of agglutination or the slope of the curve is plotted against each concentration. The control and each patient's sample are tested at two separate dilutions, and the resulting slopes or rates are calculated from the reference curve; the results are averaged and reported as a percentage of activity of VWF:A. Various automated labo-

ratory instruments now available reduce the test variability as a result of the laboratory professional's technical skill. The general reference range for VWF:A is 60–150%. VWF:A is usually decreased in plasma from patients with all three types of VWD and the platelet-type pseudo-VWD; type III has the lowest level (Web Table 6). Unlike the RIPA that uses patient PRP, which is abnormal in both BSS and VWD, the VWF:A (VWF:RCoF) assay is normal in patients with BSS.

Normal fluctuations occur with the four diagnostic tests used in diagnosing VWD (Web Figure 6). Large variations occur in test results in normal individuals as well, stressing the need for commercial reference plasmas to be standardized against international standards in preparing the standard curve for all VWF testing (Web Figures 7a ■ and b ■).

The laboratory professional should understand the test results regarding hemophilia versus VWD and be able to evaluate each patient's test results, repeat them, and perform verifications as needed. See Web VWF Assays for detailed technical information for this assay.

von Willebrand Factor Antigen Assay (VWF:Ag)

As with clinical testing for most bleeding disorders, the antigenic measurement for VWF:Ag was available before functional assays. Zimmerman⁴⁷ used the "rocket" immunoelectrophoresis technique of Laurell⁴⁸ to measure the VWF:Ag. (See Web for additional information and Web Figures 21 ■, 22 ■.)

The Laurell-based assay is an EIA that electrophoreses the plasma sample through an agarose gel containing rabbit antiserum to F-VIII. A rocket-shaped immunoprecipitate forms; its length can be measured and is directly proportional to the amount of VWF:Ag in the plasma sample. The assay is time consuming, and measuring and calculating decreased levels is difficult.

One of the more common current methods for VWF:Ag is an ELISA assay called a *sandwich technique*.⁴⁹ Its advantages are increased reproducibility, accuracy at very low levels, and reduced time needed to obtain results. This procedure coats microtiter plate wells with a specific rabbit antihuman VWF antibody (the capture antibody) that will bind VWF:Ag in the test sample. A second rabbit antihuman VWF:Ag antibody is enzyme labeled (alkaline phosphatase or peroxidase) and binds to the initial antigen-antibody complex on free antigenic sites of the VWF:Ag. Hence, the VWF protein is "sandwiched" between two specific antibodies (Figure 5 ■). A substrate specific for the enzyme label is added to the microtiter plate wells, causing a colorimetric reaction with the color intensity directly proportional to the concentration of the test sample's VWF. A microtiter plate reader, an adaptation of a spectrophotometer, determines the absorbance of each microtiter well. The assay is made quantitative by preparing a reference curve using a reference plasma calibrated against a national or international standard (as was the VWF:A assay). The controls

■ **FIGURE 5** VWF:Ag enzyme-linked immunosorbent assay (ELISA). The capture antibody that is specifically directed against the target antigen, VWF, is fixed to the surface of the microtiter well. Test sample is added to the well. If VWF is present, it will bind to the capture antibody forming an antigen-antibody complex. A second specific antibody to the VWF-antibody complex is then added. This second antibody is enzyme labeled and binds to the VWF-antibody complex if it is present. To determine the presence or concentration of VWF, substrate specific for the enzyme label on the second antibody is added to the well. The enzyme converts the substrate to a colored product whose intensity is directly proportional to the concentration of the VWF in the test sample.

(normal and abnormal) and patient samples are diluted and added to the microtiter wells in the same manner as the reference plasma at various concentrations. The general reference interval for VWF:Ag is 43–150%.

Recently, an immunoturbidimetric assay for VWF:Ag has been developed. The LIA test procedure coats microlatex particles with rabbit antihuman VWF antibodies, producing agglutination when mixed with plasma containing VWF. The extent of agglutination (turbidity) correlates to the level of VWF:Ag present in the citrated plasma sample.⁵⁰ The methodology is reliable and easy to automate and produces results in a timely manner. In addition, the methodology is able to detect low levels of antigen, thus improving the ability to diagnose variants of VWD.

VWF Multimer Analysis

The proper VWD treatment depends on determining the correct disease subtype. This previously was accomplished by using gel electrophoresis (crossed immunoelectrophoresis, CIE),^{51,52} which separated type 2 variants from type 1 VWD, and by using platelet aggregation with varying lower concentrations of ristocetin to separate type 1A from type 2B VWD (described earlier). The crossed immunoelectrophoresis method was limited to a few laboratories because the procedure was technically difficult and labor intensive.

The availability of multimeric analysis has improved VWD diagnosis, resulting in improved treatment of patients. The normal VWF distribution in plasma is as multimers ranging from dimers of approximately 600,000 Daltons (Da) to very large multimers of up to 20 million Da. The use of low concentrations of agarose (0.65 percent) and staining with radiolabeled antibody to VWF allows the full range of multimers to be visualized (by autoradiography or liminog-

raphy). DDAVP is the treatment of choice for type 1 VWD but is less effective in type 2 (see Web Table 6). Therefore, establishing the correct subtype of VWD by multimeric analysis is important in determining the appropriate therapeutic approach.²⁵

Multimeric analysis is also useful in diagnosing thrombotic thrombocytopenic purpura (TTP) in which unusually large multimers of VWF (UL-VWF) are observed. Normally, ultralarge multimers are cleaved by the VWF protease, ADAMTS-13. The presence of UL-VWF indicates a reduced or absent ADAMTS-13 activity.

Because these multimeric analyses are difficult to perform and interpret and require a very pure and specific antibody, specialized reference laboratories or coagulation centers usually perform the multimeric analysis.

Collagen-Binding Assays for VWD

Collagen-binding assays are specialized assays performed on patients to differentiate VWD type 2A and 2B from type 2M. The ELISA assays for collagen binding had initially been considered as potential replacements for the VWF:A (VWF:RCof assay) because both tests are sensitive to a reduction in high molecular weight multimers of VWF. However, because the collagen-binding assays do not reflect the interaction between VWF and GP1b, they cannot serve as substitute assays. Performing both collagen-binding and VWF:A assays increases the ability to differentiate VWD type 2 variants (discrimination of VWD types 2A or 2B from type 2M).^{7,25,53}

ADAMTS-13

The presence of this VWF-cleaving protease can be measured using the ELISA technology. Chronic relapsing TTP, which usually begins in early childhood, is due to mutations in the ADAMTS-13 gene, resulting in markedly decreased protease activity. Both antigenic and activity measurements for ADAMTS-13 are commercially available.⁵⁴ The ELISA assay uses a microtiter plate precoated with a monoclonal anti-ADAMTS-13 antibody so that the ADAMTS-13 antigen of the calibrator, controls, and patient samples are measured in citrated plasma samples. Acute TTP, more commonly seen in adults, is usually due to an acquired deficiency in ADAMTS-13 resulting from an IgG autoantibody against the protease. The ELISA assay is highly specific and can differentiate TTP samples from other samples with autoantibodies (e.g., lupus) or high IgG concentrations (e.g., IgG gammopathy).

TESTS TO EVALUATE CIRCULATING INHIBITORS

The most common circulating inhibitors seen in the hemostasis laboratory are lupus-like anticoagulants (LA) or antiphospholipid antibodies (aPL) and F-VIII inhibitors. Various procedures are used in diagnosing antiphospholipid antibodies because no single definitive assay is available.⁵⁵ In the pediatric population, the Staclot LA seems to be the most

sensitive assay. Because LAs are transient in this population, diagnosing it is often difficult. On repeated tests, the previously abnormal APTT of these patients can be normal.⁵⁶ The measurement of the inhibitor to F-VIII is determined with the F-VIII inhibitor assay (Bethesda method).

Lupus-Like Anticoagulants/ Antiphospholipid Antibodies

The inhibitors originally described as *lupus anticoagulants* (LA) are now recognized to be part of a more diverse group of inhibitors collectively referred to as aPL. They are immunoglobulins, usually of the IgG class, that are directed against the protein component of protein-phospholipid complexes. In vivo, aPL are associated with a thrombotic tendency; in vitro, they prolong phospholipid-dependent clotting assays. Classically, the APTT in these cases is abnormal with a lack of correction in 1:1 mixing studies with normal plasma. The quality of the patient sample (PPP) greatly affects the integrity of the testing. Procoagulant phospholipids (originating from platelets) can be in the patient plasma or in the normal plasma used for the mixing studies. These can neutralize weak lupus-like anticoagulant activities and produce false negative results. Thus, plasma samples should be centrifuged for 10 minutes after which the top two-thirds of the plasma is carefully removed (so as not to disturb the cells) using a plastic transfer pipette. The plasma is transferred to a second tube and recentrifuged for an additional 10 minutes.

APTT is the test generally used to screen for LA/aPLs, although APTT's sensitivity to LA/aPL depends on the reagent.^{57,58} Many modifications to the APTT, including the use of lower concentrations of phospholipids in the test reagent, have been recommended in an attempt to increase its sensitivity. Laboratory professionals must evaluate their APTT reagents as to the importance of LA/aPL sensitivity versus the importance of sensitivity to specific factor deficiencies. In cases for which the screening APTT is not prolonged but the patient presents with a positive history of thrombophilia, the physician should proceed with designated testing for LA/aPL. According to the guidelines developed by the International Society on Thrombosis (ISTH), the minimum diagnostic criteria for LA/aPL are the demonstration:

1. of an abnormality of phospholipid-dependent coagulation reactions
2. that the abnormality is due to the presence of an inhibitor rather than a factor deficiency
3. of the phospholipid-dependence of the inhibitor rather than a specific factor inhibitor⁵⁹

Each laboratory must decide which commercially available assay is the most sensitive for its patient population. The presence of heparin as a cause of the abnormal APTT is excluded by a normal thrombin time. The tests that can be used to satisfy the minimum diagnostic criteria for LA/aPL and a brief description of each test follows.

Criterion 1 for diagnosing LA/aPL (demonstration of an abnormality of phospholipid-dependent coagulation reactions) is accomplished by performing a clotting assay using a phospholipid-based reagent. LA/aPL react with anionic phospholipids and therefore can prolong the APTT, the PT (less commonly), or both. Other tests that have been used for this determination include the tissue thromboplastin inhibition test (TTI), the **dilute Russell's viper venom time (dRVVT)**, the kaolin clotting time (KCT), and the PTT-LA.⁵⁸ Making an accurate diagnosis can require performing more than one of these phospholipid-based tests because different antiphospholipid antibodies can affect various tests differently. Investigators have found that anticardiolipin antibodies (ACA) prolong the dRVVT to a greater extent than the KCT, whereas LA prolong the KCT to a greater extent than the dRVVT.^{59,60} The PT of plasma with aPL usually is only minimally to moderately sensitive to the effect of aPL (typically prolonged 0.5–3.0 seconds).

Criterion 2 for diagnosing LA/aPL (demonstration that the abnormality is due to the presence of an inhibitor rather than a factor deficiency) is accomplished by using mixing studies as described earlier. A correction of a prolonged APTT in a 1:1 mixing study with normal plasma indicates a factor deficiency rather than the presence of an inhibitor. A second tube containing the 1:1 mixture of patient plasma and normal plasma should be incubated for 1–2 hours before testing to rule out the presence of a specific-factor inhibitor.

Criterion 3 for diagnosing LA/aPL (demonstration of the phospholipid-dependence of the inhibitor rather than a specific factor inhibitor) is accomplished by reducing or adding the amount of phospholipids to the test system to demonstrate that the inhibitor is directed at phospholipids rather than a specific coagulation factor.

Tissue Thromboplastin Inhibition (TTI)

The TTI test is a modification of the PT test in which a dilute thromboplastin reagent is compared to the optimal strength reagent. The PT of a plasma with LA/aPL is more prolonged than normal plasma when diluted tissue factor (PT reagent) is used. The ratio of the patient's clotting time with dilute reagent divided by the undiluted reagent clotting time is compared to a normal control. A ratio of >1:3 indicates a positive test. The test is highly sensitive but not specific to LA/aPL because it is also positive in the presence of heparin and when the initial PT is prolonged.

Dilute Russell's Viper Venom (dRVV) Test

The dRVV test, also known as the *Stypven time*, uses a commercial preparation of the venom from the Russell viper (*Daboia*) to activate F-X in a method similar to a routine PT test. The dRVVT test is based on the premise that LA/aPL activity increases in the presence of reduced phospholipids (similar to the TTI test). The reagent contains dilute Russell's viper venom, calcium chloride, and phospholipids. The reagent is added to patient PPP, and RVV activates F-X, re-

sulting in clot formation. If LA/aPL are present, the patient's dRVVT is higher than that of the normal control. The ratio of the patient's clotting time to the clotting time of the normal control is determined. The normal ratio is usually less than 1:2. A confirmatory test also employs Russell's viper venom (RVV) but with a higher phospholipid concentration. The final result is reported as a ratio of the two clotting tests (high and low phospholipid concentration), which is compared with the values of a reference population.⁶⁰ The dRVVT appears to be more sensitive to aPL antibodies that react with β 2-glycoprotein I.

Kaolin Clotting Time (KCT)

In the kaolin clotting-time (KCT) test, kaolin, a negatively charged particulate activator, is incubated with test PPP to activate the contact factors and the intrinsic system. The KCT can be a useful screening test for LA/aPL in patients with a normal or minimally abnormal APTT. The KCT appears to be more sensitive in detecting antibodies to prothrombin-phospholipid complexes.

Platelet Neutralization Procedure (PNP)

LA/aPL have antiphospholipid activity, and tests based on the fact that an excess of phospholipids substantially shortens the prolonged APTT of aPL-containing plasma are important in differentiating aPL from other inhibitors. Ruptured (freeze-thawed) platelets can serve as a source of phospholipids. The patient's PPP is mixed with a suspension of ruptured platelets and an APTT reagent. The addition of calcium chloride activates clot formation. The clotting time is determined and compared with the APTT clotting times of the patient PPP and the saline control (1:2 dilutions of saline and patient PPP). If the aPLs are present, the clotting time with the added phospholipids is significantly shorter than the original APTT and the saline control APTT. False positive results can be seen for patients who are receiving heparin or have extremely high titer inhibitors to other clotting factors.⁶⁰

Hexagonal Phospholipids

The hexagonal phase phospholipids (HPP) test extends the PNP concept but substitutes egg phosphatidylethanolamine in a hexagonal phase configuration for the freeze-thawed platelets. The HPP assay is based on the fact that many aPL antibodies specifically recognize the HPP configuration as an antigenic epitope. Addition of HPP to the reaction mixture neutralizes the inhibitory effect of the aPL antibodies but does not neutralize most factor-specific antibodies.⁶¹ The test (StacLOT LA) is performed by incubating the test plasma at 37°C with and without the HPP reagent. An APTT is performed on both of these incubations using an aPL-sensitive reagent. If aPL are present in the test plasma, the HPP would neutralize it resulting in a shortened clotting time for the tube containing it compared to the tube without HPP. By comparing the two clotting times, the presence of aPL antibodies can be identified. This assay has two advantages:

- (1) The LA sensitive reagent contains a heparin inhibitor, which makes the test system insensitive to heparin levels up to 1 IU/mL and
- (2) the StacLOT LA procedure adds normal plasma to the test system to correct any prolongation of clotting time due to factor deficiencies that might be present. Reduction of the aPTT result by >8 seconds as the result of adding HPP is consistent with the presence of a phospholipid-dependent inhibitor.

Specific Factor Inhibitor Assay (Bethesda Titer Assay)

A group of hematologists met in Bethesda, Maryland, to create a testing method to standardize the test variables for the factor inhibitor assay and to achieve a uniform definition of an inhibitor unit.⁶² The test they developed became known as the *Bethesda titer assay*. Although it was developed to measure F-VIII inhibitors, it can be modified to assay inhibitors of other coagulation proteins. The test is routinely ordered when monitoring the treatment of a severe hemophiliac (F-VIII or F-IX deficiency) twice per year.

Specific inhibitors occur in 10–15% of hemophiliacs at any time after the first infusion of factor concentrate. To detect the presence of an inhibitor in a hemophiliac, the physician must monitor the patient's response to treatment (F-VIII concentrates, both human and recombinant) by requesting F-VIII:C assays.⁶³ When a particular patient or a family member believes that bleeding has not stopped as it should after an infusion of F-VIII concentrate (calculated to produce a known F-VIII response in that patient), an inhibitor can be suspected. Blood is drawn pre- and postinfusion of concentrate with F-VIII levels performed on each of these citrated blood samples. If the expected response level of F-VIII is not achieved, an inhibitor to the specific factor that the patient lacks is suspected, and an F-VIII inhibitor assay is ordered. Inhibitors can occasionally be found in normal (nonhemophilic) individuals.

Testing for a specific inhibitor is always performed on the preinfusion sample (a trough sample whose F-VIII:C should be <1% F-VIII, usually suggested to be >72 hours after previous infusion). If the patient has an inhibitor, the F-VIII that is infused will be cleared quickly, producing a F-VIII level of <1% at 24 hours or less.^{64,65} Presence of residual infused F-VIII can interfere with an inhibitor assay, producing a false negative value. Additionally, in patients with high levels of inhibitors, there may be an effect when assaying other clotting factors. For example, a high F-VIII inhibitor level in a patient who is being tested for F-IX deficiency could cause the F-VIII level in a F-IX deficient reagent plasma to decrease causing an abnormal factor assay result. Thus, it would appear as if the patient had a F-IX deficiency in addition to a F-VIII deficiency even if the F-IX in the patient was within the reference range. (Web Figure 9 ■)

The Bethesda titer assay for F-VIII inhibitor uses equal volumes of normal pooled plasma (containing a known F-VIII activity) and patient plasma, which are mixed and incubated

for 2 hours at 37°C. Additional tubes are prepared using various dilutions of the patient's plasma in a buffer mixed with normal pooled plasma and are incubated. The control consists of a mixture of normal plasma and a buffer. A F-VIII assay is performed on all incubation mixtures, including the control. If a F-VIII inhibitor is present, it will inactivate the F-VIII in the normal plasma used in the mixtures, and any residual F-VIII can be measured. The patient mixtures are corrected for the amount of F-VIII loss seen in the control (normal plasma + buffer). The residual F-VIII values (F-VIII level in each of the incubated patient dilutions and control) obtained between 25% and 75% activity are then obtained from the standard Bethesda chart (Web Figure 8 ■). The resulting units are multiplied by the amount of dilution used and expressed in Bethesda units (BU) (1 BU = 50% residual F-VIII in the incubation mixture)⁶² (Web Table 7 🌱).

In patients with increased inhibitor levels, multiple dilutions are needed to produce residual activity that can be read from the standard curve. The results are then averaged. When the results show that the inhibitor level appears to rise as the plasma is more diluted (Web Table 7, patient C), the patient appears to have complex reaction kinetics, and the inhibitor level is calculated from the lowest dilution that gave a corrected percent residual F-VIII closest to 50%.⁶⁶

An additional option for the treatment of a hemophiliac with an inhibitor is a porcine F-VIII concentrate (Hyate:C®, Speywood Biopharm Ltd, Wrexham, UK). The F-VIII level is monitored often, and the inhibitor assay (Bethesda-type assay for porcine F-VIII) is used to determine the anamnestic response. Instead of using pooled normal plasma (PNP) for the source of F-VIII in the assay, the porcine F-VIII concentrate is diluted with hemophilic plasma to produce a porcine F-VIII plasma with a level of approximately 100% (comparable to PNP); the remaining testing procedure is the same as previously described.⁶⁷

The Bethesda inhibitor assay has been modified with the addition of the Nijmegen modification to improve accuracy for patients with inhibitors of <1.0 BU in the standard Bethesda assay. This modification buffers the PNP to minimize the pH shift and to reduce the F-VIII loss during the 2-hour incubation. It has been shown that patients can demonstrate low levels of inhibitors (<1.0 BU) with the regular Bethesda assay but can be negative with the Nijmegen protocol.⁶⁸ These results suggest that the pH changes and F-VIII loss in unbuffered incubation mixtures resulted in low false positive inhibitor levels in some patients. The Nijmegen modification is most likely performed at hemophilia centers where the hematologist must closely monitor patients receiving factor concentrates in order to accurately identify patients with a newly developing inhibitor.

Why are ruptured platelets able to neutralize lupus-like anticoagulants?

▶ LABORATORY INVESTIGATION OF THE FIBRINOLYTIC SYSTEM

The thrombin time (TT) may be the only abnormal screening test result in patients with fibrinolytic system abnormalities because the PT and APTT results are often normal. The patient's primary disease and the physician's clinical findings (bleeding or thrombosis) can suggest a fibrinolytic system problem and indicate the need for further laboratory testing. With improvements in diagnostic algorithms and available tests, the use of the D-dimer assay has begun to replace the more generic and less specific test for fibrin degradation products (FDP) and the global assay euglobulin clot lysis.

More specific testing using ELISA and chromogenic assays is also available for fibrinolytic system components that can help evaluate an increased or decreased level of fibrinolysis. Because these assays are also used to determine a thrombotic tendency, they are described in the text section Laboratory Investigation of Hypercoagulable States (see Web Table 8 🌱).

D-DIMER

The D-dimer is a specific marker (fragment) resulting from plasmin degradation (lysis) of the fibrin clot, which has been cross-linked by F-XIIIa. D-dimer is an excellent marker for disseminated intravascular coagulation (DIC) with secondary fibrinolysis. However, D-dimers are also elevated in pulmonary embolism, deep vein thrombosis, arterial thromboembolism, recent trauma or surgery, cirrhotic liver disease, and renal failure.

The D-dimer test utilizes monoclonal antibodies against the D-dimer fragment, which can be used in three separate methodologies. The first of these is a semiquantitative assay that utilizes macroscopic latex agglutination. The D-dimer assay should not be used in patients who are taking anticoagulant therapy (heparin or warfarin). The assay can be performed on plasma (citrate, ethylenediaminetetraacetic acid [EDTA], or heparinized) and serum. The extra step of preparing serum (as in the standard FDP test) is avoided because fibrinogen and fibrin do not cross-react with the D-dimer monoclonal antibodies used in these tests. The patient specimen is mixed with latex particles coated with monoclonal antibodies (directed against D-dimer) on a glass slide for a specific amount of time (e.g., 2 minutes). At the end of this time, the laboratory professional observes the reaction mixture macroscopically for the presence of agglutination. Most procedures test both undiluted plasma and a plasma sample, diluted 1:2 in buffer which allows a semiquantitation of results. Lack of macroscopic agglutination in either sample corresponds to a D-dimer level of <0.5 µg/mL. Macroscopic agglutination in the undiluted sample but not in the 1:2 dilution corresponds to a D-dimer of 0.5–1.0 µg/mL. If both samples show agglutination, the result is >1.0 µg/mL. Normal individuals have <0.5 µg/mL.

The second methodology is a more sensitive, quantitative technique using the ELISA format. Although very sensitive and specific for D-dimer, this technique is time consuming (clinically, results are usually needed quickly) and requires the use of specialized equipment and training to perform it.

The third methodology is also based on the concept of microscopic latex agglutination but is an automated procedure and therefore eliminates errors associated with visually reading the agglutination. Antibody-coated latex particles aggregate in the presence of D-dimer, resulting in increased turbidity of the mixture. The increase in scattered light is proportional to the amount of D-dimer in the sample. This assay is extremely sensitive and has an increased detection range. It is considered to have good negative predictive value because a negative test can be used to rule out deep vein thrombosis (DVT), venous thromboembolism (VTE), and pulmonary embolism (PE). The assay, if effectively used, could reduce the use of time-consuming and expensive diagnostic tools such as venography, compression ultrasound, and spiral CT scans for some patients. If the level of D-dimer in the plasma is *not* elevated, no thrombotic process is ongoing, and VTE is not present. However, if the D-dimer level is elevated, a clotting process is occurring, which could be due to VTE as well as other clinical conditions (Table 7 🟢). The difficulty with using the D-dimer assay to exclude VTE is establishing the cutoff value. Each laboratory must establish its own cutoff value rather than relying on what the manufacturer provides (Web Table 9 🟢). These values need to be developed with input from the clinical staff and re-evaluated periodically.⁶⁹ This assay also should not be used in patients on anticoagulant therapy (heparin or warfarin). Studies have demonstrated that anticoagulants decrease circulating D-dimers and could produce a value below the cutoff, masking the presence of VTE.

Most hospitals that utilize the D-dimer assay to confirm DIC also use the D-dimer assay to test for VTE. Because the range of detection necessary for DIC and VTE varies significantly, some institutions provide them as two separate tests (different cutoff values).

FIBRIN DEGRADATION PRODUCTS

The detection of increased levels of fibrin and/or fibrinogen degradation products (FDP) in patient blood samples indi-

🟢 TABLE 7

DIC	Pregnancy
Trauma	Cancer
Surgery	Diabetes
Hematoma	Thrombolytic therapy
Arterial thrombosis	Older age
General hospitalization	

cates increased fibrinolytic activity. The patient's blood sample is collected in a special collection tube containing thrombin (to clot the sample and ensure that all fibrinogen has been removed) and a fibrinolytic inhibitor (to prevent *in vitro* fibrino[geno]lysis). The patient's serum is mixed with latex particles coated with specific antibodies that recognize FDP on a glass slide for a specific amount of time (e.g., 2 minutes). The reaction mixture is observed macroscopically for the presence of agglutination. The test is semiquantitative with various dilutions made of the patient's serum in buffer. The normal range varies according to the test's manufacturer and sensitivity. Most procedures require the preparation of two dilutions for each sample (i.e., 1:2 and 1:8), which allows a semiquantitative determination of FDP. Macroscopic agglutination in both dilutions corresponds to an FDP level of more than 20 $\mu\text{g/mL}$. No macroscopic agglutination in either dilution indicates an FDP level less than 5 $\mu\text{g/mL}$; agglutination observed in the 1:2 dilution but not in the 1:8 dilution corresponds to an FDP level of more than 5 $\mu\text{g/mL}$ but less than 20 $\mu\text{g/mL}$. Individuals normally have FDP levels less than 5 $\mu\text{g/mL}$.

The standard FDP assay does not distinguish between fibrin degradation products and fibrinogen degradation products because the antigenic epitopes recognized by the antibodies are expressed on both types of degradation products. Falsely high levels can also occur if the sample is not fully clotted (e.g., due to the presence of a high heparin concentration) and fibrinogen is still present (the antibodies also recognize fibrinogen).

The test is nonspecific because it also is abnormal in the following conditions associated with increased FDPs: liver disease, alcoholic cirrhosis, kidney disease, cardiac disease, postsurgical complications, carcinoma, myocardial infarction, pulmonary embolism, DVT, eclampsia, and DIC.²²

EUGLOBULIN CLOT LYSIS

A very elementary procedure, euglobulin clot lysis was used before specific antibodies to fibrinolytic products were available. The euglobulin protein fraction is precipitated from plasma in an acid solution (1% acetic acid). The precipitate contains fibrinogen, plasminogen, and plasminogen activators but no fibrinolytic inhibitors (which remain in the supernatant). With the removal of the fibrinolytic inhibitors from the test system, the fibrinolytic system's action is more easily demonstrated. The precipitate is redissolved, clotted with thrombin, and observed for clot lysis at 37°C. The fibrin clot generated by thrombin serves as the substrate for plasmin generated from plasminogen by plasminogen activators (also activated by thrombin). The end point is the time in minutes required for complete degradation of the clot into small fibrin strands or particles.²²

The euglobulin lysis time normally is longer than 90 minutes. Shortened lysis times indicate increased fibrinolytic activity, because of increased levels of the activator or, less commonly, increased levels of plasmin. Shortened lysis

times can occur in fibrinolysis secondary to intravascular coagulation, in liver disease because of poor clearance of activator, and in thrombolytic therapy because of the therapeutic administration of a plasminogen activator. A fibrinogen level of <100 mg/dL can produce a false positive euglobulin clot lysis test. (See Website.)

✓ Checkpoint! 7

What is the appropriate interpretation of the following coagulation test results?

PT	Prolonged
APTT	Prolonged
TT	Prolonged
FDP	>20 $\mu\text{g/mL}$
D-dimer	>1.0 $\mu\text{g/mL}$

▶ LABORATORY INVESTIGATION OF HYPERCOAGULABLE STATES

If individuals have repeated thrombotic episodes, they most likely are in a hypercoagulable state. Laboratory tests can assist in determining whether the thrombosis is due to hereditary or acquired abnormalities of the hemostatic system.

With an improved understanding of hemostasis and the regulatory role of naturally occurring anticoagulants, major advances have been made in identifying some of the hereditary defects associated with hypercoagulability. The first discoveries involved components of the antithrombin and protein C pathways. Infants in general are prone to thrombotic events, and thus the physiological hypercoagulability of the developing hemostatic system has received significant attention. The newborn infant can be expected to be at greater risk if an underlying hereditary deficiency of an anticoagulant protein also exists. As discussed earlier, provisions must be made to take small sample volumes and for assay sensitivities for components at extremely low levels.

Ideally, all testing should be performed as functional assays. All of the following tests are described as such because they are currently available. If the patient is suspected to have a type 2 deficiency (low activity, but normal antigenic measurement), an antigenic assay (ELISA, or Laurell rocket technique) is required as well. All of the following assays were initially measured in this fashion when an immunoprecipitable antibody became available. These techniques are fully described on the Web, so that the laboratory professional can understand the methodology, problem solve, and learn how to modify assays so that very low levels can be determined if needed. The theory of the chromogenic assay, which has greatly improved diagnostic capabilities of the coagulation laboratory, and LIA testing are also described. (Web Figures 18a, 18b.)

An important issue is when to test a patient who has had a thrombotic event. If the event was venous, not an arterial

(platelet-derived) thrombosis, the standard accepted approach is to treat the patient appropriately and test later. The diagnostic workup is delayed until the patient is stable and no longer hospitalized with a thrombotic event (which consumes coagulation factors and inhibitors) and not receiving warfarin (vitamin K antagonist) or heparin and/or a replacement therapy such as fresh frozen plasma (FFP). Testing for protein C and protein S (vitamin K-dependent proteins) while a patient is taking warfarin or during an active thrombotic process can lead to falsely low activity and/or antigen values and therefore can result in the misdiagnosis of an inherited hypercoagulable state.^{70,71} Repeat studies are often needed, and family studies are usually required to confirm a diagnosis.

ANTITHROMBIN

Antithrombin (AT), previously called *antithrombin III*, has powerful and immediate antiprotease action in the presence of heparin. This interaction between AT and heparin is the basis for the poor clinical response to heparin if the patient has significantly decreased levels of AT. AT can be measured by a variety of assays.

The chromogenic assay is a functional two-part assay measuring AT activity in the presence of heparin (Web Figure 19 ■). In the first part, plasma is incubated with a known excess of thrombin in the presence of heparin (heparinized buffer). AT neutralizes a proportional amount of the thrombin in the presence of heparin. The second part of the assay determines the residual thrombin activity by its enzymatic activity on an appropriate substrate (fibrinogen tagged with a chromophore, such as p-Nitroanilin [pNA], which when released produces a yellow color that is measured at 405 nm). The amount of thrombin neutralized in the first reaction step is proportional to the amount of AT present in the test sample; thus, the residual amount of thrombin (as measured by the pNA release) is inversely proportional to the test sample's AT level (Web Figure 19). A reference (standard) curve is prepared by plotting the AT activity (%) for each reference plasma dilution prepared against its corresponding absorbance. The results for patients and controls are read from this curve using respective absorbance readings. The general reference interval for AT is 80–120%.⁷²

The other common functional assay is a clot-based method in which the clotting of fibrinogen rather than the cleavage of a synthetic chromogenic substrate is the endpoint of the assay. Plasma is defibrinogenated (fibrinogen removed) and incubated with heparin and thrombin. Residual thrombin is determined by transfer to a standardized fibrinogen solution, and the time for clotting to occur is measured. As in the chromogenic assay, the clotting time is directly proportional to the concentration of AT in the patient's plasma: The higher the AT level, the higher is the amount of thrombin neutralized in the first step, resulting in a lower level of residual thrombin and a prolonged clotting time in the second step.

Immunological methods measure the concentration of the AT protein using EIA, ELISA (Web Figures 21, 22, and 23 ■), radial immunodiffusion (RID), and micro latex particle immunological assays (LIA tests, automated procedures available) (Web Figure 10 ■).

Inherited deficiencies of AT can involve a decrease in the protein (and activity) level or the presence of a dysfunctional protein. In addition to congenital deficiencies (which are very rare), acquired deficiencies occur in DIC, liver disease due to decreased synthesis, and nephrotic syndrome (the latter as a consequence of urinary protein loss). Healthy newborns have about half the normal adult concentration of AT and gradually reach the adult level by 3–6 months of age. A number of clinical disorders can be associated with reductions in the plasma concentration of AT, sometimes making it difficult to establish a definitive diagnosis of the hereditary deficiency state. Low levels on an initial screen should be confirmed at a later date. All hereditary deficiencies identified to date have been in heterozygous individuals.

Anticoagulation of patients also affects testing for AT. The administration of heparin decreases plasma AT levels presumably by accelerated clearance of the heparin-antithrombin complex. Thus, the evaluation of plasma samples during heparinization can lead to an erroneous diagnosis of AT deficiency. Plasma AT concentrations are occasionally elevated into the normal range by warfarin in individuals with AT deficiency. Confirmation of the hereditary nature of an AT deficiency may require investigation of other family members. (See Website.)

PROTEIN C/ACTIVATED PROTEIN C (APC)

Functional assays of protein C (PC) have been analyzed by measuring amidolytic activity using a chromogenic substrate or its anticoagulant activity in a clot-based assay. Chromogenic assays can be less informative than clot-based assays when screening for PC defects. Several individuals have been described with normal PC antigen (immunologic) measurements and reduced PC anticoagulant activity in clot-based assays but normal amidolytic activity in chromogenic assays.⁷³ These individuals could have defects in the ability of activated PC (APC) to interact with platelet membranes or the F-Va or F-VIIIa substrates and thus would not be detected by the amidolytic assay.⁷³

APC is an anticoagulant that inactivates F-Va and F-VIIIa. In the assay for PC, a reagent containing snake venom (*Agkistrodon c. contortrix*), protac (a particulate activator for the activation of protein C), and platelet factor 3 activate both PC and the contact factors of the intrinsic pathway. The patient's plasma is incubated with PC-deficient plasma (to compensate for any factor deficiency other than PC), an APTT reagent containing the activator, and then with calcium chloride; the time for clot formation is measured. Activation of PC, resulting in the inactivation of F-Va and

F-VIIIa in the control and patient samples, results in a prolongation of the modified APTT. The longer the modified APTT, the more functional PC is present in the plasma sample. A reference (standard) curve is prepared by plotting the PC activity for each reference plasma dilution assayed in conjunction with the patient samples against its clotting time. The results for patients and controls are obtained from this curve using the respective clotting times (see Website). The general reference interval for PC is 60–150%.⁷⁴

In spite of its limitations as discussed, the chromogenic assay for PC is widely used. In this assay, PC is incubated with a specific activator and the amount of APC measured is based on its enzymatic activity on a chromogenic substrate. The enzymatic activity releases pNA from the chromogenic substrate, and pNA is measured spectrophotometrically at 405 nm. The absorbance of pNA is directly proportional to the amount of APC. A reference (standard) curve is prepared by plotting the protein C activity (%) for each reference plasma dilution against its corresponding absorbance. The results for patients and controls are obtained from this curve using the respective readings.

The PC deficiency diagnosis is complicated for patients on oral anticoagulation therapy. Warfarin therapy reduces functional and, to a lesser extent, immunologic measurements of PC. Several researchers have proposed using the ratios of PC antigen to the F-II or F-X antigen. However, this will not identify patients with type II PC deficiency (low activity, normal antigen). This approach of using ratios can be used only for patients in a stable phase of oral anticoagulation. Other groups have used PC activity assays in conjunction with functional measurements of F-VII (a vitamin K-dependent zymogen with a similar plasma half-life). In practice, investigating individuals suspected of having PC deficiency after oral anticoagulation has been discontinued for at least 1 week and performing family studies are preferable. If discontinuing warfarin therapy is not possible, individuals can be studied while they receive heparin therapy, which does not alter plasma PC levels.⁷³

Acquired PC deficiency is found in numerous disease states. Most individuals with uremia have low levels of PC anticoagulant activity but normal levels of PC amidolytic activity and antigen. This low PC anticoagulant activity has been attributed to a dialyzable moiety in uremic plasma that interferes with most clotting assays for PC activity.⁷³

PROTEIN S

Circulating protein S (PS) exists in two forms: free (40%) and bound to C4b binding protein (60%). Only the free protein S serves as a cofactor for APC, enhancing its anticoagulant activity. The functional free form is what clot-based assays measure. Laboratory evaluation of PS also can include assays of total PS antigen (ELISA) and free PS (immunoassays using monoclonal antibody specific for the free form).⁷⁵

Functional PS assay methods are based on the ability of PS to serve as a cofactor for the anticoagulant effect of APC. A typical clot-based procedure for measuring the cofactor activity of PS requires four reagents: (1) PS-deficient plasma to ensure optimal levels of all coagulation factors except PS, (2) purified activated protein C, (3) purified activated F-Va to serve as a substrate for APC, and (4) calcium chloride. Patient PPP is mixed with PS-deficient plasma. APC and activated F-Va reagents are added to this mixture, which is incubated at 37°C. Following incubation, calcium chloride is added to initiate clot formation. The clotting time is proportional to the PS activity in the sample (i.e., the higher the level of PS, the longer is the clotting time).

A reference (standard) curve can be prepared by using dilutions of reference plasma representing 100%, 75%, 50%, and 25% PS activity. The PS activity for each plasma and control is obtained from this curve. The general reference interval for protein S is 66–122%.⁷⁶

Like PC clot-based assays, the presence of factor V Leiden, APC resistance, elevated F-VIII levels, and a lupus anticoagulant can cause false positive PS test results if clotting (functional) assays are used to diagnose PS deficiency.

Inherited deficiencies (autosomal dominant disorder) can involve a decrease in the protein or a dysfunctional protein. The clot-based procedure for PS detects both quantitative and qualitative deficiencies of PS, but immunologic methods do not detect qualitative deficiencies.

Acquired PS deficiencies are found in numerous disease states. Although total PS antigen measurements are generally increased in individuals with nephrotic syndrome, functional assays are often reduced because of the loss of free PS in the urine and elevations in C4b-binding protein levels.⁷³

ACTIVATED PROTEIN C RESISTANCE (APCR)

APC resistance (APCR) is one of the most common risk factors for thrombosis. The presence of the factor V Leiden (FVL) mutation results in the resistance of F-Va to degradation by APC, commonly referred to as *activated protein C resistance (APCR)*.

The clot-based assay is based on the principle that the addition of APC to a plasma sample induces a prolongation of the APTT mediated by the inactivation of F-Va and F-VIIIa in the plasma sample. The sensitivity and specificity of the screening test has been improved by prediluting the patient plasma with F-V-deficient substrate plasma; this permits the evaluation of patients receiving anticoagulants or who have an abnormal APTT due to factor deficiencies other than F-V. The testing proceeds with the performance of an APTT with and without the addition of APC. The APC ratio is calculated using the clotting time of the sample with APC (results should be prolonged due to the destruction of F-Va and F-VIIIa) divided by the clotting time for the sample without

APC. APCR is indicated by an APCR ratio of less than what was established for the laboratory using a particular instrument and reagent combination.⁷⁷ (See Web Figure 11 ■ for the APCR ratio calculation.) Acquired conditions such as pregnancy, oral contraceptive use, elevated F-VIII, and a stroke can also produce APCR.

The APCR functional assay (as described) is a screening, not a diagnostic, test for FVL. Other rare congenital conditions including F-V Cambridge and homozygosity for the HR2 haplotype can result in APCR. Because 10% of individuals with APCR do not have the FVL mutation, clinical diagnosis requires both the clotting and molecular (PCR) tests for the FVL genetic mutation. If FVL mutation is not identified, PCR-based confirmatory tests for APCR due to other genetic mutations are available in research laboratories.

PROTHROMBIN G20210A

Individuals heterozygous for the F-II G20210A mutation (prothrombin 20210) can have prothrombin levels up to 30% higher than noncarriers. (This mutation is now known to be a mutation in position 21538 of the *F2* gene.) However, because of the overlap with the normal range for F-II, clot-based functional assays for prothrombin are unreliable.⁷⁸ Therefore, genetic screening using PCR amplification of the F-II gene is the only reliable way to detect the presence of this phenotype. Detection methods for the amplified product can utilize specific endonucleases, gel electrophoresis, or fluorescent probing. A multiplex PCR-based assay is available for the simultaneous detection of FVL and F-II G20210A.⁷⁹

Checkpoint! 8

In diagnostic laboratory evaluation of a hypercoagulable state such as antithrombin deficiency, why is it important to determine the functional activity of the coagulation protein?

ADDITIONAL TESTING FOR THROMBOSIS

Rare abnormalities in the fibrinolytic system may result in thrombosis. The tests in this section may be performed to assist in diagnosis of these abnormalities. Except for plasminogen, the tests discussed are performed less frequently than those previously described and may require sending samples to a reference laboratory for testing. If only a limited number of these tests are performed at a particular site, they could be prohibitively costly. See Web Table 8 for material related to this topic.

Plasminogen

Plasminogen levels are measured by using a chromogenic assay based on the conversion of plasminogen to plasmin by an excess of streptokinase (SK), which acts as an activator. The first step in this assay involves incubating patient plasma with a known excess of SK, which forms a complex (plasminogen-SK) that causes plasmin-like activity. The second step determines the amount of the complex by its enzymatic activity on a chromogenic substrate. The enzymatic activity results in the release from the chromogenic substrate of pNA, which is measured spectrophotometrically at 405 nm. The pNA absorbance is directly proportional to the plasminogen quantity. A reference (standard) curve is prepared by plotting the plasminogen activity (%) for each reference plasma dilution against its corresponding absorbance. The results for patients and controls are obtained from this curve using the respective absorbance readings. The general reference interval for plasminogen levels is 74–124%.⁸⁰

Inherited deficiencies of plasminogen include quantitative deficiencies characterized by decreased antigenic and functional levels as well as qualitative deficiencies characterized by dysfunctional protein. Acquired deficiencies are associated with DIC, liver disease, and leukemia. Measuring circulating plasminogen levels is useful in monitoring hepatic regeneration of plasminogen after discontinuation of treatment with SK and in controlling and adjusting the rate of infusion of FFP being given to the patient.

Alpha₂-Antiplasmin Activity (α_2 -antiplasmin)

A chromogenic method to measure α_2 -antiplasmin that can be used with microtiter plate, test tube, and automated procedures is available. Incubation of plasma diluted with an excess of plasmin results in a rapid complex formation between the functional plasmin inhibitor (antiplasmin) present in the plasma and the added plasmin. The amount of plasmin activity inhibited is proportional to the amount of plasmin inhibitor in the patient plasma. The residual plasmin hydrolyzes the chromogenic substrate S-2403, liberating the chromophoric group, pNA. The color is observed photometrically at 405 nm.⁸¹ The inhibitor α_2 -antiplasmin is important in regulating the fibrinolytic system. Congenital deficiencies are characterized by bleeding occurring some hours after an initial injury. Clotting and wound healing are usually normal, but the hemostatic plug breaks down prematurely. Acquired decreases of α_2 -antiplasmin can be observed in liver disease and DIC. Increased levels have been reported during the postoperative period.

Plasmin- α_2 -Antiplasmin (PAP) Complex

The plasmin- α_2 -antiplasmin (PAP) complex test uses ELISA methodology to detect elevated levels that can occur during thrombotic events, in cases of endogenous hyperfibrinolysis, and during thrombolytic therapy. The blood sample is collected in special precoated plastic tubes containing citrate,

aprotinin, and benzamidine.⁸² Special specimen processing is required. (See Website.)

Plasminogen Activator Inhibitor (PAI-1)

Both functional⁸³ and antigenic measurements⁸⁴ are available to measure plasminogen activator inhibitor-1 (PAI-1), the primary inhibitor of tissue plasminogen activator (tPA). This inhibitor varies diurnally so attention must be paid to the timing of both collecting the patient sample and obtaining samples for establishing a normal range for the laboratory. An increased plasma level of PAI-1 is associated with impaired fibrinolytic function. Elevated levels of PAI-1 have been observed in thrombolytic disease, acute myocardial infarction, DVT, normal pregnancy, and sepsis (see Website).

Tissue Plasminogen Activator (tPA)

Both functional (chromogenic) and antigenic (ELISA) assays are available to measure tissue plasminogen activator (tPA), an important protein in the fibrinolytic system.⁸⁵ The physiologic role of tPA is to activate plasminogen to plasmin, which then degrades fibrin to soluble FDP. Fibrinolysis is regulated by specific interactions between tPA and fibrin and between plasmin and the plasmin inhibitor α_2 -antiplasmin. In the assay for tPA, the plasma tPA inhibitor PAI-1 is usually present in large excess and must be prevented from quenching tPA activity. This is accomplished using a special blood collection tube (Biopool Stabilyte tubes, Dia Pharma), which provides mild acidification and stabilization of the sample, blocking the effect of PAI-1.

Thrombin Activatable Fibrinolysis Inhibitor (TAFI)

TAFI induces hypofibrinolysis by decreasing fibrin's ability to bind tPA and plasminogen. High concentrations of TAFI can induce an elevated risk of thrombosis. The TAFI antigen concentration in normal human plasma is usually between 40 and 250%.⁸⁶ There are no variations for gender or pregnancy. (See Website.)

Lipoprotein(a)

Lipoprotein(a) interferes with fibrinolytic functions of plasminogen and/or plasmin and can thus promote thrombotic events. The ELISA assay uses serum or citrated plasma.⁸⁷ (See Website.)

▶ LABORATORY EVALUATION OF ANTICOAGULANT THERAPY

A critical laboratory function is to monitor patients on anticoagulant therapy. As with diagnostic testing, the same parameters of blood collection, specimen processing, and quality control are essential.

ORAL ANTICOAGULANT THERAPY AND THE PROTHROMBIN TIME—INR VALUE

The clinical laboratory now reports patient values when monitoring **oral anticoagulant therapy** (coumadin, warfarin) using an **international normalized ratio (INR)** value, which is determined from the PT result. This standardization of oral anticoagulant control has greatly improved patient care in this mobile world.

In 1977, the World Health Organization (WHO) introduced an international reference standard for thromboplastins. Since then, several different WHO standard thromboplastins, which represent the different types of commercial thromboplastins, have been established. These standards allow for the calibration of commercial thromboplastins for oral anticoagulant control. Each manufacturer has an in-house standard (a specific lot of its own thromboplastin) that has been carefully calibrated against one of the WHO standards. The **international sensitivity index (ISI)** value is calculated as a specific correction factor for a manufacturer's standard against the WHO reference preparation. The ISI for a particular reagent is instrument dependent. Its value is listed on each package (lot number) of thromboplastin reagent purchased for PT testing (different ISI values are provided for the various types of instrument with which the thromboplastin reagent will be used [i.e., mechanical, optical]).

Commercial manufacturers of thromboplastin reagents are working to produce ISI values close to 1.0. This value that the WHO recommends minimizes discrepancies between labs in reporting the INR value.^{88,89,90}

The INR has become the standard for reporting PT results when monitoring long-term oral anticoagulant therapy. The WHO and the International Committee on Thrombosis and Haemostasis recommended this method of reporting in 1983. Most laboratories currently report both the PT and the INR for a given sample. The advantage of the INR is that it is independent of the reagents and methods used to determine PT and therefore allows better assessment of long-term oral anticoagulant therapy.⁸⁸⁻⁹⁰ By definition, the INR is the PT ratio equivalent to using the WHO international reference preparation as the source of thromboplastin in the performance of a PT. Each laboratory uses the formula in Figure 6 ■ to calculate each INR value from the PT produced for each patient. The PT has thus been improved by standardizing each thromboplastin reagent against reference thromboplastins. The calculation also includes the lab's mean value for at least 20–30 normal control subjects using the specific lot of thromboplastin with a particular type of instrumentation (mean normal PT for the laboratory, not the clotting time of, for example, lyophilized pooled normal plasma). The mean value changes with each new lot of reagent.

By reporting the PT as an INR value, each laboratory is using a standardized unit related to the WHO standards. The INR value has also provided the opportunity to use a common unit for defining the **therapeutic ranges** for oral an-

$$\text{INR} = \text{R}^{\text{ISI}}$$

Where R = PT ratio obtained with the working thromboplastin
 PT ratio = Patient's PT/Mean normal PT
 ISI = International sensitivity index (provided by manufacturer)

Example: Patient's PT = 21.5 seconds
 Mean normal PT = 12.0 seconds
 ISI = 1.35

$$\text{INR} = (21.5/12.0)^{1.35} = 2.2$$

■ **FIGURE 6** International normalized ratio (INR) calculation formula.

ticoagulant therapy. Patients receiving oral anticoagulants for a hypercoagulable state (arterial or venous thromboembolism) should have an INR between 2.0 and 3.0; occasionally (e.g., with a mechanical valve replacement) the recommended ratio can be higher. Each facility should determine its own therapeutic range.

The efficacy of oral anticoagulants such as warfarin and coumadin is influenced by the patient's body mass, vitamin K content in the diet, drug interactions, wellness, and hepatic function. The INR should be carefully interpreted with regard to the patient's drug regimen (antibiotics or aspirin-containing medication) and dietary changes. The INR was devised to monitor patients on long-term anticoagulant therapy and is thus not meaningful in patients not on anticoagulant therapy. The use of the INR for clinical conditions other than oral anticoagulation has not been validated.

Point-of-care (POC) instruments that determine the individual's INR from a capillary puncture are currently available. The reagent used by these instruments is only thromboplastin; calcium is not required because the blood sample has not been citrated; thus, the calcium is not bound and is available from the patient's whole blood. These instruments determine the PT and calculate the INR. Patients, anticoagulation clinics, and laboratories in physicians' offices use them to monitor and maintain optimal therapeutic levels of oral anticoagulant.

HEPARIN THERAPY

In addition to monitoring patient treatment, physicians must be aware of two phenomena with the use of heparin. The first is the variation in an individual patient's response to heparin due either to a resistance to a specific species of heparin (bovine or porcine) or to variability in heparin-binding proteins and physiologic clearance mechanisms. These mechanisms might not produce the expected clinical results post-treatment. The second phenomenon is a dramatic decrease in the patient's platelet count caused by the heparin infusion (HIT). HIT testing is discussed earlier in this chapter.

ACTIVATED PARTIAL THROMBOPLASTIN TIME (APTT)

Traditionally, the APTT has been the most commonly used procedure to monitor standard (unfractionated) heparin therapy. Heparin response curves previously were prepared by spiking plasma with heparin at various levels and graphing the results. Thus, the patient's APTT at therapeutic levels (0.3 to 0.7 U/mL of heparin) could be determined. The degree of prolongation of the APTT is variable, depending on the APTT reagent, instrument, and even the particular lot of the same reagent (Web Figure 12 ■). Some very sensitive reagents do not give measurable clotting times at concentrations of 0.5 U/mL or above, thus eliminating their usefulness in monitoring heparin levels.³⁰

Unlike the PT, there is no standardization of the APTT to normalized differences in reagents and test systems. In addition to the sensitivity issues mentioned, complications include the variation in standard heparin preparations, the individuality of a patient's response to heparin due to heparin-binding proteins, and the physiologic clearance mechanisms. For these reasons, two individuals receiving a standard heparin bolus of 5000 units in the same facility can have very different APTT results (one indicating a therapeutic response and the other a supratherapeutic response). Thus, the common practice of 1.5 to 2.5 times the control APTT value is no longer acceptable.

The College of American Pathologists (CAP) requires that clinical laboratories establish a heparin therapeutic range for their APTT procedure.⁹¹ The laboratories determine this range by correlating the APTT results from patients on heparin therapy with the specific test results for F-Xa inhibition from those same samples. Because the therapeutic range for the F-Xa inhibition assay is established as 0.3–0.7 U/mL, the APTT therapeutic range is derived by comparison. A weight-based heparin dosing **nomogram** should also be provided to the clinicians so they can determine the appropriate dose of heparin to reach and/or maintain a therapeutic range^{92,93} (Table 8 ☆). Additionally, a variety of factors can impact heparin monitoring (Table 9 ☆).

THROMBIN TIME

TT is less commonly used to monitor heparin therapy. Its advantage is that it is not influenced by plasma factor deficiencies.^{94,95}

ANTI-XA ASSAY

The APTT might not demonstrate a response to heparin during initial heparin treatment for DVT or PE due to the presence of acute phase reactant proteins as indicated in Table 9. In this situation, another heparin assay such as the F-Xa inhibition assay frequently reflects a therapeutic level of heparin and allows proper patient management.

★ TABLE 8

Weight-Based Heparin Dosing Nomogram		
Initial Heparin Dose:	80 Units/kg Bolus	
Initial Maintenance Infusion Rate	18 Units/kg/hr	
Adjustment of maintenance infusion: Perform an APTT 6 hours after the initial heparin bolus and adjust as follows.		
APTT, sec*	Bolus	Change in infusion rate of heparin
<40	80 units/kg	Increase infusion by 4 units/kg/hr
40–49	40 units/kg	Increase infusion by 2 units/kg/hr
50–80		No change
81–100		Decrease infusion by 2 units/kg/hr
>100		Stop heparin infusion for 1 hour; then decrease infusion by 3 units/kg/hr

*Based on its established heparin therapeutic range, each laboratory should determine its own APTT ranges for the nomogram.

An APTT should be performed 6 hours after each dosage change and the appropriate changes in dosage applied.

Low molecular weight heparin (LMWH) has become a common form of heparin for anticoagulant therapy. It has more reliable **pharmacokinetics** and **bioavailability** than standard heparin and thus does not require routine laboratory monitoring in adults because its dose response is more predictable. For children, monitoring is minimal, although it is critically important in those with poor or nonexistent venous access. LMWH also reduces the risk of

★ TABLE 9

Factors Affecting the Monitoring of Heparin
<ul style="list-style-type: none"> • Conditions that influence the pharmacokinetics or general bioavailability of heparin: Heparin binds to various plasma proteins (e.g., platelet factor 4, fibrinogen, VWF, fibronectin, and vitronectin), macrophages, and endothelial cells, resulting in decreased bioavailability • Conditions that alter the characteristics of the APTT dose response to heparin • Conditions that cause an abnormal baseline APTT (factor deficiency, lupus anticoagulant) • Patient's body weight • Antithrombin level • Specimen collection and processing problems <ul style="list-style-type: none"> Time of collection (minimum of 4 hours needed to achieve steady state with heparin) Delayed testing (can result in abnormally prolonged results) Failure to achieve PPP (can result in release of PF4 from activation of residual platelets resulting in underestimation of heparin in the sample)

heparin-induced thrombocytopenia, and probably the risk of osteoporosis with long-term heparin use.

Therapeutic doses of LMWH (enoxaparin [Lovenox[®], Sinofi-aventis] and reviparin [Clivarin[®], Abbott International, Knoll]) are based on an anti-F-Xa level of 0.5 to 1.0 units/mL. The guideline used for the citrated blood sample is taken 4 to 6 hours after a subcutaneous injection.⁹³ A standard for performing the anti-F-Xa assay for LMWH is used.

The F-Xa inhibition assay (anti-Xa assay) is also a more specific test for monitoring unfractionated heparin (UFH) therapy. In testing for UFH, a special standard is used. The **chromogenic assay** for both types of heparin uses excess activated F-X (F-Xa), which is added to the patient's PPP and incubated.⁹⁶ Heparin present in the patient's PPP inhibits the F-Xa. A chromogenic substrate is added to this mixture, and any residual F-Xa enzymatically cleaves the chromogen, producing a yellow color that is measured spectrophotometrically. A reference (standard) curve is prepared by plotting the various dilutions of known concentrations of heparin against its corresponding absorbance. The results for the patients and controls are obtained from this curve using the respective absorbance readings.⁹⁶ The therapeutic range for heparin is 0.3–0.7 U/mL.

ACTIVATED CLOTTING TIME (ACT)

Bedside testing with the ACT has been used in cardiac care units and during cardiac surgery to monitor heparin. The ACT is a traditional whole blood clotting method similar to the APTT principle. The ACT test activates whole blood with a contact activator, and the clot in the sample is detected using a **POC instrument**. The ACT result in seconds is a function of the heparin concentration but is also influenced by factors such as coagulation factors, inhibitors, lysed platelets, increased hemodilution, hypothermia of the patient, and others.³⁰

✓ Checkpoint! 9

As seen in Figure 6, the patient has a PT of 21.5 seconds (producing an INR of 2.2). In this case, the patient is not on oral coagulation. What is the explanation for not reporting the INR?

▶ MOLECULAR MARKERS OF HEMOSTATIC ACTIVATION

A more detailed understanding of the biochemistry of coagulation and fibrinolysis has resulted in the development of a number of sensitive and specific assays that detect molecular markers of platelet activation, generation of coagulation enzymes, and products of intravascular fibrin formation or dissolution⁹⁷ (Table 10). The availability of testing for molecular markers is useful for the early detection of

★ TABLE 10

Immunochemical Markers of Hemostatic Activation

Coagulation	
Activation peptides	Factor IX activation peptide Factor X activation peptide Prothrombin activation fragment F1+2 Protein C activation peptide Fibrinopeptide A, fibrinopeptide B
Enzyme-inhibitor complexes	Thrombin-antithrombin complex (TAT) Factor Xa-antithrombin complex Factor IXa-antithrombin complex Activated protein C-protein C inhibitor complex
Fibrinolysis	B β 1-42 fragment (plasmin cleavage of fibrin) Plasmin-antiplasmin complex (PAP)
Platelet activation (flow cytometry)	Activated GPIIb/IIIa complex P-selectin (CD62-P) GPIb/IX/V (decrease)

platelet-driven or coagulation-driven disorders and their use can result in improved medical care for thrombotic and fibrinolytic disease. This testing is not, however, routine and may be available only at large medical centers or reference laboratories.

MARKERS OF FIBRIN FORMATION AND FIBRINOLYSIS

The process of activating coagulation converts a number of zymogens to active serine proteases. Directly measuring the levels of most hemostatic enzymes in vivo (i.e., thrombin, plasmin) is not possible because naturally occurring protease inhibitors rapidly neutralize the majority. However, the activation peptides released on activation of the zymogen can be measured by immunochemical assays (RIA, ELISA). The enzyme-inhibitor complex that forms as a result of zymogen activation can also be measured by similar immunochemical methods. Due to high cost and low volume of test requests, the routine clinical laboratory generally does not offer these assays.

The assays depend on the development of monoclonal or polyclonal antibodies capable of recognizing antigenic determinants on the activation fragment or enzyme-inhibitor complex that are hidden in the parent zymogen or inhibitor. More widely used assays include those for: fibrinopeptide A and/or fibrinopeptide B and prothrombin activation fragment F1+2. Thrombin-antithrombin (TAT) complex and plasmin-antiplasmin (PAP) complex (Table 10) testing were described earlier in the chapter.

LABORATORY MARKERS OF PLATELET ACTIVATION

Platelet hyperreactivity or circulating activated platelets have been reported to be associated with several clinical conditions including coronary artery disease, unstable angina, and acute myocardial infarction.⁹⁸ The bleeding time, platelet function analyzer, and platelet aggregation tests remain the only standard clinical tests of platelet activation and function, but they are more useful in adults than pediatric patients in assessing platelet hyperreactivity (see earlier section on platelet function testing). A number of additional tests have been developed and are available in specialized coagulation laboratories, including ELISA assays for plasma platelet factor 4 (PF4), β -thromboglobulin (β -TG) and soluble P-selectin (markers of platelet activation and secretion), and urine assays for thromboxane A₂ metabolites (TX-B₂).

Flow cytometry can be used to evaluate platelet activation and function and will likely assume an increasingly important role in the evaluation of in vivo platelet activation.⁹⁸ Platelets are labeled with a fluorescent-conjugated antibody, and specific characteristics of a large number of individual platelets can be measured rapidly (1,000–10,000 cells/minute). In the absence of an added (exogenous) platelet agonist, whole blood flow cytometry evaluates the activation state of circulating platelets according to the binding of an activation-dependent monoclonal antibody. If an exogenous agonist is included in the assay, it is possible to analyze the reactivity of circulating platelets in vitro (i.e., a physiologic assay of platelet function).

Monoclonal antibodies can be used to measure the expression of platelet surface antigens. However, antibodies that detect activation-dependent antigens (i.e., antibodies that bind to activated platelets, not to resting platelets) are particularly useful for assessing platelet hyperreactivity. Monoclonal antibodies that detect an activation-induced conformation change in GPIIb/IIIa appear to be directed against the fibrinogen-binding site of GPIIb/IIIa of activated platelets. P-selectin (CD62-P) (previously referred to as GMP-140 or PADGEM) is a component of the alpha granule membrane of resting platelets and is expressed on the platelet surface after alpha granule secretion. Thus, a P-selectin specific antibody binds only to degranulated, activated platelets, not resting platelets.

The GPIb/IX/V complex (VWF receptor) offers a different approach in evaluating in vivo platelet function. In contrast to activation-dependent monoclonal antibodies (e.g., GPIIb/IIIa), the binding of GPIb/IX/V-specific antibodies to activated platelets is markedly decreased compared to that of resting platelets. This decrease is due to a redistribution of the GPIb/IX/V complex to the membrane of the surface-connected canalicular system with platelet activation. Specific testing for these platelet markers likely is available only in a large clinical flow cytometry laboratory or a university setting.

Evidence of in vivo platelet activation can have significant clinical implications in cardiovascular and thrombotic diseases. Flow cytometric analysis of platelet activation-dependent markers can be used to determine optimal antiplatelet therapy in clinical settings and to measure platelet hyperreactivity in a number of clinical conditions.

GLOBAL TESTING

Hemostasis testing at the POC has become a requirement in the majority of hospitals. Increasing numbers of complex surgical procedures (liver transplantation, coronary bypass graft, and valve repair in patients on the heart-lung machine) have created a demand for the availability of rapid and more comprehensive information on a patient's hemostatic condition. Therapeutic decisions must be made quickly to discriminate between surgical bleeding and a hemostatic disorder.

Unlike typical coagulation tests that are performed in the absence of cellular elements and provide data only on plasma clotting components, thereby overlooking potentially important interactions essential to the clinical evaluation of in vivo hemostasis, **global testing** instruments analyze the entire hemostasis process including coagulation, anticoagulant effects, fibrin formation and stabilization, clot retraction (platelet function), and fibrinolysis. Two of the more commonly used analyzers are described here. Their current uses are primarily in surgery settings where blood product usage can be monitored and in research facilities that wish to improve diagnostic testing and monitor treatment of patients with bleeding and clotting disorders.³⁰

Thromboelastography (TEG), a viscoelastic whole blood instrument introduced by Hartert in 1948, is increasingly being used as a near patient testing method for assessing blood coagulability. The instrumentation (thromboelastograph) has become more clinically useful with direct readout of results and shortened reaction times by using activators and inhibitors in the cuvettes. The TEG provides prompt, reliable information to clinicians on the causes of blood loss in critical POC situations. It allows the discrimination between surgical bleeding and hemostasis disorders. The TEG seems to be the most suitable method for the detection of hyperfibrinolysis, an otherwise difficult to analyze coagulopathy that can lead to massive bleeding³⁰ (Web Figures 13 ■, 14 ■, 15 ■).

The TEG now is also able to assess platelet function in patients who received platelet-inhibiting drugs such as aspirin, clopidogrel, and others. The specialized testing is called *TEG[®] platelet mapping assay*.⁹⁹

The ROTEM[®] Haemostasis Whole Blood Analyser is a computerized device based on the TEG. It is designed to be used with appropriate reagents to generate both a qualitative graph and quantitative numerical results. The standardized

reagent menu allows for the differentiation of coagulation factor deficiencies, anticoagulant effects, platelet disorders, fibrin polymerization disorders, and hyperfibrinolysis (Web Figures 16 ■, 17 ■).

✓ Checkpoint! 10

A patient has a venous thrombotic episode and is to be treated appropriately. When should the blood sample be drawn to perform a thrombotic workup to diagnose an acquired or congenital deficiency? Why?

SUMMARY

This chapter reviewed the laboratory tests performed in the coagulation laboratory and specialized tests available from research or reference laboratories. It highlighted the role of the laboratory professional as an integral part in the diagnosis of bleeding and clotting disorders. The additional technical information provided on this book's Companion Website allows the CLS/CLT to access informa-

tion to improve coagulation testing so that all intricacies of sample collection, processing, quality control, accuracy, and reproducibility are available for each test.

The tests described were grouped according to the part of the hemostatic system that they assess: primary hemostasis, secondary hemostasis, the fibrinolysis, and hypercoagulable states. A combination of tests from these groups can be selected to screen for a disorder of the hemostatic system. As an example, the PFA, PT, and APTT can be used to identify a defect in either primary or secondary hemostasis. When this defect has been identified, specific laboratory tests can be selected to provide information for making a definitive diagnosis of the coagulation disorder. With the performance of screening tests for fibrinolysis (TT, FDP), further fibrinolytic testing can be performed. Laboratory tests used to evaluate hypercoagulable states (e.g., AT, PC, PS, APCR) and to monitor anticoagulant therapy (e.g., PT/INR, APTT, F-Xa inhibition assay) are some of the most frequently ordered in the coagulation laboratory. Testing is now available to detect activated platelets, coagulation enzymes, and products of intravascular fibrin formation or dissolution. Global testing once used only in the research setting is becoming clinically available.

REVIEW QUESTIONS

LEVEL I

- The hematology laboratory informs you that the hematocrit on a patient is 57% (0.57 L/L). For the proper anticoagulation of a 5.0 mL sample of the patient's blood, how much 3.2% sodium citrate should be used? (Objective 1)
 - 0.22 mL
 - 0.40 mL
 - 0.57 mL
 - 0.96 mL
- What laboratory test is used to monitor oral anticoagulant therapy? (Objective 5)
 - F-Xa inhibition assay
 - bleeding time
 - prothrombin time
 - activated partial thromboplastin time
- Which is the specimen of choice for the prothrombin time and activated partial thromboplastin time procedures? (Objective 3)
 - platelet-rich plasma, citrated
 - platelet-poor plasma, citrated
 - serum
 - plasma, heparinized
- A physician asks you to recommend a coagulation test for secondary fibrinolysis. Which laboratory test is specific for fibrinolysis? (Objective 4)
 - D-dimer
 - fibrin-degradation products
 - thrombin time
 - antithrombin

LEVEL II

- Which laboratory test is *not* used to investigate the hypercoagulable states? (Objectives 3, 5)
 - antithrombin
 - activated protein C resistance
 - plasminogen
 - activated partial thromboplastin time
- Platelet aggregation studies revealed normal aggregation curves with collagen, epinephrine, and ADP but an abnormal aggregation curve with ristocetin. Based on these findings, what is the differential diagnosis? (Objective 5)
 - von Willebrand disease and Bernard-Soulier syndrome
 - Glanzmann's thrombasthenia and von Willebrand disease
 - storage pool disease and Glanzmann's thrombasthenia
 - Bernard-Soulier syndrome and storage pool disease
- The observation of a normal reptilase time and a prolonged thrombin time indicates what disorder? (Objective 5)
 - presence of fibrin degradation products
 - dysfibrinogenemia
 - hypoplasminogenemia
 - presence of heparin
- In performing an activated protein C resistance assay on a patient specimen, you obtained the following results:

Standard APTT	28.4 sec
Modified APTT with APC	71.6 sec

 How would you interpret this assay? (Objective 5)
 - presence of F-V_{Leiden}
 - increased levels of activated F-VIII
 - presence of normal F-V
 - decreased levels of antithrombin

REVIEW QUESTIONS (continued)

LEVEL I

5. Which of the following methodologies is *not* used to determine fibrinogen concentration? (Objective 3)
- chromogenic assay
 - immunologic assay
 - precipitation assay
 - clot-based assay
6. Given the following data, calculate the INR. (Objective 7)
- | | |
|----------------|----------|
| Patient's PT | 23.5 sec |
| Mean normal PT | 11.5 sec |
| ISI | 1.15 |
- 2.0
 - 2.3
 - 2.5
 - 1.7
7. The APTT is used as a screen for the laboratory evaluation of inherited and acquired deficiencies in which of the following? (Objective 4)
- extrinsic pathway of the coagulation cascade
 - intrinsic pathway of the coagulation cascade
 - platelets
 - vascular system
8. The combination of a prolonged activated partial thromboplastin time and a prolonged test time with the mixing study procedure indicates the presence of what? (Objectives 4, 8)
- circulating inhibitor
 - F-VIII deficiency
 - antiplatelet antibodies
 - excessive vitamin K
9. Based on the following data, what is the most likely factor deficiency? (Objective 8)
- | | |
|------|-----------|
| PT | Normal |
| APTT | Prolonged |
| TT | Normal |
- F-VII
 - F-II
 - F-IX
 - F-XIII
10. Which laboratory test evaluates platelet function? (Objective 2)
- bleeding time
 - reptilase time
 - prothrombin time
 - protein C assay

LEVEL II

5. Given the following laboratory results, what is the appropriate reflex test? (Objective 6)
- | | | |
|------------------------------|--------------------|----------|
| PT | Normal | |
| APTT | Slightly prolonged | |
| Platelet aggregation studies | Collagen | Normal |
| | ADP | Normal |
| | Ristocetin | Abnormal |
- ristocetin cofactor assay
 - F-VIII assay
 - prekallikrein screen
 - bleeding time
6. What is the most likely cause of the following laboratory data? (Objective 5)
- | | |
|--------------------------------|-----------|
| PT | Normal |
| APTT | Prolonged |
| TT | Normal |
| APTT with 10-minute incubation | Normal |
- presence of lupuslike anticoagulant
 - F-XII deficiency
 - increased levels of tissue plasminogen activator
 - prekallikrein deficiency
7. Which of the following conditions does *not* have an impact on heparin monitoring? (Objective 7)
- patient's body weight
 - delay in testing
 - use of citrated platelet-poor plasma
 - underlying liver disease
8. In monitoring a patient on oral anticoagulant therapy, an INR of 1.3 was obtained. How would you interpret this result? (Objective 7)
- The patient is adequately anticoagulated and should be tested again in one month.
 - The patient is underanticoagulated and should be evaluated for a change in dietary habits.
 - The patient is overanticoagulated and should receive a vitamin K injection.
 - Insufficient data to determine status of patient.
9. Based on the following laboratory data, which is the appropriate reflex test? (Objective 6)
- | | |
|----------------|------------|
| PT | Normal |
| APTT | Prolonged |
| TT | Normal |
| Mixing Studies | Correction |
- dilute Russell's viper venom time
 - F-XI assay
 - activated protein C resistance assay
 - fibrin degradation products assay

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

10. Given the following laboratory data, which would you perform to resolve these results? (Objective 6)
- | | |
|----------------|---------------|
| PT | Prolonged |
| APTT | Prolonged |
| TT | Prolonged |
| mixing studies | No correction |
- a reptilase time to confirm heparin contamination
 - a fibrinogen determination to confirm fibrinogen deficiency
 - a dilute Russell's viper venom time to confirm lupuslike anticoagulant
 - a hematocrit to confirm a decreased hematocrit (<20%)

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Why have most clinical laboratories switched from 3.8% to 3.2% sodium citrate for specimen collection in coagulation studies?

Answer

The use of 3.2% sodium citrate minimizes the chances of overanticoagulating a specimen due to a high hematocrit or an inadequately filled collection tube.

Checkpoint! 2

What effect does aspirin taken daily for a heart condition have on the bleeding time of a patient? Explain.

Answer

Aspirin irreversibly inhibits cyclooxygenase, which is responsible for thromboxane A₂ synthesis. Thromboxane A₂ is required for platelet

aggregation; therefore, the bleeding time is prolonged. Because aspirin's action is irreversible, the platelet is affected for its life span (~7–10 days).

Checkpoint! 3

Routine coagulation testing was performed on a properly collected and processed specimen. The PT was prolonged, but APTT was normal. What is the best interpretation of these results?

Answer

These results indicate an F-VII deficiency. The PT evaluates factors in the extrinsic and common pathways, and the APTT evaluates factors in the intrinsic and common pathways. Because only the PT is prolonged, the factor deficiency must be in the extrinsic pathway.

Checkpoint! 4

Given the following coagulation test results, what is the appropriate follow-up or reflex test?

PT	normal
APTT	prolonged
Mixing studies	no correction

Answer

The appropriate follow-up or reflex test is the platelet neutralization procedure, dilute Staclot LA, or Russell's viper venom time. Any of these tests would identify the presence of lupuslike anticoagulant.

Checkpoint! 5

What is the function of the factor deficient substrate reagent and the reference plasma in a factor assay?

Answer

The factor deficient substrate reagent ensures that all coagulation factors except the coagulation factor to be assayed are at optimal activity levels. In this way, only the activity level of a single coagulation factor is evaluated. Reference plasma contains a known activity level for each coagulation factor and is used to establish the factor activity curve from which the patient's factor activity can be determined (similar to a standard curve).

Checkpoint! 6

Why are ruptured platelets able to neutralize lupus-like anticoagulants?

Answer

Platelet membrane phospholipids are exposed when platelets rupture. Because lupuslike anticoagulants are antiphospholipid antibodies, they will bind to the exposed phospholipids and will no longer interfere with the test reagent phospholipids.

Checkpoint! 7

What is the appropriate interpretation of these coagulation test results?

PT	prolonged
APTT	prolonged
TT	prolonged
FDP	>20 µg/mL
D-dimer	>1.0 µg/mL

Answer

These coagulation test results indicate disseminated intravascular coagulation (DIC). D-dimer is a specific indicator of fibrin clot degradation as is observed in DIC.

Checkpoint! 8

In diagnostic laboratory evaluation of a hypercoagulable state such as antithrombin deficiency, why is it important to determine the functional activity of the protein?

Answer

Several hypercoagulable states are characterized by a normal antigenic level of protein but have decreased functional activity. In other words, the hypercoagulable state is the result of a dysfunctional coagulation protein. The diagnosis would be missed if only the antigenic level was assessed.

Checkpoint! 9

As seen in Figure 6, the patient has a PT of 21.5 seconds (producing an INR of 2.2). In this case the patient is not on oral anticoagulation. What is the explanation for not reporting the INR?

Answer

The INR reflects the standardization of the thromboplastin reagent for a certain PT to a standardized reference thromboplastin using the same type of instrumentation. It does not reflect the level of deficiency present in the sample. Therefore, only the PT should be reported.

Checkpoint! 10

A patient has a venous thrombotic episode, and is to be treated appropriately. When should the blood sample be drawn to perform a thrombotic work-up in order to diagnose an acquired or congenital deficiency? Why?

Answer

To properly diagnose a thrombotic deficiency, the patient must be off treatment. If the sample is drawn too early, the consumptive process that occurred may produce decreased levels of coagulation proteins as well as conflicting results due to anticoagulation treatment and possible supplemental treatment with FFP. This may lead to misdiagnosis of a deficiency in one or more factors. If the patient is tested while hospitalized and the results conflict, repeat studies should then be performed. Family studies also should be considered.

Quality Assessment in the Hematology Laboratory

Cheryl Burns, M.S.
Lucia More, M.S.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Identify the components of a quality assessment program and match sources of error with component.
2. State the importance of a quality assessment program.
3. State the importance of documentation in a quality assessment program.
4. Describe the use of proficiency testing in the clinical laboratory including required frequency.
5. Given data, employ an appropriate method to determine the reference range for an analyte.
6. Define *universal precautions* and identify their source.
7. Demonstrate knowledge of OSHA standards and their application in the clinical laboratory.
8. Given a material safety data sheet (MSDS), identify critical information.
9. Define *accuracy*, *precision*, *control material*, *mean*, and *standard deviation*.
10. Given the appropriate data, calculate the mean and standard deviation and create a quality control chart.
11. Interpret quality control results utilizing established control charts.
12. Given test results, recognize CBC data and/or histogram variations that indicate the presence of white blood cell (WBC), red blood cell (RBC), and platelet abnormalities.
13. Recognize CBC data that indicate the presence of interfering substances such as lipemia, hemolysis, and ictericia.
14. Identify coagulation test results that indicate a problem with sample integrity.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Design methods of competency testing.
2. Apply and interpret statistics used in method evaluation.
3. Determine the components and interpret the results of a method evaluation study.
4. Determine and appraise a method's reportable range.
5. Interpret the Westgard rules and their use in evaluating quality control results.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Overview
- ▶ Quality assessment
- ▶ Quality control
- ▶ Review of patient results
- ▶ Summary
- ▶ Review questions
- ▶ References

■ OBJECTIVES—LEVEL II (continued)

6. Describe the use of moving averages to monitor red blood cell data.
7. Assess the use of patient samples to monitor daily quality control in hematology.
8. Select the appropriate actions to take when abnormalities are detected in hematology or coagulation results.
9. Recommend procedures to correct for the presence of lipemia, hemolysis, and ictericia.
10. Demonstrate the ability to use Delta checks in a quality control program.

KEY TERMS

Analytical sensitivity
 Analytical specificity
 Analytical time
 “Blinded” preanalyzed sample
 Clinical Laboratory Improvement Amendments of 1988 (CLIA '88)
 CLSI
 Competency assessment
 Correlation coefficient (r)
 Delta check
 Health Insurance Portability and Accountability Act (HIPAA)
 Internal quality control program
 Linearity
 Material safety data sheet (MSDS)
 Medical decision level
 Outlier
 Proficiency testing
 Quality control (QC) limit
 Random variation
 Reference interval (RI)
 Reportable range
 Slope (b)
 Split sample
 Standard deviation (SD)
 Systematic variation
 Transcription error
 Turnaround time (TAT)
 Universal precaution
 y -intercept (a)

BACKGROUND BASICS

Levels I and II

- ▶ Describe the sample collection protocol for hematology and hemostasis procedures.
- ▶ Summarize each of the routine hematology procedures, and give potential sources of error.
- ▶ Summarize the characteristics of an optimally stained peripheral blood smear, and give potential sources of error.
- ▶ Summarize each of the screening coagulation tests used in the laboratory, and give potential sources of error.
- ▶ Describe the principles of cell counting used by the automated hematology instruments and principles of clot detection for the automated coagulation instruments.

▶ OVERVIEW

One of the most important responsibilities of a clinical laboratory professional is to ensure the quality of test results. To accomplish this, laboratories must establish quality assessment and quality control programs. These programs consist of guidelines designed to ensure accurate testing and reporting of results. A protocol for reviewing patient results to determine whether results can be reported must be included. This chapter discusses components of these programs.

▶ QUALITY ASSESSMENT

Laboratories must have an established quality assessment program as mandated by subpart K—Quality Systems for Nonwaived Testing of the **Clinical Laboratory Improvement Amendments of 1988 (CLIA '88)**.¹ A laboratory's quality assessment program should be designed to monitor all aspects related to testing patient samples.² The program's goal is to ensure accurate testing and reporting of results from all samples submitted to the laboratory. Accrediting agencies such as the College of American Pathologists (CAP)

and the Joint Commission (formerly known as the Joint Commission on Accreditation of Healthcare Organizations [JCAHO]) monitor a program's comprehensiveness and quality. This chapter reviews the various aspects to consider in designing a comprehensive quality assessment program.

BASIC COMPONENTS

A common approach to the development of a quality assessment program is to divide it into three components: (1) pre-examination, which deals with all aspects affecting the test outcome occurring prior to the testing procedure, (2) examination, which incorporates all aspects affecting the testing procedure itself, and (3) postexamination, which deals with aspects affecting the test outcome occurring after the testing procedure (Table 1 🌟).

🌟 TABLE 1

Comprehensive Quality Assessment Program

- Pre-examination components
 - Patient test requisitions
 - Patient preparation
 - Sample collection protocol
 - Sample transport protocol
 - Sample processing protocol
 - Sample acceptability and rejection criteria
 - Sample storage
 - Phlebotomy training
- Examination components
 - Test method/procedure
 - Reagents
 - Internal quality control
 - External quality control (proficiency testing)
 - Maintenance of instrumentation
 - Linearity/reportable range determination
 - Method evaluation (instrument comparison)
 - Reference range determination or verification
 - Personnel requirements
 - Competency testing
 - Continuing education
- Postexamination components
 - Review of patient results
 - Posting of patient results
 - Maintenance of patient records
 - Monitoring of turnaround time
 - Surveying of customer satisfaction
 - Maintaining of all documentation

Pre Examination Component

The testing process begins with the test order. Patient test requisitions should be designed to be user friendly and to provide adequate patient information. At a minimum, this information should include the patient's name or unique patient identifier, age, sex, diagnosis, test to be performed, and source of the sample. The patient should receive appropriate information to prepare for the tests such as being informed to abstain from aspirin or aspirin-like medication prior to platelet function testing. This information should be provided in the laboratory's sample collection procedure manual and in a format easily distributed to and understood by the patient.

One of the most important factors affecting a test's outcome is sample collection.³⁻⁶ As we often hear, "The test result is only as good as the quality of the sample." Many variables enter into the sample collection process that can effect the outcome (Table 2 🌟). The sample collection procedure manual and a thorough educational program for the phlebotomist or the individual designated to perform the phlebotomy (i.e., nursing personnel) should address each potential error. Periodic continuing education should be provided to address sample collection problems or introduce new protocols.

When the sample has been collected, it must be properly labeled and transported to the laboratory for processing and testing. If testing cannot be done immediately, the sample should be properly stored. For example, a sample for routine coagulation testing requires separating plasma from cells and storing the sample at room temperature if testing will be performed within 4 hours. All of this information should be found within the sample collection procedure manual and vary depending on the test to be performed.

Examination Component

The examination component addresses all issues involving the testing procedure itself. A test method procedure manual should be available in all laboratories. This manual should address each test as to its purpose, principle, sample requirements, reagents, quality control, step-by-step procedure, interpretation of results, and potential sources of error.^{7,8}

An **internal quality control program** should be established to monitor the testing process and ensure accurate patient test results. Quality control is addressed in more detail later in this chapter. In addition, overall quality control should be assessed by an external quality control program, also known as **proficiency testing**. Proficiency testing monitors the testing process by comparing the specific laboratory to peer laboratories.⁹ This also is addressed in a subsequent section of this chapter.

Maintenance of analytical instruments (e.g., automated blood cell-counting instrument) must be followed as directed by the manufacturer, and documentation of all

★ TABLE 2

Potential Sources of Errors in Sample Collection and Their Effect on Test Outcome

Source of Error	Effect on Test Outcome
Patient misidentification	Inaccurate test results
Hemolyzed sample	Dilutional effect on analytes, false increase of analytes, and decreased erythrocyte counts
Failure to invert collection tubes that contain anticoagulant properly	Clotted sample and falsely decreased cell counts or prolonged coagulation test results
Failure to fill collection tube properly	Under- or over-anticoagulated sample for coagulation testing with citrate tube
Failure to follow the order of the draw*	Cross-contamination with collection tube additives
Tourniquet application longer than 1 minute	Hemoconcentration of sample
Collection from an IV site	Dilutional effect on analytes
Time of draw	Analyte dependent (e.g., hemoglobin is highest in the morning)
Patient anxiety or crying	Analyte dependent (e.g., increases leukocyte count)

*Order of the draw refers to the suggested order in which different anticoagulant and nonanticoagulant collection tubes are filled from a single venipuncture. For example, a heparin collection tube should be filled prior to an EDTA collection tube to avoid contamination of the heparin collection tube with potassium EDTA.

maintenance activities must be easily accessible for troubleshooting quality control problems.

Individuals performing the testing procedures must meet the personnel requirements established by CLIA '88, which vary depending on the test procedure. Continuing education is also required to keep testing personnel abreast of changes within the testing procedures and the practice of the profession.

Postexamination Component

The postexamination component addresses factors that can affect the test outcome and its use after the testing process.¹⁰ Procedures should be established for the review of patient results and identification of those results that require further attention. For example, a sample should be repeated if the hemoglobin (Hb) and hematocrit (Hct) do not match (e.g., $Hb \times 3 = Hct$).

Automated instruments can be interfaced with the laboratory information system (LIS) for electronic transfer of patient results. The LIS can also be interfaced with the hospital's or outpatient facility's computer system for reporting of patient results directly to the patient's chart. Electronic transfer of results minimizes **transcription errors**. The records of patient test results should be maintained within the laboratory. Procedures should be established for archiving and retrieving patient test results.

The laboratory is a business enterprise. Therefore, customer (e.g., physician or patient) satisfaction and communication are important issues to be addressed in the quality assessment program. An important factor affecting satisfaction level is **turnaround time (TAT)** for test results. Critical patient care decisions often depend on a laboratory test result. Computerization has made monitoring TAT more manageable. If a TAT problem is identified, laboratory management or the quality assessment committee should investigate it and recommend appropriate action.

In addition, protocols should be established to address customer complaints and other communication issues to minimize customer dissatisfaction. Surveys can be used to assess customer satisfaction and identify areas that need to be addressed. A quality assessment committee should be established to oversee the quality assessment program and determine changes that need to be made and how to implement them.

In accordance with CLIA '88 and the **Health Insurance Portability and Accountability Act (HIPAA)**, the laboratory should establish certain measures that ensure the confidentiality of patient information in each component of the quality assessment program.^{1,11} For example, many facilities use unique identifiers rather than patient names or social security numbers to identify a sample and its test requisition. For the postexamination component, the laboratory should have a policy to ensure and document that the appropriate individual receives electronically transmitted test results.

Finally, documented records of all aspects of the quality assessment program should be maintained and retrievable upon request. These documents provide important information regarding the recognition of a problem, the process used to resolve it, and the change that occurred as a result of that process.

 **Checkpoint! 1**

Explain the importance of each component of the quality assessment program to its ultimate goal.

PROFICIENCY TESTING

Proficiency testing is an external quality control program that monitors the long-term accuracy of the different test systems (e.g., prothrombin time by the Beckman Coulter

ACL TOP instrument) through comparison to peer laboratories. Since the 1960s, many clinical laboratories have participated in proficiency testing surveys such as the survey program of CAP. CLIA '88 mandated however that all clinical laboratories performing nonwaived testing (includes testing methodologies not on the waived test list) participate in a proficiency testing survey at least three times a year.¹² Failure to achieve an acceptable rating for any given analyte (e.g., prothrombin time) in two of three surveys can result in certain sanctions of a laboratory such as delineation of a plan of corrective action for that test procedure or suspension of the certification to perform that test procedure.¹³ Sanctions and penalties are issued by the Centers for Medicare and Medicaid Services (CMS). To reinstate a test procedure, the laboratory must obtain an acceptable rating for that analyte in two consecutive proficiency testing surveys.

Clinical laboratories contract with organizations such as CAP or the American Association of Bioanalysts to provide the proficiency testing service. A proficiency testing survey consists of proficiency samples, whole blood, or lyophilized serum/plasma representing the full range of values that would be expected in patient samples. These samples are sent to the laboratory at specified time intervals, usually three times per year. Proficiency samples should be tested as part of a typical patient sample run. Results are sent to the survey provider for statistical analysis. The survey provider determines the target value (TV) for each test result through comparison studies with peer laboratories and establishes the acceptable performance (AP) ranges based on CLIA '88 tolerance limit (TL). For example, hemoglobin's tolerance limit is 7%. If the target value for hemoglobin sample 1 is 12.0 g/dL, then the acceptable performance range is 11.2–12.8 g/dL (AP = TV ± TL). The survey provider notifies the clinical laboratory and CMS of its findings.

Each laboratory should have a comprehensive program to respond to an unsatisfactory result. The source of the problem can be identified by checking for changes in the test procedure or reagents, reviewing the instrument's maintenance log and previous quality control results, and identifying changes in testing personnel. With the problem identified, corrective action can be taken to solve it. The laboratory should maintain proficiency testing survey results and documentation of corrective action.

Checkpoint! 2

If a clinical laboratory loses its certification to perform protein C assays, what is involved in regaining that certification?

COMPETENCY TESTING

An additional requirement under CLIA '88 is **competency assessment** of all personnel performing nonwaived testing. CLIA '88 requires that this assessment take place twice during the first year of employment and annually thereafter.^{14,15}

Because the *Federal Register* did not clearly outline the exact mechanisms to evaluate testing personnel's competency, laboratory directors, managers, and supervisors have struggled to determine the appropriate methods to evaluate competency within their laboratories. Clearly, this assessment must be more than a simple evaluation of one's knowledge of the material. The ability to score high on a multiple-choice test regarding laboratory test procedures within one's job description does not evaluate the individual's ability to perform and troubleshoot the test procedures. Direct observation checklists, random assignment of proficiency testing materials, or **"blinded" preanalyzed samples** can be used to evaluate these competencies (see Web Table 1  for an example of a direct observation checklist). For each assessment tool, criteria must be established to judge acceptable performance. In the case of a 100-cell leukocyte differential, acceptable criteria might be based on the 95% confidence limits of the expert results (e.g., hematology supervisor or pathologist).¹⁶

No single method of assessing competency is appropriate for all test procedures. The laboratory supervisor, manager, or director is responsible for choosing appropriate methods for the particular laboratory setting. Additionally, educational materials (i.e., textbooks, selected journal articles, slide study sets, videotapes, or computer-based instruction) should be available to assist clinical laboratory professionals to improve their competency.

Checkpoint! 3

What is an appropriate method of assessing a clinical laboratory professional's competency in performing prothrombin time (PT) and activated partial thromboplastin time (APTT) using an automated coagulation instrument?

METHOD EVALUATION/ INSTRUMENT COMPARISON

Selection, evaluation, and implementation of a new methodology or instrument in the hematology/hemostasis laboratory should follow an established protocol. Each laboratory should design its own protocol. This section discusses several important components to be included.

Selection

Selection of a new methodology or instrument is a daunting task. In the ideal setting, a committee should be formed to make this selection. For the selection of a new instrument, committee membership can include the hematology/hemostasis supervisor, several clinical laboratory professionals, LIS personnel, the quality assessment supervisor, a biomedical engineer, and the laboratory manager.

The first task of this committee is to determine the desirable characteristics of the new instrument.^{17,18} A needs assessment survey could be used for this purpose, it should be

completed by those individuals who will be using the instrument and by those individuals who might be affected by the use of that instrument (Web Table 2 🌱). Desirable characteristics identified by this survey can then be used to solicit proposals from vendors (e.g., sales personnel for Beckman-Coulter, Siemens Medical, or Abbott Laboratories) (see Web Table 3 🌱 for these characteristics).

The careful evaluation of the vendor's proposal packet by the selection committee will begin to narrow the selection process to several possible instruments. Members of the selection committee should also seek input from colleagues and the literature with regard to new instrumentation available and other laboratories' experiences with that instrumentation. The in-house evaluation of each instrument is a crucial step in the selection process. At this time, all interested parties would have a hands-on opportunity to assess the actual performance of the instrument in a real-time laboratory. Thus, a more meaningful evaluation can be obtained with regard to whether the instrument meets the laboratory's needs. The more information the committee has on which to base its selection, the better the selection will be. Ultimately, the selection of the instrument comes down to a particular laboratory's needs and the cost of meeting those needs.

The selection process of a new methodology or test system is similar. The selection committee must consider the cost per test, reagents, reagents' shelf-life and storage requirements, quality control program, test's **analytical sensitivity** (the ability to detect small quantities of the analyte), **analytical specificity** (ability to determine only the analyte in question), and **linearity** (range of concentration over which the test method can be used), required instrumentation and equipment, **analytical time**, and sample types that can be analyzed (i.e., whole blood, serum, CSF). Both testing personnel and potential clients should be consulted for their input during the selection process.

Analytical Reliability

With the purchase of a new instrument or the introduction of a new methodology, the laboratory must verify the performance of the instrument and/or method through a series of performance studies. To verify an instrument's analytical reliability, the clinical laboratory professional must evaluate the instrument with regard to **random variation** (variation due to chance) and **systematic variation** (variation within the instrument that alters results but is predictable). Precision studies are used to assess random variation and evaluate the reproducibility of the test method.^{19,20} To check within run precision, the clinical laboratory professional should run 10–20 aliquots of a patient sample in the same run. These patient samples should have different concentration levels that correspond to **medical decision levels** of the analyte. For example, to check within run precision for hemoglobin, three patient samples can be chosen: sample 1 Hb = 8.0 g/dL; sample 2 Hb = 12.0 g/dL; sample 3 Hb =

19.0 g/dL. Each sample is separated into 10 aliquots, and each aliquot is analyzed. For each set of data, the mean, **standard deviation (SD)**, and coefficient of variation are calculated (Table 3 🌱). Precision can be determined by applying a statistical test called the *F-test* or by comparing the calculated coefficient of variation (CV) to the manufacturer's CV. Within run precision is acceptable if the CV is less than or equal to the manufacturer's CV. If the CV is higher than the manufacturer's CV, the clinical laboratory professional should check the data for **outliers**. Any outlier should be discarded and the data reevaluated. If the CV is still unacceptable, significant random variation exists within this method, or reagent and/or testing personnel errors have affected the study.

Systematic variation is assessed through the methods comparison procedure, which allows comparison of patient results between the new method and a method that is known to be accurate. **Split samples** (division of a single sample into two or more aliquots) are used. The **CLSI** (formerly NCCLS) recommends the use of at least 40 preferably 100, samples.^{19–22} The samples should be random so they are representative of the clinical range of samples. Ideally, they should represent different pathologic conditions as well. With the samples identified, each one is split for analysis by each method. The samples are run in duplicate for each

TABLE 3
Within Run Precision Study for Hemoglobin Determination by Daman EXCELL-16

	Sample 1	Sample 2	Sample 3
1	7.9	12.0	19.2
2	8.1	12.3	19.4
3	8.0	12.2	19.4
4	8.1	12.2	19.4
5	8.1	12.2	19.3
6	8.0	12.3	19.4
7	8.0	12.3	19.4
8	8.1	12.4	19.5
9	8.1	12.4	19.3
10	8.1	12.3	19.6
Mean	8.1	12.3	19.4
SD	0.07	0.11	0.11
CV	0.86%	0.89%	0.57%
Manufacturer's CV	<1.0%	<1.0%	<1.0%

Three patient samples were chosen, and 10 aliquots of each sample were tested. The mean, standard deviation (SD), and CV were determined for each patient sample. Comparison of each calculated CV to the manufacturer's CV reveals acceptable precision for the hemoglobin procedure because the calculated CV is less than the manufacturer's CV. This procedure demonstrates the reproducibility of this hemoglobin determination. Results are reported in g/dL.

method, but the duplicate run should be done at a different time. All analysis should be completed on the same day, preferably within 4 hours.²² Several statistical tools are used to analyze the results. The paired *t* test compares the mean of the differences of test results between the two methods and determines whether a statistically significant difference exists between the current method and the new method (see Web Table 4  for an example of a paired *t* test). The calculated *t* value for the two sets of results is compared to the critical *t* value from a statistical table. If the calculated *t* value is less than the critical *t* value, no significant difference exists between the two methods.

Linear regression analysis allows determination of the **y-intercept (a)**, **slope (b)**, standard error of the estimate ($s_{y/x}$), **correlation coefficient (r)**, and coefficient of determination (r^2) (Figure 1 ). The general formula for the linear regression line is $y = a + bx$, where *y* is the predicted mean value of *y* for a given *x* value. The coefficient of determination evaluates the strength of the relationship between the two methods. For example, an r^2 value of 0.90 for a comparison between current and new methods means that 90%

FIGURE 1 Linear regression analysis for comparison of hemoglobin by automated cell counting instrument (column 1.2) and point-of-care instrument (column 1). Data sets are those given in Web Table 4. Interpretation of the linear regression analysis reveals a strong relationship $R^2 = 0.998$ between the automated cell counting instrument's hemoglobin method and the point-of-care instrument's hemoglobin method. No proportional systematic error exists because the slope (1.012) is between 0.95 and 1.05. The y-intercept (-0.291) is slightly less than 0, which indicates a small degree of negative bias or constant systematic error. This can be considered negligible by most laboratories. Random error also is not indicated because the standard error of the estimate (0.007) is nearly 0. Overall, this analysis demonstrates excellent comparison of methods.

of the variability in the new method is directly predictable from the variability in the current method. Therefore, a strong relationship exists between the two methods.

Linear regression analysis is also used to detect systematic (constant or proportional) errors and random errors. Constant systematic errors are identified by a change in the y-intercept. A y-intercept with a value other than 0 ($y > 0$ or $y < 0$) indicates that a constant difference exists between the new method and the current method regardless of the analyte's concentration. The observation of a constant systematic error usually indicates a calibration problem. Proportional systematic errors are identified by changes in the slope. If there is no difference between the current method and the new method, the slope is $1.00 \pm 5\%$. A change in the slope represents a difference between the new method and the current method that is proportional to the analyte's concentration. That is, the higher the concentration, the greater the difference is between the two methods. A proportional systematic error is most frequently associated with erroneous calibration. Random error can be detected by an increase in the standard error of the estimate. Increased dispersion of results about the regression line results in an increased standard error of the estimate. No standard criteria exist for the interpretation of an acceptable standard error of the estimate. Thus, the result should be evaluated in conjunction with the results of the precision studies.

 **Checkpoint! 4**

Linear regression analysis was performed on results from a method comparison of the prothrombin time between automated coagulation instrument A and automated coagulation instrument B (Web Figure 1 ). The following results were obtained:

y-intercept = 0.8157
Slope = 0.9982
Standard error of the estimate = 0.0807

What conclusions can be drawn from these results?

Linearity and Reportable Range Determinations

The manufacturer typically determines an instrument's linearity. The linearity of hematology instruments is determined for each directly measured parameter (e.g., leukocyte count, hemoglobin, and mean corpuscular volume [MCV]). Determination of linearity is accomplished by analyzing serial dilutions of a linearity check material multiple times to minimize the effects of imprecision.²³ Regression analysis is used to establish the linear range and the tolerance limits (Table 4 ). The tolerance limits represent the maximum allowable difference between the measured result and the reference value for a given dilution. A similar procedure is used to determine linearity for coagulation instruments.

Verification of the instrument's **reportable range** must be included within the method evaluation for a new

★ TABLE 4

Linear Ranges and Tolerance Limits for Abbott Cell-Dyn 4000 Instrument			
Parameter	Linear Range		Tolerance Limits*
	SI	USA	
WBC	0.0–250 × 10 ⁹ /L	0.0–250 × 10 ³ /μL	±0.40 or 3.0%
RBC	0.0–7.50 × 10 ¹² /L	0.0–7.5 × 10 ⁶ /μL	±0.15 or 2.0%
Hb	10.0–250.0 g/L	1.0–25.0 g/dL	±0.3 or 2.0%
MCV [†]	37.0–197.0 fL	37.0–197.0 fL	±2.0 or 2.0%
PLT	0.0–2000.0 × 10 ⁹ /L	0.0–2000.0 × 10 ³ /μL	±5.0 or 4.0%
MPV [†]	2.1–19.0 fL	2.1–19.0 fL	±1.0 or 5.0%
RETIC	0.0–1500.0 × 10 ⁹ /L	0.0–1500.0 × 10 ³ /μL	±18.5 or 3.0%

WBC = white blood cells; RBC = red blood cells; Hb = hemoglobin; MCV = mean corpuscular volume; PLT = platelets; MPV = mean platelet volume; Retic = reticulocyte count.

* The number to be used is the higher of the two at a given count or concentration.

[†] This parameter was tested with standard reference particles.

SI (Système International) refers to the internationally recognized unit of measure for each parameter.

USA refers to the conventional unit of measure for each parameter that has been traditionally used in the United States.

(Courtesy of Abbott Laboratories, Abbott Park, IL)

hematology or coagulation instrument or as one of the installation procedures for that new instrument.²⁴ To verify the reportable range, the clinical laboratory professional should analyze in duplicate at least three different levels of calibrators or linearity check materials that fall within the reportable range.¹⁹ If these results fall within the instrument's defined tolerance limits, the reportable range is verified. In addition, these data can be plotted to visualize the linearity. If the data do not fall within tolerance limits or are nonlinear, the process should be repeated using more calibrators in the affected part of the range. If the data do not verify the instrument's reportable range, the laboratory should modify the reportable range to reflect the instrument's performance characteristics in its current setting.

With the verification of the reportable range, each laboratory should establish its protocol for handling results that exceed the reportable range, either above or below. For example, results above the reportable range may be diluted, reanalyzed, and the result multiplied by the dilution factor to determine the accurate result. Hematology results below the reportable range may require reanalysis of the sample and review of the peripheral blood smear before the result is reported as less than the lower limit of the reportable range.

REFERENCE INTERVAL DETERMINATION

Hematology and coagulation **reference intervals (RI)** are available in various recognized hematology textbooks and hematology/coagulation instrument and reagent manufacturer's manuals. To use these reference intervals, a laboratory

must verify that the reference intervals are appropriate for its patient population as CLIA '88 requires.²⁴ Reference intervals are influenced by the diversity of instrumentation, choice of reagents, and patient population served by the laboratory. The laboratory can choose to validate the manufacturer's reference intervals or establish them for itself. The process of validating a reference interval is less time consuming and more cost effective. The recommended procedure for validation of a reference interval is described in Web Table 5. ²⁵ Once validated, the reference intervals can be used as representative for the laboratory and its patient population. If the reference intervals are not validated, the more rigorous process of establishing the laboratory's own reference interval should be performed.

Establishing a reference interval is an arduous task. It involves careful planning to define the criteria for subject selection, the process for data acquisition, and the analysis of the data. In the ideal situation, reference intervals should be established based on age and sex stratification of the patient population. For reliable estimates of a reference interval, a minimum of 120 individuals should be tested in each age and sex category.^{22,25} One method of categorizing age groups is by decade of life. However, simple mathematical calculation would show the overwhelming number of individuals needed for such a process. Winsten suggests a mechanism to decrease the number of individuals needed by dividing the patient population into four age categories (Table 5).²⁶ All subjects should complete brief histories to determine their acceptability for this study and be provided the appropriate instructions to prepare for the blood draw. In addition, each

TABLE 5

Winsten's Recommended Age Categories for Reference Interval Determination

- Newborns
- Prepubertal individuals
- Adult (includes postpubertal and premenopausal)
- Older adults (includes males >60 years and postmenopausal females)

subject must sign an institutional review board (IRB) approved consent form. Ideally, 5–10 subjects should be tested per day to minimize possible random introduction of a shift in the reference interval due to instrument or reagent differences.

When all data have been acquired, they must be analyzed. Computer-based spreadsheets facilitate data analysis. CLSI recommends the use of percentile analysis, a nonparametric method,²⁵ which is appropriate because the analysis does not make any specific assumptions regarding the distribution of data points (e.g., Gaussian or non-Gaussian distribution). Using percentile analysis, the upper and lower limits of the reference interval depend on the ranks of reference data arranged in order of increasing values. The lower limit identifies the estimated 2.5th percentile, and the upper limit identifies the estimated 97.5th percentile, thus defining the 95% reference interval (see Web Table 6 for an example of percentile analysis to determine a reference interval).

Checkpoint! 5

Define the term reference interval.

SAFETY

The laboratory environment includes biohazards, chemical hazards, and physical hazards. All laboratory employees must know the requirements for performing their jobs in a manner that protects them and their coworkers from these hazards. Several governmental agencies have established guidelines and standards for ensuring the safety of the clinical laboratory professional.

Universal Precautions

The Centers for Disease Control (CDC) introduced **universal precautions** in 1982.²⁷ With the discovery of the human immunodeficiency virus (HIV) and its potential transmission through exposure to infected blood or other body fluids, the CDC recognized the need for preventative guidelines to minimize the potential exposure of health care workers to this virus. Universal precautions state that health care workers should consider all body fluids as potentially infectious. Therefore, health care workers must use the appropriate personal protective equipment (PPE) when handling body fluids to minimize the risk of exposure to biohazardous agents such as HIV, hepatitis B, and other blood-borne pathogens.

The CDC has updated the original guidelines and continues to do so. Currently, guidelines recommend that all health care workers receive the hepatitis B vaccine. See Web Table 7 for selected recommendations from the CDC and the Occupational Health and Safety Administration (OSHA) designed to minimize the potential exposure to and transmission of blood-borne pathogens to clinical laboratory professionals.²⁸ Within a health care facility such as a hospital or medical center, the term *standard precautions* is used to define the facility's policies regarding universal precautions and infection control.²⁹

OSHA Standards

OSHA regulates many aspects of the clinical laboratory to ensure a safe work environment. The clinical laboratory must meet OSHA's standards for chemical, physical, and fire safety. For biologic safety, OSHA implemented the Blood-borne Pathogen Standards in 1992. All OSHA standards require education and training of laboratory employees, an exposure control plan, and a record-keeping mechanism. OSHA's Website (<www.osha.gov>) is a source of additional information and details regarding these standards.

Material Safety Data Sheets

The **material safety data sheet (MSDS)** provides safety information for clinical laboratory professionals who use hazardous materials. Web Figure 2 is an example of an MSDS. It includes pertinent safety information regarding the following for the chemical: proper storage and disposal, precautions that should be taken in handling it, potential health hazards associated with exposure to it, and whether it is a fire or explosive hazard. Under the Hazard Communication Standard, or "Right to Know Law," clinical laboratory professionals must receive training regarding the hazardous chemicals that they work with.³⁰ This training should include the potential health risks associated with the chemical, interpretation of MSDS and chemical labels, and review of the laboratory's hazard communication program. MSDS must be available at all times to the clinical laboratory professionals.

Checkpoint! 6

If a spill occurred when handling the CELL-DYN Sapphire hemoglobin reagent, what is the appropriate procedure to clean it up? Refer to Web Figure 2.

▶ QUALITY CONTROL

The clinical laboratory's quality control program monitors the testing process to ensure that reliable test results are obtained for the patient samples, to detect potential problems within the testing system, and to allow correction of the problem before patient results are affected.

CONTROL MATERIALS

Control materials are assayed samples with predetermined test results. The manufacturer assigns a lot number to each batch of control material. Within a given lot number, the assayed characteristics of the control are the same. For most hematology procedures, stabilized cell suspensions are used. These stabilized cell suspensions closely match the characteristics of human whole blood. The stability of cell suspensions is limited, for most commercially available cell suspensions, the time from a given lot number's start date to its expiration date is 4 months. For coagulation procedures (e.g., PT and APTT), lyophilized control materials are used. When reconstituted, the lyophilized control has behavioral characteristics similar to platelet-poor citrated plasma. For these lyophilized controls, a given lot number is ordered in sufficient quantities to meet the laboratory's testing needs for 1 year. This is advantageous because it limits the number of times new control limits with the new lot number must be established to once a year, and it provides a continuous monitor of the testing process over reagents and clinical laboratory personnel changes.

ESTABLISHMENT OF QUALITY CONTROL LIMITS

Quality control (QC) limits must be established for each control material prior to its use within the quality control program. Standard protocol for determining quality control limits calls for testing the new control material to collect a minimum of 20 data points (control measurements) over 10 working days.³¹ These data points are collected while the current control material is used to monitor the integrity of the testing process and are used to determine the initial control limits. However, as more data points are collected, the limits should be recalculated using all data points to establish truly reliable control limits. The statistics used to establish the QC limits are the mean (\bar{x}) and standard deviation (SD). Based on the mean and SD, the control limits $\pm 1s$, $\pm 2s$, and $\pm 3s$, are established.

The mean and control limits are then used to establish the QC chart (also known as a *Levey-Jennings chart*) (Figure 2). The QC chart is used to plot the control material results over time to provide a graphical display of the distribution of control results over a given period, usually 1 month.

✓ Checkpoint! 7

To establish the control limits for a new lot number of level 1 PT coagulation control, the following data points were collected (results are in seconds): 11.8, 11.6, 12.1, 12.0, 12.3, 12.6, 11.9, 12.2, 12.0, 11.5, 12.7, 12.1, 11.2, 12.3, 12.9, 13.0, 12.3, 11.9, 12.4, 12.5. What are the $\pm 2s$ control limits?

FIGURE 2 Quality control chart for level 1 hemoglobin control. The $\pm 2SD$ limits are 6.10–6.70 g/dL with mean = 6.40 g/dL. The quality control results would be interpreted as being in control.

INTERPRETATION OF QUALITY CONTROL CHARTS

Statistically, 95% of the control results should fall within $\pm 2SD$, and 99% should fall within $\pm 3SD$. Careful and continual evaluation of the QC charts alerts the clinical laboratory professional to potential problems in the testing process before a serious breakdown in the test's integrity occurs. Using the Westgard multirule approach, the problem can be identified and corrected.

Westgard Rules

James O. Westgard, PhD, and colleagues developed the Westgard rules to evaluate control results when two or more levels of control material are used.³² Table 6 lists and defines the most commonly used Westgard rules.

Evaluation of Quality Control Charts Using Westgard Multirule Approach

Each laboratory creates its multirule protocol for a given instrument by selecting a combination of Westgard rules. The selection depends on the acceptable level of false rejection (rejection of a control run that is not truly out of control) and error detection (rejection of a control run when a true error is detected) and the number of control levels run on that instrument.³³ The goal of the multirule protocol is to minimize the chance of false rejection of a control run while maximizing the ability to detect true error. For example, the multirule protocol for an instrument using two control levels might be $1_{2s}/1_{3s}/2_{2s}/R_{4s}/4_{1s}/10_x$. The 1_{2s} rule (S is used by Westgard as alternate abbreviation for S.D.) is used as a warning indicating the possibility that a rule has been violated. If a 1_{2s} warning is observed for one of the control results from the current test run, the clinical laboratory profes-

TABLE 6

Westgard Rules

Westgard Rule	Definition	Type of Error
1 _{2s}	One control result exceeds a 2s limit. This is considered a warning of a potential out-of-control problem.	
2 _{2s} for across runs	Two consecutive control results exceed the same 2s limit. Run should be rejected and out-of-control problem investigated.	Systematic
4 _{1s} for across runs	Four consecutive control results exceed the same 1s limit. Run should be rejected and out-of-control problem investigated.	Systematic
10 _x for across runs	Ten consecutive control results exceed the mean in the same direction (e.g., results are above the mean). Run should be rejected and out-of-control problem investigated.	Systematic
4 _{1s} for across runs and between control levels	Two consecutive control results for two control levels exceed the 1s limit in the same direction across the last two control runs. Run should be rejected and out-of-control problem investigated.	Systematic
10 _x for across runs and between control levels	Five consecutive control results for two control levels exceed the mean in the same direction across the last five control runs. Run should be rejected and out-of-control problem investigated.	Systematic
2 _{2s} for within run	Two consecutive control results for two control levels exceed the 2s limit in the same direction for the current control run. Run should be rejected and out-of-control problem investigated.	Systematic
1 _{3s} for within run	One control result exceeds a 3s limit. Run should be rejected and out-of-control problem investigated.	Random
R _{4s} for within run	One control result exceeds +2s limit and the other control result exceeds -2s limit when using two control levels. Run should be rejected and out-of-control problem investigated.	Random

These rules can be applied “across runs” for two or more runs of a single control or both controls or “within run” for a single control or both controls.

sional should evaluate the QC charts, considering previous control results to determine whether a violation has occurred (Figure 3 ■).

Depending on the violation, the problem can be classified as a random or systematic error. A random error occurs by chance and can result from missampling or misidentifying the control. Random errors can be identified and corrected by carefully repeating the control. Systematic errors indicate a problem within the testing system, which can result from poor calibration, a change in reagent or an expired reagent, expired or improperly stored control, or deteriorating light source. Review of the daily and periodic maintenance logs for the instrument can help identify the problem. Once the problem has been identified, the correct solution can be implemented.

Checkpoint! 8

After performing daily quality control on the automated hematology instrument, the clinical laboratory professional observes a 4_{1s} violation for the hemoglobin parameter. What type of error is indicated?

BULL’S TESTING ALGORITHM (MOVING AVERAGES)

Moving averages (continuous statistical analysis on consecutive patient erythrocyte indices by an automated cell counting instrument) is a method of using the erythrocyte indices, MCV, mean corpuscular hemoglobin (MCH), and mean cor-

puscular hemoglobin concentration (MCHC), to monitor the instrument’s performance in determining the erythrocyte parameters.³⁴ The Bull’s testing algorithm (X-B analysis) represents a calculation of the moving averages for erythrocyte indices of the patient population. It is based on the premise that the erythrocyte indices within a patient population are stable. Therefore, moving averages can be used to monitor the precision and accuracy of the instrument’s performance.

To establish the acceptable ranges for the moving averages, MCV, MCH, and MCHC, the erythrocyte indices on 500 consecutive patient samples are determined and the mean for each index is calculated. The acceptable range is ±3% of the mean; however, each laboratory should determine its acceptable range.³⁵ These ranges are entered into the instrument’s computer. The majority of hematology instruments calculate the moving average from each group of 20 patient samples and determine whether those moving averages fall within the acceptable range (Web Figure 3 ■). The instrument alerts the clinical laboratory professional if the moving average exceeds the acceptable range. If a moving average is unacceptable, the clinical laboratory professional should identify the previous 20 samples because this method is sensitive to the patient population. If the previous 20 samples were patients from the renal dialysis clinic or oncology clinic, the change in moving averages could result from the patient population, not an instrument problem. A true alert would indicate an instrumentation problem affecting one or more of the erythrocyte parameters: erythrocyte count, hemoglobin, or hematocrit.

FIGURE 3 Violation of 2_{2s} rule. Inspection of the current run, day 27, reveals that both control materials exceed the $-2s$ limit, indicating a violation of the 2_{2s} rule within a run. This run should be rejected and the problem resolved before patient samples are run. Because the 2_{2s} violation indicates a systematic error, the clinical laboratory professional should investigate the possibility of a reagent, control, or instrument problem.

MONITORING QUALITY CONTROL WITH PATIENT SAMPLES

Patient samples can be retained and used in conjunction with purchased control materials to monitor the reproducibility of a hematology instrument over a 24-hour period as a result of the stability of cell counts in an ethylenediaminetetraacetic acid (EDTA)-anticoagulated sample. For example, four or five patient samples are selected from the morning test run; each sample is analyzed to determine its mean; and the samples are separated into two sets. The first set of separated samples is used to monitor the precision of the instrument during a 24-hour period. This set is tested

every 4 hours. Using the SD and CV for this data, the instrument's precision is evaluated to determine its acceptability. The second set of separated samples is refrigerated for 24 hours. This set is used to monitor precision from day to day. After 24 hours, the second set is analyzed to determine each sample's 24-hour mean. The original mean is compared to the 24-hour mean to determine acceptability. Each laboratory should establish its own limits for acceptability.

Another potential use of retained patient samples is as quality control materials for the laboratory's secondary hematology instrument. Patient samples that are analyzed on the primary hematology instrument, which has been determined to be in control by purchased control materials, can be used to demonstrate that the secondary hematology instrument is in control during the same time interval.

REVIEW OF PATIENT RESULTS

Although automated verification or autoverification of patient results can be utilized in the hematology/hemostasis laboratory, the underlying criteria for the process come from the laboratory's protocol for review of patient results (Web Table 8).³⁷ Automated verification allows a faster turnaround time for patient results that meet the established criteria. The clinical laboratory professional is responsible for addressing those patient results that require special attention. This section describes review protocols and certain corrective actions for abnormal results in hematology and hemostasis.

HEMATOLOGY

Clinical laboratory professionals use the review protocol to examine patient data obtained from an automated cell-counting instrument and determine whether the complete blood count (CBC) results can be reported or further action is required.

Detection of Abnormal Test Results

The initial identification of potential abnormalities in the CBC results is accomplished by the instrument's computer system, which is programmed to evaluate the numerical data and histograms and generate suspect flags and user-defined flags (e.g., definitive flags). The numerical data, histograms, and alert flags (suspect and user defined) provide information to the clinical laboratory professional that can indicate the presence of interfering substances, abnormal cell morphology, or abnormal cells. Table 7 reviews common abnormal results or alert flags and their corrective actions.³⁸

Checkpoint! 9

In reviewing a patient's CBC results, the clinical laboratory professional notes an MCHC of 37 g/dL. What corrective action should be taken?

TABLE 7

Common Abnormal Results or Alert Flags and Their Corrective Actions

Abnormal Result/Alert Flag	Confirmation/Corrective Action	Rationale
Hemoglobin <7.0 g/dL	Confirm on alternate instrument.	A hemoglobin <7.0 g/dL is a critical value and should be confirmed before it is reported.
Hemoglobin × 3 does not equal hematocrit ±3	Confirm on alternate instrument or perform manual hematocrit.	This rule applies to normal individuals only and is used to identify common interfering substances in hematocrit determination (MCV) or hemoglobin determination (see MCHC below).
MCHC >36 g/dL	1. Perform manual hematocrit. 2. Check for presence of cold agglutinins, lipemia, or ictericia.	Poor correlation between hemoglobin and hematocrit and an MCHC >36 g/dL is associated with cold agglutinins, lipemia, and ictericia. Cold agglutinins cause erythrocyte clumping and result in falsely elevated MCV, falsely decreased red blood cells, falsely decreased hematocrit, and MCHC >36 g/dL. Lipemia causes a falsely elevated hemoglobin because of the increased turbidity of sample and MCHC >36 g/dL. Corrective actions are discussed within the text.
Platelet count <50 × 10 ⁹ /L	1. Perform platelet estimate on peripheral blood smear and examine feather edge for platelet clumps. 2. Examine for grapelike cluster clumps of platelets associated with EDTA-dependent agglutination. If present, re-collect using sodium citrate anticoagulant and multiply result by 1.1 (dilution factor). 3. Examine for platelet satellitism.	Presence of platelet clumps or platelet satellitism results in falsely decreased platelet counts. Platelet satellitism and platelet clumps can be EDTA dependent. Therefore, use of sodium citrate as the anticoagulant circumvents the mechanism of platelet clumping and platelet satellitism and allows determination of the platelet count.
WBC <2.0 × 10 ⁹ /L or >30.0 × 10 ⁹ /L	Perform leukocyte estimate on peripheral blood smear. Leukocyte estimate should agree within ±25% of the leukocyte count.	Poor correlation between leukocyte estimate and leukocyte count can be caused by instrument errors or sample collection error.
MCV <70 fL, >110 fL (adult), >120 fL pediatrics	Review peripheral blood smear for microcytosis or macrocytosis.	Clinically significant changes in MCV are associated with nutritional deficiencies and thalassemias.
Automated differential flagged	Perform manual differential.	Confirm presence of abnormal cells or abnormal erythrocyte morphology.
Platelets >900 × 10 ⁹ /L	Perform platelet estimate on peripheral blood smear. Platelet estimate should agree within ±25% of the platelet count. Examine for presence of erythrocyte fragments.	Poor correlation between platelet estimate and platelet count could be caused by the presence of erythrocyte fragments that are similar in size and volume to platelets. Erythrocyte fragments can cause a falsely elevated platelet count.
Automated differential vote out	Perform manual differential.	Due to the presence of abnormal cells, the instrument is unable to properly classify the cells and determine the automated differential. The leukocyte differential must be obtained by performing a manual differential.
MCHC >36 g/dL, no correction after warming to 37°C	Examine peripheral blood smear for presence of spherocytes.	Spherocytes have a decreased surface area-to-volume ratio and typically have an MCHC >36 g/dL. After ruling out the possibility of cold agglutinins, the presence of spherocytes should be suspected.
Microcytic/fragmented red blood cell flags	1. Review erythrocyte morphology on peripheral blood smear. 2. Perform platelet estimate on peripheral blood smear.	Microcytic erythrocytes or erythrocyte fragments are similar in size and volume to platelets. Therefore, the presence of microcytic cells/fragments can result in a falsely elevated platelet count. Poor correlation between the platelet estimate and platelet count is associated with this observation.
WBC, RBC, or platelets > upper limit of established reportable range (or +++++)	Perform a 1:2 or 1:3 dilution of the sample with diluent. Run the sample and multiply the result by the dilution factor. Report the elevated parameter from the diluted sample only.	Cell counts that exceed the upper limit of their reportable range require a dilution of that sample to lower the number of cells present and bring the diluted cell count into the instrument's reportable range. The actual cell count is then obtained by multiplying the diluted sample's cell count by the dilution factor.

WBC = white blood cells; RBC = red blood cells; MCV = mean corpuscular volume; MCH = mean corpuscular hemoglobin; MCHC = mean corpuscular hemoglobin concentration

On occasion, spurious CBC results are obtained (e.g., results at first appear accurate but on review are invalid). These results might not be grossly abnormal or flagged by the instrument's computer, but the results do fall significantly outside the reference interval. The clinical laboratory profes-

sional should be alert for this possibility because spurious results can indicate a problem with the sample itself. Before these CBC results can be reported, the sample should be examined for potential sources of error (i.e., clots, lipemia, and agglutination). Table 8  reviews the spurious hematology

★ TABLE 8
Spurious Hematology Results, Underlying Problems, and Possible Causes

Erroneous Parameter	Underlying Problem	Possible Cause
Pseudoleukocytosis	Abnormal precipitant	Fibrin strands, cryoglobulinemia, cryofibrinogenemia, paraproteinemia
	Unlysed erythrocytes	Cold agglutinins, presence of abnormal hemoglobins such as hemoglobin S (HbS) or hemoglobin C (HbC)
	Platelet abnormalities	Platelet clumps, giant platelets, EDTA-dependent platelet aggregation
	Extraneous cell type or intracellular parasites	Nucleated erythrocytes, malarial parasites
	Carryover	Extreme leukocytosis in previous sample
Pseudoleukopenia	Cell lysis	Storage artifact, leukemia (esp. chronic lymphocytic leukemia [CLL]), uremia, immunosuppression
	Aggregates counted as single cells	Cold agglutinins, other antibody-related aggregation, aggregation related to presence of mucopolysaccharide
Pseudoincreased hemoglobin	Inappropriate dilution	Overfilled collection tubes
	Interference at 540 nm	Carboxyhemoglobin
	Turbidity	High leukocyte count, lipemia, abnormal hemoglobin (e.g., HbS and HbC), ictericia (hyperbilirubinemia), cryoglobulinemia, paraproteinemia
Pseudodecreased hemoglobin	Interference at 540 nm	Sulfhemoglobin
Pseudoincreased RBC count	Other cells/particles counted	High leukocyte count, high platelet count, giant platelets, presence of cryofibrinogen or cryoglobulin
Pseudodecreased RBC count	Aggregates counted as single cells	Warm agglutinin, cold agglutinin, EDTA-dependent agglutination
	Absent/very small erythrocytes	In vitro hemolysis with microcytic erythrocytes or erythrocyte fragments (MCV <50 fL)
Pseudoincreased MCV	Other cells/particles	High leukocyte count
	Aggregates sized as single cells	Warm agglutinin, cold agglutinin, EDTA-dependent agglutination
	Osmotic swelling	Storage artifact, hyperglycemia, hypernatremia, hyperosmolar states
Pseudodecreased MCV	Instrument-related artifact	Hypochromic erythrocytes
	Other cells/particles	Giant platelets, cryoglobulinemia, cryofibrinogenemia
Pseudoincreased hematocrit, automated	Artificial increase in MCV	High leukocyte count (>50,000/ μ L), hyperosmolar states, erythrocyte agglutination
	Artificial increase in erythrocyte count	Cryoglobulin, cryofibrinogen, giant platelets
Pseudodecreased hematocrit, automated	Artificial reduction in MCV	Hyperosmolar states
	Artificial reduction in erythrocyte count	In vitro hemolysis, microcytic erythrocytes, cold agglutinin
Pseudoincreased hematocrit, manual	Increased plasma trapping	Polycythemia, microcytosis, sickle cell trait/disease, spherocytosis
	Decreased erythrocyte flexibility	Prolonged storage
Pseudodecreased hematocrit, manual	Decreased plasma trapping	Prolonged centrifugation, increased centrifugal force
	Increased cell shrinkage	Excess EDTA; K ₃ EDTA rather than K ₂ EDTA or Na ₂ EDTA
Pseudoincreased MCH	Spuriously high hemoglobin	(See hemoglobin)
	Spuriously low erythrocyte count	(See erythrocyte count)

TABLE 8

Spurious Hematology Results, Underlying Problems, and Possible Causes (continued)

Erroneous Parameter	Underlying Problem	Possible Cause
Pseudodecreased MCH	Spuriously low hemoglobin	(See hemoglobin)
	Spuriously high erythrocyte count	(See erythrocyte count)
Pseudoincreased MCHC	Spuriously high hemoglobin	(See hemoglobin)
	Spuriously low hematocrit or product of MCV × erythrocyte count	(See hematocrit)
Pseudodecreased MCHC	Spuriously low hemoglobin	(See hemoglobin)
	Spuriously high hematocrit or product of MCV × erythrocyte count	(See hematocrit)
Pseudothrombocytosis, automated	Very small erythrocytes or RBC fragments	In vitro hemolysis with microcytes or erythrocyte fragments (MCV <50 fL)
	Cytoplasmic fragments of nucleated cells	Cytoplasmic fragmentation of blasts in acute leukemia or leukemic cells in certain lymphomas
	Microorganisms, bacteria, or fungi	Bacterial septicemia; infection with <i>Candida sp.</i> that are similar in size to platelets
	Other particles	Cryoglobulinemia
Pseudothrombocytopenia, automated	Aggregates counted as single cell or aggregates exceed upper threshold and are not counted	EDTA-dependent agglutination
	Platelet satellitism	Platelets surround WBCs, EDTA-dependent process
	Giant platelets that exceed upper threshold for platelet count	Myeloproliferative disorders or myelodysplastic syndromes associated with abnormally large platelets
Pseudoincreased reticulocyte count, automated	Inaccurate gating of RBCs	Platelet clumps, giant platelets, WBC fragments, nucleated RBCs
	Other RBC inclusions	Howell-Jolly bodies, Pappenheimer bodies, Heinz bodies, basophilic stippling
	Intraerythrocytic parasites	Plasmodium, Babesia
	Other particles	Cold agglutinins, paraproteinemia
	Autofluorescence of RBCs	Porphyria, certain drugs

results that can be encountered in the clinical laboratory including the underlying problem that led to the erroneous parameter and the possible causes.^{39–41}

Use of Delta Checks

Delta checks rely on consecutive testing of a particular patient. Comparison of current hematology results to the most recently reported previous result for a given patient allows the detection of certain random errors.⁴² This method of error detection is termed the **delta check** and has been one of the greatest benefits of the LIS (Web Figure 4■).

Limits can be defined to determine the allowable difference among consecutive results of a specific test (e.g., hemoglobin) over an established time interval. The limits define when the LIS will flag a result. The delta check difference can be calculated as either a difference in the absolute value or as a percentage of the difference. Regardless of the method used, the delta limit should be set so that true changes in test results are not flagged as delta check failures.

If the time limit between comparisons and the maximum allowable differences have been carefully set, correct results will not be flagged. Therefore, the most likely causes of a delta check is a sample mislabeling or random testing error.

In the hematology laboratory, certain tests have very little intraindividual variation, especially the erythrocyte indices, platelet counts, PT, and other coagulation studies. When a delta check occurs for one of these parameters, an investigation should be undertaken before any results are reported (see Web Table 9🔄 for the investigation process).

Correction for Interfering Substances

The presence of lipemia, icterus, or hemolysis in the plasma of an EDTA-anticoagulated blood sample can cause an artificial elevation of the hemoglobin because of increased absorbance. The presence of interfering substances is commonly detected by the application of the Rule of 3, or hemoglobin × 3 = hematocrit ±3. To correct for the presence of these substances, an aliquot of the well-mixed blood

sample is placed in another test tube and centrifuged at 1500 rpm for 5 minutes. A hemoglobin determination is performed on the plasma (supernatant). The corrected hemoglobin is calculated by subtracting the plasma hemoglobin result from the whole blood hemoglobin result ($\text{Hemoglobin}_{\text{corrected}} = \text{Hemoglobin}_{\text{original}} - \text{Hemoglobin}_{\text{supernatant}}$). Alternatively, the plasma can be removed from the centrifuged sample and replaced with an equal volume of saline. The cells are resuspended in the saline, and the corrected hemoglobin is obtained by performing a hemoglobin determination on this sample. The MCH and MCHC need to be recalculated using the corrected hemoglobin result and initial red blood cell count and hematocrit regardless of the correction method used for the hemoglobin.

Certain patients develop IgM antibodies or cold agglutinins directed against erythrocyte antigens. As the blood sample cools, these antibodies begin to agglutinate erythrocytes. The automated cell-counting instrument evaluates the agglutinated erythrocytes as one cell, resulting in a decreased erythrocyte count, increased MCV, decreased hematocrit, and $\text{MCHC} > 36 \text{ g/dL}$. Incubation of the blood sample at 37°C for 15 minutes disrupts the antigen-antibody reaction and dissociates the agglutinated erythrocytes. The warmed sample should be mixed thoroughly and analyzed immediately; its results are reportable unless the platelet count decreases by more than $50 \times 10^9/\text{L}$. Warming the sample occasionally causes loss of platelets. If this occurs, the original platelet count should be reported. Some patients exhibit a strong cold agglutinin titer, and the results may not correct after extended warming. In this situation, a manual hematocrit is performed, and the following additional results are reported from the original sample: white blood count, hemoglobin, and platelet count. The other CBC parameters cannot be reported.

HEMOSTASIS

As in hematology, patient results for coagulation tests should be reviewed for accuracy. This includes ensuring correct procurement of samples, checking for interfering substances, and using delta checks.

Overanticoagulation/Underanticoagulation

The proper ratio of blood: anticoagulant is 9:1 for the coagulation sample. All sample tubes should be examined visually to ensure that they have been properly filled. Comparison tubes can be prepared by adding water to empty collection tubes up to the expected fill level. Coagulation sample collection tubes containing less than 90% of the expected volume must be rejected because the sample is overanticoagulated due to a decrease in the 9:1 ratio.

For coagulation testing, the samples should have a hematocrit between 20% and 55%. If the hematocrit is below 20%, the amount of citrate will be insufficient to anticoagulate the sample, resulting in falsely shortened clotting times

(e.g., prothrombin time). A hematocrit result of more than 55% results in an overanticoagulated sample and falsely prolonged clotting times. This effect on clotting times (i.e., PT and APTT) has been observed with the use of 3.2% sodium citrate as an anticoagulant.⁴³ The formula to adjust the blood-to-anticoagulant ratio for samples with low or high hematocrits is given in Web Figure 5 ■.

Checkpoint! 10

The clinical laboratory professional observes that the 3.2% sodium citrate tube for a PT and APTT is only two-thirds full. Explain the effect this will have on the patient's coagulation results.

Interfering Substances

Hemolyzed samples are unacceptable for coagulation testing because thromboplastin-like substances will have been released, resulting in shortened clotting times. Coagulation instruments based on photo-optical detection could be unable to test samples that contain interfering substances such as lipemia or ictericia because these substances affect the end-point detection (e.g., absorbance). An electromechanical or manual clot detection method should be used to obtain accurate results from these samples.

Use of Delta Checks

Each laboratory must determine appropriate limits for delta checks in the hemostasis laboratory. In general, a change in the PT of ± 5 seconds or in the APTT of ± 15 seconds from a sample tested in the previous 24 hours could indicate a mislabeled sample.

SUMMARY

This chapter reviewed the components of a laboratory's quality assessment program. These can be divided into three components: pre-examination, examination, and postexamination. The pre-examination component includes all aspects that occur before testing that could affect the results including such things as sample collection and handling as well as test requisition. The examination component includes all testing aspects including proficiency testing and personnel competency. Proficiency testing monitors the reliability of a laboratory's test results by comparison to those of its peers and provides a good indication of a test method's long-term accuracy. Competency testing ensures that clinical laboratory professionals are proficient in the performance, interpretation, and troubleshooting of test procedures within their assigned area of the laboratory. The postexamination includes aspects that occur after the testing is performed that could affect the results. This includes review of patient results and turn around time.

When a new instrument or method is introduced to the laboratory, method evaluation studies must be performed to compare the new method to the current method, assess for random and systematic variation, and validate the reportable range. Precision stud-

ies allow the assessment of random variation, and linear regression analysis assesses systematic variation. A laboratory that chooses to use the manufacturer's reference intervals must validate them so they can be used for that laboratory and patient population. The laboratory can choose to establish its own reference interval. OSHA and other federal and state agencies mandate safety procedures. Each laboratory must adhere to those standards.

The laboratory's quality control program including the use of Westgard rules and moving averages monitors the day-to-day reliability of a test method and provides an early indicator of potential problems with it. Each laboratory creates its multirule protocol for an instrument by selecting a combination of Westgard rules.

Review of patient results is necessary to ensure that results reflect the patient's condition. This review is a very important component of the quality assessment program. The clinical laboratory professional's ability to recognize and take corrective action when abnormal patient results occur is at the heart of the clinical laboratory science profession. Review and recognition of abnormal patient results followed by corrective action represent the final steps before a test result is reported. The physician uses the reported test results to make critical decisions in a patient's diagnosis and treatment or management of disease. Therefore, a good quality assessment program directly affects patient care.

REVIEW QUESTIONS

LEVEL I

- Which source of error represents a pre-examination factor? Failure to: (Objective 1)
 - refrigerate the thromboplastin reagent
 - correct the platelet count when using sodium citrate
 - invert collection tubes properly
 - perform daily maintenance on cell counting instrument
- Under CLIA '88, how frequently should proficiency testing be performed? (Objective 4)
 - once a year
 - twice a year
 - three times a year
 - four times a year
- When validating a manufacturer's reference interval, what is the minimum number of subject samples that should be used? (Objective 5)
 - 10
 - 20
 - 60
 - 120
- Which governmental organization implemented universal precautions? (Objective 6)
 - Occupational Safety and Health Administration (OSHA)
 - Centers for Disease Control (CDC)
 - Food and Drug Agency (FDA)
 - Centers for Medicare and Medicaid Services (CMS)
- Which of the following is an OSHA recommendation to be followed in the clinical laboratory? (Objective 7)
 - Gloves should be worn when working with blood but are not required when performing a venipuncture.
 - Safe needle devices should be used when performing a venipuncture or capillary puncture.
 - Mouth pipetting is acceptable for transferring liquid reagents (e.g., saline or deionized water).
 - Hand washing is necessary only if hands become contaminated with blood or other body fluids.

LEVEL II

- Which is the first step in the selection of a new instrument? (Objective 3)
 - conducting a needs assessment survey
 - determining the cost per test
 - performing an in-house evaluation of the instrument
 - evaluating the quality control program
- Which performance study in the method evaluation process assesses random variation? (Objective 3)
 - precision study
 - method comparison study
 - linearity study
 - calibration study
- Given the following linear regression results, which is the appropriate interpretation? (Objective 2)

y-intercept	0.869
Slope	1.027
Standard error of the estimate	0.014

 - No significant difference exists between the new method and current method results.
 - A proportional systematic error exists between the new method and current method results.
 - A random error exists between the new method and current method results.
 - A constant systematic error exists between the new method and current method results.

REVIEW QUESTIONS (continued)

LEVEL I

6. Which critical information regarding a chemical is found on its MSDS? (Objective 8)
 - a. expiration date
 - b. lot number
 - c. storage requirements
 - d. intended use
7. You are responsible for determining the control limits for the low fibrinogen control. The data points were collected and the mean (\bar{x} = 64 mg/dL) and SD (s = 3.0 mg/dL) determined. What are the 3SD limits? (Objective 10)
 - a. 61.0–67.0 mg/dL
 - b. 58.0–70.0 mg/dL
 - c. 55.0–73.0 mg/dL
 - d. 52.0–76.0 mg/dL
8. How should the clinical laboratory professional interpret the PT control results for the current control run if the $\pm 2SD$ control limits are 11.80–14.20 seconds for Level I and 25.00–28.00 seconds for Level II? (Objective 11)

Current Run	Level I	11.6 seconds
	Level II	24.6 seconds

 - a. acceptable
 - b. unacceptable
9. Which of the following parameters will be affected by the presence of lipemia? (Objective 13)
 - a. RBC, Hb, Hct, MCV, MCH, MCHC
 - b. RBC, Hct, MCV, MCHC
 - c. Hb, MCH, MCHC
 - d. Hct, MCV, MCHC
10. In interpreting a patient's CBC results, the clinical laboratory professional notes that the platelet count is $25 \times 10^9/L$. Which of the following could be associated with this finding? (Objective 12)
 - a. observation of erythrocyte fragments on the blood smear
 - b. presence of cryoglobulins
 - c. observation of platelet clumps at the feather edge of the blood smear
 - d. presence of intracellular parasites such as malaria

LEVEL II

4. A clinical laboratory professional performed a procedure to verify the hemoglobin reportable range on the Cell-Dyn 4000. The highest level of linearity check material was 22.0 g/dL. This material was run several times with 21.2 g/dL representing the mean. How should this finding be interpreted? (Refer to Table 4) (Objective 4)
 - a. The result is within the tolerance limits, and the reportable range is verified.
 - b. The result exceeds the tolerance limits and the procedure should be repeated with new check material.
 - c. The result exceeds the tolerance limits, and additional check material should be run in the upper limits of the reportable range.
 - d. The result exceeds the tolerance limits, and the verification of reportable range should be repeated after the instrument is recalibrated.
5. After performing daily quality control on the automated hematology instrument, the clinical laboratory professional observes a 2_{2s} violation for the hemoglobin, MCH, and MCHC parameters. All other parameters were in control. What type of error is indicated? (Objective 5)
 - a. random
 - b. systematic
6. Regarding question 5, which is the most likely cause of the error? (Objective 5)
 - a. failure to adequately mix the control materials
 - b. improper storage of the control materials
 - c. depleted supply of lysing reagent
 - d. expired diluting fluid
7. For the automated hematology instruments, moving averages can be used to monitor the instrument's performance in determining which parameters: (Objective 6)
 - a. leukocyte
 - b. erythrocyte
 - c. platelet
 - d. reticulocyte
8. Initial interpretation of a patient's CBC results showed an MCHC of 38 g/dL. The clinical laboratory professional warmed the sample to 37°C and reanalyzed it. No change was observed. What is the appropriate course of action? (Objective 8)
 - a. observe the blood smear for the presence of spherocytes
 - b. replace patient's plasma with equal volume of saline and reanalyze.
 - c. recollect patient sample using sodium citrate and analyze
 - d. examine the blood smear for the presence of nucleated erythrocytes

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

9. The following coagulation test results were obtained: PT = 7.5 seconds and APTT = 20 seconds. How should the clinical laboratory professional approach these findings? (Objective 8)
 - a. report results to patient's chart
 - b. observe sample for the presence of hemolysis
 - c. check sample for small clots
 - d. examine collection tube to determine whether it was underfilled
10. Which source of error would be detected by a delta check? (Objective 10)
 - a. depleted reagent supply
 - b. improper calibration of the instrument
 - c. deteriorating light source
 - d. failure to correctly label the patient's sample

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Explain the importance of each component of the quality assessment program to its ultimate goal.

Answer

The preexamination component is critical to the quality assessment (QA) program because the test outcome is only as good as the sample from which it is determined. The QA program must ensure proper collection and handling of samples prior to testing. The examination component represents all factors that impact the testing system. The test outcome will be affected if a breakdown in the testing system occurs due to lack of a proper QA program. A breakdown in the QA program within the postexamination component affects the recording/reporting of the test outcome. This may delay appropriate treatment for the patient.

Checkpoint! 2

If a clinical laboratory loses its certification to perform protein C assays, what is involved in regaining that certification?

Answer

The clinical laboratory professional should determine the reason for the failure, correct the problem, and document the process. Following the corrective action, successful participation in two consecutive proficiency testing surveys for protein C would result in the laboratory's recertification to perform protein C assays.

Checkpoint! 3

What is an appropriate method of assessing a clinical laboratory professional's competency in performing the prothrombin time (PT) and partial thromboplastin time (APTT) using an automated coagulation instrument?

Answer

A combination of direct observation checklist and blinded preanalyzed samples provides an appropriate method of assessing competency in performing PT and APTT.

Checkpoint! 4

Linear regression analysis was performed on results from a method comparison of the prothrombin time between automated coagulation instrument A and automated coagulation instrument B (Web Figure 1). The following results were obtained:

y -intercept = 0.8157

slope = 0.9982

standard error of the estimate = 0.0807

What conclusions can be drawn from these results?

Answer

Based on the linear regression results, a constant difference occurs between the automated instrument A and the automated instrument B because the y -intercept is more than zero. That is, the automated instrument A gives consistently higher results than the automated instrument B. Therefore, a constant systematic error exists. The slope between 0.95 and 1.05 indicates there is no proportional systematic

error between the two methods. There is no random error because the standard error of estimate is nearly zero, indicating very little dispersion of results about the linear regression line.

Checkpoint! 5

Define the term *reference interval*.

Answer

For a given analyte, the *reference interval* represents the usual results for a healthy population. For example, the reference interval for hemoglobin in the adult male population is 13.3–17.7 g/dL.

Checkpoint! 6

If a spill occurred when handling the CELL-DYN Sapphire hemoglobin reagent, what is the appropriate procedure to clean it up? Refer to Web Figure 2.

Answer

According to the MSDS sheet, absorb the spill reagent with a liquid-binding material such as sand and use a neutralizing agent. Then, wash the spill area with appropriate cleaning material. The contaminated materials should be disposed of in accordance with federal, state, and local regulations.

Checkpoint! 7

To establish the control limits for a new lot number of level 1 PT coagulation control, the following data points were collected (results are in seconds): 11.8, 11.6, 12.1, 12.0, 12.3, 12.6, 11.9, 12.2, 12.0, 11.5, 12.7, 12.1, 11.2, 12.3, 12.9, 13.0, 12.3, 11.9, 12.4, 12.5. What are the $\pm 2s$ control limits?

Answer

The first step to determine these control limits is to calculate the mean and standard deviation for these results. Based on these data points, the mean is 12.2 seconds and the standard deviation is 0.50. Therefore, the $\pm 2s$ control limits would be 11.20–13.20 seconds.

Checkpoint! 8

After performing daily quality control on the automated hematology instrument, the clinical laboratory professional observes a 4_{1s} violation for the hemoglobin parameter. What type of error is indicated?

Answer

The 4_{1s} violation indicates a systematic error that may be due to an expired lysing reagent or a deteriorating hemoglobin lamp.

Checkpoint! 9

In reviewing a patient's CBC results, the clinical laboratory professional notes an MCHC of 37 fL. What corrective action should be taken?

Answer

The clinical laboratory professional must first determine the cause of the falsely elevated MCHC. The presence of cold agglutinins, lipemia, ictericia, or spherocytes in a patient sample has been associated with an MCHC of more than 36 fL. Lipemia and ictericia are substances that cause falsely elevated hemoglobin and consequently falsely elevated MCHC. Centrifuging the sample and examining the plasma can identify these substances. If either is present, the saline replacement procedure is performed to obtain an accurate hemoglobin and MCHC. If cold agglutinins are suspected, the hematocrit will be falsely decreased (i.e., $MCV \times RBC = Hct$), and consequently, the MCHC falsely elevated. A manual hematocrit may quickly identify this problem. If cold agglutinins are present, the sample is warmed to 37°C for 15 minutes to dissociate the agglutinated cells prior to analysis to obtain accurate results. If other possibilities are ruled out, the peripheral blood smear is examined for the presence of spherocytes. No corrective action is needed if spherocytes are present.

Checkpoint! 10

The clinical laboratory professional observes that the 3.2% sodium citrate tube for a PT and APTT is only two-thirds full. Explain the effect this will have on the patient's coagulation results.

Answer

If the sample collection tube is only two-thirds full, excess anticoagulant is present and the plasma is overanticoagulated. Therefore, the coagulation results are falsely prolonged.
